In the 2008 ISA, the evidence was sufficient to infer a causal relationship between reactive N deposition and biogeochemical cycling of N and C in estuarine and near-coastal marine systems. Nitrogen pollution is the major cause of harm to the majority of estuaries in the U.S. ([Bricker et al., 2008](#); [NRC, 2000](#)) and can lead to eutrophication, the process of increasing nutrient over-enrichment leading to water quality deterioration. Eutrophic systems are characterized by an increase in the rate of supply of organic matter (primary production and organic carbon accumulation) in excess of what an ecosystem is normally adapted to processing ([Diaz et al., 2013](#); [Nixon, 1995](#)). Evidence reviewed in the 2008 ISA, along with new studies indicate elevated N inputs to coastal areas can alter key processes that influence C and N cycling in near-coastal environments. **The body of evidence is sufficient to infer a causal relationship between N deposition and the alteration of biogeochemistry in estuarine and near-coastal marine systems** which is consistent with the conclusions of the 2008 ISA.

As N fluxes to coastal areas have increased in recent decades in many parts of the U.S., the varying rates of different N cycling processes within estuaries themselves can also affect the magnitude of eutrophication experienced as a result of external N enrichment. Nitrogen additions not only cause the total pool of N to be larger but may also perturb N cycling in such a way that the system may exacerbate eutrophication to a greater extent than expected based on N additions alone. Research conducted since the 2008 ISA has shown that many of these N cycling processes are more important in the estuarine environment than previously understood. The removal of N through denitrification is a valuable ecosystem service in terms of constraining the extent and magnitude of eutrophication. Additional research has established DNRA as a more important N reduction pathway in some estuaries. Ammonium produced via DNRA can lead to enhanced productivity and respiration, which may exacerbate hypoxia. Recent studies indicate that DNRA rates are higher in warmer months and can also take up a larger percentage of total N reduction activity when temperatures are higher. The roles of sedimentary microbial processes of denitrification and anammox have been further characterized. New research has shown that the community of N fixing microorganisms is more diverse in estuarine and coastal waters than previously thought, and that N fixation occurs more widely than previously assumed. Influence of benthic macrofauna on N cycling has received increased research attention in part due to the potential for these organisms to mitigate external N enrichment.

New studies and evidence reviewed in the 2008 ISA continue to show that at many U.S. coastal areas, atmospheric deposition constitutes an important proportion of N inputs to estuaries; ranging from <10 to approximately 70% of the N inputs ([Table 7-9](#)). As stated

in the 2008 ISA, estuaries tend to be N limited ([Elser et al., 2007](#); [Howarth and Marino, 2006](#); [NRC, 2000](#); [Nixon, 1995](#); [Vitousek and Howarth, 1991](#); [Howarth, 1988](#); [D'Elia et al., 1986](#)), and many currently receive high N loads from human activities (e.g., atmospheric deposition, agricultural runoff, wastewater, and other sources), which can cause eutrophication ([Howarth et al., 1996a](#); [Vitousek and Howarth, 1991](#)). It is well known that the development and continuation of hypoxia in estuary and marine systems can be accelerated by increased nutrient loading. Monitoring efforts across the U.S. ([Appendix 7.2.7](#)) continue to show that N enrichment is a widespread problem. Numeric Nutrient Criteria have been established to varying degrees by coastal states in an effort to manage N inputs ([Appendix 7.2.9](#)). Water quality deterioration from N inputs to estuaries including development of hypoxic zones, can be linked to biological changes. Biological indicators of estuarine condition (e.g., chlorophyll *a*, HABs, macroalgae, SAV) are described in [Appendix 10](#).

Since the 2008 ISA, a number of papers have identified links between nutrient enrichment, effects on carbonate chemistry, and coastal acidification, and several mechanisms have been identified. One of the initial studies found that CO<sub>2</sub> production during decomposition of organic matter delivered to coastal zones from rivers experiencing eutrophication has enhanced the acidification of coastal subsurface waters in the Gulf of Mexico and the East China Sea ([Cai et al., 2011c](#)) and additional studies provide evidence of acidification in estuaries due to this mechanism ([Laurent et al., 2017](#); [Wallace et al., 2014](#); [Cai et al., 2011c](#); [Orr et al., 2005](#)). In addition to microbial degradation of organic matter, respiration of living algae and seagrasses during the night can also drive acidification ([Howarth et al., 2014](#)). The CO<sub>2</sub> produced in eutrophic estuarine waters combines with water molecules, producing carbonic acid, which makes the water more acidic ([Sunda and Cai, 2012](#); [Cai et al., 2011c](#); [Howarth et al., 2011](#)). Acidification of coastal waters tends to occur in locations where there is either thermal or saline stratification with spatial or temporal decoupling of production and respiration processes. Long-term monitoring ([Appendix 7.2.7.2](#)) documents increasing acidification trends in some U.S. coastal areas. Acidification also can be enhanced indirectly through the creation of anoxic waters and oxidation of HS<sup>-</sup> ([Cai et al., 2017b](#)). Modeling of coastal acidification via N enrichment and atmospheric CO<sub>2</sub> dissolution suggests that the combined effects of these two pathways are synergistic.

---

## APPENDIX 8 BIOLOGICAL EFFECTS OF FRESHWATER ACIDIFICATION

This appendix characterizes the biological effects of acidifying deposition of nitrogen (N) and sulfur (S) in freshwater systems. Indicators of surface water chemistry are linked to biological endpoints ([Appendix 8.1](#)) in freshwater systems experiencing either chronic or episodic acidification ([Appendix 8.2](#)). Affected biota include plankton, invertebrates, fish, and other organisms ([Appendix 8.3](#)). Next, documentation of biological recovery in previously acidified systems ([Appendix 8.4](#)) is reviewed. [Appendix 8.5](#) includes levels of deposition at which effects are manifested and empirical and modeled critical loads (CLs) for acidifying deposition. A summary section with causal determinations based on a synthesis of new information and previous evidence of biological effects of aquatic acidification is presented in [Appendix 8.6](#). Overall, the updated research synthesized in this ISA reflects incremental improvements in scientific knowledge of aquatic biological effects and indicators of acidification as compared with knowledge summarized in the 2008 ISA. The causal relationships between acidifying deposition and biological effects on aquatic ecosystems are now, and were in 2008, well supported.

---

### 8.1 Introduction

In the *2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur-Ecological Criteria* (2008 ISA), the body of evidence was sufficient to infer a causal relationship between acidifying deposition and changes in freshwater biota. Changes in biogeochemical processes and water chemistry caused by deposition of N and S to surface waters and their watersheds ([Appendix 7](#)) have been well characterized for several decades and have ramifications for biological functioning of freshwater ecosystems. The 2008 ISA and studies since have shown that acidification from acid deposition can result in the loss of acid-sensitive organisms, population declines, and decreased species richness. This evidence is consistent and coherent across multiple species. More species are lost with greater acidification, providing evidence of biological gradients in effects. Both earlier and more recent studies indicate that aquatic biota in sensitive aquatic ecosystems have been affected by acidification at virtually all trophic levels. **New information is consistent with the conclusions of the 2008 ISA that the body of evidence is sufficient to infer a causal relationship between acidifying deposition and changes in biota, including physiological impairment and alteration of species richness, community composition, and biodiversity in freshwater ecosystems.**

As reported in the 2008 ISA, effects of acidifying deposition on biotic integrity of freshwater ecosystems can be linked to changes in several key chemical effects indicators, including pH, dissolved inorganic aluminum (Al) concentration, calcium (Ca), and acid neutralizing capacity (ANC). Biological effects are primarily attributable to low pH and high inorganic Al concentration. The ANC, a measure of the overall buffering capacity against acidification, is commonly used because it integrates overall acid status, it is not affected by dissolved carbon dioxide (CO<sub>2</sub>), and surface water acidification models do a better job projecting ANC than pH and inorganic Al concentrations. However, ANC does not cause harm to biota. The usefulness of ANC lies in the association between it and the surface water constituents that directly cause or ameliorate acidity-related stress, in particular inorganic Al, Ca, and H<sup>+</sup> (measured as pH).

Chemical factors such as pH, Ca, ANC, ionic metals and dissolved organic carbon (DOC) are affected by acid deposition and can profoundly affect the structure and function of biological communities in lakes and streams. Inorganic Al is minimally soluble at soil or surface water pH above about 6.0, but solubility increases markedly as pH values drop below about 5.5. Low concentrations of base cations like Ca enable low pH and high concentrations of inorganic Al to occur ([Baker et al., 1990b](#)). However, DOC can bind to inorganic Al ions and reduce their bioavailability and their toxic impact on aquatic biota. The base cation surplus (BCS) is an alternate index that is similar to ANC and that also adjusts for the organic acid status of surface waters ([Lawrence et al., 2007](#)). BCS is based on a measurement of ANC (calculated from the charge balance of ionic concentrations in water) and also accounts for the influence of natural organic acidity by including the strongly acidic organic acid anions in the calculation.

Acid-sensitive freshwater systems can either be chronically acidified or subject to occasional episodes of decreased pH, decreased ANC, and increased inorganic Al concentration ([Appendix 7](#)). Changes to flow and surface water chemistry, characteristic of these events, reflect the influence of acidic inputs from precipitation, gases, and particles, as well as local geology and soil conditions. As stated in the 2008 ISA, surface water chemistry is a good indicator of the effects of acidification on the biotic integrity of freshwater ecosystems because it integrates the sum of soil and water processes that occur within a watershed. Surface water chemistry reflects and integrates N saturation, forest decline, soil acidification, nutrient cycling, and land use ([U.S. EPA, 2003](#)).

Acidification studies reviewed in the 2008 ISA included laboratory experiments, bioassays, mesocosm exposures, field observations, and whole ecosystem acidification or deacidification studies. [Baker et al. \(1990a\)](#) conducted a rigorous review of the effects of acidification on aquatic biota for the 1990 National Acid Precipitation Assessment Program (NAPAP) State of Science/Technology report series. In the [Baker et al. \(1990a\)](#)

report, hundreds of laboratory studies, in situ bioassays, field surveys, whole-system field experiments, and mesocosm studies on the effects of acidification on aquatic biota were evaluated. The findings in that report, along with literature published after 1990 up to December 2007, were assessed in the 2008 ISA. Measures of health, vigor, reproductive success, and biodiversity of aquatic biota were identified in the 2008 ISA as being affected by acidified waters caused by acidifying deposition. Effects had been most clearly documented for fish, aquatic invertebrates, and algae.

Since publication of the 2008 ISA, the overarching understanding of aquatic acidification has not changed appreciably. More recent research has confirmed and strengthened this understanding and provided more quantitative information, especially across the regional landscape. This appendix highlights post-2007 research findings through the spring of 2017.

---

## 8.2 Chronic versus Episodic Acidification

Traditionally acidification involves both chronic and episodic processes. As defined in the 2008 ISA, chronic acidification refers to annual average conditions, which are often represented as summer and fall chemistry for lakes and as spring baseflow chemistry for streams. Episodic acidification refers to conditions during rainstorms or snowmelt when proportionately more drainage water is routed through upper soil horizons, which tend to provide less neutralization of atmospheric acidity as compared with deeper soil horizons. Surface water chemistry exhibits lower pH and ANC during episodic than during baseflow conditions. Chronically acidic lakes and streams maintain ANC  $<0$   $\mu\text{eq/L}$ , on average, throughout the year ([Driscoll et al., 2001b](#)). They are no longer prevalent in regions of the U.S. affected by acidic deposition [cf; [Fakhraei et al. \(2016\)](#); [Fakhraei et al. \(2014\)](#)]. The ANC during acidic episodic events may fall below  $0$   $\mu\text{eq/L}$  for only a few hours to weeks in a given year. It is known that the biota in many streams/lakes are impacted when the ANC is consistently below  $50$   $\mu\text{eq/L}$ . For this reason, the U.S. EPA National Lakes Assessment used an ANC threshold of  $>50$   $\mu\text{eq/L}$  as indicative of nonacidified water bodies ([U.S. EPA, 2009b](#)). In addition, dynamic models, such as MAGIC and PnET-BGC, estimate that some lakes and streams in the Adirondack and southern Appalachian Mountains had preindustrial ANC below  $50$   $\mu\text{eq/L}$ , but few or none had preindustrial ANC below  $20$   $\mu\text{eq/L}$ .

A large portion of the available aquatic acidification data reported in the 2008 ISA focused on lakes and streams in the Northeast and the southern-Appalachian Mountains ([U.S. EPA, 2008a](#)) because these systems have been among the most impacted by acidifying deposition in the past and have the best available surface water monitoring

information. Since completion of the literature review for the 2008 ISA, additional research has been conducted on changes in chronic surface water chemistry in the U.S. in response to changing levels of acidic deposition ([Appendix 7](#)). Many of these studies have further documented chemical recovery as S and N deposition continue to decline in most areas in the U.S. Biological recovery has been observed in some systems, but available data generally indicate that it typically lags behind chemical recovery ([Appendix 8.4](#)).

Many streams that exhibit chemical conditions during base flow that are suitable for aquatic life are subject to occasional episodic acidification that may exceed the acid tolerance of many aquatic species. Episodic events vary in timing, duration, and intensity. Episodic acidification is most common in the early spring and late fall, and least common in summer, when high flows tend to be infrequent ([Driscoll et al., 2001b](#)). This seasonality of episodic events reflects to some extent the influence of deposition accumulating in the landscape that is flushed to drainage water during precipitation or snowmelt events. Other natural processes can also be involved, including altered hydrologic flowpaths, biological uptake, and the neutral salt effect, whereby deposition of a neutral salt (e.g., NaCl) can lead to ion exchange of  $H^+$  for  $Na^+$  in soil, followed by drainage water acidification. Episodic processes are mostly natural, but  $SO_4^{2-}$  and  $NO_3^-$  influxes due to atmospheric deposition play important roles in the episodic acidification of some surface waters. Dilution of base cation concentrations in runoff during episodes—a quantitatively important component of the episodic response—may be affected in part by past base cation depletion of watershed soils, due to acidification, which limits the release of Ca and Mg in response to rapid runoff during storms and/or snowmelt ([Wigington et al., 1996a](#); [Wigington et al., 1996b](#)).

As reported in the 2008 ISA, episodes are generally accompanied by changes in two or more of the following chemical parameters: ANC, pH, concentrations of base cations,  $SO_4^{2-}$ ,  $NO_3^-$ , aluminum ions, organic acid anions, and DOC ([Sullivan, 2000](#)). During short-term episodes (hours or days), both flow and water chemistry can change markedly. Biological effects of episodes sometimes include fish mortalities, changes in species composition, and declines in aquatic species richness across multiple taxa, ecosystems, and regions. The U.S. EPA's Episodic Response Project (ERP) in the 1980s confirmed the chemical and biological effects of episodic pH depressions in lakes and streams in parts of the U.S. ([Wigington et al., 1993](#)). In the ERP report, streams having acidic episodes showed long-term effects on fish populations compared with streams in which ANC remained above 0  $\mu eq/L$ . Results reported in the 2008 ISA from in situ bioassay studies conducted across the eastern U.S. showed that acidic episodes (with associated low pH and elevated inorganic Al concentrations and high stream-water discharge) caused rapid fish mortality under some conditions ([Driscoll et al., 2001b](#); [Bulger et al.,](#)

[1999](#); [Baker et al., 1996](#)). [Baker et al. \(1990a\)](#) concluded that episodes are most likely to affect biota if the episode occurs in waters with pre-episode pH above 5.5 and minimum pH during the episode of less than 5.0. In a later study, acid episodes reduced the size of fish populations and eliminated acid-sensitive species if median high-flow pH was less than 5.2 and inorganic Al concentration exceeded 100 µg/L (3.7 µM), despite the relatively short duration of the episodes studied ([Baker et al., 1996](#)). Research from several regions in the U.S. indicated that acidifying deposition likely has increased the magnitude, frequency, and biological effects of episodic acidification events.

---

## 8.3 Aquatic Organisms Impacted by Acidifying Deposition

[Appendix 8.3.1](#) through [Appendix 8.3.8](#) describe effects of acidification on phytoplankton, zooplankton, benthic invertebrates, fish, birds, and other biota. Changes in biota are linked to chemical indicators ([Appendix 7](#)) in surface water. In the 2008 ISA, biological effects were divided into two major categories: (1) effects on health, vigor, and reproductive success of taxonomic groups and (2) effects on biodiversity. The first category included changes at the species level of biological organization such as cumulative sublethal physiological effects (individual condition factor) and recruitment success. Effects on biodiversity include changes in community structure, species composition, and taxonomic richness. Studies reviewed in the 2008 ISA showed that the earlier aquatic lifestages were particularly sensitive to acidification.

In [Appendix 8.3.1](#) through [Appendix 8.3.8](#), findings from the 2008 ISA are summarized for each major taxonomic group, followed by a review of new literature including studies that report physiological alterations, changes in the abundance or presence of taxa, community shifts, and other biological responses associated with acidifying conditions. Effects on organisms at lower trophic levels, such as plankton and invertebrates, are discussed first followed by observations for fish and other vertebrates. Ecological thresholds of chemical indicator(s) associated with the observed responses are included, when available, from the reviewed studies. [Appendix 8.4](#) considers the evidence for biological recovery of different taxa.

---

### 8.3.1 Plankton

Plankton, floating or drifting organisms in the water column, play an important role in freshwater ecosystems. Phytoplankton, or suspended algae, are primary producers at the base of the aquatic food web. These photosynthetic organisms, encompassing diatoms, cyanobacteria, dinoflagellates, and other groups of algae, vary in tolerance of acidic

conditions. Zooplankton comprise many groups of freshwater organisms including protozoans, rotifers, cladocerans, and copepods. Zooplankton feed on phytoplankton or other zooplankton. Abundance and community composition of plankton respond to changes in surface water chemistry associated with acidifying deposition to water bodies.

---

### 8.3.1.1 Phytoplankton

Studies reviewed in the 2008 ISA reported reduced species richness of phytoplankton with decreases in pH and increases in inorganic Al concentrations associated with acid-affected surface waters ([U.S. EPA, 2008a](#)). There was also a shift in the composition of dominant taxa, but species composition shifts could not be accurately predicted. This kind of effect was most prevalent in the pH 5 to 6 range ([Baker et al., 1990a](#)). It appeared that the phytoplankton community restructured as the water became acidified. However, the response of phytoplankton communities often vary, with some lakes showing increasing biomass, others decreasing, and others having no change in phytoplankton biomass ([Baker et al., 1990a](#)). [Leavitt et al. \(1999\)](#) suggested that the complex interactions between pH, DOC, and light can explain the high variability in phytoplankton-biomass-acidification relationships.

More recent studies of the responses of phytoplankton to changes in surface water acidity have been limited. Effects on primary productivity are uncertain. In regards to phytoplankton species composition, changes were not apparent in the lake diatom communities or the diatom-inferred lake pH of sequential core segments in four alpine/subalpine lakes in the Cascade Mountains of Washington and Oregon that have not experienced substantial water acidification ([Eilers et al., 2016](#)). The study lakes were very low in specific conductance ( $\leq 3.6 \mu\text{S}/\text{cm}$ ) and ANC ( $\leq 11 \mu\text{eq}/\text{L}$ ). Sediment cores were collected from each lake and analyzed for nutrients and diatom microfossils in dated (210-Pb and 14-C) core segments. Water chemistry was simulated using a modified version of the CE-QUAL-W2 model to account for the assumed large influence of in-lake chemical processes. Model projections of future chemistry suggested that the three study lakes in Oregon will not change their acid-base chemistry in the future under N and S deposition increases to 3 times ambient, largely due to long lake water residence times, which allow in-lake processes to neutralize acid inputs. Foehn Lake in Washington was much more acid-sensitive, increasing in acidity in response to projected increases in N and S deposition at levels of 50% above ambient. Shallow depth, large amount of exposed bedrock, and sparse sediment accumulation enhance its acid sensitivity. This lake was formed less than a century ago, probably in response to climate warming and melting of an adjacent snowfield.

[Lacoul et al. \(2011\)](#), reviewed information on the effects of acidification on plankton and other organisms in Atlantic Canada and observed that the greatest changes in phytoplankton species richness occurred over a pH range of 4.7 to 5.6, just beyond the interval (pH 5.5 to 6.5) where bicarbonate becomes rapidly depleted in the water. Under acidifying conditions, phytoplankton communities shifted from dominance by chrysophytes, other flagellates, and diatoms to dominance by larger dinoflagellates. However, biomass and productivity were not much affected. Algal biomass in five Pennsylvania streams decreased with the severity of episodic acidification ([Macdougall et al., 2008](#)). Although no significant trends were observed for taxon richness or diversity, the degree of acidification during episodes appeared to affect the quantity of algae in the streams. [Bloch and Weyhenmeyer \(2012\)](#) evaluated physical and chemical time-series data for 13 nutrient-poor Swedish lakes across a latitudinal gradient. Phytoplankton biomass and species richness showed only weak relations with water chemistry. The only significant association observed across seven of the surveyed lakes was the number of chlorophyte taxa and changes in water temperature and color.

As stated in the 2008 ISA, diatoms, which comprise an important component of the phytoplankton, are excellent biological indicators of environmental change in aquatic ecosystems, being sensitive to changes in acidity, nutrient status, salinity, and climate ([Stoermer and Smol, 1999](#); [Sullivan and Charles, 1994](#)). Since the 2008 ISA, studies have further linked phytoplankton community shifts to acidification using paleolimnological analysis of fossil diatoms or long-term sampling of phytoplankton from the water column. Most of these studies have documented phytoplankton recovery in historically acidified lakes ([Appendix 8.4.1](#)). Stratigraphy of sediment chrysophyte remains in Brooktrout Lake in the Adirondack Mountains, NY revealed shifts in *Mallomonas* spp. and *Synura* spp., with some species declining and others increasing. After the 1950s, *Fragilariforma acidobiontica*, a diatom that is often abundant at pH <5.0, was present in lake sediments. These observations in Brooktrout Lake correspond to historical acidification, which was most severe during the 1970s and 1980s ([Sutherland et al., 2015](#)). Phytoplankton have also been used as indicators of acidification and recovery in Canada and Europe. In a recent analysis of diatom fossils from 10 lakes located about 80–250 km east and northeast of the oil sands development near Fort McMurray and Fort Mackay, northwestern Saskatchewan, [Laird et al. \(2013\)](#) observed increases in scaled chrysophytes and diatom flux rates in post-1980 sediments potentially related to atmospheric deposition in the oil sands region. A slight decrease (0.25 pH unit) in diatom-inferred pH occurred in one study site closest to the oil sands development, but there was no evidence of widespread acidification. Over time, phytoplankton assemblages in Swedish lakes recovering from acidification have become more similar to those in reference lakes ([Johnson and Angeler, 2010](#)).

---

### 8.3.1.2 Zooplankton

In studies reviewed in the 2008 ISA, decreases in ANC and pH and increases in inorganic Al concentration were shown to contribute to the loss of zooplankton species or decreased abundance in lakes ([Keller and Gunn, 1995](#); [Schindler et al., 1985](#)). A decrease in pH from 6 to 5 reduced species richness in lake zooplankton communities ([Holt et al., 2003](#); [Holt and Yan, 2003](#); [Locke and Sprules, 1994](#)). [Sullivan et al. \(2006a\)](#) found that zooplankton communities varied with ANC in Adirondack lakes, with lower taxonomic richness (number of species of crustaceans, rotifers, and total zooplankton) in lakes having lower ANC. In general, lake-water ANC explained nearly half of the variation in total zooplankton and crustacean taxonomic richness, but less for rotifer richness. Particularly low zooplankton community richness occurred when ANC levels were below 0 µeq/L (15 species in highly acidic lakes compared to 35 at the highest values of ANC in the study [near 200 µeq/L]). Observations from in situ enclosure acidification studies at Emerald Lake in the Sierra Nevada showed shifts in zooplankton community with decreased pH ([Barmuta et al., 1990](#)). *Daphnia rosea* and *Diaptomus signicauda* were eliminated below pH 5.0 while other species such as *Bosmina longirostris* and *Keratella taurocephala* became more abundant. Possible mechanisms for zooplankton sensitivity to low pH and ANC include ion regulation failure, reduced oxygen uptake, inability to reproduce, and Al toxicity ([U.S. EPA, 2008a](#)).

A number of studies have been conducted since the 2008 ISA to determine the response of zooplankton to lake acidification. Highlighted here are several studies conducted in the U.S. and Canada. Many of these studies indicate that multiple factors could influence zooplankton community changes. *Bosmina* is among the most common North American temperate lake pelagic invertebrate genera. It is a genus of cladoceran filter feeders that can change body size and appendage length over multiple generations in response to changing environmental conditions. This makes it a good candidate ecological indicator. [Labaj et al. \(2016\)](#) evaluated *Bosmina* size responses in lakes near Sudbury, Ontario, Canada, that had been acidified and then chemically recovered in response to changes in nearby metal smelter emissions. Even with the recent return to presmelter lake pH, the *Bosmina* size structure has not yet recovered to preacidification conditions. [Labaj et al. \(2016\)](#) suggested that the observed effects of acidification and deacidification on the size of *Bosmina* may have been mediated by food web dominance of small copepod predators. [Vinebrooke et al. \(2009\)](#) reported variations in zooplankton communities during a whole-lake experimental acidification of Lake 302S in the Experimental Lakes area in Ontario, Canada. There was a negative effect on zooplankton species richness as pH decreased from 6.8 to 4.5. However, no correlation was found between functional properties (productivity or net total biomass) and species richness with this pH change, indicating that other factors such as multiple stressor interactions, species occurrences,

and altered trophic interactions might also influence zooplankton community change. In northwestern boreal shield lakes downwind of N emissions from the Athabasca oil sands extraction in Saskatchewan, Canada, zooplankton community structure was influenced by local environmental factors, including acidity, predation, and lake productivity. The role of regional atmospheric deposition on zooplankton community composition could not be distinguished from natural variability due to a lack of baseline data prior to oil extraction operations ([Anas et al., 2014](#)). Thus, the role of acidic deposition in driving changes in zooplankton community composition in that region was not clear.

Acidification often reduces Ca availability in lake water, which may impact invertebrates that require Ca for growth such as *Daphnia* spp. and crayfish ([Appendix 8.4.3](#)). [Jeziorski et al. \(2012b\)](#) examined the growth and survival of daphnid species across a Ca gradient (from 50 to 150 µeq/L) in central Ontario soft-water lakes. Considerable variability in growth and survival was observed within the *Daphnia pulex* species complex, and the variation across all cladoceran genera was best explained by pH and lake depth. This research adds support to the previous observation that among the cladocerans, daphnids are especially sensitive to decreases in Ca which leads to declines in their growth and survival as lake water acidifies with inputs of acidifying deposition.

---

### 8.3.2 Periphyton

Periphyton mats are biofilms of algae, cyanobacteria, fungi, microinvertebrates, organic detritus, inorganic particles, and heterotrophic microbes imbedded within a matrix and attached to submerged substrates in aquatic systems (e.g., stream or lake bottoms or submerged vegetation). Periphyton is an important food source for invertebrates, tadpoles, and some fish. As reported in the 2008 ISA, acidification impacts periphyton species differently, with some excluded from impacted water bodies while others become dominant. Such changes decrease species richness and alter community structure ([U.S. EPA, 2008a](#)). For example, many of the brown algae and cyanobacterial periphyton species cannot tolerate acidic conditions, causing their abundance to decline along with pH, while green algae, particularly the filamentous Zygnemataceae, increase in relative abundance at lower pH ([Baker et al., 1990a](#)). There is evidence that the biomass of attached periphyton increases at lower pH. No new studies of acidifying effects on periphyton were identified for this review.

---

### 8.3.3 Benthic Invertebrates

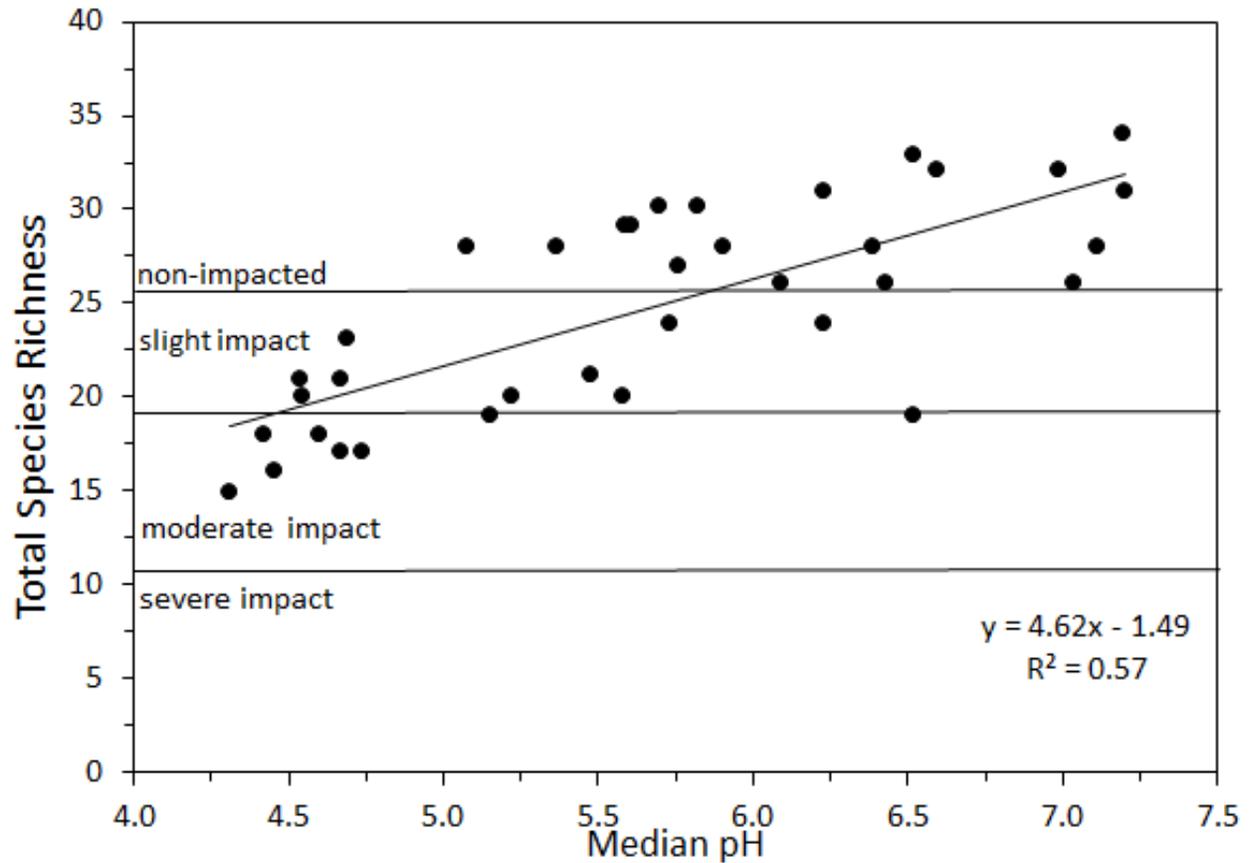

Benthic invertebrates live in freshwater sediments and include groups such as bivalves, worms, gastropods and insect larvae. As reviewed in the 2008 ISA, acidification as measured by decreases in ANC and pH and increases in inorganic Al concentration has been shown to contribute to the loss or decline in abundance of benthic invertebrate species in streams. The Ephemeroptera (mayflies)-Plecoptera (stoneflies)-Tricoptera (caddisflies; EPT) Index is a common measure of stream macroinvertebrate community integrity. The EPT metric is calculated as the total number of families present in those three insect orders. Mayflies tend to be the most sensitive of the three, and stoneflies tend to be the least sensitive ([Peterson and Van Eeckhaute, 1992](#)). The mayfly order alone is often selected for study because it includes a number of genera and species having varying degrees of sensitivity to acidification, including some that are highly sensitive ([Sullivan et al., 2003](#)). Typically, pH values below 5 result in the virtual elimination of all mayflies along with some other aquatic organisms from some streams ([U.S. EPA, 2008a](#); [Baker and Christensen, 1991](#)). These benthic invertebrates are impacted by acidification because  $H^+$  and inorganic Al can be directly toxic, causing disruption of their ion regulation and reproductive success. U.S. EPA first published freshwater criteria for Al in 1988 and is in the process of updating the Aquatic Life Criteria. The current 1988 acute and chronic criteria are 750 and 87  $\mu\text{g/L}$ , respectively, not to be exceeded once every 3 years on average ([U.S. EPA, 1988](#)).

Work since the 2008 ISA by [Baldigo et al. \(2009\)](#) assessed effects of acidification on benthic macroinvertebrate community dynamics in the southwestern Adirondack Mountains. Water chemistry and benthic macroinvertebrates were surveyed in 36 streams with different levels of acidity to characterize community response and identify thresholds for biological effects ([Figure 8-1](#)). In the study streams, macroinvertebrate assemblages were severely impacted at  $\text{pH} < 5.1$ , moderately impacted at  $\text{pH}$  from 5.1 to 5.7, slightly impacted at  $\text{pH}$  from 5.7 to 6.4 and usually unaffected above  $\text{pH}$  6.4. Inorganic Al concentrations reached potentially toxic levels in two-thirds of the study streams. The authors applied the Acid Biological Assessment Profile [acidBAP] index, which is based on percentage mayfly richness and percentage acid-tolerant macroinvertebrate taxa ([Burns et al., 2008b](#)). The acidBAP was strongly correlated with  $\text{pH}$ , ANC, BCS, and the concentration of inorganic Al, indicating the loss of mayflies in the stream as the surface water  $\text{pH}$  declines from  $\text{pH}$  7.0 to 4.2. A loss of about 12 species occurred in streams that had a  $\text{pH}$  between 7 and 4.2. Regression across all 36 streams showed a loss of 4.6 species per unit  $\text{pH}$  decrease ([Figure 8-1](#)). Inorganic Al toxicity was likely the main cause of the loss of macroinvertebrates. The Al concentration is strongly correlated with surface water  $\text{pH}$  (as  $\text{pH}$  decreases solubility of inorganic Al increases) and acid-base balanced as measured by BCS.

Several pH thresholds for aquatic invertebrate response have been published since the 2008 ISA ([Table 8-1](#)). [Lacoul et al. \(2011\)](#) reviewed available information on the effects of water acidification on aquatic organisms in Atlantic Canada. The median pH for sensitive invertebrate species occurrence was between 5.2 and 6.1, below which species tended to be absent. For example, several species of mayfly and most gastropods are intolerant of acidity and only occur at pH  $\geq 5.5$  and  $\geq 6$ , respectively.

The make-up of the stream invertebrate community is governed in part by the condition of riparian vegetation and associated humic acid levels in surface water. [O'Toole et al. \(2017\)](#) investigated riparian vegetation condition under high and low humic acid influence as affected by riparian vegetation. Both perennial and intermittent streams in western Australia were evaluated. Streams having well-developed riparian vegetation showed proportionately more algal grazers and detritivores. Intermittent streams with high humic content had lower numbers of cladocerans and chironomids and higher numbers of grazing gastropods as compared with intermittent streams that had relatively low humic content.

Several European studies published since the 2008 ISA have evaluated the use of benthic invertebrates as biological metrics to classify the ecological status of water bodies. These studies have developed or applied indices to predict dose-response relationships between macroinvertebrate communities and water chemistry. One study by [Schartau et al. \(2008\)](#) applied existing macroinvertebrate metrics developed for river acidification to lakes and also developed and tested new species-based indicators of lake acidification based on 668 samples of littoral macroinvertebrates taken from 427 lakes across Sweden, the U.K., and Norway. Although there was high variation in the data, a response threshold between pH 5.8 and 6.5 was identified for littoral macroinvertebrate communities, suggesting they could be used to assess ecological quality of lakes.

**Figure 8-1** Total macroinvertebrate species (community) richness as a function of median pH in 36 streams sampled in the western Adirondack Mountains of New York, 2003–2005; the four standard (New York State) impact categories for species richness are defined.

**Table 8-1 Thresholds of biological response to changes in water acidity for benthic invertebrates published since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur—Ecological Criteria.**

Life Forms	Region	Potential Thresholds	Reference
Sensitive invertebrates present	Atlantic Canada	pH 5.2 to 6.1	<a href="#">Lacoul et al. (2011)</a>
Littoral macroinvertebrates	Northern Europe	pH 5.8 to 6.5	<a href="#">Schartau et al. (2008)</a>
Stream macroinvertebrates	Southwestern Adirondacks Mountains	pH 5.1 to 5.7	<a href="#">Baldigo et al. (2009)</a>
Stream macroinvertebrates	Sweden	pH 5.7 to 6.0	<a href="#">Andrén and Wiklund (2013)</a>

Using macroinvertebrate monitoring data (1,462 samples) from Northern Europe [Moe et al. \(2010\)](#) tested new and existing acidification metrics with the aim of selecting a common metric to assess pH effects on biota in this region. Most investigated metrics responded to pH, with most of the variance explained by a few variables, including the number of Ephemeroptera families and the proportion of sensitive Ephemeroptera. Most biological metrics were higher (less impacted) in humic than in clear waters, suggesting smaller acidification effects in humic waters. [Murphy et al. \(2013\)](#) described an approach for developing diagnostic indices for assessing acidity in British streams that could be useful in the U.S. Variation in macroinvertebrate assemblages in 76 test sites was quantified with a 197-site calibration set. The Acid Water Indicator Community Index expressed at the species level was related to base-flow pH and to storm-flow pH and ANC, accounting for 38 to 56% of the variation in acid condition.

Interactions among Al, pH, and organic matter, and their collective influence on toxicity to aquatic biota, are discussed in [Appendix 8.3.6](#). In general, decrease in pH brings larger amounts of Al into solution whereas when dissolved organic matter is also present, it binds with Al, converting it into organo-Al complexes, decreasing its toxicity. In six humic (mean total organic carbon [TOC] 10–18 mg/L) streams in central Sweden, [Andrén and Wiklund \(2013\)](#) evaluated acute and sublethal toxicity of macroinvertebrate salmonid prey items exposed to episodes of acidity during spring snowmelt. The threshold for mortality was pH <5.7 and inorganic Al >20 µg/L (0.7 µM) for mayflies (*Baetis rhodani*) and pH <6.0 and inorganic Al >15 µg/L (0.6 µM) for the freshwater amphipod *Gammarus pulex*. [Traister et al. \(2013\)](#) investigated shifts in macroinvertebrate communities and food webs in nine small forested streams in the Czech Republic across a

pH gradient from 4.0 to 7.7. Acidification was related to reduced taxon richness and reduced Ephemeroptera family richness and lower population densities.

---

### 8.3.4 Bacteria, Macrophytes, and Bryophytes

At the time of the 2008 ISA, most observations of biological effects of acidification were for phytoplankton ([Appendix 8.3.1.1](#)), benthic invertebrates ([Appendix 8.3.3](#)), and fish ([Appendix 8.3.6](#)), and relatively little information was available regarding the response of other biological taxa to surface water acidification. This has not changed appreciably. A few studies have been conducted on bacteria, macrophytes (aquatic plants), and bryophytes, as described below.

[Percent et al. \(2008\)](#) assessed bacterioplankton community diversity and structure in 18 Adirondack lakes across a range of acid-base chemistry using sequencing and amplified ribosomal DNA restriction analysis of constructed rRNA gene libraries. Based on principal components analysis, pH was positively correlated with bacterioplankton community richness and diversity. The richness of several bacterial classes, including Alphaproteobacteria, was directly correlated with pH. However, other environmental factors, such as lake depth, hydraulic retention time, dissolved inorganic C, and nonlabile (organically bound) monomeric Al, were also important in explaining bacterioplankton community richness and diversity, suggesting that acidity is only one factor that controls community composition.

Macrophyte studies provide additional information on the biological responses to acidic conditions in lakes. For example, a pH threshold for the absence of sensitive macrophytes was determined to be 5.5 in Atlantic Canada lakes by [Lacoul et al. \(2011\)](#). In an analysis of factors affecting the distribution of aquatic macrophytes in lakes in the Pyrenees Mountains of southern Europe, [Pulido et al. \(2015\)](#) constructed statistical models to predict optimum ranges and ecological niches of 11 aquatic macrophyte species. Macrophytes were most suited to lakes with low water concentrations of  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$  in vegetated watersheds at low elevation. It was possible to delineate individual species ranges along gradients of specific conductance and water pH.

Bryophytes, most notably mosses and liverworts, are nonvascular plants that often constitute an important component of the biodiversity and productivity of low-order streams. [Tessler et al. \(2014\)](#) assessed bryophyte assemblages in southeastern New York streams and found that some species like *Hygrohypnum egyptium* and *Codriophorus aduncooides* were generalists and able to tolerate pH in the range from approximately 4 to 7, whereas others were more strongly limited by pH. For example, *H. ochraceum* occurred only at circumneutral pH near 6.5, while *Andreaea rothii* was restricted to pH

<5. Stream pH and amount of bedrock substrate were identified in this study as the primary determinates of bryophyte assemblage composition.

---

### 8.3.5 Amphibians

Amphibians such as frogs, newts, toads, and salamanders have aquatic lifestyles and may be in contact with acidified waters in areas affected by acidifying deposition. Although some species of amphibian are on the decline, in the 2008 ISA, there was no evidence to suggest that acidic deposition was an important factor that impacts the health and abundance of amphibian communities ([U.S. EPA, 2008a](#)). Nevertheless, there are both relatively acid-sensitive and acid-tolerant amphibians. Examples of acid-sensitive amphibians in [Baker et al. \(1990a\)](#) include the spotted salamander (*Ambystoma maculatum*) and Jefferson salamander (*Ambystoma jeffersonianum*). Jefferson salamanders were absent from ponds with very low pH [ $<4.5$ ; [Freda and Dunson \(1986\)](#)]. Based on transplant studies into ponds or to the laboratory, embryos of this species did not hatch in water with pH less than about 4.5. Acid-tolerant embryos such as the Pine Barrens treefrog (*Hyla andersonii*) may hatch at a pH of 3.7 ([Freda and Dunson, 1986](#)). Toxicity is not solely a matter of pH, but is also influenced by  $\text{Ca}^{2+}$ , inorganic Al, and DOC concentrations, lifestyle, and water temperature ([Baker et al., 1990a](#)). Large-scale amphibian extinctions due to acidifying deposition had not been detected in any geographic region at the time of the 2008 ISA ([Baker et al., 1990a](#)) and have not been documented in more recent years.

Studies published since the 2008 ISA further indicate that amphibian species are relatively tolerant of acidifying conditions. In a review of toxicity data for amphibian species found in Atlantic Canada, [Lacoul et al. \(2011\)](#) concluded that some amphibians can survive at pH as low as 3.5 to 4.0. [Chambers et al. \(2013\)](#) explored the relationship between pH and hormonal response in salamanders. In their field studies with Jefferson salamander larvae from eight natural breeding populations and a mesocosm experiment with varying pH, they observed an increase in baseline corticosterone concentration with lower pH (in the range of 5 to 5.8). Elevation of baseline corticosterone level is a physiological alteration associated with stress response. In contrast, no significant relationship was observed between corticosterone and pH in adult Allegheny Mountain dusky salamanders (*Desmognathus ochrophaeus*) living in nine streams in the Central Appalachian ecoregion with differing pH ([Woodley et al., 2014](#)). Three-week laboratory exposures with the same species showed that low pH (3.5) decreased locomotory activity but had no effect on plasma corticosterone levels. A change of average pH from pH 7 to pH 6 resulted in a shift in the skin microbial community composition on larval American bullfrogs [*Rana catesbeiana*; [Krynak et al. \(2015\)](#)]. Following metamorphosis, shifts in

pH did not alter skin microbial community structure significantly in juvenile frogs. However, antimicrobial peptide production was affected by interactions between pH and degree of shading, suggesting that environmental variability may influence amphibian susceptibility to fungal pathogens.

---

### 8.3.6 Fish

Physiological and population-level responses associated with exposure of fish to acidified waters have been well characterized for many decades. As summarized in the NAPAP report by [Baker et al. \(1990a\)](#) and studies reviewed in the 2008 ISA, fish populations in acidified streams and lakes of Europe and North America have declined, and some have been eliminated due to atmospheric deposition of acids and the resulting decrease in pH and ANC and increase in inorganic Al concentrations in surface waters. By 1990, it was well established that freshwater acidification could cause significant adverse biological effects on fish, although the effects were not uniform across species. Summary information from the 2008 ISA for pH, ANC, and Al and effects on fish are presented in [Appendix 8.3.6.1](#) to [Appendix 8.3.6.5](#) along with results of new studies. In general, understanding of the effects of acidification on fish has not changed since the 2008 ISA. Effects of acidification on fish and other organisms must be viewed in the context of other stressors and management actions, in particular climate change and the effects of fish stocking.

Responses among fish species and lifestages within species to changes in pH and Al in surface waters are variable. In general, early lifestages such as larvae and smolts are more sensitive to acidic conditions than the young-of-the-year, yearlings, and adults ([Baker et al., 1990a](#); [Johnson et al., 1987](#); [Baker and Schofield, 1985](#)). Some of the most commonly studied species have been brown trout (*Salmo trutta*), brook trout (*Salvelinus fontinalis*), and Atlantic salmon (*Salmo salar*). Among these three species, [Gjedrem and Rosseland \(2012\)](#) recently showed substantial additive genetic variation in tolerance to acidic water, with heritabilities ( $h^2$ ) ranging from 0.09 to 0.27 for dead-eyed eggs (a development period that is highly sensitive to low pH [4.7 to 5.2]).

Several new studies of Atlantic salmon provide additional information documenting the sensitivity of this species to acidification during different lifestages. Evidence suggests that acidification has been an important stressor that has limited the distribution and abundance of Atlantic salmon in the northeastern U.S. Atlantic salmon are anadromous and they are susceptible to physiological effects of acidification as they develop and move to different habitats. The salmon start their life cycle in freshwater then migrate to the ocean, returning to freshwater to spawn. In rivers, eggs hatch into fry, which develop

into parr. Before migrating to the ocean, parr start developing into smolt, which are more sensitive to acidification than the parr lifestage ([Kroglund et al., 2008](#); [Monette and McCormick, 2008](#)). Recent research has shown that exposure to concentrations of inorganic Al that have no apparent effects in freshwater may subsequently affect smolt survival in seawater. Thus, the timing of acidification episodes in relation to fish lifestage and migration from freshwater to seawater may impact fish survival due to the delayed response to inorganic Al exposure ([Kroglund et al., 2008](#); [Kroglund et al., 2007](#)).

---

### 8.3.6.1 Physiological Responses to Acidification

The modes of action of biological impacts on fish from surface water acidification were reasonably well known at the time of the 2008 ISA. Physiological disturbances to fish exposed to acidic waters reported in the 2008 ISA included iono- and osmoregulatory failure, acid-base regulatory failure, and respiratory and circulatory failure. These impacts can often be directly attributed to effects on gill function or structure. Al has been shown to accumulate on the gill surface when fish are exposed to water having high inorganic Al concentration. The primary mechanism for the toxic effects of low pH and elevated inorganic Al on fish involves disruption of normal ion regulation at the gill surface, resulting in increased rates of ion loss and inhibition of ion uptake ([Bergman et al., 1988](#); [Wood and McDonald, 1987](#); [Leivestad, 1982](#); [McWilliams and Potts, 1978](#)). The disruption of salt and water balance causes red blood cells to rupture and blood viscosity to increase ([Driscoll et al., 2003b](#)). Additional effects might include disruption of Ca metabolism ([Reader et al., 1988](#); [Gunn and Noakes, 1987](#); [Peterson and Martin-Robichaud, 1986](#)) and loss of Ca from important binding sites in the gill epithelium, which reduces the ability of the gill to control membrane permeability ([Exley and Phillips, 1988](#); [Havas, 1986](#); [Mcdonald, 1983](#)).

Newly available literature since the last review supports previous findings of effects of acidification on fish physiology. Several in situ studies on brook trout in the southeastern U.S. and New England provide additional information on sensitivity of different fish lifestages to episodic acidification. Changes in native brook trout physiology were determined during two acid runoff episodes in the Great Smoky Mountains National Park by [Neff et al. \(2008\)](#). Results of an in situ bioassay of whole-body sodium concentrations before and after acidification showed that stream acidification negatively impacted native trout physiology. Loss of whole-body sodium when stream pH dropped below 5.1 indicated that trout lost the ability to ionoregulate. Stream water ANC and pH decreased episodically during the stormflow events studied. An ANC contribution analysis indicated that acidic deposition may have been the major cause of episodic stream acidification; increased concentrations of organic acid anions and base cation dilution

during episodes also appeared to be important. Subsequently, [Neff et al. \(2009\)](#) investigated the effects of hydrologic episodes on loss of blood plasma  $\text{Na}^+$  in native southern brook trout, a response associated with physiological stress from acid exposure. In situ bioassays were conducted at three sites during a 2-year period. Whole-body  $\text{Na}^+$  concentrations decreased by 10 to 20% following acidic episodes during which 24-hour mean pH values of 4.88, 5.09, and 4.87 and total dissolved Al concentration of 210, 202, and 202  $\mu\text{g/L}$  (7.8, 7.5, and 7.5  $\mu\text{M}$ ) were observed.

In a combination lab and field study designed to establish whether the smolt or parr lifestage is more sensitive to short-term acid/Al pulses, [Monette and McCormick \(2008\)](#) observed that compared with control fish, smolts exposed to elevated acid/Al levels showed greater losses of blood plasma  $\text{Cl}^-$  (9–14 mM) after 2 and 6 days and increases in plasma cortisol (4.3-fold) and glucose (2.9-fold) levels after 6 days of exposure, while parr were not affected. Gill  $\text{Na}^+/\text{K}^+$ -ATPase (NKA) activity was not affected in either lifestage. Smolts were shown to be more sensitive than parr to short-term acid/Al exposure although gill accumulation of Al was observed in both lifestages.

[McCormick et al. \(2009\)](#) determined the effects of pH and Al on survival, development of smolts, ion regulation, and stress levels of Atlantic salmon in southern Vermont. Two 6-day field studies during the peak of smolt development (late April and early May) were conducted in five streams having different acid-base chemistry. The researchers found increased mortality, loss of blood plasma chloride ( $\text{Cl}^-$ ), altered NKA activity in the gills, and higher gill Al in fish that were caged in streams that experienced low pH (5.4–5.6) and high inorganic Al concentration (50–80  $\mu\text{g/L}$  [1.9–3  $\mu\text{M}$ ]). Fish confined at sites that were less impacted by acidification showed more moderate decrease in blood plasma  $\text{Cl}^-$  and more moderate increase in plasma cortisol, glucose, and gill Al.

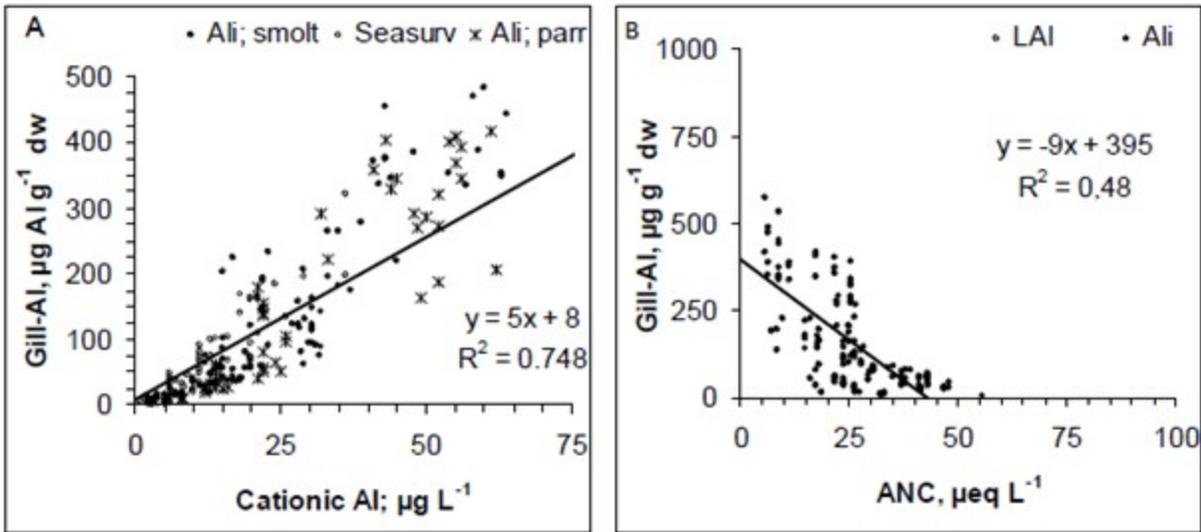

Individual Atlantic salmon physiological responses were strongly inter-correlated, with a single principal component axis (PC1) that comprised cortisol, glucose,  $\text{Cl}^-$ , and NKA accounting for 90% of the total variation in the physiological response variables data set ([McCormick et al., 2009](#)). The authors suggested that physiological impairment was the most appropriate interpretation of PC1. In a stepwise linear regression model using water chemistry variables only, PC1 scores were best explained by low pH ( $r^2 = 0.53$ ). Gill Al also was a strong predictor of physiological impairment.

Recent studies on salmon examined Al toxicity following transfer to seawater to simulate the physiological changes associated with migration to the marine environment. In an exposure to high acidity and inorganic Al followed by 24-hour seawater exposure, blood plasma  $\text{Cl}^-$  levels were higher in exposed fish than in controls, suggesting reduced seawater tolerance ([Monette et al., 2008](#)). Loss of seawater tolerance was accompanied by lower levels of gill NKA activity. Exposure to acidity and inorganic Al also caused

decreased plasma insulin-like growth factor (IGF-I) and levels of 3,3',5'-triiodo-L-thyronine (T-3). Results of this research suggest that smolt development and seawater tolerance can be affected by exposure to high acidity and inorganic Al despite an absence of detectable impacts on blood plasma ion regulation in freshwater. In 2- and 5-day Al/acid exposures of Atlantic salmon followed by a seawater challenge test, [Monette et al. \(2010\)](#) showed that seawater tolerance of smolt is reduced by prior acute exposure to acidic conditions and low levels of Al, and that the mechanisms of blood ion regulation depend on the extent and duration of Al exposure. In both seawater and freshwater, exposure to pH 5.3 and moderate Al levels led to accumulation of gill Al, alterations in gill morphology, reduced gill NKA activity, and impaired ion regulation. In contrast, gill Al accumulation was decreased, with only slight effects on gill morphology in smolts exposed to acidic conditions and the lowest level of Al concentration.

Sockeye salmon (*Oncorhynchus nerka*) fry were raised in freshwater for 126 days under sublethal conditions of low to moderate pH (4.8–6.8) by [Kennedy and Picard \(2012\)](#). Effects on growth, stress, and seawater tolerance were determined after smoltification. At the lower pH treatment (5.0), fish gained significantly less mass (average 46% of control [pH 6.8] values), exhibited lower condition factor, and showed lower liver somatic index values than control fish. The concentrations of liver glycogen (49% of control values) and whole-body lipids (65% of control values) were also significantly lower. Acid exposure caused increased stress, as measured by increased concentrations of blood plasma cortisol. Fish exposed to pH 5.0 in freshwater for 30 days, and then challenged with seawater, exhibited 14% higher mortality, on average, compared to control fish. They also showed osmoregulatory stress (increased blood plasma Na<sup>+</sup> and Cl<sup>-</sup> concentrations) and lower critical swimming speed (22% reductions compared to control fish). Results suggested that sockeye salmon are acid sensitive and do not acclimate to low pH under chronic exposure conditions. This sensitivity could decrease the probability of fish surviving after moving to the marine environment.

In a synthesis of results of bioassay studies on Atlantic salmon in Norway, gill Al concentration was significantly correlated with water inorganic Al and ANC [[Figure 8-2; \(Kroglund et al., 2008\)](#)]. They also analyzed results of seawater challenge tests showing that the fish had impaired hyporegulatory capacity due to inorganic Al exposure in freshwater.

Al = aluminum; Ali = inorganic monomeric aluminum; ANC = acid neutralizing capacity; dw = dry weight; g = gram; L = liter; LAI = labile aluminum; µg = microgram; seasurv = seawater survival.

Notes: Linear relationships are entered into the graphs whenever significant.

Source: [Kroglund et al. \(2008\)](#).

**Figure 8-2 Relationship between (a) inorganic monomeric aluminum and gill aluminum for parr and smolt, and (b) acid neutralizing capacity and gill aluminum.**

To assess the ability of Atlantic salmon smolts to recover from acid/Al exposure, [Nilsen et al. \(2013\)](#) subjected salmon for 2- and 7-day periods to low pH (5.7) and inorganic Al (40 µg/L [1.5 µM]). Fish were subsequently transferred to good quality water (control exposure; pH 6.8; inorganic Al <14 µg/L [0.52 µM]). Accumulations of Al on fish gills measured after 2 and 7 days of acid/Al exposure were  $35.3 \pm 14.1$  and  $26.6 \pm 11.8$  µg/g (dry weight), respectively. High gill Al decreased 2 days after moving exposed fish to control water, but gill Al was still higher than under sustained control conditions (5–10 µg/L [0.18–0.37 µM] inorganic Al) over the following 2-week period. Decreases in blood plasma  $\text{Na}^+$  levels were observed in both test groups and remained significantly lower than in control fish for the 2-week period after transferring fish to control water. Blood plasma  $\text{Cl}^-$  levels in smolts exposed for 7 days were significantly lower than in control smolts and then remained low in both treatments following transfer to control water. Treated smolts maintained high blood plasma glucose levels, indicative of increased stress, after being transferred to control water and for more than a week following exposure.

Responses of Atlantic salmon smolts to episodic pH fluctuations were assessed during in situ experiments in rivers and streams in eastern Maine ([Liebich et al., 2011](#)). Altered plasma chloride and plasma glucose were strongly correlated with pH, consistent with the laboratory findings of [Monette and McCormick \(2008\)](#) and others. High DOC concentrations in streams could reduce the inorganic Al impact by enhancing complexation with organic ligands.

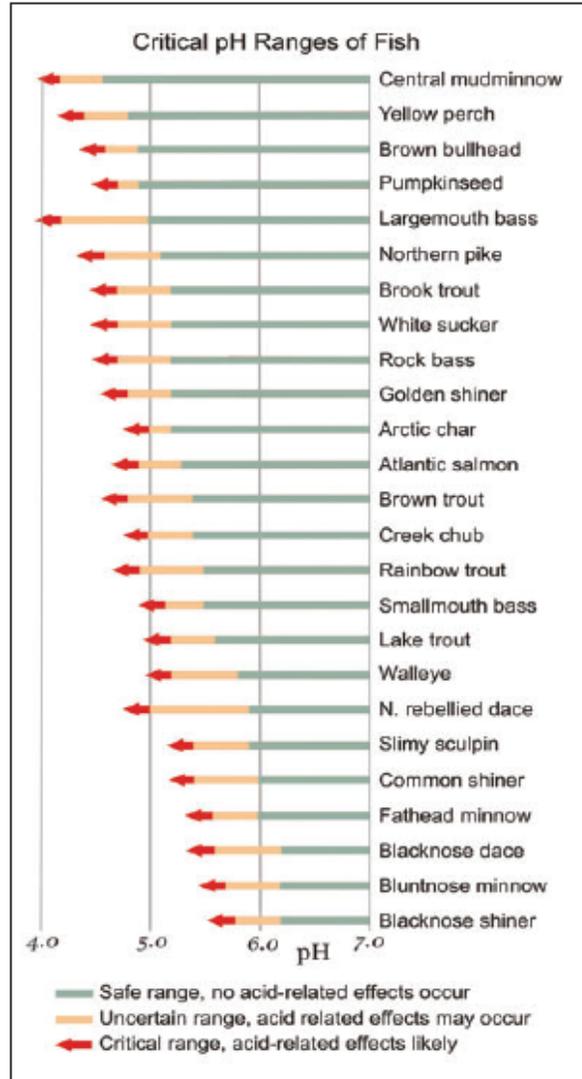

Recently, gill Al and NKA activity were assessed in smolts migrating downstream in New England ([Kelly et al., 2015](#)). Smolt immigrating from the Connecticut River, where most tributaries were well buffered, had low levels of gill Al and high levels of NKA activity. In the Merrimack River watershed, where most tributaries were characterized by low pH and high inorganic Al concentrations, salmon smolt immigrating downstream showed higher gill Al and lower gill NKA activity. Stocked salmon return rates were lower in the Merrimack River watershed, and the authors suggested that episodic acidification could be affecting salmon smolts in poorly buffered streams in New England.

---

### **8.3.6.2 Fish and pH Thresholds**

The detrimental effects on fish associated with pH are also closely tied to ANC, which is strongly correlated with water pH and Al [[Appendix 8.3.6.4](#); ([Driscoll et al., 2001b](#))]. In the 2008 ISA, pH effects on fish were well characterized. A pH range of 5.0 to 5.5 was found to cause the absence of several fish species ([Haines and Baker, 1986](#)). Among lakes with fish, there was an unambiguous relationship between the number of fish species and lake pH, ranging from about one species per lake for lakes having pH less than 4.5 to about six species per lake for lakes having pH higher than 6.5 ([Driscoll et al., 2001b](#); [Baker et al., 1990b](#)). The observations from field studies of pH effects on fish have been corroborated by bioassay data ([Figure 8-3](#)). Some species and lifestages experienced significant mortality in bioassays at relatively high pH [e.g., pH 6.0–6.5 for eggs and fry of striped bass and fathead minnow; [McCormick et al. \(1989\)](#); [Buckler et al. \(1987\)](#)], whereas others were able to persist at quite low pH without adverse effects. Many minnows and dace (Cyprinidae) are highly sensitive to acidity, but some common game species such as brook trout, largemouth bass, and smallmouth bass are less sensitive (threshold effects at pH <5.0 to near 5.5). In many Appalachian Mountain streams that have been acidified by acidic deposition, brook trout is the last fish species to disappear; it is generally lost at pH near 5.0 ([MacAvoy and Bulger, 1995](#)), which usually corresponds in these streams with ANC near 0 µeq/L ([Sullivan et al., 2003](#)). While brook trout and other fish species may be absent at pH <5.0, detrimental effects on

population size and density may occur at higher pH values ([Baker et al., 1990a](#); [Baker and Schofield, 1985](#)).

Notes: [Baker and Christensen \(1991\)](#) generally defined bioassay thresholds as statistically significant increases in mortality or by survival rates less than 50% of survival rates in control waters. For field surveys, values reported represent pH levels consistently associated with population absence or loss.

Source: [Fenn et al. \(2011b\)](#) based on [Baker and Christensen \(1991\)](#).

**Figure 8-3 Critical aquatic pH ranges for fish species.**

Studies in the Adirondack Mountains reviewed in the 2008 ISA demonstrated the effect of acidification on fish species richness. Of the 53 fish species recorded in Adirondack lakes, about half (26 species) were absent from lakes with pH below 6.0. Those 26 species included important recreational species plus ecologically important minnows that serve as forage for sport fish ([Baker et al., 1990b](#)). There is often a positive relationship between pH and number of fish species, at least for pH values between about 5.0 and 6.5, or ANC values between about 0 and 50 to 100  $\mu\text{eq/L}$  ([Cosby et al., 2006](#); [Sullivan et al., 2006a](#); [Driscoll et al., 2003b](#); [Bulger et al., 1999](#)).

Since the 2008 review, additional pH thresholds have been published for fish species ([Table 8-2](#)). A pH threshold of  $<5.9$  was identified as potentially harmful to Atlantic salmon smolts in eastern Maine ([Liebich et al., 2011](#)). [Kirby et al. \(2008\)](#) showed that when streams in central Pennsylvania had pH below 5 because of their underlying geology, brook trout were only present in 9 of 28 streams, whereas all streams that had  $\text{pH} \geq 6$  had brook trout. Overall, the available data suggested that the threshold for brook trout mortality is at about  $\text{pH} = 5.0$ .

Despite recent reductions in acidic deposition in northern Europe, mobilized Al remains a threat to brown trout that are native to many European fresh waters and stocked in many U.S. waters. [Andrén and Rydin \(2012\)](#) identified a threshold for healthy brown trout populations by exposing yearling trout to a pH and inorganic Al gradient in humic streams in Scandinavia. Results suggested a threshold of less than 20  $\mu\text{g/L}$  (0.74  $\mu\text{M}$ ) inorganic Al and pH higher than 5.0. Toxic effects beyond these thresholds included Al accumulation on the gills, increased hemoglobin and plasma glucose, decreased plasma chloride, and increased mortality.

Brown trout embryo and first-year juvenile survival in 12 streams in northern Sweden were investigated by [Serrano et al. \(2008\)](#) during snowmelt using in situ bioassays. The study streams had high DOC, which causes a pH decrease, but also protects fish against Al toxicity. High juvenile brown trout mortality was documented during the spring flood, in association with low pH. No significant effect of inorganic Al concentration on juvenile or embryo mortality was observed, likely due to Al complexation by organic acid anions. An empirical model developed to predict juvenile brown trout mortality in high-DOC streams suggested a critical chemical threshold of pH in the range of 4.8–5.4. High embryo and yolk sac fry survival was recorded, even at stream sites with pH as low as 4.0. As expected, the observed pH threshold in DOC-rich water was lower than previously observed thresholds for low-DOC freshwaters. First-year juveniles are likely to be most sensitive to adverse effects of low pH in northern boreal stream ecosystems, especially during snowmelt-driven episodic pH depressions.

**Table 8-2 pH thresholds in fish published since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur—Ecological Criteria.**

Interference of chemical alarm cues to assess predation risk in juvenile Atlantic salmon <sup>a</sup>	Canada	pH <6.6	<a href="#">Elvidge and Brown (2014)</a>

DOC = dissolved organic carbon; Na = sodium; NP = national park.

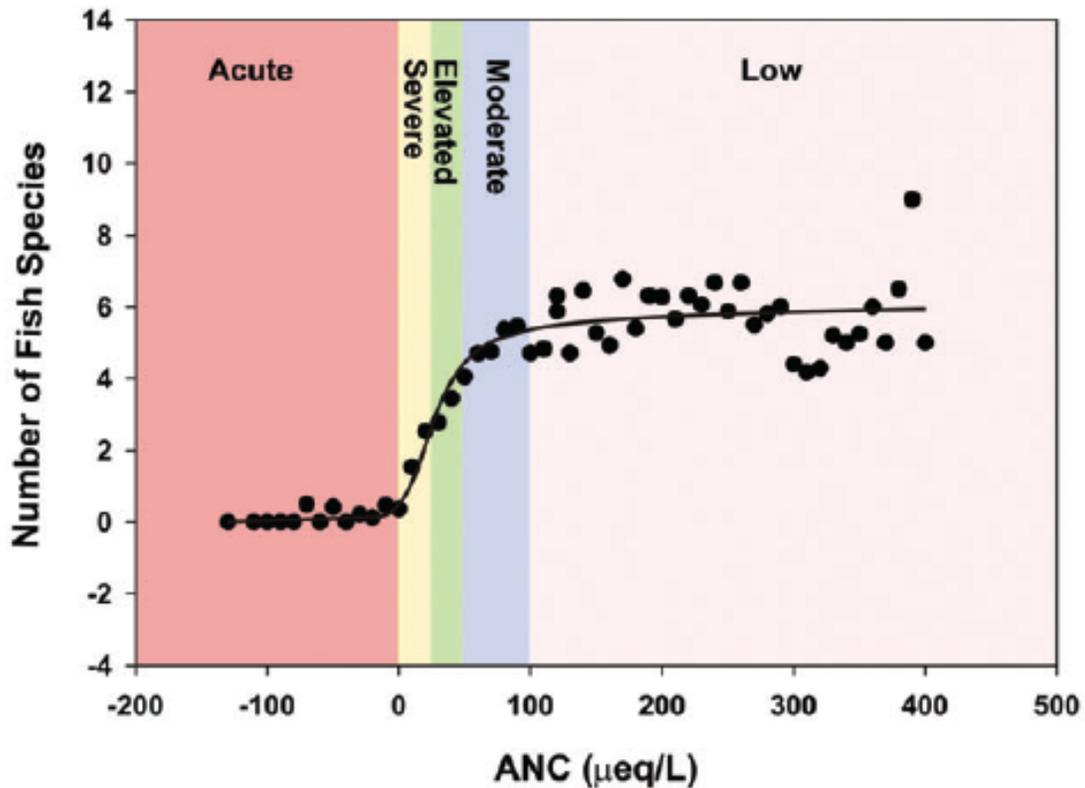

<sup>a</sup>Behavioral responses of fish are discussed in [Appendix 8.3.6.5](#). Table B-23 and Table B-24 in the 2008 ISA summarize pH thresholds from the NAPAP report ([Baker et al., 1990a](#)).

### 8.3.6.3 Fish and Acid Neutralizing Capacity Thresholds

ANC has been found in various studies reviewed in the 2008 ISA to be a good single indicator of the biological response and health of aquatic communities in acid-sensitive systems ([U.S. EPA, 2008a](#); [Sullivan et al., 2006a](#)). For fish and other aquatic biota, ANC is closely tied to pH ([Appendix 8.3.6.2](#)) and the bioavailability of Al [[Appendix 8.3.6.4](#); ([Driscoll et al., 2001b](#))]. There is often a positive relationship between pH or ANC and number of fish species, at least for pH values between about 5.0 and 6.5, or ANC values between about 0 and 50 to 100 µeq/L ([Cosby et al., 2006](#); [Sullivan et al., 2006a](#); [Bulger et al., 1999](#)). In Shenandoah National Park streams in Virginia, fish species richness was lower by one species, on average, for every 21 µeq/L decrease in ANC ([Sullivan et al., 2003](#); [Bulger et al., 1999](#)). Interpretation of species richness can be difficult, however,

because more species tend to occur in larger lakes and streams as compared with smaller ones, irrespective of acidity (Sullivan et al., 2003). This might be due to increased aquatic habitat complexity and diversity in larger watersheds (Sullivan et al., 2003).

As summarized in the 2008 ISA, lakes and streams having an annual average ANC < 0  $\mu\text{eq/L}$  generally do not support fish (Figure 8-4). The analysis shown in this figure suggests that there could be a loss of fish species with decreases in ANC below a threshold of approximately 50 to 100  $\mu\text{eq/L}$  (Sullivan et al., 2006a).

ANC = acid neutralizing capacity; L = liter;  $\mu\text{eq}$  = microequivalent.

Notes: The data are presented as the mean (filled circles) of species richness within 10  $\mu\text{eq/L}$  ANC categories, based on data collected by the Adirondacks Lakes Survey Corporation.

Source: Modified from Sullivan et al. (2006a).

**Figure 8-4** Number of fish species per lake verses acidity status, expressed as acid neutralizing capacity, for Adirondack lakes.

Various ecological effect criteria, including effects on fish communities, have been used to classify ranges of ANC values (Table 8-3). The use of these criteria lies in the

association between ANC and the surface water constituents that directly affect acidity-related stress. These include, in particular, pH,  $\text{Ca}^{2+}$ , and inorganic Al concentration. [Bulger et al. \(2000\)](#) developed ANC thresholds for brook trout response to acidification in forested headwater catchments in western Virginia. Across the eastern U.S., brook trout are often selected as a biological indicator of aquatic acidification because they are native to many eastern surface waters and because residents place substantial recreational and aesthetic value on this species. Note that because brook trout are comparatively acid tolerant, adverse effects on many other fish species would be expected at higher ANC than the threshold values that impact brook trout. Annual average ANC greater than about 50  $\mu\text{eq/L}$  is generally considered suitable for brook trout in southeastern U.S. streams. Such streams have sufficient buffering capacity to prevent acidification from eliminating this species, and there is reduced likelihood of lethal storm-induced acidic episodes. In streams having ANC > 50  $\mu\text{eq/L}$ , reproducing brook trout populations are expected if the habitat is otherwise suitable ([Bulger et al., 2000](#)), but some streams may periodically experience episodic chemistry that affects species more sensitive than brook trout. Streams having annual average ANC from 20 to 50  $\mu\text{eq/L}$  may experience episodic acidification during storms to pH and ANC levels that can be lethal to brook trout, as well as other fish ([Bulger et al., 2000](#)). Streams that are designated as episodically acidic (chronic ANC from 0 to 20  $\mu\text{eq/L}$ ) are considered marginal for brook trout because acidic episodes are likely ([Hyer et al., 1995](#)), although the frequency and magnitude of episodes can vary widely. Streams that are chronically acidic (average ANC less than 0  $\mu\text{eq/L}$ ) are not expected to support healthy brook trout populations ([Bulger et al., 2000](#)).

[Hesthagen et al. \(2008\)](#) used a regional water chemistry database to determine critical values of pH, ANC, and inorganic Al for survival of brown trout in 790 Norwegian lakes. The threshold value ( $\text{ANC}_{\text{limit}}$ ) to avoid fish damage was compared with that found in a similar study conducted in 1986. In 1995, the threshold ANC value to avoid toxic effects to fish and retain unaffected fish populations was 67  $\mu\text{eq/L}$ , compared with 20  $\mu\text{eq/L}$  in 1986. The higher  $\text{ANC}_{\text{limit}}$  found for 1995 was attributed to lower pH and higher inorganic Al concentration at a given ANC value in 1995 than in 1986. This, in turn, was attributed to increases in total organic carbon in these lakes. Thus, the value of ANC as an indicator of biological effects may differ between acidification and recovery periods.

**Table 8-3 Expected ecological effects and concern levels in freshwater ecosystems at various levels of acid neutralizing capacity.**

Category Label	ANC Level µeq/L	Expected Ecological Effects
Low concern (no effect)	>100	Fish species richness may be unaffected. Reproducing brook trout populations are expected where habitat is suitable. Zooplankton communities are unaffected and exhibit expected diversity and distribution.
Moderate concern (minimally impacted)	50 to 100	Fish species richness begins to decline (sensitive species are lost from lakes). Brook trout populations are sensitive and variable, with possible sublethal effects. Diversity and distribution of zooplankton communities begin to decline as species that are sensitive to acid deposition are affected.
Elevated concern (episodically acidic)	0 to 50	Fish species richness is greatly reduced (more than half of expected species are missing). On average, brook trout populations experience sublethal effects, including loss of health and reproduction (fitness). During episodes of high acidity, brook trout may die. Diversity and distribution of zooplankton communities decline.
Acute concern	<0	Near complete loss of fish populations is expected. Planktonic communities have extremely low diversity and are dominated by acid-tolerant forms. The numbers of individuals of plankton species that are present are greatly reduced.

ANC = acid neutralizing capacity; L = liter; µeq = microequivalent.

Based on data from southern Appalachian streams and from Shenandoah National Park.

### 8.3.6.4 Fish and Aluminum Thresholds

The detrimental effects of Al on fish are closely tied to Al solubility, complexation, and speciation, which are all strongly influenced by pH ([Appendix 8.3.6.2](#)), ANC ([Appendix 8.3.6.3](#)), and concentrations of organic acids ([Driscoll et al., 2001b](#)). Al has no established biological function and dissolved inorganic Al can be highly toxic to fish and other aquatic biota. The current U.S. EPA acute and chronic Aquatic Life Criteria for Al are 750 and 87 µg/L, respectively, and not more than once every 3 years on average ([U.S. EPA, 1988](#)). In the 2008 ISA, elevated concentrations of inorganic Al associated with acidification of surface waters were shown to affect fish populations and communities in parts of the Adirondack Mountains of northern New York ([Simonin et al., 1993](#); [Kretser and Gallagher, 1989](#); [Johnson et al., 1987](#); [Schofield and Driscoll, 1987](#); [Baker and Schofield, 1982](#)), in acid-sensitive streams of the Catskill Mountains of southeastern New York ([Charles and Christie, 1991](#)), and the Appalachian Mountains from Pennsylvania to Tennessee and South Carolina ([Bulger et al., 2000](#); [Bulger et al., 1999](#); [SAMAB, 1996](#)). In one study reviewed in the 2008 ISA, 20% mortality of caged young-of-year brook

trout in poorly buffered headwater streams in the Adirondacks was documented during a 30-day period with a median inorganic Al concentration of 54 µg/L [2 µM/L; [Baldigo et al. \(2007\)](#)]. The authors estimated that 90% mortality would occur over 30 days, in response to a median inorganic Al concentration of 108 µg/L (4.0 µM/L). Threshold values for Al from [Baker et al. \(1990a\)](#) for various species and effects were summarized in the 2008 ISA. These values, along with additional Al thresholds for various fish species and endpoints, are listed in [Table 8-4](#). Field studies of the effects of Al on aquatic biota are typically confounded by simultaneous pH effects. Both inorganic Al and H<sup>+</sup> can be toxic, and the solubility of inorganic Al is strongly pH-dependent.

Since the 2008 ISA, additional Al thresholds for salmonids have been published ([Table 8-4](#)). In a synthesis of 347 short term (<14 days) exposures (in tanks fed river water or in tanks where water quality was manipulated) of salmon parr and smolt performed between 1990 and 2003 in Norway, [Kroglund et al. \(2008\)](#) identified dose-response relationships for pH, inorganic Al concentration, ANC, gill Al, and time of first fish mortality over a 10-day exposure period ([Figure 8-5](#)). Results of smolt releases were also evaluated after pre-exposure to moderately acidic waters. All smolt survived at pH >5.8 and inorganic Al <200 µg/L (7.4 µM). For parr, mortality increased at pH <5.6 or inorganic Al >45 µg/L (1.7 µM). In the same study, seawater challenge tests were analyzed where smolts were pre-exposed to sublethal concentrations of Al in freshwater and then moved to saltwater. As freshwater pH decreased and inorganic Al concentration increased, hypo-osmoregulatory capacity decreased, and increased mortalities were observed. Smolt exposed to >5 to <10 µg/L (0.18–0.37 µM) inorganic Al in freshwater and then released into seawater had a 25 to 50% reduction in survival based on data from a sea survival program in the River Imså in Norway ([Kroglund et al., 2008](#); [Kroglund et al., 2007](#)).

Additional studies have characterized the role of DOC in influencing Al bioavailability and subsequent effects on fish. In a field study of Atlantic salmon smolts in streams in eastern Maine, observations suggested that streams with moderate to high DOC concentrations buffered the effects associated with low pH and high total Al concentrations ([Liebich et al., 2011](#)). Smolts exposed to high DOC waters had lower gill Al concentrations compared to smolts in low DOC waters having similar pH and Al concentrations.

**Table 8-4 Threshold values of aluminum for various fish species and associated effects.**

Type of Study	Taxa	pH	Al ( $\mu\text{g/L}$ )	Observed Effect	Form of Al	Country	Reference
Field study	Brook trout ( <i>Salvelinus fontinalis</i> )	4.9	286	No survival of trout stocked into lakes with higher total Al (even after accounting for pH effects)	Total	U.S.	<a href="#">Schofield and Troinar (1980)</a>
Laboratory exposure	White sucker ( <i>Catostomus commersoni</i> )	5.2	200	>50% larval mortality	Total	U.S.	<a href="#">Baker and Schofield (1982)</a>

### 8.3.6.5 Behavioral Responses to Acidification

New studies in salmonids have shown effects of acidification on behavioral endpoints. Using hatchery-reared juvenile Atlantic salmon, [Elvidge and Brown \(2014\)](#) conducted a tethering experiment in reaches of neutral ( $\text{pH} \geq 6.6$ ) and low pH ( $< 6.6$ ) salmon nursery streams, plus one additional stream that varied between pH classes. The researchers observed that the tethered fish in the low-pH streams were more likely to be preyed upon than fish in the neutral streams although there were fewer predatory fish species, similar availability of physical refugia, and similar threat from terrestrial predators. [Leduc et al. \(2009\)](#) quantified alarm behavior of juvenile Atlantic salmon exposed to chemical alarm cues in a stream before and after rainfall. Before rainfall, fish exhibited an alarm response in the study streams. After rainfall, fish from the higher pH (near 7.5) stream continued to respond, but those from the lower pH (near 6.2) stream did not. The researchers suggested that episodic acidification in small nursery streams may disrupt the information mediated by chemical alarm cues and contribute to higher fish mortality. This may be the first published study documenting the disruption of a chemical messenger by acidification of stream water.

---

### 8.3.7 Fish-Eating Birds

The 2008 ISA reviewed the limited studies that documented effects of acidification on birds. Acidification has been shown to disrupt food web dynamics causing alteration to bird diet, breeding distribution, and reproduction. [Lacoul et al. \(2011\)](#) reviewed studies of acidification on aquatic birds and noted that in the Atlantic Canada region, breeding was limited to lakes and streams that had pH higher than 5.5. A substantial amount of research has recently been conducted on air pollution effects on birds, but the focus of that work has been on mercury exposure, and results are not discussed here. Deposition effects of mercury on biota in the Adirondacks are described in [Appendix 12](#).

---

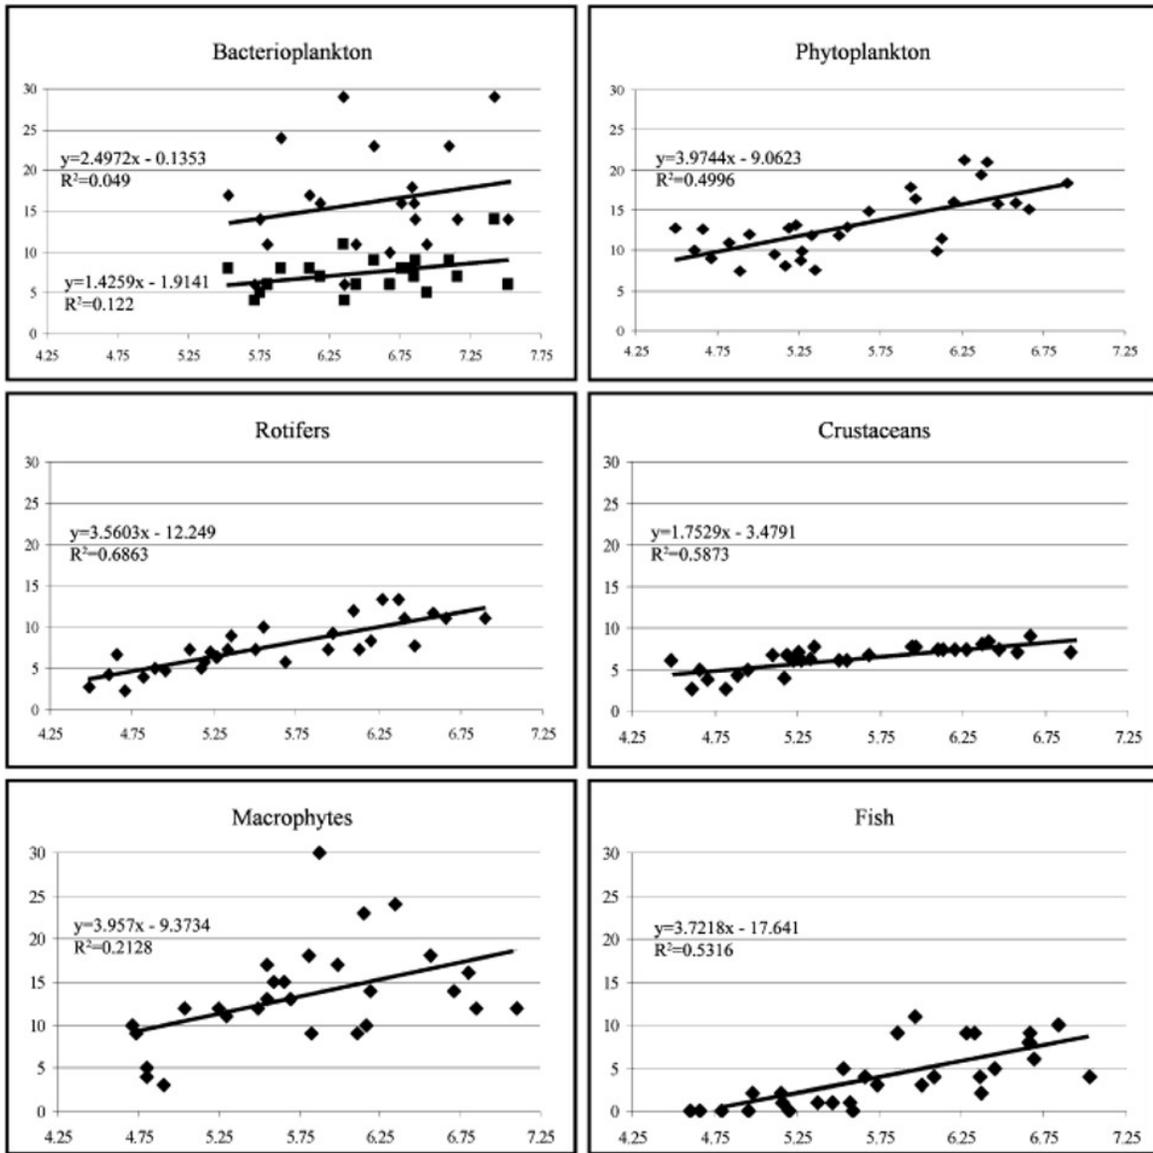

### 8.3.8 Aquatic Assemblages

In the 2008 ISA, decreases in species richness in response to surface water acidification were reported in lakes and streams for all major trophic levels of aquatic organisms ([Baker et al., 1990a](#)), even after adjusting for lake size ([Matuszek and Beggs, 1988](#); [Schofield and Driscoll, 1987](#); [Frenette et al., 1986](#); [Rago and Wiener, 1986](#); [Harvey and Lee, 1982](#)). Acidification was also found to cause decreases in food web complexity (indicated by the number of trophic links or species) in Adirondack lakes ([Havens and Carlson, 1998](#)).

Since the 2008 ISA, several studies have considered effects of species assemblages associated with acid-impacted water bodies. [Nierzwicki-Bauer et al. \(2010\)](#) presented baseline midsummer chemistry and community composition of phytoplankton, bacteria, rotifers, crustaceans, macrophytes, and fish in 30 lakes of the southwestern Adirondacks ([Figure 8-6](#)). Species richness in the lakes was correlated with acid-base chemistry at all trophic levels except bacteria. The decrease in number of taxa per unit pH was similar among groups and ranged from 1.75 (crustaceans) to 3.96 (macrophytes).

Following the 5-year experimental acidification of Little Rock Lake in Wisconsin from pH 6.1 to 4.7, [Hogsden et al. \(2009\)](#) observed greater reductions in species richness at higher trophic levels (fish and zooplankton) compared to algae. The authors suggested that the observed asymmetrical food web response could have implications for biological recovery of lakes. This study was limited, however, by the fact that the experimental acidification only involved the lake and not the watershed. Cladoceran assemblages reconstructed by [Moss crop et al. \(2015\)](#) from lake sediment cores from 30 lakes in Ontario, Canada showed that in shallow lakes, there was no significant difference in the remains of cladoceran taxa deposited in sediments between present-day and preindustrial sediments. In deeper lakes, relative abundance of cladocerans had shifted over time. The researchers hypothesized that cladoceran assemblages in shallower lakes might be influenced more by habitat than by water chemistry and that Ca availability may vary spatially in shallow lake areas or that cladoceran species living in littoral zones may be less sensitive to low Ca.

In an analysis of pH effects on grazing and herbivory in 20 stream food webs across the British Isles, considerable species differences were observed across a pH gradient from 5.0 to 8.4 ([Layer et al., 2013](#)). Three dose-response relationships were characterized for diatom assemblages ([Figure 8-7](#)). Macroinvertebrate taxon richness and benthic density were plotted against stream pH for all primary consumer taxa as well as by trophic group (shredders, herbivore-detritivores, collectors, grazers; [Figure 8-8](#)). At low pH, generalist herbivore-detritivores dominated the primary consumer assemblage. At higher pH, they were partially replaced by specialist grazers. The researchers concluded that the ability of acid-tolerant herbivore-detritivores to exploit food resources and the low nutritional value of basal resources in acidified streams might decrease recolonization by specialist grazers in streams where chemical conditions are becoming less acidic.

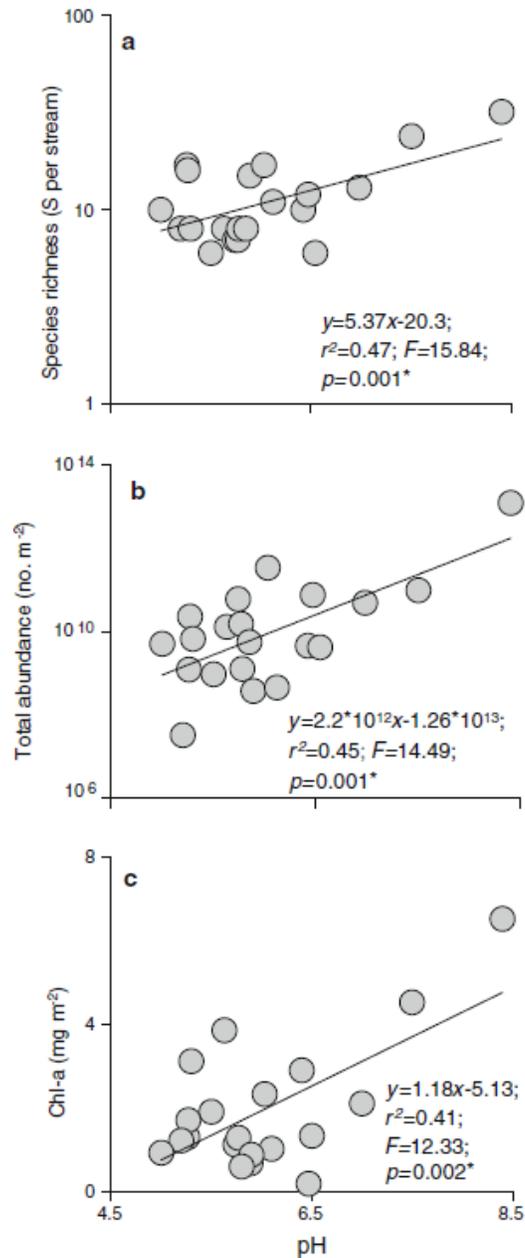

## Lake pH

Notes: The y-axis denotes number of groups (bacteria), taxa (phytoplankton) or species (rotifers, crustaceans, macrophytes, fish). The x-axis denotes the pH range that occurred in the 30 study lakes. Note: in the bacterioplankton graph, two regressions were run on the basis of genera (diamonds) and classes (squares).

Source: [Nierzwicki-Bauer et al. \(2010\)](#).

**Figure 8-7** Structure of diatom assemblage in 20 streams across a pH gradient of 4.5–8.5. (a) Species richness ( $\log_{10}$ -transformed numbers of diatom species per stream), (b) total abundance of diatoms ( $\log_{10}$ -transformed numbers of individuals per  $m^2$ ), (c) chlorophyll a concentration (mg chlorophyll a per  $m^2$ ), as a measure of algal biomass.

n.s. = not significant; S = sulfur.

Notes: statistical significance was determined using linear regression analysis. Asterisk denotes a statistically significant result at  $p < 0.05$ .

Source: [Layer et al. \(2013\)](#).

**Figure 8-8** Macroinvertebrate community composition in 20 streams across a pH gradient. Taxon richness (total number of primary consumer taxa; left panel) and benthic density [number of individuals  $\log_{10}(x + 1)$ -transformed; right panel] plotted against stream pH, all primary consumers (a, b), shredders (excluding Leuctridae and Nemouridae) (c, d), herbivore-detritivores (Leuctridae and Nemouridae) (e, f), collectors (g, h) and grazers (i, j).

[Lacoul et al. \(2011\)](#) reviewed available information on the effects of water acidification on aquatic organisms in Atlantic Canada. The pH threshold 5.0 was critical to sensitive macrophytes.

New analytical methods have recently been developed for detecting and quantifying ecological thresholds, such as tipping points for ANC or other acid-base chemical parameters at which adverse impacts on aquatic assemblages occur ([Baker and King, 2010](#)). Previous methods for designating ecological community thresholds have been based on univariate indicators or multivariate dimension-reduction of community structure. They tend to be insensitive to the responses of taxa that have low occurrence frequencies or highly variable abundance. The Threshold Indicator Taxa Analysis (TITAN) statistical tool detects changes in taxa distributions and abundances along an environmental gradient, such as ANC for example. It uses indicator species scores to integrate occurrence, abundance, and directionality of taxa responses by optimizing the value of a continuous variable that partitions sample units while maximizing taxon-specific scores. It emphasizes the relative magnitude of change and increases the contributions of taxa that have low occurrence frequencies and high sensitivity to the gradient. As an example, [Baker and King \(2010\)](#) assessed macroinvertebrate community response to a nutrient (e.g., P) gradient using TITAN. Results supported previous threshold estimates but with lower confidence limits. Several taxa were shown to decline at lower levels of P concentration.

In 28 subwatersheds of the Neversink River Basin in the Catskill Mountains, NY, [Harpold et al. \(2013\)](#) used a simple hydrogeomorphic model as a tool to predict impacts of acidification on biological communities. The model, which considered watershed slope and drainage density to estimate ANC, successfully predicted several measures of macroinvertebrate and fish community richness.

---

## 8.4 Documentation of Biological Recovery

The biological impact of acidifying deposition is mediated through changes in water quality that in turn impact biota. Deposition of N and S can lead to a cascade of biogeochemical changes ([Appendix 4](#) and [Appendix 7](#)) that may induce biological effects. It is often difficult to separate nutrient enrichment ([Appendix 9](#)) and acidification stressors, as they act simultaneously in some water bodies. [Posch et al. \(2011\)](#) argued that linking nutrient and acidity chemical criteria to vegetation occurrence on a regional scale is an approach that can be used to identify optimal N and S deposition limits to sustain a prescribed biodiversity goal (see [Appendix 8.5.4](#)).

Trajectories of biological recovery as used in this ISA are defined in [Section IS.11](#). Complete biological recovery would entail a return to similar species make-up, richness, and abundance as existed in the ecosystem in question prior to the advent of human-caused acidic deposition (around the year 1860 in North American ecosystems). Biological recovery from past acidification is a process affected by chemical, climatic, biological, chance, and hydrologic influences over time. It may, under certain conditions, follow chemical recovery of such water quality constituents as pH, ANC, and the concentrations of  $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ , inorganic Al, and DOC. Both chemical and biological recovery can, and often do, lag behind changes in the levels of S and/or N emissions and deposition because of chemical, hydrological, and biological processes and constraints. In addition, the ANC level that reflects recovery of pH or inorganic Al may differ between the acidification and recovery phases ([Hesthagen et al., 2008](#)). In a practical sense and depending on the level of impact, complete biological recovery may not be attainable at many acidified locations within a reasonable management timeframe because soil reserves of base cations at many locations have been depleted in response to many decades of acidic deposition and because other stressors, in addition to acidic deposition, have also altered ecosystem structure and/or function or will do so in the coming decades. Such stressors include changes in climate, land use, and other perturbations. More commonly, only partial biological recovery may be possible. Ecosystems deemed to be on a recovery trajectory are those found to be moving towards a mix of species presence and abundance that approximates the undisturbed state.

Biological recovery can occur only if chemical recovery ([Appendix 7](#)) is sufficient to allow growth, survival, and reproduction of acid-sensitive plants and animals ([Driscoll et al., 2001b](#)). Also, chemical recovery of ANC or pH may not necessarily follow the reverse of the acidification path due to changes in relationships among ANC, pH, DOC, and Al; depletion of soil base cation pools; hydrology; climate; and/or partially reversible (or irreversible) S adsorption on soils. In the 2008 ISA, studies of biological recovery generally indicated that the time required for biological recovery is uncertain and that biological responses typically lag behind chemical recovery and may take decades from the onset of chemical recovery ([U.S. EPA, 2008a](#)).

Literature reviewed in the 2008 ISA suggested that the time required for recovery of biota varies. In general, macroinvertebrate populations in streams recover more rapidly (within approximately 3 years in response to improved chemical conditions), relative to lake populations of zooplankton, followed by increases in lake fish populations which may occur 5 to 10 years after zooplankton recovery ([Driscoll et al., 2001b](#); [Gunn and Mills, 1998](#)). Biological recovery of previously acidified surface waters can lag behind chemical recovery because of factors such as limits on dispersal and recolonization ([Gray and Arnott, 2011](#)), barriers imposed by water drainage patterns ([Jackson and Harvey, 1995](#)),

the influence of predation ([Layer et al., 2011](#); [Mcnicol et al., 1995](#)), and other environmental stressors ([Yan et al., 1996b](#); [Yan et al., 1996a](#); [Gunn et al., 1995](#); [Havas et al., 1995](#); [Jackson and Harvey, 1995](#); [Mcnicol et al., 1995](#)). Biological recovery is likely to occur in stages due to differences among species in acid sensitivity and the rate of recovery of affected organisms ([Driscoll et al., 2007b](#)). In a study reviewed in the 2008 ISA, recovery of the zooplankton community in an experimentally acidified lake did not retrace the same trajectory as the initial deterioration due to acidification, indicating substantial hysteresis in recovery ([Frost et al., 2006](#)). Biological recovery research from the Sudbury region of Ontario, Canada was highlighted in the 2008 ISA. This region, formerly impacted by smelter operations, has been important for clearly documenting the chemical and biological effects of S and metal deposition as well as subsequent recovery from acidification.

New studies at multiple trophic levels continue to support findings presented in the 2008 ISA that biological recovery has lagged behind chemical recovery in many systems and that the lag response may vary among taxa and water bodies. Several long-term studies of water acidification indicate that biological recovery has been limited despite significant deposition reductions and improvements in water chemistry ([Baldigo et al., 2016](#); [Battarbee et al., 2014](#); [Murphy et al., 2014](#); [Angeler and Johnson, 2012](#)). Other studies, such as Honnedaga Lake and Brooktrout Lake in the Adirondacks, show more evidence for return of biota to levels approaching preacidification levels ([Sutherland et al., 2015](#); [Josephson et al., 2014](#)). In Brooktrout Lake, biological recovery of the food web structure has begun, in part, due to reintroduction and reestablishment of brook trout in the lake. Ongoing biological recovery cannot necessarily be expected to conclude with the return of the biological community to preacidification conditions, however. This is due to factors such as differences in the rate of recovery of aquatic organisms, permanent loss of some acid-sensitive species, and irreversible chemical and physical alterations to aquatic environments during acidification ([NAPAP, 2011](#)). Effects of other stressors can modify the recovery trajectories of aquatic ecosystems that have experienced acidification. Of particular importance in this regard are the introduction of species of fish or other organisms, either purposely as in the case of fish stocking by state agencies or local organizations or inadvertently. In the coming years, warming of surface waters in response to climate change may become increasingly important. For example, ([McDonnell et al., 2015](#)) showed that stream acidity (a top-down stress) together with stream warming (a bottom-up stress) cause a reduction in the extent of stream habitat in the southern Appalachian Mountains that is suitable for cold-water aquatic biota.

---

## 8.4.1 Phytoplankton Recovery

In the 2008 ISA, phytoplankton recovery from experimental acidification showed an increase in phytoplankton species richness and diversity with increased lake pH. In Lake 223 in the Experimental Lakes area of Ontario, there was little increase in phytoplankton diversity as pH changed from 5.0 to 5.8 but a strong recovery of diversity at pH above 6 ([Findlay and Kasian, 1996](#)). In Lake 302S, profound biological changes began at pH 5.5, with phytoplankton assemblages at pH below 5.5 resembling those in acidified lakes. [Findlay \(2003\)](#) reported that lakes that were previously low in pH (5.0 to 5.5) and are now above pH 6 have shifted towards phytoplankton assemblages more typical of circumneutral environments. Recent studies on responses of phytoplankton to decreased acidity have been limited. [Josephson et al. \(2014\)](#) reported that observed increases in chlorophyll *a* and decreases in water clarity in Honnedaga Lake, NY in recent years reflect an increase in phytoplankton abundance in association with chemical recovery from acidification.

The 2008 ISA reported results of several paleolimnological studies that used fossil remains of diatoms or chrysophytes in lake sediments to infer lake chemistry at discrete time periods in the past. These studies provided valuable information regarding the extent of historical acidification, especially in the Adirondack Mountains, by using well-established relationships between water chemistry and diatom community structure. The studies also provided the foundation for testing the performance of process-based dynamic models, such as Model of Acidification of Groundwater in Catchments (MAGIC), by comparing MAGIC hindcast simulations of water chemistry with diatom inferences of preindustrial pH and ANC ([Sullivan et al., 1990](#)).

Since the 2008 ISA, a number of additional paleolimnological studies have been conducted that have documented historical acidification and subsequent recovery ([Table 8-5](#)); however, most of the studies have been conducted in other countries. In one study from the U.S., diatom shifts were linked to historical changes in pH at Brooktrout Lake in the Adirondacks. *Fragilariforma acidobiontica*, a diatom that is often abundant at pH <5.0, was present in lake sediments deposited since the 1950s and shifts in *Mallomonas* and *Synura* were also observed ([Sutherland et al., 2015](#)). In another study, [Arseneau et al. \(2016\)](#) concluded that Adirondack lakes that were not previously acidified by acidic deposition will likely not recover to predisturbance chrysophyte community structure because of the influence of other stressors, including changes in climate.

**Table 8-5 Paleolimnological responses to changing lake chemistry published since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur—Ecological Criteria.**

Lake(s) Sampled/Region	Observation	Reference
Brooktrout Lake, Adirondacks	<i>Fragilariforma acidobiontica</i> , a diatom that is often abundant at pH <5.0, was present in lake sediments deposited since the 1950s.	<a href="#">Sutherland et al. (2015)</a>
Glasgow Lake, Nova Scotia	Diatoms inferred to have responded to acidification in response to a peak S loading of about 14 kg S/ha/yr during the mid-1970s.	<a href="#">Gerber et al. (2008)</a>
Four sampled lakes in Nova Scotia	Decline in <i>Daphnia</i> beginning in the early 20th century.	<a href="#">Korosi and Smol (2012)</a>
36 small headwater lakes in the Boreal Shield of south central Ontario	Large declines documented in relative abundances of Ca rich <i>Daphnia</i> spp. and increases in the Ca poor species <i>Holopedium glacialis</i> .	<a href="#">Jeziorski et al. (2012a)</a>
Lakes downwind of iron sintering plant northeast of Wawa, Ontario	Recent cladoceran sedimentary assemblages remain in an altered state, although lakes have returned to circumneutral pH.	<a href="#">Jeziorski et al. (2013)</a>
Low-Ca lakes (mean 2 mg/L) from the Experimental Lakes area, Ontario	Present-day cladoceran assemblages including <i>Bosmina</i> spp. and <i>H. glacialis</i> differed from preindustrial assemblages.	<a href="#">Jeziorski et al. (2014)</a>
Middle Lake (limed in 1973) in the Experimental Lakes area, Ontario	Cladoceran assemblages have not returned to preacidification levels, and many rare species are not present.	<a href="#">Labaj et al. (2014)</a>
Two boreal lakes in the Killarney lakes region, Ontario recovering from acidification	Cladoceran assemblages varied little from preindustrial times to recovery. <i>Bosmina</i> spp. dominated in the lakes.	<a href="#">Labaj et al. (2015)</a>
54 lakes in the Muskota-Haliburton region of Ontario	Numbers of planktonic diatoms such as <i>Cyclotella stelligera</i> have increased with lake DOC and warming from 1992 to present.	<a href="#">Hadley et al. (2013)</a>
Four boreal lakes recovering from acidification and four minimally disturbed lakes in Sweden	Phytoplankton and littoral assemblages in acidified lakes become more similar to reference lakes over time. Differences were greatest for phytoplankton assemblages.	<a href="#">Johnson and Angeler (2010)</a>

Ca = calcium; DOC = dissolved organic carbon; L = liter; mg = milligrams; S = sulfur.

In a lake study from Sweden, [Johnson and Angeler \(2010\)](#) compared phytoplankton and littoral assemblages in four boreal lakes recovering from acidification and four minimally disturbed reference lakes over a two-decade period. They observed that assemblages in the previously acidified lakes became more similar to assemblages in reference lakes over

time. Differences were greater for phytoplankton assemblages than for invertebrate assemblages. Biological responses were correlated with inter-annual variability in climate, in addition to decreased water acidity. [Hadley et al. \(2013\)](#) conducted a resurvey of 54 lakes in the Muskota-Haliburton region of south-central Ontario. They documented recent changes in chemistry and biology for the lakes using sediment cores and diatom transfer functions. Observed pH increases were accompanied by decreases in acidophilic diatoms. However, diatoms were observed to be moving toward a novel assemblage rather than the preacidification assemblage. Lake DOC concentration has increased from 1992 in the lakes sampled [Hadley et al. \(2013\)](#), as have the numbers of planktonic diatoms such as *Cyclotella stelligera* commonly linked to climate warming. The concentration of Ca has decreased, and land use changes have further impacted the lakes. All of these factors may be influencing diatom assemblage recovery.

Sixteen lakes in Cape Breton Highlands National Park in Nova Scotia were assessed through sedimentary records for historical trends in water chemistry and changes in diatom assemblages. Only one lake (Glasgow Lake) was inferred to have acidified under peak S deposition (about 438 eq S/ha/yr) in the 1970s ([Gerber et al., 2008](#)). Six of the lakes, including Glasgow Lake, were modeled using the MAGIC model. The five other lakes that were modeled showed simulated patterns of acidification and subsequent chemical recovery but no evidence of acidification from the diatom analysis ([Gerber et al., 2008](#)). The authors suggested that the diatom approach was conservative and/or that the MAGIC model slightly overestimated changes in acid-base chemistry.

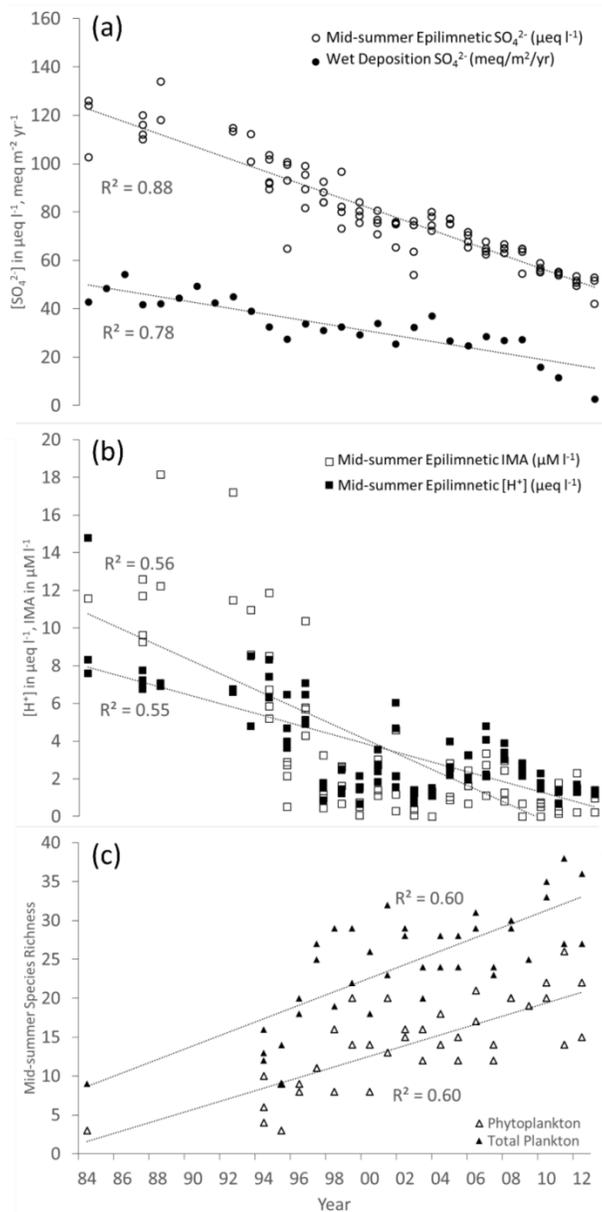

---

#### 8.4.2 Zooplankton Recovery

Several studies reviewed in the 2008 ISA reported zooplankton recovery in response to experimental deacidification of lakes. Zooplankton recovery was observed in experimentally acidified Lake 223 in the Experimental Lakes region in Canada as pH increased back to 6.1 ([Malley and Chang, 1994](#)). A lag of 1 to 6 years was observed in recovery of zooplankton in the experimentally acidified Little Rock Lake in Wisconsin ([Frost et al., 2006](#)). [Locke and Sprules \(1994\)](#) reported that acidification below pH 5 in the 1970s overcame the resistance stability of the zooplankton community in Ontario Precambrian Shield lakes. The subset of study lakes that showed pH recovery from acidification 20 years later in 1990 also showed recovery in the stability of the zooplankton community. [Holt and Yan \(2003\)](#) also noted recovery in zooplankton community composition (based on similarity to neutral lakes) in the subset of Killarney Park (Ontario) lakes in which the pH increased to over 6 during the 1971 to 2000 study period. They did not, however, note differences in the increase in species richness between the recovering lakes and nonrecovering lakes.

Studies published since the 2008 ISA provide further evidence for plankton recovery. In Brooktrout Lake in the Adirondacks, phytoplankton and rotifer taxonomic richness showed substantial increases ([Figure 8-9](#)) in association with pronounced decreases in lake  $\text{SO}_4^{2-}$ ,  $\text{H}^+$ , and inorganic Al concentrations ([Table 8-6](#)). In contrast, species richness of crustaceans changed little. [Sutherland et al. \(2015\)](#) suggested that the absence of crustacean recovery may have been due to the severity of the initial stress and continuing toxic pH conditions during some seasons, and/or to a large population of predatory chaoborus larvae present since the early 1980s when fish were absent from the lake. Paleolimnological evidence of zooplankton responses to changing lake chemistry published since the 2008 ISA is summarized in [Table 8-5](#).

Evidence from newly published studies in lakes near the former smelting complexes at Sudbury, Ontario, Canada indicate some evidence of biological recovery, although the relative recovery due to decreasing acidification versus recovery from decreased metal emissions and deposition is not clear. [Valois et al. \(2011\)](#) surveyed zooplankton community structural changes related to gradients of acidification, metal contamination, trophic status, and lake depth in 87 lakes around the smelter area. At  $\text{pH} > 6.0$ , community composition of copepods and cladocerans did not differ substantially from those in reference lakes. Recovery was evident in lakes that had  $\text{pH} > 5.5$ , with decreased community richness of copepod communities in lakes with lower pH. In the lakes around Sudbury, the survival of some zooplankton species, especially *Daphnia mendotae*, is limited by fish populations, notably yellow perch [*Perca flavescens*; ([Valois et al., 2010](#))]. The relative importance of changing acidity and metal contamination in driving the observed biological responses is not known. Nevertheless, results suggest that the re-establishment of the zooplankton community in lakes recovering from acid and metal stress may require improvements in both habitat quality and the integrity of the food web. [Babin-Fenske et al. \(2012\)](#) reported results of phylogenetic analyses of freshwater amphipod (*Hyalella* spp.) colonization in lakes near Sudbury. Two major groups of *Hyalella* were revealed, based on mitochondrial cytochrome c oxidase I sequences. One group was associated with recolonization of lakes that had historically been most acidified. The second group was associated with the more peripheral, less impacted, lakes.

H = hydrogen; IMA = inorganic monomeric aluminum;  $\mu\text{eq}$  = microequivalent;  $\mu\text{M}$  = micromolar; m = meter;  $\text{SO}_4^{2-}$  = sulfate; yr = year.

Source: [Sutherland et al. \(2015\)](#).

In a synthesis of 21 regional surveys of zooplankton recovery in lakes affected by acidic deposition in North America and Europe, [Gray and Arnott \(2009\)](#) identified the most commonly used metrics and factors indicating and limiting recovery of acid-impacted lakes. In the studies evaluated, species richness, the presence of indicator species, and relative species abundances were commonly assessed. At pH >6.0, recovery of zooplankton was significant, although often incomplete in both North American and European lakes. The authors identified slow chemical recovery, dispersal limitation, and community resistance as primary factors limiting biological recovery although the relative importance varied across the lakes and regions evaluated.

[Gray et al. \(2012\)](#) assessed the chemical and biological recovery of 45 previously acidified lakes in Killarney Park, Ontario. Zooplankton data were compared for the periods 1972–1973 and 2005. Significant increases in pH over time were documented for the majority of the study lakes. Species richness and diversity of many acid-damaged lakes only increased to a minor extent. They observed differing importance of biotic and abiotic conditions and dispersal processes in determining the relative contribution of copepod and cladoceran zooplankton in the post-recovery community structure, suggesting different expectations for recovery among different taxonomic groups. In a study of zooplankton communities in four of the lakes, dispersal limitation was identified as a factor impeding biological recovery ([Gray and Arnott, 2011](#)). The researchers observed a relatively quick return of acid-sensitive zooplankton species that disperse from streams and the egg bank and a slower return of species that depend on overland dispersal via wind or animal transport.

Several studies have focused on changes in cladoceran assemblages in response to lake chemistry. Cladocerans require relatively large amounts of available Ca for growth and survival. Soil Ca pools and drainage water concentration can be reduced under acidifying conditions. Under conditions of partial chemical recovery of previously acidified surface waters, Ca concentrations have remained chronically low in some waters in some regions, likely impeding biological recovery ([Jeziorski et al., 2012a](#)).

An important approach for studying biological effects of aquatic acidification entails long-term monitoring of biological community composition. This can be done via evaluation of sedimentary remains of aquatic organisms in sequential slices of lake sediment cores. Cladocerans have commonly been the focus of long-term monitoring and paleolimnological studies to document biological responses to changes in water chemistry and trophic structure [e.g., ([Cooper et al., 2016](#); [Nevalainen et al., 2014](#); [Davidson et al., 2010](#); [Kurek et al., 2010](#))].

[Jeziorski et al. \(2008\)](#) documented major reductions in the abundance of Ca-rich *Daphnia* spp. in association with decreases in the concentration of Ca in lake water. They reported that a high proportion of Canadian Shield lakes had Ca concentration near or below the threshold level (1.5 mg/L) for decreased survival and fecundity in laboratory studies. In a study from Nova Scotia, cladoceran remains from three of four sampled lakes showed a decline in *Daphnia* beginning in the early 20th century that suggested limnological changes in response to acidic deposition or increased fish predation ([Korosi and Smol, 2012](#)). Following closure of a S emitting iron sintering plant in 1998 in the region northeast of Wawa, Ontario, pH from three previously acidified lakes returned to circumneutral conditions due to the high buffering capacity of the local geology. However, biological recovery has lagged behind, with no recovery observed in

cladoceran sedimentary assemblages ([Jeziorski et al., 2013](#)). Analysis of sedimentary cladoceran assemblages from low-Ca lakes (mean < 2 mg/L) in the Experimental Lakes area of Ontario, Canada, [Jeziorski et al. \(2014\)](#) indicated differences between present-day and preindustrial cladoceran assemblages. In Middle Lake, a lake in the Experimental Lakes area that was limed in 1973, alterations in cladoceran assemblages were assessed using the sedimentary record ([Labaj et al., 2014](#)). Overall, the results suggested that biological recovery has not occurred in the lake because many rare species have not yet returned to preacidification levels.

Bosminids dominated the sedimentary cladoceran assemblage from two acidified lakes in the Killarney Lake region in Ontario, and minimal shifts were observed in the paleolimnological record from preacidification conditions to recovery ([Labaj et al., 2015](#)). In contrast, cladoceran abundance in acidified lakes near Sudbury, Ontario experienced greater shifts in cladoceran abundance best explained by contamination by copper (Cu) and nickel (Ni). In an earlier study, [Jeziorski et al. \(2012a\)](#) documented large declines in the relative abundances of Ca rich *Daphnia* spp. and increases in the Ca poor species *H. glacialis* in 36 small headwater lakes in the Boreal Shield of south central Ontario having Ca concentration <3 mg/L. [Reid and Watmough \(2016\)](#) estimated that timber harvesting at planned levels in the Muskoka River watershed in Ontario, Canada, will cause approximately a 30% increase in the number of sampled lakes that decline to Ca levels below 1 mg/L, too low to support some key aquatic species, including *D. pulex*, compared with a scenario of no further tree harvesting.

[Vrba et al. \(2016\)](#) evaluated the recovery of planktonic and littoral invertebrate communities over 12 years (1999–2011) in eight Bohemian Forest lakes in Europe. During the decades of the 1990s and 2000s, S and N deposition decreased by 86 and 44%, respectively. Half of the study lakes (those having Al concentrations lower than 200 µg/L [7.4 µM]) showed some degree of biological and chemical recovery. The lakes having Al concentrations higher than 200 µg/L (7.4 µM) did not show pronounced decreases in lake acidity or improved biological condition. Differences between data collected in 1999 and data collected in 2011 showed pronounced differences in biological recovery depending on the Al conditions, with largest recovery responses observed for zooplankton. Such changes were driven by species gains in ciliates and crustaceans and replacements of species of rotifers in the high-Al lakes. Changes in the low-Al lakes were dominated by both species gains and losses. Results of multivariate analyses suggested that the major driver of differences in biological recovery was Al concentration. Species in low-Al lakes responded to improved chemistry by exhibiting gradual patterns of change. Recovery of high-Al lakes was constrained by a toxicity threshold response. Overall, biological recovery in these Bohemian lakes lagged behind recovery of water

acid-base chemistry. Species gains and losses were due to responses of many aquatic species rather than to changes in a relatively few indicators.

Effects of regional landscapes on trait divergence in a freshwater copepod (*Leptodiaptomus minutus*) were investigated by testing differences in acid tolerance in three spatially distinct groups of lakes in northern Canada: (1) exclusively circumneutral lakes (pH >6.0) in Quebec, (2) heterogeneous mix of acidic and circumneutral lakes of Killarney, Ontario, and (3) a mainly acidic group of largely bog-influenced lakes interspersed with some circumneutral lakes at Cape Race in Newfoundland ([Dastis and Derry, 2016](#)). Acid-tolerant *L. minutus* from an acidic source pond survived better subsequent to transfer to both low (3.6) and high (7.0) pH conditions. Nevertheless, copepod survival was dependent on the population source. Copepods from the circumneutral source pond were negatively impacted after 5 days of exposure to water having pH 3.6. For copepods from the acidic source pond, survival was higher, and the negative impact occurred after a much longer period of time, 17 days. The authors interpreted this result as being indicative of a fitness trade-off regarding tolerance of acidity. To assess community responses to multiple stressors, the researchers contend that it will be important to understand contingencies that are landscape-dependent, including pH tolerance.

---

### 8.4.3 Benthic Invertebrate Recovery

In the 2008 ISA, few studies reported benthic recovery in previously acidified waters. One study by [Soulsby et al. \(1995\)](#) indicated recovery in some streams in Scotland that experienced ANC increases although recovery was not observed in the most severely acidified streams.

Since the publication of the 2008 ISA, additional studies have been conducted that assess recovery of benthic organisms. Most of that research has been conducted in Canadian and European waters. Indices to evaluate biological effects of aquatic acidification on benthic communities commonly rely on species of Ephemeroptera, Plecoptera, Trichoptera, Gastropoda, and Crustacea. In a study from the Neversink River basin in the Catskill Mountains in New York, [Burns et al. \(2008b\)](#) collected water chemistry data and surveyed macroinvertebrates, fish, and periphytic diatoms from 12 streams. This survey was conducted in 2003 and compared with a 1987 survey conducted at the same locations. Differences between the two surveys were not significant overall. However, a shift toward a less acid-tolerant macroinvertebrate community in the 2003 survey in streams in the upper river basin that were the most acidic in 1987 suggests biological

changes that are consistent with improvement in water chemistry. Further monitoring will be needed to determine the eventual extent of biological recovery.

Crayfish and other benthic invertebrates that require large amounts of Ca for growth may be reduced or absent in acidified water bodies that have experienced Ca depletion, reducing Ca bioavailability, caused by acidification ([U.S. EPA, 2008a](#); [Baker et al., 1990a](#)). [Hadley et al. \(2015\)](#) studied the limnological record of four lakes in Algonquin Park, Ontario where native populations of the crayfish *Cambarus bartonii* have not recovered despite improvements in pH. Cladoceran remains were used as proxies for historical Ca trends. Ca levels in the lakes are currently <2 mg/L, which is below the minimum requirement for crayfish survival (2 to 10 mg/L). Depletion of Ca in the soils and reduced Ca export from soil to lakes appear to contribute to the lack of recovery of crayfish populations in the region.

Two studies examined the response of littoral benthic macroinvertebrate community composition to changing water chemistry in 17 lakes on the Precambrian Shield in eastern Canada that were recovering from acidification. The first study [Lento et al. \(2008\)](#) tracked benthic invertebrate community composition over a 14-year period (1988–2002). There was a strong correlation between changes in chemical variables and shifts in benthic invertebrate communities. The rate of change in invertebrate community composition was greatest between 1993 and 1997, which corresponded most closely with water chemistry changes. The second study ([Lento et al., 2012](#)) evaluated temporal trends in 15 years of data from the same lakes. In analyses of both single and multiple lakes, decreasing proportions of Chironomidae and increasing proportions of Ephemeroptera, Plecoptera, and Trichoptera (quantified collectively as the EPT Index) were observed. Six of the nine lakes that showed significant recovery trends in more than one benthos metric exhibited a significant decrease in Chironomidae and concurrent increase in EPT. The results of these two studies, thus, suggested that the benthic macroinvertebrate communities of these study lakes changed in response to deacidifying changes in lake chemistry by shifting towards more acid-sensitive taxa. The observed response was consistent with benthic invertebrate recovery from acidification.

Some species of the order Odonata (including dragonflies) respond to changes in water acidity. For example, reduced water acidity in response to surface water liming can cause direct or indirect effects on some of the most common dragonfly species. ([Al Jawaheri and Sahlen, 2017](#)) investigated aquatic dragonfly communities in 47 Swedish lakes. Several were currently (n = 13) or previously (n = 8) limed. Seven of the most common dragonfly species were less common in limed lakes as compared with reference lakes that were not limed perhaps due to fish predation. [Al Jawaheri and Sahlen \(2017\)](#) suggested use of this order of stream invertebrate as indicators of water quality.

In a bioassessment in the Athabasca oil sands region of Alberta, Canada, [Parsons et al. \(2010\)](#) sampled 32 lakes to assess potential impacts of pollutant emissions and acid deposition on benthic macroinvertebrate communities. Five of the lakes were selected from an area with modeled high deposition. All of the statistical methods used (one sample *t*-tests, multivariate analysis of variance, and test site analysis) showed that assemblages differed between test lakes and reference lakes. However, results suggested these differences were more due to intrinsic lake physicochemical factors, such as geology and water chemistry, than to atmospheric deposition.

Several studies conducted in Europe have also considered macroinvertebrate recovery following ongoing chemical recovery. [Frame et al. \(2016\)](#) tested whether the growth of *Baetis rhodani* (an acid-sensitive mayfly nymph) is decreased by competition with *Leuctra inermis* (an acid-tolerant stonefly nymph) in a stream in the U.K. recovering from acidification. This experiment tested the biotic resistance hypothesis, which suggests that past acidification of surface waters has changed acidified waters to an extent that prevents reinvasion of acid-sensitive species even if acidity is substantially reduced. Introduction of *Baetis* to water containing different densities of *Leuctra* had no effect on *Baetis* growth. In one of the previously most acidified areas of Europe, [Svobodová et al. \(2012\)](#) compared water chemistry and macrozoobenthos composition of the outflows from two lakes in the Bohemian Forest. The water chemistry was recovering in response to reduced levels of acidic deposition. Evidence of biological recovery was found for Lake Laka (current pH  $\approx 5.2$ ), but not for the more strongly acidified Lake Čertovo (pH  $\approx 4.6$ ). At the Lake Laka outflow, increasing numbers of Ephemeroptera and Tricoptera taxa were observed. Comparable changes were not observed at the outflow for the more strongly acidified lake. In an analysis of a 20-year data set (1988–2008) from the Acid Waters Monitoring Network (AWMN) in the U.K., macroinvertebrate recovery was observed in 5 of the 11 stream sites and at 5 of 12 lakes ([Murphy et al., 2014](#)). An increase in ANC over time was observed at all 10 sites where biological recovery was evident based on trends in the macroinvertebrate community. An additional seven sites showed ANC recovery but no recovery of the macroinvertebrate community. The authors attributed this observation to differences in chemical environments and/or ecological interactions that interfere with recovery such as food-web dynamics and predation. In another 20-year data set, [Angeler and Johnson \(2012\)](#) analyzed littoral invertebrates in acidified and circumneutral lakes in Sweden. The concentration of  $\text{SO}_4^{2-}$  decreased in both acidified and circumneutral lakes but converged in the latter part of the study. Chemical recovery was generally weak in the acidified lakes, with pH increasing by only about 0.1 to 0.2 pH units in the study lakes. These results from Sweden suggest that because invertebrate communities respond to complex processes, including both local and regional factors, partial recovery of water chemistry from acidification is at times not accompanied by observable biological recovery, especially as related to biodiversity.

Data from two national-scale benthic macroinvertebrate surveys, the AWMN in the U.K. and a lakes survey in Norway, were used to compare field sampling results to predictions of maximum species richness as a function of chemical conditions in surface waters recovering from acidification ([Stockdale et al., 2011](#)). In general, there was good agreement between model predictions and observed trends in EPT taxa. Biological recovery rates for actual and predicted species richness were generally consistent with each other, at 1.2 to 2.0 species per decade change. However, actual recovery rates in the AWMN lakes were less than in the rivers (0.6 vs 2.0 species per decade recovery), whereas predicted rates were similar (1.7 vs 2.0 species per decade). At sites where there was poorer agreement between model predictions and observations, differences in water chemistry explained some of the observed reduction in species richness. The authors speculated that factors not included in the model, such as biotic interactions and site conditions, could also affect species richness.

---

#### **8.4.4 Fish and Amphibian Recovery**

Some of the most in-depth studies of the effects of acid stress on fish ([Appendix 8.3.6](#)) have been conducted in streams in Shenandoah National Park, VA ([Cosby et al., 2006](#)) and lakes in the Adirondack Mountains, NY ([Sullivan, 2015](#)). Effects on fish have also been documented in acid-sensitive streams of the Catskill Mountains of southeastern New York and the Appalachian Mountains from Pennsylvania to Tennessee and South Carolina ([Baldigo and Lawrence, 2001](#); [Bulger et al., 2000](#); [Bulger et al., 1999](#); [SAMAB, 1996](#); [Charles and Christie, 1991](#)). Since the 2008 ISA, several studies have documented vertebrate recovery that corresponds to decreasing acidic deposition.

Evidence for recovery of fish populations following reduction in acidic deposition or through liming ([Appendix 8.4.6](#)) was reported in several studies reviewed in the 2008 ISA ([Gunn et al., 1988](#); [Kelso and Jeffries, 1988](#); [Beggs and Gunn, 1986](#); [Dillon et al., 1986](#); [Keller and Pitblado, 1986](#); [Raddum et al., 1986](#); [Hultberg and Andersson, 1982](#)). There have been additional studies of fish response to surface water acidification and subsequent recovery since the 2008 ISA. These studies have been conducted in both North America and Europe.

[Sutherland et al. \(2015\)](#) documented the reintroduction and re-establishment of a naturalized native fish species (brook trout) in an Adirondack lake (Brooktrout Lake) from which this species had previously been extirpated. The historical decline in water quality and loss of the fishery were reconstructed from available data dating back more than a century. Lake chemistry has improved substantially in response to decreases in acidifying deposition since the 1980s, with pronounced decreases in midsummer

epilimnetic inorganic Al and H<sup>+</sup> concentrations. In Brooktrout Lake, the mean ANC increased from -2 µeq/L during the 1980s to 12 µeq/L during the period 2010–2012 ([Table 8-6](#)). Substantial changes were also noted for other variables, including SO<sub>4</sub><sup>2-</sup>, H<sup>+</sup>, NO<sub>3</sub><sup>-</sup>, DOC, and inorganic Al. During the period from 2005–2007, brook trout were reintroduced to the lake and have subsequently survived and successfully reproduced. In 2012, young brook trout were observed and photographed, documenting reproduction in, or in tributary streams near, the lake. Other acid-impacted lakes in the Adirondacks such as Honnedaga Lake lost acid-sensitive fish species between 1920 and 1960 while continuing to support brook trout ([Josephson et al., 2014](#)). By the late 1970s, brook trout were also considered extirpated from Honnedaga Lake, but persisted in tributary refugia. By 2000, brook trout had recolonized the lake coincident with reductions in surface-water SO<sub>4</sub><sup>2-</sup>, NO<sub>3</sub><sup>-</sup>, and inorganic Al concentrations.

In addition to these studies of recolonization of lakes by brook trout where acid-base chemical conditions were improving, new reports of shifts in fish communities in response to acidification have been published since the 2008 ISA. [Warren et al. \(2008\)](#) used historical records to document a fish community shift in the upper mainstem of Hubbard Brook in New Hampshire corresponding to chronically acidified conditions in the 1970s. Records indicated that there were at least three fish species in the 1960s: slimy sculpin (*Cottus cognatus*), blacknose dace (*Rhinichthys atratulus*) and brook trout. Only brook trout were present in surveys conducted in 2005, 2006, and 2007. In an evaluation of fish recovery in nearly 5,000 small headwater lakes in Finland where at the end of the 1980s populations were either diminished by acid deposition or extirpated, [Rask et al. \(2014\)](#) noted recovery of perch (*Perca fluviatilis*), a relatively acid-tolerant species, starting in the 1990s. The perch population structure has returned to normal during the monitoring period, which ended in the mid-2000s. Little or no recovery of the acid-sensitive roach (*Rutilus rutilus*) was observed over that time period.

Despite observed reductions in acidic deposition and improvement in water quality of New York lakes, [Baldigo et al. \(2016\)](#) found no evidence of widespread or substantial biological recovery of brook trout populations or broader fish communities in the Adirondack Mountains. The study focused on 43 lakes sampled by the Adirondack Lakes Survey Corporation during three time periods (1984–1987, 1994–2005, and 2008–2012). Metrics reflecting fish species richness, abundance of fish species, and abundance of brook trout did not change significantly over the 28-year period across the group of study lakes despite a significant average ANC increase and a decrease in inorganic Al over time. Fish species richness and catch of all fish species per net-night were positively related to lake chemistry reflecting some limited degree of biological recovery. The authors speculated that additional time may be needed for fish recolonization.

Recovery of fish populations in streams may be affected by habitat considerations as well as water chemistry. [Warren et al. \(2010\)](#) evaluated the relative influence of stream habitat and pH on total fish biomass in 16 streams in the northeastern U.S. Physical and chemical factors evaluated in the study included total pool area, cover, large wood frequency, and water temperature. Both pool area and pH were closely correlated with prediction of fish biomass. Physical habitat is likely more important at pH >5.7 (at low flow) and becomes less important at lower pH when conditions are too acidic to support fish.

Recovery of young brown trout (*Salmo trutta*) in acidified streams in southern Norway was assessed by [Hesthagen et al. \(2016\)](#) over the period 1987–2010. The density of fish, both young-of-the-year and older parr, increased significantly during the study period. Water quality also improved (pH 5.0–5.5 increasing to 5.8–6.0). Nevertheless, the densities of both fish age groups (young-of-the-year and older parr) decreased for a period of time in the early 1990s. This was attributed to seasalt acidification associated with severe weather conditions that caused increased marine salt deposition. This finding emphasizes the fact that recovery from acidification should be evaluated in the context of other changes, including natural or other human-caused disturbance regimes.

Even if the preindustrial acid-base chemistry of a water body is fully restored, there is no guarantee that any aquatic species that had previously been eliminated in response to acidification will in fact return to that water body. There may be physical, chemical, or biological barriers to species reintroduction. Methods have not been well developed and tested for reintroduction of species other than fish.

Potential impacts of aquatic acidification on amphibian species occur in the context of multiple stressors, including fish introductions and the presence of fungal pathogens. A dramatic example of environmental stress in amphibians is the widespread prevalence of the disease chytridiomycosis, which is caused by the fungus *Batrachochytrium dendrobatidis*. Major die-offs of frogs, toads, salamanders, and other amphibians have been documented in the U.S. and elsewhere ([Martel et al., 2014](#); [Rosenblum et al., 2010](#)). These die-offs have not been attributed to acidification.

---

#### **8.4.5 Bird Recovery**

Common loon (*Gavia immer*) breeding success was assessed from 1982 to 2007 in 38 lakes historically impacted by deposition from smelter activities in the Sudbury, Ontario region ([Alvo, 2009](#)). No fledglings were observed on any lakes that had pH <4.4. In two of the lakes that were previously too acidic for loon reproduction, chicks were observed as acid conditions improved over the duration of the study. However, it was not clear from the results whether there is a critical pH for loon fledging survival.

---

#### 8.4.6 Mitigation

Application of lime or other sources of base cation(s) is well known to increase the bioavailability of nutrient bases to terrestrial and aquatic biota. Neutralization of acidity by addition of limestone or other Ca source to watershed soils or directly to water bodies has been used for several decades in Europe and to a lesser extent in North America to mitigate effects of acidifying deposition. Analyses of long-term data suggest that liming watershed soils increases Ca availability to aquatic and terrestrial biota and limits mobilization of Al from soils to surface water. Watershed liming of soils generally promotes long-lasting effects whereas direct liming to streams and lakes causes short-term chemical fluctuations and less pronounced ecosystem recovery ([Lawrence et al., 2016](#)). Prior to the 2008 ISA, relatively few studies were conducted in the U.S. that focused on mitigation of harm to aquatic organisms caused by acidification. Limited lake liming had occurred in the Adirondacks in an effort to reverse the adverse effects of water acidification ([Schofield and Keleher, 1996](#)).

It has been well documented that the intensity and duration of acidity mitigation achieved by Ca addition depends to a large degree on the method of Ca application. In particular, different results have been achieved depending on the site of Ca addition: directly to the water body and/or more broadly across the watershed that contributes drainage water (and associated base cations) to the water body in question. Application of lime to the terrestrial watershed leads to acidity mitigation that is more gradual and of longer duration than lime application directly to surface waters ([Davis and Goldstein, 1988](#)).

A liming study at the Woods Lake watershed in the Adirondack Mountains applied calcite ( $\text{CaCO}_3$ ) to two paired watersheds, with and without pronounced wetland influence ([Driscoll et al., 1996](#)). Lake water showed gradual improvements in pH, ANC, and the concentration of Ca at the site of watershed liming, in contrast to the more abrupt and short-lived effects of direct surface water lime application. The liming decreased the concentrations of inorganic Al and increased DOC. Water quality improvements affected both the treated stream and the downstream lake ([Burns, 1996](#)). Brook trout spawning was restored to the tributary stream ([Schofield and Keleher, 1996](#)). Only limited additional research has been conducted in the U.S. in more recent years. [Knoepp et al. \(2016\)](#) estimated that about 11.6 to 21.1 Mg/ha of  $\text{CaCO}_3$  would be needed to increase surface soil (upper 30 cm) pH to 5.0 in three high-elevation watersheds in the Appalachian Mountains. Stream acid-base chemistry was related to the concentrations of N and Al in the soil O-horizon and to the total amount of C and Ca in the soil.

[Lawrence et al. \(2016\)](#) re-examined the liming approach as a method for accelerating the recovery of acidified ecosystems where chemical and/or biological recovery have lagged behind reductions in atmospheric S and N deposition. They presented evidence

suggesting that recovery rates are fastest for lakes and slowest for soils, with intermediate stream recovery rates. They also emphasized that lime should not be applied to environments, including wetlands, where indigenous species are adapted to naturally acidic conditions.

An experimental stream and watershed liming study is currently in progress in the Adirondacks. This work is being conducted by a group of researchers under the coordination of the U.S. Geological Survey in Troy, NY. Results are not yet available at the time of this writing.

In an effort to mitigate Atlantic salmon population declines in Norway due to acidification, liming was implemented in 21 acid-impacted rivers. [Hesthagen et al. \(2011\)](#) electrofished 13 rivers 1 year before and annually for 12 years after initiation of liming. Increases in salmon parr densities were slow, and the authors estimated that it will take more than 20 years of liming to restore lost salmon stocks. Rivers that were stocked and those lacking hydropower developments generally had higher fry densities and faster increase in parr densities subsequent to lime application.

[Mant et al. \(2013\)](#) conducted a review and meta-analysis of the impacts of liming streams and rivers on the biological recovery of fish and aquatic invertebrates. The meta-analysis included studies in the U.K., Norway, Sweden, U.S., and Canada. On average, liming increased the abundance and richness of acid-sensitive invertebrates and increased fish abundance. Nevertheless, benefits were variable and did not occur in all rivers.

The large national-scale lake and stream liming program in Sweden offers a unique opportunity to evaluate the expected recovery of fisheries in response to water deacidification at the national level. ([Holmgren et al., 2016](#)) reported results from monitoring since the 1980s of 1,029 limed streams and 750 limed lakes, plus reference (unlimed) sites (195 streams and 101 lakes). Over time, the proportion of limed streams that had no fish decreased. Species richness and the percentage of streams in which brown trout (*Salmo trutta*) was detected both increased over time after initiation of liming. The abundance of several species, including brown trout, perch (*Perca fluviatilis*) and roach (*Rutilus rutilus*), increased more at sites that were limed as compared with sites that were not limed. Species richness increased slightly in limed streams (less than 2 on average before liming to more than 2.6 species 16 years after initiation of liming). Nonlimed streams did not show a change in richness over time. Patterns were less clear for lakes, perhaps due to the influence of lake size and/or productivity, either of which might mask the effects of liming.

---

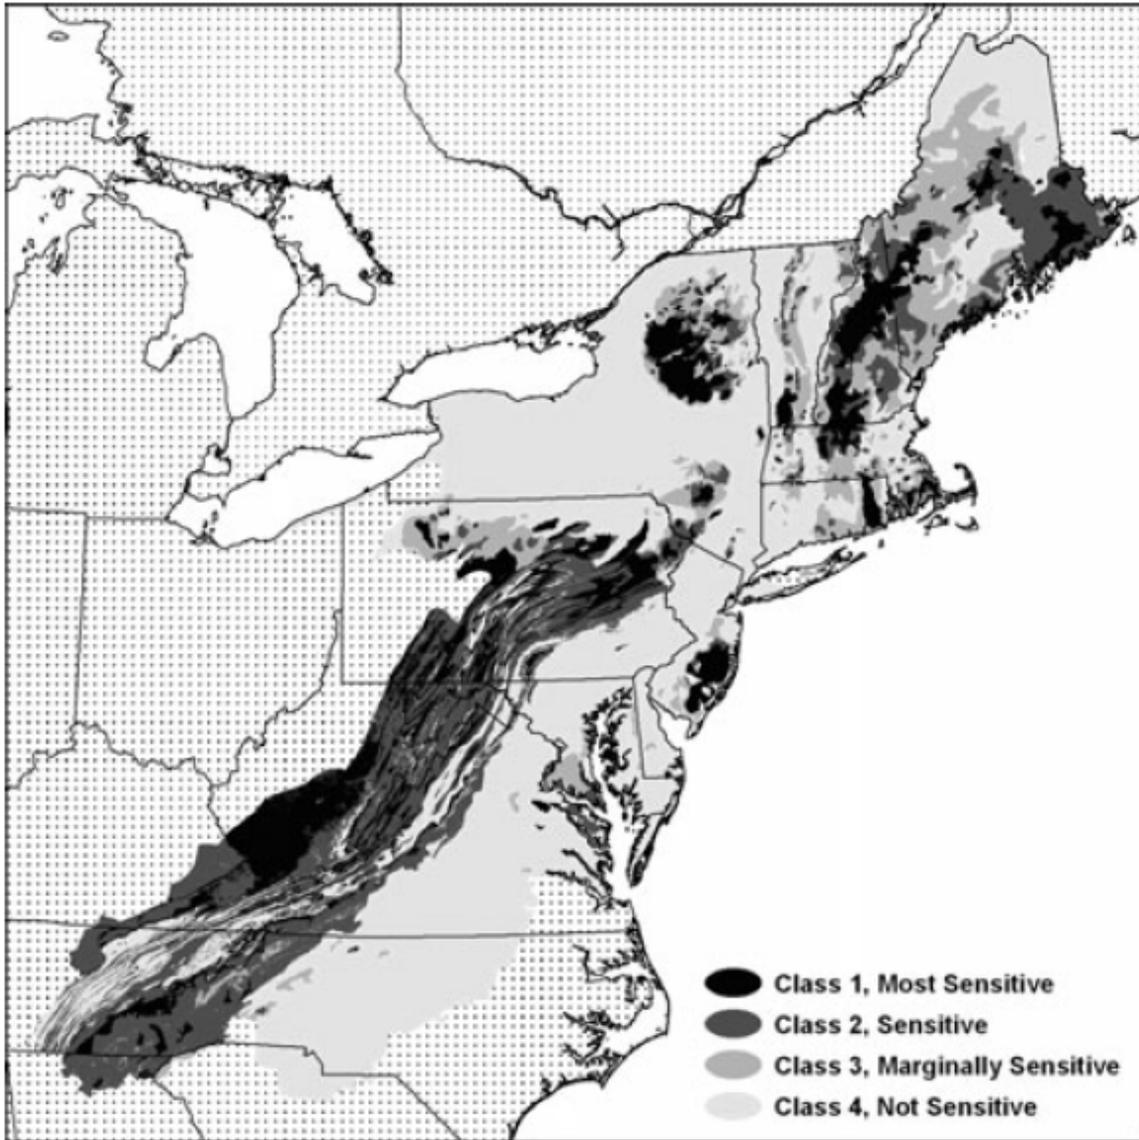

## 8.5 Levels of Deposition at Which Effects Are Manifested

The level of N and S deposition and their impacts vary across the landscape. Not all environments are sensitive to acidifying deposition at the levels seen in the past and present. Effects on biological communities are related to both the characteristics ([Appendix 8.5.1](#)) and extent and distribution ([Appendix 8.5.2](#)) of acid sensitive freshwaters across the U.S. as well as climate factors ([Appendix 8.5.3](#)). [Appendix 8.5.4](#) includes both empirical and modeled thresholds (critical loads) of effects of acidifying deposition.

---

### 8.5.1 Most Sensitive and Most Affected Ecosystems and Regions

The characteristics of acid-sensitive ecosystems were well known and summarized in the 2008 ISA. In brief, the effects of acid deposition on aquatic systems depend largely upon the ability of an ecosystem to neutralize additional acid inputs. No one level of deposition can be used to generalize the sensitivity or impacts of acidifying deposition across a region or the country. The principal factor governing the sensitivity of aquatic ecosystems to acidification from acidifying deposition is geology [particularly surficial geology; ([Greaver et al., 2012](#))]. Geologic formations having low base cation supply, due mainly to low soil and bedrock weathering, generally underlie the watersheds of acid-sensitive lakes and streams. Till thickness has been shown to be a key control on the pH and ANC of Adirondack lakes ([Driscoll et al., 2016](#)), whereby lakes in watersheds inferred to be underlain by thin till tend to be highly sensitive to acidification ([Driscoll and Newton, 1985](#)). [Figure 8-10](#) is a map of aquatic ecosystem sensitivity in the eastern U.S. based on underlying geology in unglaciated areas and ANC in the glaciated region. Other factors contribute to the sensitivity of surface waters to acidifying deposition, including topography, soil chemistry and physical properties, land use and history, and hydrologic flowpath.

Source: [Lovett et al. \(2009\)](#).

**Figure 8-10** Map of landscape sensitivity to acidic deposition for the northeastern and mid-Atlantic U.S. Stippled areas were not considered.

The 2008 ISA summarized findings from several national surveys on the effects of acidifying deposition, including the National Lakes Survey and the National Streams Survey conducted in the mid-1980s, the Wadeable Streams Assessment (WSA) in 2004, the U.S. EPA Long-Term Monitoring program that began in 1983, and the Temporally Integrated Monitoring of Ecosystems probability surveys that began in 1991. Results of

these surveys suggested that acidifying deposition had acidified surface waters in the southwestern Adirondacks, New England uplands, eastern portion of the upper Midwest, forested Mid-Atlantic highlands, and Mid-Atlantic coastal plain ([U.S. EPA, 2008a](#)).

At ANC of 100  $\mu\text{eq/L}$  or less, acid-sensitive aquatic species may be adversely affected [[Figure 8-4](#); ([U.S. EPA, 2008a](#); [Sullivan et al., 2006a](#); [Bulger et al., 2000](#); [Bulger et al., 1999](#))]. Sensitive water bodies, therefore, can be defined as those that have ANC of 100  $\mu\text{eq/L}$  or less. Sensitivity increases with further decreases in ANC. In general, streams in the eastern U.S. that are sensitive tend to be headwater streams of first- to third-order. Streams and lakes in the western U.S. tend to be headwater systems in high elevation areas. Recent research has not changed this understanding but rather has served to strengthen it ([Appendix 7](#)).

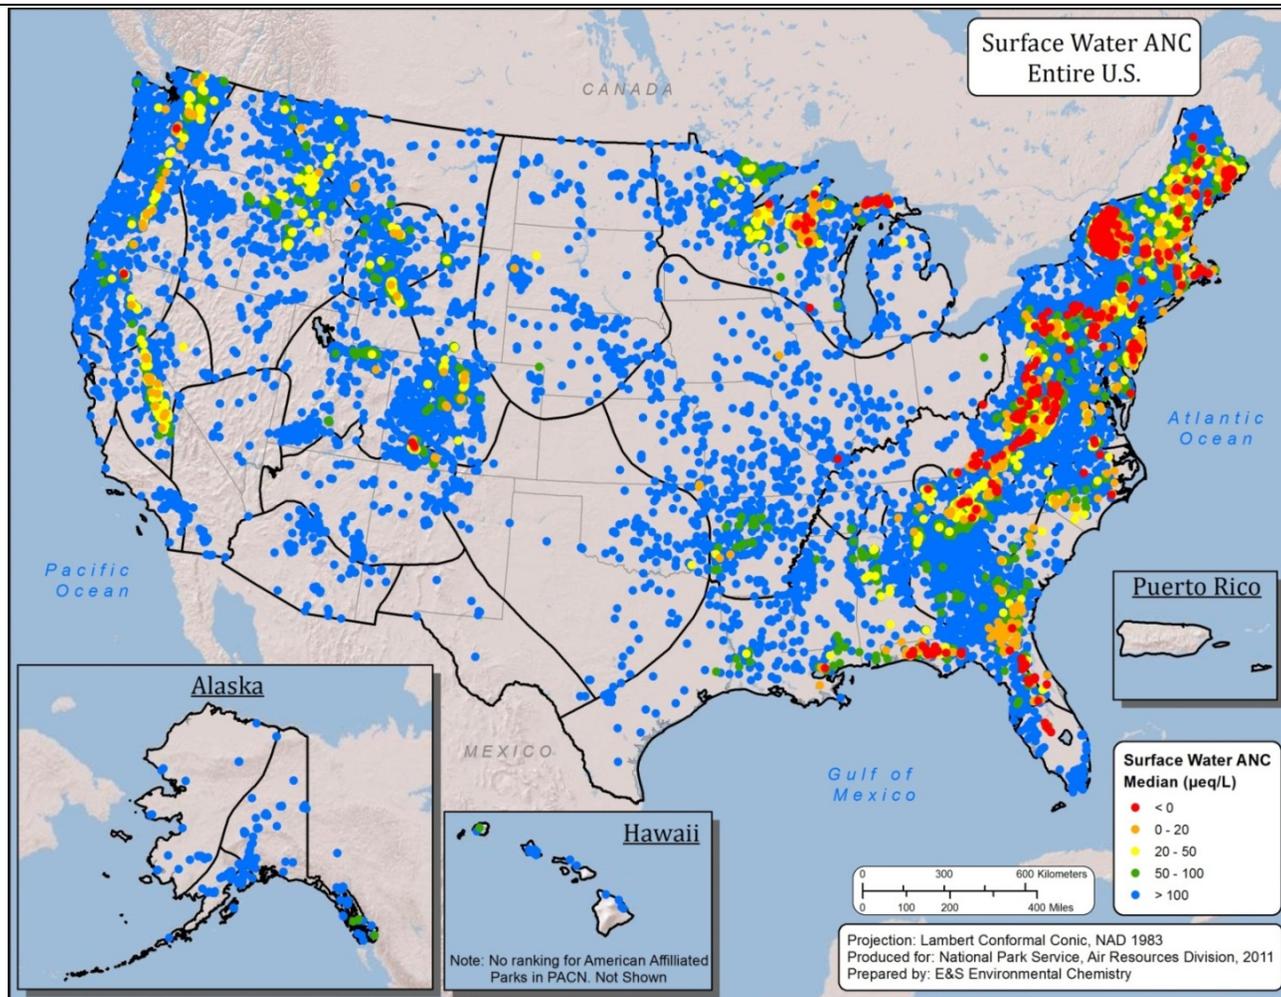

Controls on surface water acidification and recovery are not necessarily spatially homogeneous. For example, the adsorption and desorption of S on soils can exert major controls on acidification, and likely chemical recovery from acidification, in the unglaciated soils of the southeastern U.S. ([Rice et al., 2014](#)). Limitations in the extent of S driven acidification and recovery attributable to S adsorption is less pronounced in the northeastern U.S.

---

## 8.5.2 Extent and Distribution of Sensitive Ecosystems/Regions

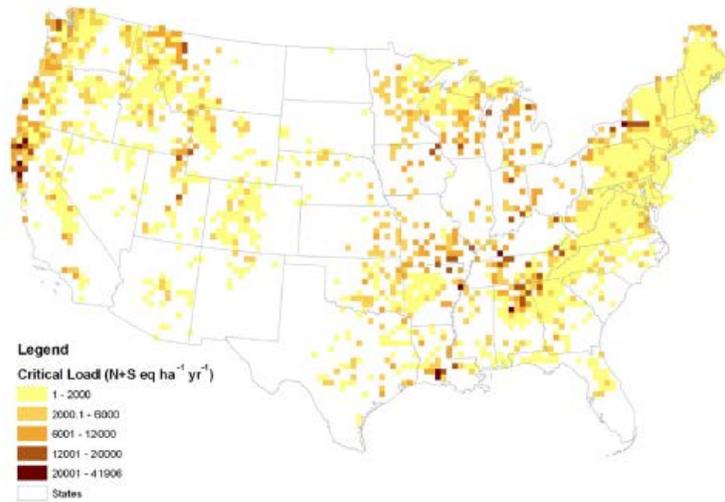

The 2008 ISA summarized the extent and distribution of freshwater ecosystems sensitive to acidifying deposition. Measured data on lake and stream ANC across the U.S. exhibit clear spatial patterns. In the U.S., surface waters that are most sensitive to acidification based on ANC are largely found in the Northeast, southern Appalachian Mountains, Florida, the upper Midwest, and the mountainous West ([Sullivan, 2017](#); [McDonnell et al., 2014b](#); [Greaver et al., 2012](#); [Campbell et al., 2004a](#); [Driscoll et al., 2001b](#); [Baker et al., 1990b](#); [Omernik and Powers, 1983](#)). [Figure 8-11](#) is a national map of surface ANC for the U.S. that includes nearly 200,000 measurements taken at nearly 20,000 spatially unique locations sampled between 1980 and 2011 ([Sullivan, 2017](#)). Samples expected to be strongly influenced by acid mine drainage, sea salt spray, or road salt application were excluded. Thus, the included data represent sites not likely confounded by major disturbances not related to acidic deposition. [Sullivan \(2017\)](#) found 6,065 sites that had ANC < 100  $\mu\text{eq/L}$ . Acidic waters were mostly restricted to northern New York, New England, the Appalachian Mountain chain, upper Midwest, and Florida (see [Figure 8-11](#)). Low, but positive, ANC values were depicted for these same regions plus high-elevation portions of the West and parts of Arkansas and the Gulf states. These geographical patterns are thought to largely reflect base cation supply in soils. Levels of acidifying

deposition in the West are low in most areas, acidic surface waters are rare, and the extent of chronic surface water acidification that has occurred to date has been limited ([Sullivan, 2017](#); [Charles and Christie, 1991](#)). Episodic acidification, however, occurs in both the East and West at some acid-sensitive locations. These areas can be identified by CL maps for the U.S. based, for example, on an ANC target of 50  $\mu\text{eq/L}$  [[Figure 8-12](#); ([Blett et al., 2014](#))].

Grids represent the average calculated critical load from all data within the 36 × 36-km grid cell. The critical chemical criterion used was an acid neutralizing capacity 50  $\mu\text{eq/L}$ .

---

### 8.5.3 Climate Modification of Ecosystem Response to Nitrogen and Sulfur

Acidification and recovery of freshwaters will be affected by the physical, chemical, and biological modifications to acid inputs projected to occur with changes in annual mean temperature and magnitude of precipitation ([Greaver et al., 2016](#)). Projected shifts in runoff and timing and quantity of flushing will alter the frequency and duration of episodic events ([Whitehead et al., 2009](#)). In acid sensitive regions, altered hydrologic regimes are likely to affect weathering rate of base cations, lake water levels and organic matter inputs to catchments ([Adrian et al., 2009](#); [Porcal et al., 2009](#)). Air temperature increases will lead to warmer surface waters altering thermal stratification of water bodies, distribution of aquatic biota in streams and lakes and community composition ([Adrian et al., 2009](#); [Keller, 2007](#)). Climate change may play a role in shifting baselines for ecosystem recovery in previously acidified lakes ([Appendix 8.4](#)). [Warren et al. \(2017\)](#) suggested that the major stressor affecting native coldwater fish species in the eastern U.S. is shifting from acidification to thermal stress and some lakes recovering from acidification may provide a degree of protection against climate affects. As DOC in the water increases with increasing lake pH in recovering lakes, decreased water clarity may create cooler refuge habitat for fish. [Appendix 13](#) includes a more detailed discussion of how climate (e.g., temperature and precipitation) modifies ecosystem response to acidification.

---

### 8.5.4 Critical Loads

A critical load (CL) is a quantitative estimate of exposure to one or more pollutants below which significant harmful effects on specified sensitive elements of the environment do not occur according to present knowledge [([Spranger et al., 2004](#); [Nilsson and Grennfelt, 1988](#)) Chapter 1.2.2.3]. The following sections express deposition in eq/ha/yr of S, N, or S + N because one or both pollutants could be contributing to the observed effects.

---

#### 8.5.4.1 U.S. Critical Loads

The 2008 ISA documented use of the CL approach to determine sensitivity to acidification. Critical load applications for surface water in the U.S. have been reviewed by [Porter et al. \(2005\)](#), [Burns et al. \(2008a\)](#), [Pardo et al. \(2011a\)](#), [NAPAP \(2011\)](#), [Lovett \(2013\)](#), and [Sullivan and Jenkins \(2014\)](#). Most aquatic CL studies conducted in the U.S. have used surface water ANC as the metric of water quality change in response to acidifying deposition. This should not be taken as an indication that ANC should

necessarily be the only environmental predictor of harm to aquatic species on which to base CLs. Other potentially useful variables include water pH or BCS. Either, or both, can be used instead of, or in addition to, ANC.

The initial step in developing a CL is to define a threshold for a significantly harmful effect. This biological change can be defined for the protection of a single species or an entire biological community, and defining varying levels of protection for either can be achieved through adoption of different indicators of harm. Because CLs depend on what is being protected, any given biological community requires a set of CLs. The closely related target load (TL) estimates the reduction needed to achieve a certain condition at a designated future time period. A target load can be less than, equal to, or greater than the CL. As described in the 2008 ISA, there are different types of CLs: empirical CL, modeled steady-state CL (time invariant), and modeled dynamic CL [change through time with a specific target date, often to the year 2100 as a management TL; ([U.S. EPA, 2008a](#))]. Several CL studies were summarized in the 2008 ISA.

As discussed in the 2008 ISA, a useful aspect of the CL approach is the calculation of exceedance. Knowledge of where and to what extent ambient air pollutant loads exceed levels that are sustainable without causing ecological harm can inform vulnerability assessments ([Sullivan and Jenkins, 2014](#)). Therefore, the exceedance is calculated as the difference between the ambient deposition of S, N, or S + N and the CL or the TL. It can be expressed as an absolute deposition amount or as a percentage.

Since 2006, the primary forum for coordination of research on CL development in the U.S. has been the Critical Loads of Atmospheric Deposition (CLAD) science committee of the National Atmospheric Deposition Program [NADP; ([Blett et al., 2014](#))]. Efforts are underway in association with CLAD to collect needed data and improve methods for CL calculations throughout the U.S.

#### **8.5.4.1.1 Empirical Critical Loads**

An empirical CL is developed from observational spatial or temporal gradient studies or additions of pollutants to determine the deposition load at which chemical or biological changes (e.g., changes to foliage, lichens, soil, aquatic chemistry/biota) occur in the environment. Empirical CLs are generally applied to sites or landscapes that are ecologically comparable to location(s) from which the CLs were determined [cf; [Pardo et al. \(2011a\)](#)]. Empirical CLs for acidification are difficult to apply to sites other than those used in defining them and to generalize across the landscape because sensitivity to acidification is highly spatially variable (see [Appendix 8.5.1](#)). A given CL for

acidification often only applies to a narrow subset of environmental conditions, in some cases only to a single water body.

At the time of the 2008 ISA, very few empirical CLs were available for U.S. freshwater ecosystems. Rocky Mountain National Park has been the site of research addressing the environmental effects of N deposition. [Williams and Tonnessen \(2000\)](#) reported ANC in surface water  $< 0$   $\mu\text{eq/L}$  near the park as a result of acidifying inputs of N deposition, suggesting that current deposition levels are having an observable impact on catchments in the Colorado Front Range. The authors recommended a CL of 286 eq N/ha/yr to prevent episodic freshwater acidification in alpine lakes (ANC  $< 0$   $\mu\text{eq/L}$ ). However, determination of biological change in the field was not a focus of this study.

Other studies conducted in the western U.S. have identified CLs for freshwater systems ([Table 8-7](#)). In Moat Lake in the Sierra Nevada mountains, acidic deposition ( $\text{SO}_4^{2-} + \text{NO}_3^-$ ) equal to about 74 eq/ha/yr was correlated with the decline in ANC observed in the lake between 1920 and 1930 ([Heard et al., 2014](#)). This was taken by the authors to be the CL to protect against acidification for Moat Lake, but they did not specify the level of acidification or how the biological community would be protected. Diatom-reconstructed ANC of Moat Lake changed from near 100  $\mu\text{eq/L}$  prior to 1920 to near 60  $\mu\text{eq/L}$  during the 1970s. Reconstructed ANC patterns were not correlated with climate, productivity, or  $\text{NO}_x$  emissions.

Although most CLs are focused on chronic acidification, and by strict definition as a steady-state metric must be, [Baron et al. \(2011b\)](#) estimated CLs to be about 571 eq N/ha/yr in the Northeast and 286 eq N/ha/yr in the Rocky Mountains for  $\text{NO}_3^-$  concentrations as triggers of episodic acidification. CLs for N deposition in California were estimated based in part on changes in  $\text{NO}_3^-$  leaching in stream water, which can cause or contribute to water acidification ([Fenn et al., 2008](#)). The empirical CL and the CL simulated by the DayCent model for  $\text{NO}_3^-$  leaching were both 1,214 eq N/ha/yr. Nitrogen deposition exceeds that level at some locations in California.

#### **8.5.4.1.2 Modeled Critical Loads**

Steady-state and dynamic models are used to quantify relationships between deposition and biogeochemistry for watersheds in order to develop CL estimates (see description of models in [Appendix 7](#)). Modeled CLs for aquatic acidification are summarized in [Table 8-8](#).

**Table 8-7 Recent empirical critical loads to protect against aquatic acidification in U.S. ecosystems.**

Ecosystem	Site	Critical Load for N Deposition	Response	Study
Alpine lakes	Central Rockies/Colorado Front Range	286 eq N/ha/yr	Episodic freshwater acidification	<a href="#">Williams and Tonnessen (2000)</a>
Mediterranean California stream water	California	1,214 eq N/ha/yr	Changes in NO <sub>3</sub> <sup>-</sup> leaching in stream water	<a href="#">Fenn et al. (2008)</a>

#### 8.5.4.1.2.1 Steady-State Critical Load Modeling

Steady-state CLs can be derived from mathematical mass-balance models under assumed or modeled equilibrium conditions based in part on water quality measurements. The models used to derive steady-state CLs vary in complexity with regard to process representation. However, a fundamental aspect of the various modeling approaches is the calculation of elemental mass balances.

[NAPAP \(2011\)](#) calculated steady-state aquatic CLs to protect southern Appalachian Mountain streams and Adirondack Mountain lakes against the combined load of S and N deposition below which the ANC level would be expected to support healthy aquatic ecosystems. Research has shown that surface waters with ANC values greater than  $50 \mu\text{eq/L}$  tend to protect most fish (including native [to eastern U.S.] brook trout) and other aquatic organisms [see [Table 8-3](#), which describes these changes; [Driscoll et al., 2001b](#)]. The CL can be calculated to represent the individual or combined deposition load of S and/or N to which a stream and its watershed could be subjected and still have a surface water ANC of  $50 \mu\text{eq/L}$  on an annual basis.

[Sullivan et al. \(2012b\)](#) and [McDonnell et al. \(2012\)](#) developed an approach for deriving regional estimates of base cation weathering to support steady-state CL estimates for the protection of southern Appalachian Mountain streams against acidification in three ecoregions of Virginia and West Virginia. Weathering estimates at the study watersheds were developed using MAGIC and extrapolated to the full study region using landscape characteristics available as regional coverages. Calculated CL values were low at many locations, suggesting high acidification sensitivity. In the Blue Ridge ecoregion, calculated CL values to maintain stream ANC at  $50 \mu\text{eq/L}$  were less than  $500 \text{ eq/ha/yr}$  at

one-third of the study sites. About half or more of the stream length in the study region was in exceedance of the CL of S for protecting aquatic resources to an ANC level of 50  $\mu\text{eq/L}$  over the long term.

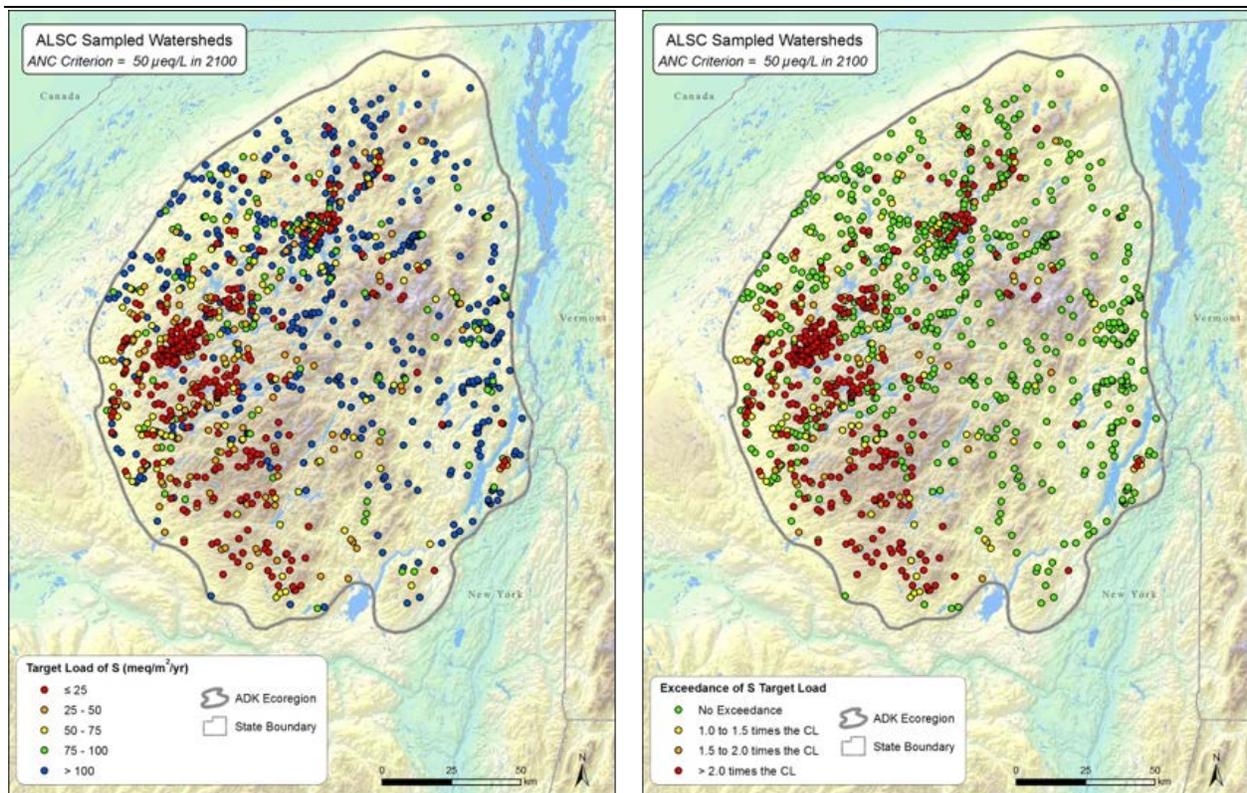

In another model simulation for Appalachian Mountain streams, [McDonnell et al. \(2014b\)](#) calculated critical values, including steady-state aquatic CLs to protect streams against acidification. They considered an ANC threshold of 50–100  $\mu\text{eq/L}$  to be generally protective of ecological health [cf; [U.S. EPA \(2009c\)](#); [Cosby et al. \(2006\)](#)]. The study area included mainly streams in southern Pennsylvania, Maryland, Virginia, West Virginia, North Carolina, Tennessee, and northern Georgia. Weathering values were first determined using the MAGIC model ([Povak et al., 2014](#)) and extrapolated to the full study region using machine learning/linear regression models. These values were then used as inputs to the Steady-State Water Chemistry (SSWC) model to calculate regional CLs. Nearly one-third of the stream length assessed in the study region had a CL of S deposition <500 eq/ha/yr, which was below the estimated regional average S deposition (600 eq/ha/yr). The percentage of streams in exceedance was highest for mountain wilderness areas and national parks and lowest for privately owned valley bottom lands.

[Shaw et al. \(2014\)](#) applied two variants of the SSWC model (one based on the F-factor approach and the other determined empirically) to estimate CLs for 2008 lakes in Class I and II wilderness areas in the Sierra Nevada. It was estimated that slightly more than one-third of the lakes received acidic deposition higher than the estimated CL. Lakes included in the model runs were generally dilute, with mean ANC = 56.8  $\mu\text{eq/L}$ . Critical loads for acid deposition were estimated to protect ANC to benchmark values of 0, 5, 10, and 20  $\mu\text{eq/L}$ , which span the range of minimum ANC values observed in Sierra Nevada lakes. Median CLs were 217, 186, 157, and 101 eq (S + N)/ha/yr to achieve ANC = 0, 5, 10, and 20  $\mu\text{eq/L}$ , respectively. The median CL for granitic watersheds based on a critical ANC limit of 10  $\mu\text{eq/L}$  was 149 eq/ha/yr.

#### **8.5.4.1.2.2 Target and Dynamic Critical Load Modeling**

To simulate the dynamic aspects of damage and recovery, a dynamic model based on hydrogeochemical processes is required. Dynamic models can be used to simulate soil or water chemistry or biological response or to calculate a TL within a specified management timeframe, such as for example the year 2100. Alternatively, a dynamic model can be used to calculate a comparable long-term steady-state CL by applying the model to a point in the distant future. Since the 2008 ISA, dynamic modeling of CLs has been focused on the Adirondacks, Appalachians, and the Rocky Mountains/Sierra Nevada ([Table 8-8](#)).

In the Adirondacks region, the MAGIC model was used by [Sullivan et al. \(2012a\)](#) to estimate the TLs that would protect the acid-base chemistry of lakes at different ANC levels. The 117 TLs were calculated for two time periods (2050 and 2100) and three levels of protection (ANC = 0, 20, and 50  $\mu\text{eq/L}$ ) based on the MAGIC model. Results of the 117 simulated TLs, and associated exceedances, were extrapolated to the regional population of Adirondack lakes. About 30% of the lakes had TL <500 eq/ha/yr to protect lake ANC to 50  $\mu\text{eq/L}$ . About 600 lakes received S deposition in exceedance of the TL required to protect to ANC = 50  $\mu\text{eq/L}$ , in some cases by more than a factor of two. Based on the model simulations, some critical criteria threshold values were not obtainable, even when S deposition was decreased to zero ([Figure 8-13](#)).

ADK = Adirondack; ALSC = Adirondack Lakes Survey Corporation; ANC = acid neutralizing capacity; CL = critical load; L = liter; meq = milliequivalent;  $\mu\text{eq}$  = microequivalent.; S = sulfur.

To convert mapped values to units of eq S/ha/yr, multiply by 10.

Source: [Sullivan et al. \(2012a\)](#).

**Figure 8-13 Target loads for sulfur deposition in the Adirondack Park to protect lake acid neutralizing capacity to 50  $\mu\text{eq/L}$  in the year 2010 (left map) and their exceedance (right map).**

Simulations using the dynamic PnET-BGC model ([Zhou et al., 2015c](#)) for the Constable Pond watershed (a chronically acidified drainage area in the Adirondack Park) suggested that future decreases in  $\text{SO}_4^{2-}$  deposition would be more effective in increasing the lake water ANC than equivalent decreases in  $\text{NO}_3^-$  deposition. Biophysical factors that affected CLs and TLs included hydrologic residence time. Lakes with longer hydrologic residence time exhibited less historical acidification and, therefore, could achieve a higher ANC in response to chemical recovery compared with lakes that had short hydrologic residence times. This difference was attributed to in-lake production of ANC in the lakes having long hydrologic residence time. The model outputs further suggested that forest cutting could enhance acidification by the removal of nutrient base cations along with the removal of forest biomass. However, forest cutting could also enhance retention of atmospherically deposited N in an aggrading forest ecosystem.

In another modeling study using PnET-BCG, [Zhou et al. \(2015b\)](#) evaluated lake water chemistry and the species richness of fish and total zooplankton in 20 Adirondack watersheds in response to historical acidic deposition and under future deposition scenarios. Historical acidification in the lakes was related to the total ambient deposition of  $\text{SO}_4^{2-} + \text{NO}_3^-$ , the Ca weathering rate, and the simulated preindustrial ANC in the year 1850. In the modeled watersheds, changes in the concentration of  $\text{Al}^{3+}$  since the onset of acidic deposition were related to the Ca weathering rate and the hindcast value of ANC in the year 1850. Estimated preindustrial ANC for the study lakes ranged from 18 to 190  $\mu\text{eq/L}$ . Modeling results suggested that lake ANC, fish richness, and total zooplankton species richness would increase under hypothetical decreases in future acidic deposition. However, the simulations suggested that biological and chemical recovery may not be attainable in all of the lakes ([Zhou et al., 2015b](#)).

Total maximum daily load (TMDL) modeling analysis by [Fakhraei et al. \(2014\)](#) for 128 Adirondack lakes designated by New York as acid-impaired under the Clean Water Act suggested that a further decrease in S deposition of 60% from ambient levels would allow about 30% of the impaired lakes to achieve the brook trout protection ANC level of 11  $\mu\text{eq/L}$  by the year 2050, with an additional 30% recovering by the year 2200.

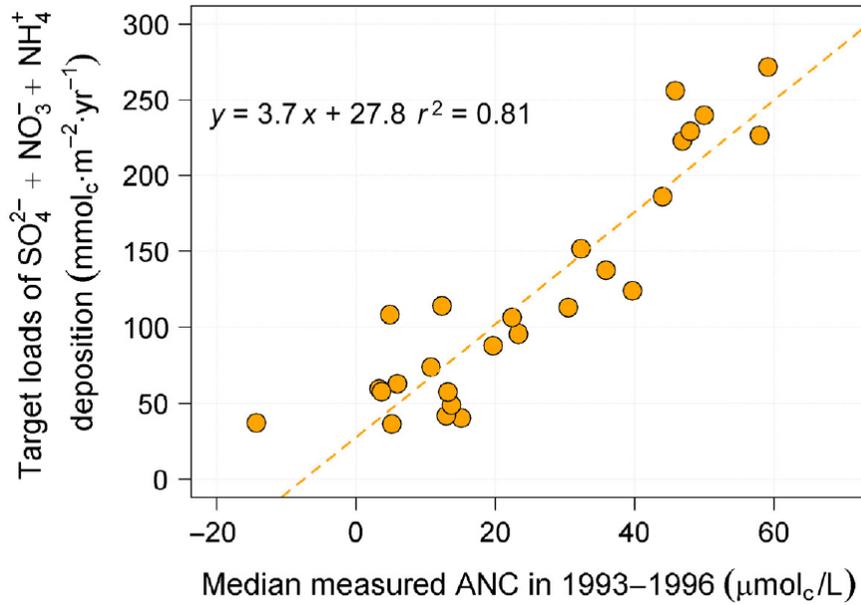

Using the same model (PnET-BGC), [Zhou et al. \(2015a\)](#) simulated past and future effects of N and S acidity on stream chemistry of 12 watersheds in the Great Smoky Mountain National Park. Three target levels of ANC (0, 20, and 50  $\mu\text{eq/L}$ ) were based on a range of protection of aquatic life from “minimal” to “considerable.” Model simulations suggested that the level of  $\text{NO}_3^- + \text{SO}_4^{2-}$  deposition necessary to achieve a given ANC target was approximately a linear function of current ANC. Target loads of  $\text{NO}_3^- + \text{SO}_4^{2-}$  deposition for the 12 study streams ranged from 270 to 3,370  $\text{eq/ha/yr}$  to reach an ANC of 0  $\mu\text{eq/L}$  by 2050, 0–2,340  $\text{eq/ha/yr}$  to reach ANC of 20  $\mu\text{eq/L}$  by 2050, and 0–1,400  $\text{eq/ha/yr}$  to

reach an ANC of 50  $\mu\text{eq/L}$  by 2050. However, the majority of the 12 streams could not achieve the ANC target of 50  $\mu\text{eq/L}$  by 2050. This was also true to a lesser extent for the target of ANC = 20  $\mu\text{eq/L}$ .

[Fakhraei et al. \(2016\)](#) and [Fakhraei et al. \(2017a\)](#) addressed the likelihood that acidified streams in Great Smoky Mountains National Park (GRSM) can recover from the adverse impacts of S and N deposition and restore biotic health, and how long that might take. They defined the point of harmful effects on the aquatic ecosystems based on converting pH criteria to ANC then modeling ANC below defined thresholds, using the PnET-BGC biogeochemical model. The studies updated the previous model application by [Zhou et al. \(2015b\)](#) by including recent large decreases in S and oxidized N deposition and all streams in the park listed by Tennessee as water quality impaired under the Clean Water Act (303(d) listed). Model simulations suggested that TLs varied with measured ANC ([Figure 8-14](#)) and that stream recovery from previous acidification has lagged behind decreases in S and N deposition due to the dynamics of S adsorption on soils. The TLs varied with measured ANC in this simulation because the relationship between pH and ANC is not linear and because stream  $\text{CO}_2$  can have a strong impact on pH. Simulated ANC increases were larger per unit decrease in  $\text{NH}_4^+$  deposition than per unit decrease in  $\text{SO}_4^{2-}$  or  $\text{NO}_3^-$  deposition. This finding was attributed to high S adsorption and limited N retention in watershed soils. Modeling results were extrapolated to other streams throughout the park. The extrapolation was based on observed linear relationships between median ANC measured during the period 1993–1996 and the TLs to achieve various ANC targets. A fixed ANC target of 20  $\mu\text{eq/L}$  was considered, along with two other targets that were based on model simulation of preindustrial ANC (ANC in 1850 and ANC 20  $\mu\text{eq/L}$  lower than ANC in 1850). The latter target was selected because the model suggested that ANC in 1850 was generally not obtainable in response to further decreases in S and N deposition. [Figure 8-15](#) shows spatial patterns in TL exceedance of ambient S and N deposition for two endpoint years (2050 and 2150) and two ANC recovery targets (20  $\mu\text{eq/L}$  and 20  $\mu\text{eq/L}$  less than modeled preindustrial ANC). For the 303(d)-listed stream watersheds at high elevations within the park critical loads ranged between 240 and 960  $\text{eq/ha/yr}$  of  $\text{SO}_4^{2-} + \text{NO}_3^- + \text{NH}_4^+$  deposition to eight of the twelve watersheds ([Fakhraei et al., 2017a](#)). For streams in the remaining four watersheds, no reduction in deposition was sufficient to achieve pH of 6 by 2150 and recovery in these streams is projected to take centuries.

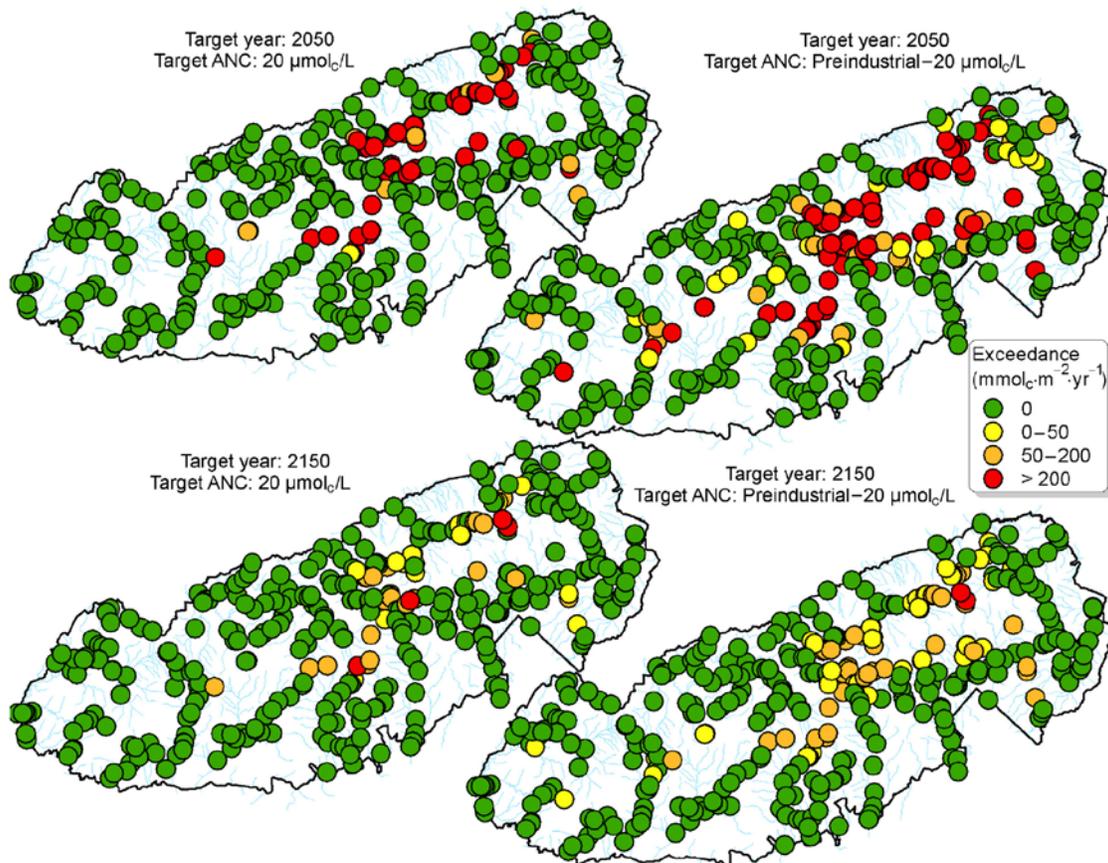

MAGIC modeling based on simulations of past and future acid-base chemistry of 14 streams in Shenandoah National Park identified a TL of about 188  $\text{eq S/ha/yr}$  in the median modeled stream located on sensitive (siliciclastic) bedrock to achieve ANC = 50  $\mu\text{eq/L}$  in 2100. This was 77% lower than the S deposition in 1990 ([Sullivan et](#)

al., 2008). Many streams had ambient ANC < 20  $\mu\text{eq/L}$ . Hindcast simulations suggested that preindustrial ANC was above 50  $\mu\text{eq/L}$  in all of the study streams.

**Figure 8-14.** Modeled target loads and median measured Acid Neutralizing Capacity (ANC) in the period 1993 to 1996 from 30 Great Smoky Mountain National Park (GRSM) streams to achieve an ANC of 20  $\mu\text{eq/L}$  by the year 2150.

Source: [Fakhraei et al. \(2016\)](#).

**Figure 8-15.** Exceedance level of current  $\text{NO}_3^- + \text{SO}_4^{2-}$  atmospheric deposition for 387 stream sites in the GRSM. Exceedances were calculated for the years 2050 and 2150 using two targets for modeled stream ANC recovery of  $20 \mu\text{molc/L}$  and  $20 \mu\text{molc/L}$  less than the simulated preindustrial ANC.

#### 8.5.4.2 International Critical Loads

Critical load concepts were initially developed in Europe and only more recently widely applied in the U.S. and Canada. Work on CLs has continued internationally as a basis for setting environmental policy. Some of the recent work conducted outside the U.S. is summarized below. Previous regional CL assessments in Canada have often employed an empirical clay-based soil texture approximation to estimate weathering as input for aquatic and terrestrial steady-state CL modeling [Krzyzanowski and Innes \(2010\)](#)

estimated steady-state CLs, using the SSWC model, and associated exceedances for protecting freshwater ecosystems in First Nations territory in British Columbia against water acidification. Estimates of acidic deposition were not in exceedance of the CL at any of the study lakes.

The 1999 Gothenburg Protocol, under the Long-Range Transboundary Air Pollution (LRTAP) Convention of the United Nations Economic Commission for Europe (UNECE) was aimed at reducing the total area of Europe where acidic deposition exceeded CLs. In 2007, the Coordination Centre for Effects (CCE) of the International Cooperative Programme for Modeling and Mapping (part of the LRTAP Convention) issued a call to European countries for results from dynamic models of soil and water acidification. In response to this call, Norwegian scientists used the MAGIC model to project recovery of surface waters in Norway. [Larssen et al. \(2010\)](#) described the results for water quality and fish population status and considered implications for policy options. The modeling results suggested that surface waters will continue to recover slowly under existing emissions controls, but about 18% of Norway will still have lakes that receive acidic deposition that exceeds the CL to protect against aquatic acidification and in which water quality will continue to be insufficient to support viable populations of fish and other aquatic organisms.

Both measured and modeled data indicate past acidification and suggest some future chemical recovery at acid-sensitive locations throughout northern Europe. Some surface waters have experienced much greater levels of acidification than have acid-sensitive sites in the eastern U.S., For example, the MAGIC model was used by [Skeffington et al. \(2016\)](#) to simulate past and future trajectories in stream chemistry of a seriously acidified small forest watershed in England. Hindcast simulations suggested that ANC decreased from about 150 to 100  $\mu\text{eq/L}$  and pH decreased from 7.1 to 4.2. Hypothesized decreases in future acidic deposition suggested slow and prolonged chemical recovery over a period of 250 years to ANC = 43  $\mu\text{eq/L}$ .

[Bishop et al. \(2008\)](#) applied the SSWC model to lakes in northern Sweden, many of which are rich in organic matter. They argued that the SSWC model is not suitable for judging the acidification of individual lakes in regions such as northern Sweden where the extent of chronic acidification is relatively small and where organic influence on lake chemistry is pronounced. A variant of the SSWC model predicted preindustrial lake chemistry at 58 sites where paleolimnological reconstructions of lake chemistry were available. The authors noted a large discrepancy between SSWC predictions and diatom reconstructions, and this was attributed largely to short-term fluctuations in modern lake chemistry.

---

## 8.6 Aquatic Acidification Summary and Causal Determinations

In the 2008 ISA, the body of evidence was sufficient to infer a causal relationship between acidifying deposition and changes in freshwater biota. Overall, the updated research synthesized in this ISA reflects incremental improvements in scientific knowledge of aquatic biological effects and indicators of acidification as compared with knowledge summarized in the 2008 ISA. Studies indicate that aquatic organisms have been affected by acidification at virtually all trophic levels in sensitive ecosystems and that these responses have been well characterized for several decades. Research and observations reported in the 2008 ISA showed consistent and coherent evidence for effects on aquatic biota, especially algae, benthic invertebrates, and fish that are most clearly linked to chemical indicators of acidification (pH, ANC, inorganic Al concentration). Effects on fish species are especially well understood, and many species have been documented to be adversely affected. Both in situ and lifestage experiments in fish support previous thresholds of chemical indicators and biological effects. Physiological perturbations at the organism level of biological organization can lead to effects on reproduction, growth, and survival. More species are lost with greater acidification, providing evidence of a biological gradient in effects. Biological shifts such as loss of acid-sensitive organisms, population declines, and decreased species richness have been reported from acid-sensitive regions of the U.S. and other countries. Despite reductions in acidifying deposition, many aquatic ecosystems across the U.S. are still experiencing effects on ecological structure and functioning at multiple trophic levels. New information is consistent with the conclusions of the 2008 ISA that **the body of evidence is sufficient to infer a causal relationship between acidifying deposition and changes in biota, including physiological impairment and alteration of species richness, community composition, and biodiversity in freshwater ecosystems.** [Baker et al. \(1990a\)](#) conducted a rigorous review of the effects of acidification on aquatic biota for the 1990 National Acid Precipitation Assessment Program (NAPAP) State of Science/Technology reports. In the review, hundreds of laboratory studies, in situ bioassays, field surveys, whole-system field experiments, and mesocosm studies were evaluated to provide a synthesis of the effects of acidification on aquatic biota. The findings in that report, along with literature published after 1990 up to 2007, were included in the 2008 ISA. The summaries below integrate information known at the time of the 2008 ISA with newer studies. For most topics related to aquatic acidification, the fundamental understanding of mechanisms and biological effects has not changed; rather, additional studies lend further support to the findings from the previous ISA.

The effects of acidification on freshwaters in the U.S. and elsewhere were well characterized at the time of the 2008 ISA. The sensitivity of a watershed depends on watershed characteristics such as underlying geology and hydrological flowpaths

([Appendix 7](#)), and the sensitivity of species that make up the local biological community. Changes in biota are linked to chemical indicators in surface water ([Appendix 7](#); [Table 8-9](#)). As stated in the 2008 ISA, biological effects are primarily attributable to low pH and high inorganic Al concentration. ANC is also used as a chemical indicator of acidification because it integrates overall acid-base status and because surface water acidification models do a better job projecting ANC than pH and inorganic Al concentrations. However, ANC does not relate directly to the health of biota. The usefulness of ANC lies mainly in the association between ANC and the surface water constituents or parameters that directly cause or ameliorate acidity-related stress, in particular pH, Ca, and inorganic Al.

Acid-sensitive freshwater systems can either be chronically acidified or subject to periodic episodes of decreased pH and ANC and increased inorganic Al concentration. Chronically acidic lakes and streams were traditionally defined as having ANC <0 µeq/L. The ANC in freshwater systems where episodic acidification occurs may fall below 0 µeq/L for only a few hours to weeks in a given year ([Driscoll et al., 2001b](#)). During these acid episodes, water chemistry may exceed acid tolerance of resident aquatic biota. Biological effects of episodes may include fish mortality, changes in species composition, and declines in aquatic species richness across multiple taxa. Biological effects of chronic and episodic acidification have been most clearly documented for phytoplankton, zooplankton, aquatic invertebrates, and fish and can be linked to changes in the chemical indicators of aquatic acidification ([Table 8-9](#)). An ANC of >50 ueq/L was used as an indicator for acidification to an ANC level that may harm biota in the U.S. EPA National Lake Surveys ([U.S. EPA, 2009b](#)).

**Table 8-9 Ecological indicators for aquatic acidification.**

Key Indicators	Ecological Effect	Key References
Acid neutralizing capacity	Commonly set at ANC values less than 0, 20, 50, and 100 $\mu\text{eq/L}$ to correspond with decreasing levels of concern ( <a href="#">Figure 8-4</a> )	<a href="#">Driscoll et al. (2001b)</a> , <a href="#">MacAvoy and Bulger (1995)</a> , <a href="#">Baker et al. (1990a)</a> , <a href="#">U.S. EPA (2009b)</a>
Base cation surplus	0 $\mu\text{eq/L}$ —risk of inorganic Al leaching to streams	Section 3.2.1.5 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur-Ecological Criteria <a href="#">U.S. EPA (2008a)</a> <a href="#">Lawrence et al. (2007)</a>
pH	<6.0—reduced number of fish species	<a href="#">Driscoll et al. (2001b)</a> , <a href="#">MacAvoy and Bulger (1995)</a> , <a href="#">Baker et al. (1990a)</a>

### 8.6.1 Phytoplankton

Phytoplankton, photosynthesizing forms of plankton, play important roles in freshwater systems as primary producers at the base of the aquatic ecosystem food web. These organisms, encompassing diatoms, cyanobacteria, dinoflagellates, and other algae, vary in tolerance of acidic conditions. Studies reviewed in the 2008 ISA reported reduced species richness of phytoplankton with the decreases in pH and increases in inorganic Al concentrations that are associated with acid-affected surface waters ([U.S. EPA, 2008a](#)). Effects were most prevalent in the 5 to 6 pH range ([Baker et al., 1990a](#)). Since the 2008 ISA, several paleolimnological and field studies have further linked phytoplankton community shifts to chemical indicators of acidification. For example, [Lacoul et al. \(2011\)](#) reviewed information on the effects of acidification on plankton in Atlantic Canada and observed that the greatest changes in phytoplankton species richness occurred over a pH range of 4.7 to 5.6, just beyond the interval (pH 5.5 to 6.5) where bicarbonate becomes depleted in the water.

---

## 8.6.2 Zooplankton

Zooplankton, the animal forms of plankton, comprise many groups of small freshwater organisms including protozoans, rotifers, cladocerans, and copepods. Decreases in ANC and pH and increases in inorganic Al concentration were shown to contribute to the loss of zooplankton species and/or abundance in lakes in studies reviewed in the 2008 ISA ([Keller and Gunn, 1995](#); [Schindler et al., 1985](#)). Possible mechanisms for zooplankton sensitivity to low pH and ANC include ion regulation failure, reduced oxygen uptake, inability to reproduce, and inorganic Al toxicity ([U.S. EPA, 2008a](#)). Reported pH thresholds for zooplankton community alteration generally ranged from 5 to 6 in studies reviewed in the 2008 ISA. For example, a decrease in pH from 6 to 5 caused decreased species richness in zooplankton communities in lakes ([Holt et al., 2003](#); [Holt and Yan, 2003](#); [Locke and Sprules, 1994](#)). Newer studies support effects in a similar pH range. [Vinebrooke et al. \(2009\)](#) reported variations in phytoplankton and zooplankton communities during a whole-lake experimental acidification of Lake 302S in the Experimental Lakes area in Ontario. There was a negative effect on zooplankton species richness as pH decreased from 6.8 to 4.5. Acidification often reduces Ca availability in lake water and can affect growth and survival of *Daphnia* spp., an important prey item in many freshwater food webs ([Jeziorski et al., 2012b](#)). At ANC <0 µeq/L, zooplankton richness was low in Adirondack lakes [15 species in highly acidic lakes compared to 35 species at the highest values of ANC in the study [near 200 µeq/L; [Sullivan et al. \(2006a\)](#)].

---

## 8.6.3 Benthic Invertebrates

Sediment-associated invertebrates such as bivalves, worms, gastropods, and insect larvae can be impacted by acidification because H<sup>+</sup> and Al can be directly toxic, causing disruption of ion regulation and reduced reproductive success. As reviewed in the 2008 ISA, decreases in ANC and pH and increases in inorganic Al concentration have been shown to contribute to the decline in abundance or loss of benthic invertebrate species in streams. Typically, pH below 5 virtually eliminate all mayflies, a common taxa used to assess water quality, along with other aquatic organisms from some streams ([U.S. EPA, 2008a](#); [Baker and Christensen, 1991](#)). Since the 2008 ISA, a survey of benthic macroinvertebrates by [Baldigo et al. \(2009\)](#) in 36 streams in the southwestern Adirondack Mountains indicated that 44 to 56% of macroinvertebrate communities were severely impacted by acidification at pH <5.1, moderately impacted at pH 5.1 to 5.7, and unaffected at pH above 6.4 ([Baldigo et al., 2009](#)). Thresholds of pH 5.2 to 6.1 were identified for sensitive invertebrates from Atlantic Canada; below these pH values,

changes in the abundance or presence of invertebrate taxa were observed ([Lacoul et al., 2011](#)).

---

#### 8.6.4 Fish

The primary mechanism that controls the toxic effects of acidification on fish involves disruption of normal ion regulation at the gill surface, resulting in increased rates of ion loss, inhibition of ion uptake, and loss of gill function ([Bergman et al., 1988](#); [Wood and McDonald, 1987](#); [Leivestad, 1982](#); [McWilliams and Potts, 1978](#)). Responses to acidifying conditions include respiratory and circulatory failure. The effects of low pH, low ANC, and high inorganic Al concentrations have been well characterized in fish for many decades. Responses among fish species and lifestages within species to pH and Al in surface waters have been variable. In general, early lifestages are more sensitive to acidic conditions than the young-of-the-year, yearlings, and adults ([Baker et al., 1990a](#); [Johnson et al., 1987](#); [Baker and Schofield, 1985](#)). Some of the most commonly studied species include brown trout, brook trout, and Atlantic salmon.

Further characterization of physiological responses (ion regulation, stress responses, gill Al accumulation) to acidification in fish, mostly Atlantic salmon, trout, and other salmonids, adds to the existing information on sublethal effects on individual fish species. Many of the newer studies were conducted in situ and reported varying sensitivity of different lifestages. Findings are consistent with physiological alterations in fish reported in the 2008 ISA. Several studies have assessed physiological changes associated with migratory activities. For example, a recent study assessed gill Al and NKA activity in smolts moving downstream in well-buffered and acid-impacted migration corridors in the northeastern U.S. ([Kelly et al., 2015](#)). In the acid-impacted river basin, the fish had elevated gill Al and lower gill NKA activity.

As summarized in [Baker et al. \(1990a\)](#) and studies reviewed in the 2008 ISA, fish populations in acidified streams and lakes of both Europe and North America have declined, and some have been eliminated as a result of atmospheric deposition of acids and resulting changes in pH, ANC, and inorganic Al concentrations in surface waters. There is often a positive relationship between pH and number of fish species, at least for pH values between about 5.0 and 6.5 ([Cosby et al., 2006](#); [Sullivan et al., 2006a](#); [Driscoll et al., 2003b](#); [Bulger et al., 1999](#)). Additional pH thresholds published since the 2008 ISA generally reinforce these ranges, and several new studies consider the role of DOC in modulating pH and subsequent effects on biota. New studies on fish responses to chemical alarm cues show behavioral effects at pH <6.6. Characterization of ANC and its levels of concern have not changed appreciably with the newly available information.

Few or no fish species are found in lakes and streams that have very low ANC (near zero) and low pH [near 5.0; ([U.S. EPA, 2008a](#); [Sullivan et al., 2006a](#))]. The number of fish species generally increases at higher ANC and pH. The pH largely controls the bioavailability of Al ([Driscoll et al., 2001b](#)). Al is very toxic to fish, and thresholds of response to elevated concentrations of this metal in acidified waters are summarized in [Table 8-4](#).

Some of the most in-depth studies of the effects of acid stress on fish have been conducted in streams in Shenandoah National Park, VA ([Cosby et al., 2006](#)), and lakes in the Adirondack Mountains, NY ([Sullivan, 2015](#)). Effects on fish have also been documented in acid-sensitive streams of the Catskill Mountains of southeastern New York and the Appalachian Mountains from Pennsylvania to Tennessee and South Carolina ([Bulger et al., 2000](#); [Bulger et al., 1999](#); [SAMAB, 1996](#); [Charles and Christie, 1991](#)).

---

### **8.6.5 Thresholds of Response**

As reviewed above, new thresholds have been identified in aquatic organisms ([Table 8-10](#)). However, this new information does not appreciably change the understanding of biological effects associated with chemical indicators or the levels at which effects occur. Evidence continues to strengthen findings in the 2008 ISA that high levels of acidification (especially to pH values below 5) eliminate sensitive species from freshwater streams.

**Table 8-10 Results of recent biological effects studies in surface waters indicative of thresholds of biological response to changes in water acidity.**

Life Forms and Effects	Region	Potential Tipping Points	Reference
Sensitive invertebrates present	Atlantic Canada	pH 5.2 to 6.1	<a href="#">Lacoul et al. (2011)</a>
Littoral macroinvertebrates	Northern Europe	pH 5.8 to 6.5	<a href="#">Schartau et al. (2008)</a>
Brook trout loss of whole-body Na	Great Smoky Mountains NP	pH 5.1	<a href="#">Neff et al. (2008)</a>
Brook trout loss of whole-body Na of 10 to 20%	Great Smoky Mountains NP	pH 4.9 to 5.1	<a href="#">Neff et al. (2009)</a>
Fish damage in lakes	Norway	ANC 67 µeq/L	<a href="#">Hesthagen et al. (2008)</a>
Juvenile brown trout mortality in high DOC streams	Sweden	pH 4.8 to 5.4	<a href="#">Serrano et al. (2008)</a>
Embryo and yolk sac fry survival during episodes in DOC-rich lakes	Sweden	pH 4.0	<a href="#">Serrano et al. (2008)</a>
Toxicity to brown trout in humic streams	Northern Europe	pH 5.0; inorganic aluminum 20 µg/L	<a href="#">Andrén and Rydin (2012)</a>
Presence of macrophytes	Atlantic Canada	pH 5.0	<a href="#">Lacoul et al. (2011)</a>
Aquatic bird breeding	Atlantic Canada	pH 5.5	<a href="#">Lacoul et al. (2011)</a>

ANC = acid neutralizing capacity; DOC = dissolved organic carbon; L = liter; µeq = microequivalent; µg = microgram; Na = sodium; NP = National Park.

### 8.6.6 Biological Recovery

Biological recovery ([Section IS.11](#)) can occur only if chemical recovery ([Appendix 7](#)) is sufficient to allow growth, survival, and reproduction of acid-sensitive plants and animals ([Driscoll et al., 2001b](#)). Modeling studies in the northeastern and southeastern U.S. suggest that full chemical recovery may take many decades or not occur at all due to the dynamics of S adsorption and desorption and to long-term Ca depletion of soils. As reported in the 2008 ISA, biological recovery lags behind chemical recovery in many aquatic systems, and the time required for biological recovery after chemical recovery is complete is uncertain ([U.S. EPA, 2008a](#)). Ecosystems deemed to be on a recovery trajectory are those found to be moving towards a mix of species presence and abundance that approximates the undisturbed state.

Since the publication of the 2008 ISA, additional studies have assessed recovery of benthic organisms, although most of this research has been conducted in Canadian and European waters. New studies continue to support these earlier observations. In general, recovery of plankton and benthic invertebrates is observed prior to recovery of fish populations, although most biological communities studied to date have not returned to preacidification conditions, even after recovery of chemical parameters. In a study reviewed in the 2008 ISA, zooplankton recovery in experimentally acidified Little Rock Lake in Wisconsin took one decade, with approximately 40% of the zooplankton species experiencing a lag time of 1 to 6 years ([Frost et al., 2006](#)). In an experimentally acidified lake in Canada, zooplankton species diversity partially rebounded to preacidification levels as pH returned back to 6.1, with rotifers recovering less than crustaceans ([Malley and Chang, 1994](#)). Newer studies from the Sudbury Lakes region of Canada indicate substantial recovery of copepods and cladocerans at pH 5.5 and higher in previously acidified lakes ([Valois et al., 2011](#)).

In the 2008 ISA, recovery of fish populations following liming or reduction of deposition was reported in several studies. Newer studies have documented successful reintroduction of brook trout in previously acidified Adirondack water bodies (Brooktrout Lake) or recolonization (Honedaga Lake) by populations in tributary refuges ([Sutherland et al., 2015](#); [Josephson et al., 2014](#)). Fish community shifts from historical acidification have been observed in the upper mainstem of Hubbard Brook ([Warren et al., 2008](#)) and other locations.

---

### 8.6.7 Most Sensitive and Most Affected Regions

The extent and distribution of sensitive ecosystems and regions in the U.S. were well known at the time of the 2008 ISA. In the U.S., surface waters that are most sensitive to acidification based on ANC are largely found in the Northeast, southern Appalachian Mountains, FL, the upper Midwest, and the mountainous West ([McDonnell et al., 2014b](#); [Greaver et al., 2012](#); [Campbell et al., 2004a](#); [Driscoll et al., 2001b](#); [Baker et al., 1990b](#); [Omernik and Powers, 1983](#)). Levels of acidifying deposition in the West are low in most areas, acidic surface waters rare, and the extent of chronic surface water acidification that has occurred to date has been limited ([Charles and Christie, 1991](#)). Episodic acidification does occur in both the East and West at some acid-sensitive locations, and this is part natural and part human-caused. Geographic patterns in acidification sensitivity vary in response to spatial differences in geology, hydrologic flow paths, presence and depth of glacial till, climate, and others. [Sullivan \(2017\)](#) mapped the locations of known lakes and streams that had low ANC across the country ([Figure 8-11](#)).

---

## 8.6.8 Critical Loads

Since the 2008 ISA, considerable CL research has been conducted in the U.S. New generalized empirical CL estimates include 571 eq N/ha/yr in the Northeast and 286 eq N/ha/yr in the West for episodic acidification of high elevation lakes under high-flow conditions ([Baron et al., 2011b](#)). [Heard et al. \(2014\)](#) estimated CL = 74 eq/ha/yr to protect against chronic acidification in high-elevation lakes in the Sierra Nevada. Steady-state CLs have been derived at many locations since the 2008 ISA. Steady-state CLs of S and N for lakes in the Adirondack Mountains (1,620 eq/ha/yr) and for the central Appalachian streams (3,700 eq/ha/yr) were calculated for maintaining a surface water ANC of 50  $\mu\text{eq/L}$  on an annual basis ([NAPAP, 2011](#)). [Sullivan et al. \(2012b\)](#) calculated CL values in the Blue Ridge ecoregion for maintaining stream ANC at 50  $\mu\text{eq/L}$ . The calculated CLs were less than 500 eq/ha/yr at one-third of the study sites. Observations showed that about one-half or more of the stream length in the study region was in exceedance of the CL of S deposition for protecting aquatic resources to an ANC = 50  $\mu\text{eq/L}$  over the long term. [McDonnell et al. \(2014b\)](#) calculated steady-state aquatic CLs to protect southern Appalachian Mountain streams against acidification to ANC = 50  $\mu\text{eq/L}$  and other critical benchmark values. Results showed that nearly one-third of the stream length in the study region (mainly streams in Virginia, West Virginia, North Carolina, and Tennessee) had a CL of S deposition <500 eq/ha/yr, which was less than the estimated regional average S deposition (600 eq/ha/yr). Critical loads for acid deposition to lakes in Class I and II wilderness areas of the Sierra Nevada were estimated in 2008 to protect ANC to 0, 5, 10, and 20  $\mu\text{eq/L}$  levels, which span the range of minimum ANC values observed in those lakes. Median CLs were 217 (ANC = 0), 186 (ANC = 5), 157 (ANC = 10), and 101 (ANC = 20) eq/ha/yr. The median CL for granitic watersheds based on a critical ANC limit of 10  $\mu\text{eq/L}$  was 149 eq/ha/yr. It was estimated that slightly more than one-third of the lakes received acidic deposition higher than their CL.

In addition to the steady-state and empirical CLs described above, CL estimates are available from dynamic modeling.  $\text{NO}_3^-$  leaching in stream water in California was both simulated (by the DayCent model) and determined empirically to be approximately 1,214 eq N/ha/yr ([Fenn et al., 2008](#)). [Zhou et al. \(2015a\)](#) simulated past and future effects of N and S on stream chemistry of 12 watersheds in the Great Smoky Mountain National Park. Three target levels of ANC (0, 20, and 50  $\mu\text{eq/L}$ ) were used, based on a range of protection of aquatic life from minimal to considerable. TLs of  $\text{NO}_3^- + \text{SO}_4^{2-}$  deposition for the 12 study streams ranged from 270 to 3,370 eq/ha/yr to reach ANC = 0  $\mu\text{eq/L}$  by 2050, 0 to 2,340 eq/ha/yr to reach ANC = 20  $\mu\text{eq/L}$  by 2050, and 0 to 1,400 eq/ha/yr to reach ANC = 50  $\mu\text{eq/L}$  by 2050. However, the majority of streams could not achieve the ANC target of 50  $\mu\text{eq/L}$ . This was also true to a lesser extent for the target of

ANC = 20  $\mu\text{eq/L}$ . Modeling studies also suggested that complete recovery may not be possible in the Appalachian Mountains ([Sullivan et al., 2011b](#)). For some sites, one or more of the selected critical ANC levels (0, 20, 50, 100  $\mu\text{eq/L}$ ) could not be achieved by 2100, even if S deposition was decreased to zero and maintained at that level throughout the simulation. MAGIC modeling based on simulations of past and future acid-base chemistry of 14 streams in Shenandoah National Park identified a target load of about 188 eq kg S/ha/yr to achieve ANC = 50  $\mu\text{eq/L}$  in 2100 in the median modeled stream located on sensitive (siliciclastic) bedrock, which was 77% lower than the S deposition in 1990 ([Sullivan et al., 2008](#)). Many streams had ambient ANC <20  $\mu\text{eq/L}$ , although hindcast simulations suggested that preindustrial ANC was above 50  $\mu\text{eq/L}$  in all of the study streams.

In the Adirondack Mountains, TLs were calculated for two time periods (2050 and 2100) and three levels of protection (ANC = 0, 20, and 50  $\mu\text{eq/L}$ ). Results of simulated TLs, and associated exceedances, were extrapolated to the regional population of lakes. About 30% of the lakes had TL <500 eq/ha/yr to protect lake ANC to 50  $\mu\text{eq/L}$  ([Sullivan et al., 2012a](#)). Also in the Adirondack Mountains, [Zhou et al. \(2015c\)](#) ran simulations using the PnET-BGC model, which suggested that future decreases in  $\text{SO}_4^{2-}$  deposition would be more effective in that region in increasing the lake water ANC than equivalent decreases in  $\text{NO}_3^-$  deposition. In another modeling study of 20 Adirondack watersheds, lake ANC and fish and total zooplankton species richness were projected to increase under hypothetical decreases in future acidic deposition, but model projections suggested that lake ecosystems may not achieve complete chemical and biological recovery in the future ([Zhou et al., 2015b](#)). Estimates of preindustrial ANC for the study lakes ranged from 18 to 190  $\mu\text{eq/L}$ . The magnitude of simulated historical acidification represented by ANC loss ranged from about 26 to 100  $\mu\text{eq/L}$ .

---

## APPENDIX 9    BIOLOGICAL EFFECTS OF FRESHWATER NITROGEN ENRICHMENT

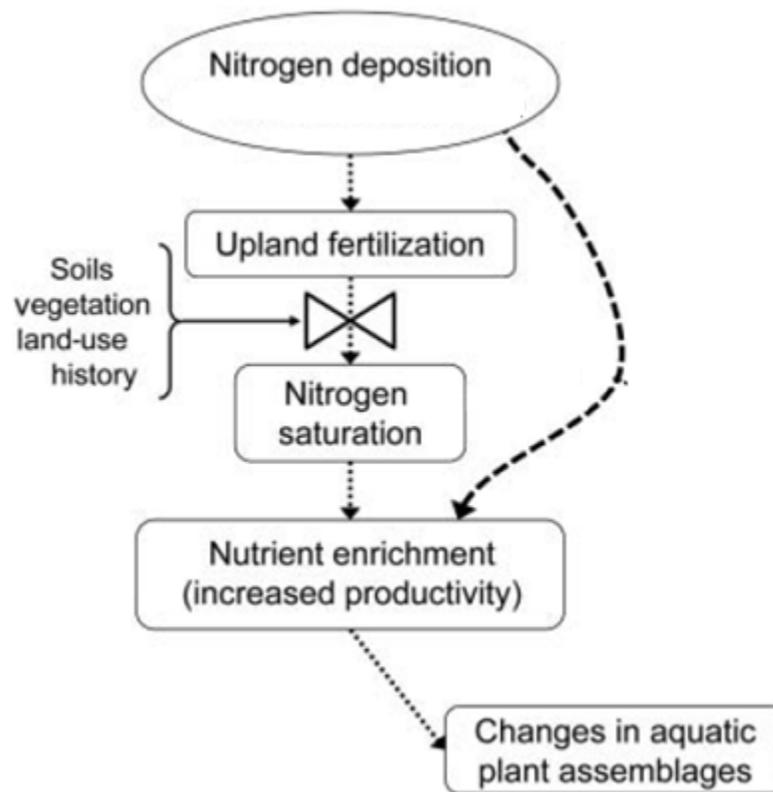

This appendix characterizes the biological effects of nitrogen (N) nutrient enrichment from atmospheric deposition to freshwater systems. Biogeochemical processes and chemical indicators associated with nutrient enrichment of fresh waters are discussed in [Appendix 7](#). Atmospheric deposition constitutes only a portion of total N load in many water bodies; however, it may be the dominant source of N in some remote aquatic ecosystems, such as headwater and lower order streams and alpine lakes, which are more affected by N deposition than other sources of N. [Appendix 9.1](#) presents an overview of freshwater nutrient enrichment in these systems and includes a discussion on the characteristics of water bodies sensitive to N deposition, the effects of N deposition on nutrient limitation, phosphorus (P) interactions, and climate modification of N response. Inputs of P have direct implications for how ecosystems respond to N deposition, and recent trends in increased atmospheric deposition of P are discussed in this context. Indicators of biological responses to nutrient enrichment ([Appendix 9.2](#)) effects of N on species diversity, ecosystem structure, and function ([Appendix 9.3](#)) and emerging research on the links between nutrient enrichment and animal behavior and disease ([Appendix 9.4](#)) provide a basis for identifying thresholds of biological response ([Appendix 9.5](#)) and determining causation based on new information and evidence from prior N assessments ([Appendix 9.6](#)).

---

### 9.1    Introduction to Nitrogen Enrichment and Eutrophication in Freshwater Systems

In the *2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur—Ecological Criteria* (2008 ISA), the body of evidence was sufficient to infer a causal relationship between N deposition and the alteration of species richness, species composition, and biodiversity in freshwater ecosystems ([U.S. EPA, 2008a](#)). Increased atmospheric N inputs to freshwater systems via runoff or direct deposition, especially to N limited and N and phosphorus (P) colimited systems, can stimulate primary productivity ([Figure 9-1](#)). Eutrophication is the process of enriching a water body with nutrients resulting in increased growth and change in the composition of primary producers (algae and/or aquatic plants). One of the consequences of eutrophication is low oxygen levels in the water body when these primary producers decompose. Changes in biological indicators of N enrichment, including chlorophyll *a*, phytoplankton

(free-floating algae) biomass, periphyton (algae attached to a substrate) biomass, and diatoms (major algal group with cell walls made of silica), provide evidence for N effects. The transport of atmospheric N inputs downstream can exacerbate eutrophic conditions in higher order streams, rivers, and lakes. Atmospheric deposition to watersheds affects processes along the freshwater-to-ocean continuum, including coastal and estuarine systems ([Appendix 10](#)). New information is consistent with the conclusions of the 2008 ISA that **the body of evidence is sufficient to infer a causal relationship between N deposition and changes in biota, including altered growth and productivity, species richness, community composition, and biodiversity due to N enrichment in freshwater ecosystems.**

Source: Modified from [Baron et al. \(2011b\)](#).

**Figure 9-1** Conceptual model of the influence of atmospheric nitrogen deposition on freshwater nutrient enrichment.

Based on the studies described throughout [Appendix 9](#) and in the 2008 ISA, the freshwater ecosystems in the U.S. most likely to be sensitive to N deposition are headwater streams, lower order streams, and alpine lakes, which have very low nutrients and productivity and are far from local pollution sources ([U.S. EPA, 2008a](#)). Even small inputs of N in these water bodies can increase nutrient availability or alter the balance of N and P, which can stimulate growth of primary producers and lead to changes in species richness, community composition, and diversity. Remote mountain lakes in the western U.S. are naturally oligotrophic and are considered among the aquatic ecosystems most sensitive to N deposition ([Williams et al., 2017b](#)). A portion of these lakes and streams in the western U.S. are in Class I wilderness areas ([Williams et al., 2017b](#); [Clow et al., 2015](#); [Nanus et al., 2012](#)). Survey data and fertilization experiments from studies reviewed in the 2008 ISA have documented increases in algal productivity as well as species changes and reductions in diversity at high-elevation lakes in the western U.S. in response to increased availability of N ([U.S. EPA, 2008a](#)). Some examples include the Snowy Range in Wyoming, the Sierra Nevada, Lake Tahoe, and the Colorado Front Range. In studies reviewed in the 2008 ISA, atmospheric N deposition (approximately 1 to 5 kg N/ha/yr) can cause an increase in phytoplankton and periphyton biomass in some alpine lakes. For example, in both the Beartooth Mountains of Wyoming and the Rocky Mountains of Colorado, N deposition as low as 1.5 kg N/ha/yr affects algal productivity ([Baron, 2006](#); [Saros et al., 2003](#)). The responses of high-elevation lakes can vary considerably depending on catchment characteristics and the amount of deposition ([Appendix 9.1.1](#)).

With increased characterization of nutrient inputs in remote high-elevation lakes and streams, fate and transport processes, N and P dynamics, phytoplankton response, and downstream effects in coastal/estuarine systems, the understanding of the role of N in freshwater eutrophication has evolved in recent decades. As conveyed in the 2008 ISA, the historical emphasis on P as a major cause of freshwater eutrophication was based on a number of highly influential studies in the 1960s and 1970s that focused on the role of wastewater, in particular phosphate detergents, in causing excessive algal blooms in Lake Mendota (WI), Lake Washington (WA), Lake Erie, and many other locations ([Edmondson, 1991](#); [Schindler, 1974](#); [Schindler et al., 1971](#); [Edmondson, 1969](#); [Vollenweider, 1968](#); [Hasler, 1947](#)). These observations guided approaches to freshwater lake and stream ecology for many years. Over time, an increasing recognition that N inputs can stimulate phytoplankton growth under certain conditions, coupled with further understanding of aquatic biogeochemistry ([Appendix 7](#)) and of the connectivity between freshwater and receiving estuaries and coastal waters, has led to recommendations to consider both N and P in nutrient reduction strategies ([Dodds and Smith, 2016](#); [Gobler et al., 2016](#); [Paerl et al., 2016b](#); [Lewis et al., 2011](#); [Scott and McCarthy, 2010](#); [Conley et al., 2009](#); [Paerl, 2009](#); [Lewis and Wurtsbaugh, 2008](#)).

There is increasing understanding of the frequency and shifts in the types of nutrient limitation in various systems. In oligotrophic clear water lakes where atmospheric N inputs are low and light is not limiting, phytoplankton primary production is typically N limited ([Bergstrom et al., 2015](#); [Hessen, 2013](#)). In the 2008 ISA, results from surveys, paleolimnological reconstructions, experiments, and meta-analyses of hundreds of studies have shown N limitation to be common in fresh waters, especially in remote areas, and a nearly universal eutrophication response to N enrichment in lakes and streams that are N limited ([U.S. EPA, 2008a](#); [Elser et al., 2007](#); [Bergström et al., 2005](#); [Elser et al., 1990](#)). Tropical and subtropical lakes, and lakes having small watersheds relative to the lake surface/volume, also tend to be N limited ([Paerl and Scott, 2010](#); [Elser et al., 2007](#)). As reported in the 2008 ISA, some alpine lakes have exhibited shifts from N limitation to between N and P limitation or to P limitation ([U.S. EPA, 2008a](#)). In a meta-analysis reviewed in the 2008 ISA, [Elser et al. \(2007\)](#) found that N limitation occurred as frequently as P limitation in freshwater ecosystems. Newer studies published since the 2008 ISA add to the evidence that reservoirs, rivers, and freshwater lakes can exhibit N limitation and N and P colimitation ([Paerl et al., 2014](#); [Lewis et al., 2011](#); [Conley et al., 2009](#); [Sterner, 2008](#)). N limitation appears to be increasingly common in freshwater systems, probably because their nutrient dynamics are being altered significantly by growing agricultural and urban P inputs ([Paerl et al., 2016b](#); [Grantz et al., 2014](#); [Paerl et al., 2014](#); [Finlay et al., 2013](#)).

A source of P to remote water bodies is deposition of dust. In an analysis of data from the U.S. EPA National Lakes surveys and National Rivers and Streams surveys [Stoddard et al. \(2016\)](#) found continent-wide increases in total phosphorus (TP) between 2000 and 2014, especially at sites that exhibited low disturbance ([Appendix 9.1.1.2](#)). Among the large natural P emission sources are soils, vegetation, and biomass combustion ash. Other notable sources include industry, agriculture, and mining. Although P is not a criteria pollutant, inputs of P may contribute to eutrophication and effect shifts in lake trophic status from P to N limitation or to colimitation. In addition, [Stoddard et al. \(2016\)](#) observed that total N (TN) was strongly correlated with TP in lakes and streams on a national scale. Although the authors determined that TP was increasing at “minimally disturbed sites,” they observed that TN was not increasing at those sites. Responses of aquatic ecosystems to atmospheric N deposition are heavily dependent on surface water P concentrations. Thus, because P inputs can alter N response, the impact of recent trends in increased P deposition is important to consider when evaluating nutrient status in water bodies sensitive to atmospheric inputs ([Appendix 9.1.1.4](#)).

---

## 9.1.1 Deposition to Freshwater Systems

Both N and P inputs to fresh waters sensitive to atmospheric deposition can affect nutrient limitation. The composition of N deposition is shifting in the U.S. from oxidized to reduced forms of N, with implications for the receiving systems. Atmospheric deposition of P may affect lake response to N inputs, and recent trends point to widespread increases in P deposition in the U.S. ([Stoddard et al., 2016](#)) and globally [[Brahney et al. \(2015\)](#); [Tipping et al. \(2014\)](#); [Appendix 9.1.1.2](#)].

---

### 9.1.1.1 Nitrogen Deposition Sources and Trends

Sources of N and trends in atmospheric deposition are described in [Appendix 2](#). Briefly, N is deposited in various reduced and oxidized forms, including organic N. Deposition can be wet (rain or snow), or dry. Atmospheric deposition of reduced N has increased relative to oxidized N in parts of the U.S. including the East and Midwest in the last few decades, shifting from a  $\text{NO}_3^-$  dominated to a  $\text{NH}_4^+$  dominated condition, and this trend is expected to continue under existing emissions controls ([Li et al., 2016d](#); [Pinder et al., 2008](#); [U.S. EPA, 2008a](#)). In the soil or water, much of the deposited  $\text{NH}_4^+$  is either taken up by biota or nitrified to  $\text{NO}_3^-$  and leaches to water bodies mainly as  $\text{NO}_3^-$  ([Hessen, 2013](#)). Up to 70% of deposited  $\text{NO}_3^-$  in remote alpine lakes in the western U.S. is anthropogenic in origin, with the largest sources being atmospherically delivered fertilizers from agriculture (approx. 60%) and fossil fuel combustion [approx. 10%; [Hundey et al. \(2016\)](#)]. N deposition to snow and glaciers are important sources of N to alpine lakes and streams that are fed by meltwaters. For example, approximately 50% of lakes in Glacier National Park and 10–20% of lakes in the central Rockies receive glacial meltwater ([Saros et al., 2010](#)). At high-elevation sites like those in the Rockies and Sierra Nevada, N deposition estimates are uncertain, especially for dry deposition ([Appendix 9.5](#)).

Moving from lower order streams to higher order streams, atmospheric N from direct deposition, runoff, and leaching from terrestrial ecosystems combines with other diffuse and point sources of N. The contribution from other terrestrial sources of N, such as fertilizer, livestock waste, septic effluent, and wastewater treatment plant outflow, often becomes much more important in downstream than in upland areas. About 75% of N inputs are retained in the watershed or denitrified, and 25% are exported to surface waters regardless of the dominant N input, including deposition ([Howarth et al., 2012](#); [Howarth et al., 1996a](#)). [Table 7-1](#) summarizes studies quantifying N deposition contribution to total N loading in U.S. freshwater systems.

---

### 9.1.1.2 Characteristics of Freshwater Systems Sensitive to Atmospheric Deposition of Nitrogen

Various factors affect the sensitivity of remote water bodies to atmospheric deposition. These factors include the spatial and temporal patterns of nutrient limitation and the physical and chemical attributes of the catchment ([Williams et al., 2017b](#); [Hundey et al., 2014](#); [Nanus et al., 2012](#); [U.S. EPA, 2008a](#)). Thus, the same amount of N deposition can lead to different N loading depending on the characteristics of the receiving watershed and water body ([Hessen, 2013](#); [Bergström, 2010](#)).

In high-elevation lakes above the tree line in areas with steep slopes, sparse vegetation, exposed bedrock, and shallow rocky soils, changes in productivity and biodiversity of algal assemblages can occur with little or no lag time ([Baron et al., 2011b](#)). The hydrology of these systems is dominated by spring snowmelt ([Spaulding et al., 2015](#)). Seasonal meltwaters can deliver a nutrient pulse to alpine lakes and streams, with glacial meltwater contributing more  $\text{NO}_3^-$  than snowmelt does ([Slemmons et al., 2015](#); [Slemmons et al., 2013](#); [Saros et al., 2010](#); [Baron et al., 2009](#)). Other freshwater systems, such as some nonalpine freshwater lakes, reservoirs, and rivers that exhibit N limitation and N and P colimitation, are sensitive to additional N inputs ([Paerl et al., 2016b](#); [Paerl et al., 2014](#); [Lewis et al., 2011](#); [Conley et al., 2009](#); [Elser et al., 2009b](#); [Sterner, 2008](#)). N from atmospheric deposition represents a proportion of total N in these systems, although agricultural and wastewater inputs are often predominant.

In the 2008 ISA, lakes and streams with high concentrations of  $\text{NO}_3^-$ , indicative of ecosystems being N saturated ([Appendix 7.1.2.1](#)), were reported at a variety of locations throughout the U.S., including the San Bernardino and San Gabriel mountains within the Los Angeles Air Basin ([Fenn and Poth, 1999](#); [Fenn et al., 1996](#); [Riggan et al., 1985](#)), the Front Range of Colorado ([Williams et al., 1996a](#); [Baron et al., 1994](#)), the Allegheny Mountains of West Virginia ([Gilliam et al., 1996](#)), the Catskill Mountains of New York ([Stoddard, 1994](#); [Murdoch and Stoddard, 1992](#)), the Adirondack Mountains of New York ([Wigington et al., 1996b](#)), and the Great Smoky Mountains in Tennessee ([Cook et al., 1994](#)). All of these regions, except the Colorado Front Range, received more than about 10 kg N/ha/yr atmospheric deposition of N throughout the 1980s and 1990s. The Front Range of Colorado received up to about 5 kg N/ha/yr of total (wet + dry) deposition ([Sullivan et al., 2005](#)), less than half of the total N deposition received at many of these other locations. Since the 2008 ISA, several long-term monitoring studies have shown temporal decreases in surface water  $\text{NO}_3^-$  concentration corresponding to decreases in atmospheric N deposition ([Appendix 7.1.2.1](#)). These regions include the Appalachian Mountains, the Adirondacks, and the Rocky Mountains ([Driscoll et al., 2016](#); [Kline et al., 2016](#); [Strock et al., 2014](#); [Eshleman et al., 2013](#); [Elser et al., 2009b](#); [Bergström and](#)

[Jansson, 2006](#)).  $\text{NO}_3^-$  in extremely high concentrations can have direct adverse effects on fish, as well as invertebrates and amphibians. These effects are observed at concentrations much higher than would commonly be attributable to atmospheric deposition, are not included in this ISA, and were not defined as a primary biological indicator in the 2008 ISA.

---

### 9.1.1.3 Nitrogen Deposition Effects on Nutrient Limitation

The 2008 ISA reported on gradient studies of undisturbed northern temperate, mountain, or boreal lakes that receive low levels of atmospheric N deposition. These studies found strong relationships between N limitation and primary productivity where N deposition was low and between P and N + P limitations where N deposition was high ([Bergström and Jansson, 2006](#); [Bergström et al., 2005](#); [Fenn et al., 2003a](#)). As reviewed in the 2008 ISA, a comprehensive survey of 42 unproductive lakes (oligotrophic lakes with TP less than or equal to 25  $\mu\text{g/L}$ ) along gradients of N deposition in Europe and North America showed increased inorganic N concentration and productivity to be correlated with atmospheric N deposition ([Bergström and Jansson, 2006](#)). Unproductive lakes receiving low atmospheric N deposition were N limited (<2.5 kg N/ha/yr). At about 2.5 to 5 kg N/ha/yr, colimitation of N and P was observed, while at N deposition above 5 kg N/ha/yr, the lakes were P limited. Based on the study findings and paleolimnological evidence, [Bergström and Jansson \(2006\)](#) suggested that most lakes in the northern hemisphere may have originally been N limited and that atmospheric N deposition has changed the balance of N and P in lakes.

Studies published since the 2008 ISA have continued to characterize nutrient relationships and evaluate the potential for N deposition to contribute to the eutrophication of water bodies ([Table 9-1](#)). Consistent with the 2008 ISA findings, research literature after 2007 indicates that N deposition is correlated with a shift from N to P limitation in certain high-elevation water bodies ([Hessen, 2013](#)). [Elser et al. \(2009b\)](#) conducted a nutrient-limitation study across a gradient of lakes in the Rocky Mountains of Colorado that receive low (<2 kg N/ha/yr; N = 20) and high (>6 kg N/ha/yr; N = 16) N deposition. Nutrient enrichment bioassays indicated that P limitation or colimitation was prevalent in the population of high-deposition lakes (9 of 16 lakes), while only one of the lakes showed N limitation. In contrast, only 4 of 20 low-deposition lakes showed P limitation. Based on relative response ratios (RR; chlorophyll concentration in a given treatment normalized to chlorophyll in control), chlorophyll responded more strongly to N relative to P in low-deposition lakes where N limitation was stronger ([Figure 9-2](#)). These data were included in [Elser et al. \(2009a\)](#) who reported that lakes in Norway, Sweden, and Colorado affected by N deposition showed a similar pattern. In lakes with

high N deposition, phytoplankton was predominately P limited, whereas in lakes with low N deposition, N limitation was more common.

Based on an analysis of lake water chemistry data from 106 alpine lakes in Sweden, Slovakia, Poland, and the Rocky Mountains of Colorado and nutrient bioassays from high mountain lakes in Sweden and the Rocky Mountains of Colorado, [Bergström \(2010\)](#) documented how N:P mass ratios (TN:TP and dissolved inorganic N (DIN):TP) vary in oligotrophic lakes located in northern Europe and the Rocky Mountains. Nutrients (N, P, N + P, control) were added to water from 28 unproductive lakes. The majority of the lakes were N limited and the shift from N to P limitation was strongly affected by N deposition. More than half (54%) of the oligotrophic study lakes had a TN:TP mass ratio <25. A DIN:TP ratio of 1.5 was indicative of an N limited lake while a ratio of 3.4 was P limited. The DIN:TP ratio was a better indicator than the TN:TP ratio for nutrient limitation of phytoplankton because TN may include a large fraction of biologically unavailable N.

**Table 9-1 Summary of studies using diatoms as biological indicators of nitrogen enrichment evaluated in the literature since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur— Ecological Criteria.**

Study Site	Ambient N Deposition	Diatom Response	Species	Reference
Three national parks in Washington State (Mt. Rainier, North Cascades, and Olympic)	0.25 ± 0.15 to 1.10 ± 0.21 kg/ha/yr NH <sub>4</sub> <sup>+</sup> -N; 0.34 ± 0.04 to 1.32 ± 0.19 kg/ha/yr NO <sub>3</sub> <sup>-</sup> -N; 0.59 ± 0.07 to 2.42 ± 0.27 kg/ha/yr inorganic N	Overall, only one lake (Hoh Lake) of 10 study lakes where cores were collected showed clear evidence of impacts from N deposition based on changes in sediment diatom communities.	<i>A. formosa</i> , <i>F. crotonensis</i> , and <i>F. tenera</i>	<a href="#">Sheibley et al. (2014)</a>
Western U.S. (Glacial National Park, Greater Yellowstone Ecosystem, and eastern Sierra Nevada)	Sierra Nevada = 2 kg/ha/yr (current) to 4 kg/ha/yr (early 1990s) total wet inorganic N deposition. GNP = 0.5–1.5 kg/ha/yr (1980–2006). GYE = 0.5–1.1 kg/ha/yr (1980–2006)	A critical load of 1.4 kg N/ha/yr wet deposition changed diatom community structure in both the eastern Sierra Nevada and the Greater Yellowstone Ecosystem, although N deposition rates between the two regions and the timing of diatom community shifts were different. No diatom community changes were observed in Glacier National Park lakes.	<i>A. formosa</i> and <i>F. crotonensis</i>	<a href="#">Saros et al. (2011)</a>
Rocky Mountains	Central Rockies NO <sub>3</sub> <sup>-</sup> and NH <sub>4</sub> <sup>+</sup> = 1.4–2.5 kg N/ha/yr. N. Rockies = 2.0–3.4 kg N/ha/yr.	Lakes fed by snowpack meltwater had greater sediment diatom taxonomic richness over the last century (35 to 54 taxa) compared with lakes that were fed by both glacial and snowpack meltwater (12 to 26 taxa) which are higher in NO <sub>3</sub> <sup>-</sup> . (~50% of Glacier National Park lakes and ~0–20% of lakes in central Rockies receive glacial meltwater).	Multiple	<a href="#">Saros et al. (2010)</a>
Rocky Mountains	Wet deposition ranged from 0.8 to 3.2 kg N/ha/yr at study sites.	High abundance of key indicator species of N enrichment ( <i>A. formosa</i> , <i>F. crotonensis</i> ) in lakes with low to moderate NO <sub>3</sub> <sup>-</sup> precluded an attempt to quantify the surface water NO <sub>3</sub> <sup>-</sup> concentrations that elicit diatom community changes in high-elevation lakes using a diatom-based transfer function.	Multiple	<a href="#">Arnett et al. (2012)</a>

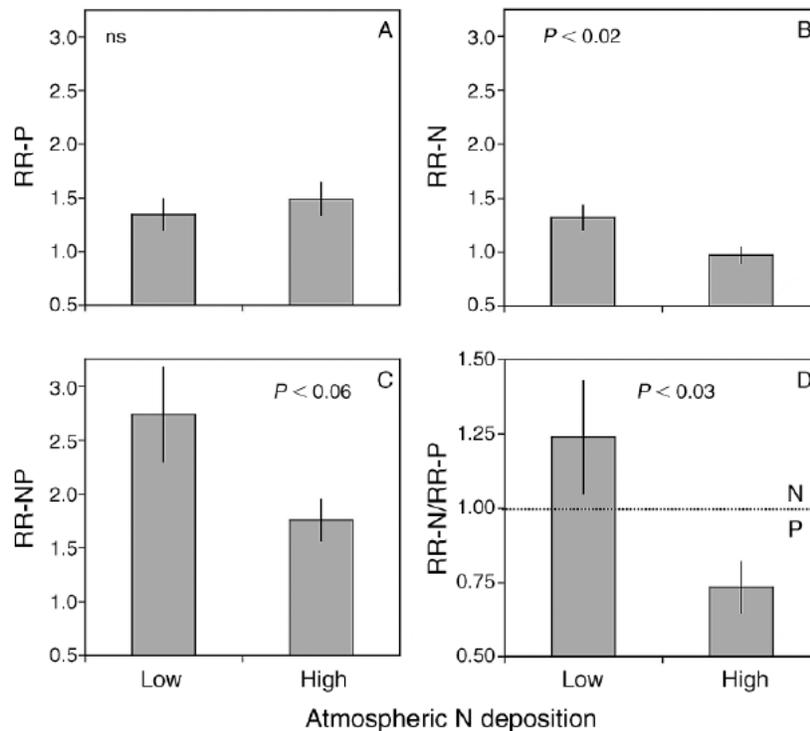

**Table 9-1 (Continued): Summary of studies using diatoms as biological indicators of nitrogen enrichment evaluated in the literature since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur—Ecological Criteria.**

Study Site	Ambient N Deposition	Diatom Response	Species	Reference
Rocky Mountains	>3 kg N/ha/yr	A maximum growth rate of $0.2 \pm 0.04$ /day at $0.5 \mu\text{M}$ N for the diatom <i>A. formosa</i> was measured following N addition to identify a $\text{NO}_3^-$ threshold for this species in surface water.	<i>A. formosa</i>	<a href="#">Nanus et al. (2012)</a>
Central Rocky Mountains/Beartooth Mountains located along the Montana and Wyoming borders	Not specified	Fossil-diatom assemblages from two lakes near each other (one snowpack-fed and one glacier-fed) indicated greater diatom assemblage turnover in the glacier-fed lake. The glacier-fed lake showed evidence for mild N enrichment starting approximately 1,000 yr ago, and the increase in abundances of <i>A. formosa</i> and <i>F. crotonensis</i> occurred much earlier, suggesting glacial meltwater was a source of N.	<i>A. formosa</i> and <i>F. crotonensis</i>	<a href="#">Slemmons et al. (2015)</a>
Central Rocky Mountains/Beartooth Mountains located along the Montana and Wyoming borders	Not specified	Diatom species richness from the top of sediment cores was $1.8\times$ higher in snowpack-fed lakes compared with glacier- and snowpack-fed lakes, whereas richness did not differ between core bottoms (ca. 1850) of the lakes. Compared with snow-fed lakes, N enriched glacial snowpack-fed lakes were dominated by <i>A. formosa</i> and <i>F. crotonensis</i> .	<i>A. formosa</i> and <i>F. crotonensis</i>	<a href="#">Slemmons and Saros (2012)</a>
Grand Teton National Park	Estimated at 2.5 kg N/ha/yr	Directional change in benthic diatom assemblages after 1960 that is correlated with atmospheric deposition.	Benthic diatoms	<a href="#">Spaulding et al. (2015)</a>
Uinta Mountains, UT	0.02–0.04 kg km <sup>2</sup>	Four of five lakes with recent increase in productivity (between 1940 and 1960) show comparable shifts in diatom community composition linked to atmospheric deposition of N and P. Lake sediment records show an increasing abundance of nitrophilous <i>A. formosa</i> .	<i>A. formosa</i>	<a href="#">Hundey et al. (2014)</a>
Mount Rainier, North Cascades, and Olympic national parks, WA	0.38–3.24 kg N/ha/yr (wet)	20 taxa of phytoplankton responded to N enrichment. <i>F. tenera</i> and <i>F. crotonensis</i> are recommended as indicators of N enrichment in the Pacific NW. The threshold for phytoplankton biomass growth was 13–25 $\mu\text{g}$ DIN/L.	Multiple	<a href="#">Williams et al. (2016a)</a>
Northern Cascade Mountains, WA	1.1 to 3.4 kg N/ha/yr	No significant difference in diatom biovolume or phytoplankton community structure between snow-fed lakes and glacial snowpack-fed lakes.	Multiple	<a href="#">Williams et al. (2016b)</a>

**Table 9-1 (Continued): Summary of studies using diatoms as biological indicators of nitrogen enrichment evaluated in the literature since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur—Ecological Criteria.**

Study Site	Ambient N Deposition	Diatom Response	Species	Reference
National parks of the western Great Lakes (Superior and Michigan) region	1.5–5 kg N/ha/yr (1980–2010)	In 63% of study lakes, change in diatom community correlates with lake sediment $\delta^{15}\text{N}$ , which in turn relates to measured $\text{N}_r$ inputs (deposition and indirect watershed inputs). In about 36% of the lakes, sediment $\delta^{15}\text{N}$ was statistically correlated to some form of deposited $\text{N}_r$ . A number of such lakes are in watersheds believed to have high N retention associated with shallow subsurface flow during snowmelt. The authors consider this to be the primary path for $\text{NO}_3^-$ transport. Diatom community change is also expected to be related to nutrient inputs indirectly by runoff and climate variability.	Multiple, including <i>F. crotonensis</i> and <i>A. formosa</i>	<a href="#">Hobbs et al. (2016)</a>
U.S.	Not specified	Shifts in diatom community composition away from N intolerant species.	Multiple	<a href="#">Pardo et al. (2011a)</a>
North America and Greenland	0.8 to 2 (<50°N) to <0.5 (>50°N)	A meta-analysis of 52 alpine, Arctic, and boreal montane lakes showed increased beta diversity in the 20th century. Observed diatom assemblage turnover in alpine and Arctic lakes is related to temperature changes, while in mid-latitude alpine lakes changes are linked to N deposition.	Multiple	<a href="#">Hobbs et al. (2010)</a>
Baptiste Lake, Alberta, Canada	Not specified	Lake sediment cores indicate prevalence of diatom assemblages that favor nutrient-rich conditions for at least the last 150 yr. From ~1980 to present, a distinct increase in <i>Stephanodiscus hantzschii</i> was observed.	Multiple	<a href="#">Adams et al. (2014)</a>
George Lake, Killarney Provincial Park, Ontario, Canada	6–7 kg N/ha/yr (2013)	Relative abundance of <i>A. formosa</i> increased over a 20-yr period while lake total N concentration and regional N deposition decreased. Increases in <i>A. formosa</i> were directionally related to increases in air and epilimnetic temperatures.	Multiple, including <i>A. formosa</i>	<a href="#">Sivarajah et al. (2016)</a>
Whitefish Bay, Ontario, Canada, also meta-analysis of 200 lakes in North America and Europe	<5 to <1 kg N/ha/yr	No effects of N deposition were observed on diatom community structure in Whitefish Bay. Observed shifts in Arctic lakes (1850) and temperate lakes (1970) were in response to climate change.	Multiple planktonic and benthic diatoms	<a href="#">Rühland et al. (2008)</a>

Ha = hectare; kg = kilogram; km = kilometer;  $\mu\text{M}$  = micromole; N = nitrogen;  $\text{NH}_4^+ \text{-N}$  = nitrogen as ammonium;  $\text{NO}_3^-$  = nitrate; P = phosphorus; yr = year.

N = nitrogen; P = phosphorus.

The response ratio (RR) has no units. (A) Response to P enrichment alone (RR-P); (B) response to N enrichment alone (RR-N); (C) response to combined N and P enrichment (RR-NP); (D) relative response to N vs. P (RR-N/RR-P, equivalent to final chl N/final chl P). For RR-N/RR-P, a value >1 indicates stronger N limitation while a value <1 indicates stronger P limitation. Error bars indicate  $\pm$  SE. The result of *t* tests comparing low- and high-deposition means for each parameter are given in each panel.

Source: [Elser et al. \(2009b\)](#)

**Figure 9-2** **Phytoplankton responses to nitrogen and/or phosphorus enrichment for Rocky Mountain lakes receiving low or high atmospheric nitrogen deposition, given as the ratio of final chlorophyll concentration in the enriched treatment (+phosphorus, +nitrogen, or +nitrogen + phosphorus) to the chlorophyll concentration in the unenriched control.**

N deposition gradient studies conducted in Sweden support findings of shifts from N to P limitation in lakes. [Liess et al. \(2009\)](#) compared a population of lakes in northern Sweden with lower N deposition (N = 7) to lakes in the south with higher deposition (N = 6). Atmospheric N deposition showed a strong positive correlation with TN. In the sampled lakes, northern lakes received 2 to 6 kg N/ha/yr, while southern lakes received 10 to 12 kg N/ha/yr. Sampling of epilithic communities indicated a weakly positive correlation of atmospheric N deposition to epilithon N:P ratios, suggesting that epilithic communities

were generally more N limited in the northern lakes and more P limited in the southern lakes, which received higher N deposition. [Bergström et al. \(2008\)](#) evaluated phytoplankton responses to N and P enrichment in unproductive Swedish lakes along a gradient of atmospheric N deposition. They found that regional and seasonal patterns in nutrient limitation were related to the level of N deposition. In the south, high N deposition was accompanied by high lake DIN concentrations during early summer, with subsequent P limitation. Later in the summer, DIN concentrations declined, and lakes switched to N and P colimitation, and then to N limitation. [Bergström et al. \(2008\)](#) concluded that N limitation is probably the natural state of these unproductive lakes and that P limitation has been induced by increased N availability caused by atmospheric N deposition.

Other studies in high alpine systems have shown that N deposition does not necessarily have a consistent effect on N or P limitation. In an assessment of 29 alpine lakes and ponds in the Canadian Rocky Mountains (Banff National Park, Alberta and Yoho National Park, British Columbia), certain ponds appeared to be N limited while most water bodies sampled did not show evidence of N limitation ([Murphy et al., 2010](#)). DIN:TP ratio analysis indicated N limitation in only 14% of the sampled water bodies. N limitation was observed more frequently in shallow ponds than lakes, and during the late summer sampling period, the ponds had a significantly lower mean DIN:TP ratio. In another study from the Rocky Mountains, surface sediment samples and surface water  $\text{NO}_3^-$  concentrations were collected from an N deposition gradient (1 to 3.2 kg N/ha/yr in wet deposition) across 46 high-elevation lakes to characterize diatom community changes ([Arnett et al., 2012](#)). The researchers found that even in lakes with  $\text{NO}_3^-$  concentrations below quantification (<1  $\mu\text{g/L}$ ), diatom assemblages were already dominated by key indicator species characteristic of moderate N enrichment, and the authors were unable to identify a threshold. They noted that small inputs of reactive N can shift diatom species composition along the length of the  $\text{NO}_3^-$  gradient and that the lakes switch from N limited oligotrophy to P limitation. In a study of 11 lakes in northern subarctic Sweden situated along an altitudinal/climate gradient with low N deposition (<1 kg N/ha/yr), the lakes did not show a shift from mainly N to mainly P limitation reported from U.S. lakes where N deposition was higher. However, mainly P limitation was observed in high alpine lakes with rocky catchments and high DIN:TP ratios, while mainly N and N + P colimitation was occurring in subalpine and lower mid-alpine lakes ([Bergström et al., 2013](#)). The authors attributed these observations to climate and catchment characteristics and suggested warming would have a greater impact than N deposition on the subset of sparsely vegetated high alpine lakes, in contrast to the majority of subarctic lakes with N or N + P colimitation, where both warming and N inputs will alter phytoplankton response.

---

#### 9.1.1.4 Phosphorus Deposition Interactions

P deposition has direct implications for how ecosystems respond to N deposition. Although this appendix is focused on the biological effects of N enrichment, inputs of P may effect shifts in lake trophic status from P to N limitation or to colimitation and increase the total nutrient supply to water bodies affecting how the system responds to N. Since the 2008 ISA, several meta-analyses have reported an increase in P deposition to water bodies ([Stoddard et al., 2016](#); [Brahney et al., 2015](#); [Tipping et al., 2014](#)). This recent evidence suggests that the predominantly dry deposition of fine (<10  $\mu$ ) and coarse (<100  $\mu$ ) particulates (“dust”) containing P play a role in the enrichment effects of N deposition to fresh waters and their catchments. Data from the U.S. EPA National Lakes Assessment and National Rivers and Streams Assessment were analyzed by [Stoddard et al. \(2016\)](#) to determine whether total P (TP) concentrations changed between 2000 and 2014. The authors found continent-wide increases in TP, especially at sites with low disturbance. Median stream TP concentrations increased from 26  $\mu\text{g/L}$  (2000–2004) to 56  $\mu\text{g/L}$  (2013–2014); median lake TP increased from 20  $\mu\text{g/L}$  (2007) to 37  $\mu\text{g/L}$  (2012). From the 2004–2014 surveys, the percentage of stream length where TP was  $\leq 10 \mu\text{g/L}$  decreased from 24.5 to 1.6; the percentage of lakes where TP was  $\leq 10 \mu\text{g/L}$  decreased from 24.9 to 6.7 between 2007 and 2012. Additional research has corroborated the findings of [Stoddard et al. \(2016\)](#) in other locations ([Zhu et al., 2016a](#); [Brahney et al., 2015](#); [Tipping et al., 2014](#)) and has investigated shifts from N to P limitation or colimitation, as well as P deposition’s role in prolonging N limitation ([Appendix 9.2.2](#)).

In a regression analysis of deposition and water quality data in 700 upland lakes across 21 alpine regions globally, [Brahney et al. \(2015\)](#) suggested that P deposition may play a large role in alpine lake trophic status. The authors evaluated the strength in N, P, and N:P relationships in deposition and in lakes. Their 5-year, Community Atmospheric Model (CAM4) simulation modeling indicates that P deposition may have increased globally by 1.4 times the preindustrial deposition rate. TIN:TP of deposition and in lakes showed a strong relationship ( $r^2 = 0.82$ ,  $p < 0.0001$ ) with P deposition and lake water ( $r^2 = 0.64$ ,  $p < 0.0001$ ) and N deposition and lake water ( $r^2 = 0.20$ ,  $p < 0.05$ ). Where the deposition’s molar ratio of N:P was less than 20, intermittent or persistent N limitation was observed to be induced atmospherically. The authors concluded that the chemistry of atmospheric deposition influences nutrient limitation of alpine oligotrophic lakes by changing nutrient ratios as well as increasing the absolute supply of nutrients to these ecosystems. A global-scale analysis by [Tipping et al. \(2014\)](#) supported the observation by [Brahney et al. \(2015\)](#) about oligotrophic lakes and indicated the importance of accounting for sustained P deposition to assess the impact of productivity of anthropogenically emitted N deposition. The authors analyzed data on P deposition measured globally (82% of sites were in Europe and North America) from 1954–2012 at 250 sites. They found

that “oligotrophic lakes, tropical forests, and ombrotrophic peatlands” are the most likely to experience significant effects of atmospheric P deposition increase.

[Zhu et al. \(2016a\)](#) examined P deposition in China’s forest, grassland, desert, lake, marsh, and karst ecosystems and confirmed that China’s wet P deposition in terrestrial ecosystems (0.21 kg P ha/yr) is comparable to [Tipping et al. \(2014\)](#) TP deposition estimates (2013 ambient mean wet deposition =  $13.69 \pm 8.69$  kg N/ha/yr with fluxes ranging from 0.47 to 47.71 kg N/ha/yr). The average N:P ratio for wet deposition in China was reported as 77:1. The mean annual N concentration at 41 monitoring sites correlated linearly with precipitation ( $r^2 = 0.120$ ;  $p = 0.0027$ ), and N deposition also correlated significantly with rainfall ( $r^2 = 0.217$ ,  $p = 0.002$ ). The authors suggested that the high N:P ratios in atmospheric wet deposition could shift systems to P limitation, influencing ecosystem structure and function.

---

### 9.1.1.5 Climate Modification of Ecosystem Response to Nitrogen

Nutrient inputs to fresh waters are occurring within the context of physical, chemical, and biological modifications caused by increased annual mean temperature and magnitude of precipitation associated with climate change ([Greaver et al., 2016](#)). Projected shifts in runoff and timing and quantity of flushing will alter local and regional hydrology ([Whitehead et al., 2009](#)). Nutrient loads to surface waters are expected to increase due to predicted increases in surface water flow ([Adrian et al., 2009](#); [Whitehead et al., 2009](#)). Air temperature increases will lead to warmer surface waters, altering the thermal stratification of water bodies and affecting the community composition and distribution of aquatic biota in streams and lakes ([Adrian et al., 2009](#); [Keller, 2007](#)). The increased surface water temperatures will increase the rate of algal growth ([Whitehead et al., 2009](#)). In regions with no evidence of increased atmospheric nutrient inputs, warming trends are observed to enhance competitiveness of planktonic diatoms like *Asterionella formosa*, which are typically associated with elevated N, indicating that climate change has significant direct and indirect effects on algal species composition. Climate change may thus enhance the effects observed in areas with nutrient increases alone ([Rühland et al., 2015](#)). [Appendix 13](#) includes a more detailed discussion of how climate (e.g., temperature and precipitation) modifies ecosystem response to N loading.

---

## 9.2 Biological Indicators

Increased  $\text{NO}_3^-$  in surface water is a chemical indicator of freshwater N nutrient enrichment ([Appendix 7.1.2.1](#)). Many of the critical loads discussed in [Appendix 9.5](#) are

based on  $\text{NO}_3^-$  in surface water. A critical load is a quantitative estimate of exposure to one or more pollutants below which significant harmful effects on specified sensitive elements of the environment do not occur according to present knowledge [[Spranger et al. \(2004\)](#); [Nilsson and Grennfelt \(1988\)](#); [Section IS.2.2.3](#)]. Biological indicators of freshwater N enrichment discussed in the 2008 ISA included chlorophyll *a*, phytoplankton and periphyton biomass, and changes in lake nutrient status ([U.S. EPA, 2008a](#)). Paleolimnological records of shifts in diatom community composition were also used to assess the effects of N deposition. Dose-response relationships between N and biological indicators were reported in the 2008 ISA, and the new literature continues to support these findings. Diatom community shifts ([Appendix 9.2.1](#)), and phytoplankton biomass nutrient limitation shifts ([Appendix 9.2.3](#)) have been used as a basis for determining critical loads for nutrient enrichment ([Appendix 9.5](#)). These same biological indicators are discussed further below along with new studies. In the current review, the response of microbial enzymes to N and P and increased incidence of harmful algal blooms (HABs) in freshwater habitats are discussed as possible biological indicators of the effects of elevated N.

---

### 9.2.1 Diatoms

Diatoms are commonly used to monitor environmental conditions in water bodies over time. While many diatom studies explain patterns of variation in community composition in relation to environmental ([Smol and Stoermer, 2010](#)), as well as spatial factors ([Soininen et al., 2016](#); [Vilmi et al., 2016](#)), few studies have used experimental methods to address the processes underlying the patterns ([Smol and Stoermer, 2010](#); [Pither and Aarssen, 2006](#)). Changes in diatom species assemblages in paleolimnological studies of mountain lakes disturbed only by atmospheric deposition and climate change were reported in the 2008 ISA. Chlorophytes, such as *A. formosa* and *Fragilaria crotonensis*, generally prefer high concentrations of N and are able to rapidly dominate the flora when N concentrations increase ([U.S. EPA, 2008a](#); [Findlay et al., 1999](#)). These two nitrophilous species of diatom are used as biological indicators of the effect of N in water bodies; however, increased relative abundance of *A. formosa* has also been attributed to lake warming in some regions where N deposition is decreasing ([Sivarajah et al., 2016](#)). [Table 9-1](#) summarizes diatom studies published since the 2008 ISA. The majority of these studies highlight the observed influence of 20th century N deposition on diatoms, causing an increasing abundance of nitrophilous diatoms such as *A. formosa* and *F. crotonensis*. [Appendix 9.3](#) considers the effects of N deposition on diatom diversity. Thresholds of diatom response are reported in [Appendix 9.5](#).

---

## 9.2.2 Ratios of Nitrogen and Phosphorus

Trophic status is a way to characterize bodies of water in terms of their productivity. Increasing deposition of N to water bodies shifts element ratios, which in turn affect algal growth, diversity, and community structure ([Appendix 9.3.2](#)). Algal species have different nutrient optima for growth and cellular uptake of N, and P alters the elemental composition of primary producers at the base of the freshwater food web. When N is the limiting nutrient, atmospheric deposition of N will increase benthic algal ([Liess et al., 2009](#)) and phytoplankton ([Hessen, 2013](#); [Elser et al., 2010](#)) N:P ratios. Nutritional responses of aquatic ecosystems to atmospheric N deposition are heavily dependent on surface water P concentrations, which may also be affected by atmospheric P inputs ([Appendix 9.1.1.4](#)). Thus, various chemical ratios of N to P can be useful for evaluating biological responses of water bodies affected by deposition ([Table 9-1](#)).

In the 2008 ISA, several studies reported N:P ratios in which a shift in nutrient limitation was observed. When DIN:TP values are greater than reference values, growth stimulation, N and P colimitation, or P limitation commonly occur ([Sickman et al., 2003](#)). In a Swedish lake survey reviewed in the 2008 ISA, N limitation occurred in lakes where the DIN:TP mass ratio was less than 7 (DIN concentrations <33  $\mu\text{M}$ ). Colimitation of N and P was found in lakes with DIN:TP ratio between about 8 and 10, and P limitation occurred at DIN:TP values greater than 10 ([Bergström et al., 2005](#)). Other thresholds for N limitation were reported in the literature to occur at DIN:TP ratios <4 ([Lohman and Prisco, 1992](#)) and <10 ([Wold and Hershey, 1999](#)). [Bergström et al. \(2005\)](#) reported an index (DIN:[chlorophyll *a*:TP]) to assess the eutrophication of lakes in response to N deposition.

[Hundey et al. \(2014\)](#) assessed trophic status for six remote alpine lakes in the Uinta Mountains, UT based on TP, TN, chlorophyll *a*, Secchi depth, and N:P relationships. One of six lakes was P limited, two were N limited, one varied by month, and the limitation was uncertain in the other two. Trophic status was difficult to determine in some of the lakes because the ratios were values that could indicate either N or P limitation depending on the threshold used, and some lakes were on the boundary between oligotrophic and mesotrophic. In Green Lake in Colorado's Front Range, the ratio of DIN:TP in the epilimnion over the course of the study was consistently above 4 and averaged  $16.3 \pm 2.76$ , suggesting the lake was P limited ([Gardner et al., 2008](#)). Nutrient ratios (TN:TP, DIN:TP, and  $\text{NO}_3^-$ :TP) were compared to nutrient bioassays to evaluate the use of these ratios in predicting the limiting nutrient. There was agreement in 29% of the bioassay results, suggesting that nutrient ratios are not the best predictor of nutrient limitation in this subarctic region.

In an in situ mesocosm bioassay study of two subalpine lakes in the Sierra Nevada, CA, [Heard and Sickman \(2016\)](#) modeled the effective dose of N addition along an N gradient (N as  $\text{KNO}_3$  and  $\text{NaNO}_3$  ranging from 0 to 50  $\mu\text{mol/L}$ ) with P addition as  $\text{KH}_2\text{PO}_4$  held constant at 1.5  $\mu\text{mol/L}$ . DIN:TP ratios in the two lakes were  $<4.0$ . Given that DIN:TP ratios  $<0.6$  indicate N limitation and DIN:TP ratios  $>0.6$  indicate intermediate limitation, both lakes were deemed N limited. The authors observed that the P addition delayed the shift to P limitation (prolonged N limitation) for phytoplankton. Effective doses for N for the two lakes were lower than the other study lakes receiving N addition only. They acknowledged the spatial and temporal variation in lake P concentrations, as well as concern for increased P deposition.

In a comparison of diatom-inferred lake nutrient records and surface water monitoring data (collected since the early 1980s) from Baptiste Lake in the Canadian Rockies, [Adams et al. \(2014\)](#) found total Kjeldahl nitrogen (TKN) was a significant predictor of chlorophyll *a*, where chlorophyll *a* was independent of TP. They observed that the lake experienced eutrophic conditions for  $>150$  years based on diatom sediment core data. Diatom-inferred TKN data tracked current TKN dynamics measured in the water column.

---

### 9.2.3 Phytoplankton Biomass Nitrogen (N) to Phosphorus (P) Limitation Shift

As described in [Appendix 9.1.1.3](#), lakes may shift from N limitation to P limitation with elevated N deposition and this can be assessed using a response ratio (RR) considering the RR-N compared to the RR-P [[Figure 9-2](#); [Elser et al., 2009b](#)]. Phytoplankton biomass growth may shift from N to P enrichment, altering lake primary production ([Hessen, 2013](#)). [Williams et al. \(2017a\)](#) used the RR-N/RR-P to define a biological threshold of RR-N/RR-P = 1 above which phytoplankton biomass P limitation is more likely than N limitation and developed critical loads for western U.S. mountain lakes ([Appendix 9.5](#)).

---

### 9.2.4 Periphyton/Microbial Biomass

Periphyton mats are biofilms of algae, cyanobacteria, fungi, microinvertebrates, organic detritus, inorganic particles, and heterotrophic microbes imbedded within a matrix and attached to submerged substrates in aquatic systems (e.g., stream or lake bottoms). In the 2008 ISA, no studies reported resource requirements for periphyton, although several papers described stimulated growth with N amendments in ecosystems throughout the U.S. (Annex C of the 2008 ISA), including streams in Alaska, Arizona, Iowa, Texas, Minnesota, and Missouri and lakes in California, Colorado, and Massachusetts ([U.S.](#)

[EPA, 2008a](#)). Additional lake bioassay experiments that enriched the water column down into the sediments found enhancement of periphyton growth on bioassay container walls in experiments in California, Wyoming, and Massachusetts ([Smith and Lee, 2006](#); [Nydic et al., 2004](#); [Axler and Reuter, 1996](#)). Strong N limitation of benthic algae has also been inferred in streams of Arizona ([Grimm and Fisher, 1986](#)), California ([Hill and Knight, 1988](#)), Missouri ([Lohman et al., 1991](#)), and Montana ([Lohman and Priscu, 1992](#)).

Since the 2008 ISA, few studies on N effects on periphyton biomass have been identified. In Ditch Creek, WY, a relatively undisturbed stream with N accumulation primarily from high N<sub>2</sub> fixation, biofilm growth on rocks increased after snowmelt and N<sub>2</sub> fixers dominated the algal assemblage ([Kunza and Hall, 2014](#)). A shift to non-N<sub>2</sub> fixing taxa was observed later in the season. In this stream with little to no anthropogenic influence, N fixation was higher than denitrification. [Burrows et al. \(2015\)](#) assessed microbial respiration and biomass using nutrient-diffusing substrata in 20 boreal streams in Sweden. An increase in N availability led to increased microbial activity. Microbial biomass was primarily N limited, and distinct microbial communities were associated with inorganic N in stream water. In a series of nutrient-diffusing substrata studies across rivers in the U.S. mountainous West, arid West, and the Midwest, [Reisinger et al. \(2016\)](#) assessed nutrient limitation patterns of benthic biofilms. Regarding regional differences, there was little evidence of N limitation in midwestern rivers due to high nutrient concentrations, while nutrient limitation of biofilms was common in the summer in mountainous western rivers. Increasing developed lands decreased the probability of nutrient-limited river biofilms. In a meta-analysis of nutrient-diffusing substrate studies from North America [Beck et al. \(2017\)](#), broad spatial factors such as ecoregion described most of the variation in nutrient limitation. Variables affecting algal biomass response to N included land use, riparian canopy cover, the presence of soluble reactive P, and season.

Microbial communities involved in plant litter decomposition in streams have been shown to be altered by nutrient concentrations. Most studies have examined the effects of N and P in combination. However, [Fernandes et al. \(2014\)](#) conducted a series of N addition studies in microcosms to assess leaf litter decomposition with increasing N concentration and temperature in streams. In general, increased temperature led to an increase in decomposer activity and a decrease in the amount of N needed. Field studies in six low-order streams spanning an N gradient in the Ave River basin, Portugal, suggested that eutrophication modulates leaf litter decomposition processes ([Lima-Fernandes et al., 2015](#)). Leaf litter diversity synergistically affected leaf litter decomposition while biomass fungal and invertebrate decomposers increased with stream eutrophication status but decreased in the most eutrophic of the six streams. [Dunck et al. \(2015\)](#) reported decreased primary production and leaf litter decomposition in highly

eutrophic streams and streams with little human influence compared to streams that were intermediate along the trophic gradient. [Kominoski et al. \(2015\)](#) observed that microbial litter breakdown rates increased across low to moderate nutrient enrichment gradients in experimental stream channels where N:P ratios were varied to allow for examination of N effects. A meta-analysis of plant matter decomposition in streams by [Ferreira et al. \(2015\)](#) suggested that the effects of nutrient inputs might be strongest in oligotrophic streams due to the low background nutrient concentrations and high magnitude of nutrient enrichment in these systems.

---

### 9.2.5 Chlorophyll *a*

The concentration of chlorophyll *a*, a pigment present in all photosynthetic organisms, is a common measure of algal productivity and is hence an easily documented biological indicator of change in aquatic ecosystem productivity. Quantification of chlorophyll *a* is one approach for estimating phytoplankton biomass. Chlorophyll *a* is used as the primary indicator of trophic state in the U.S. EPA National Lakes Assessment and as a water quality indicator in many state and federal monitoring programs ([U.S. EPA, 2016h, 2009b](#)). Chlorophyll *a* is being used as an indicator of nutrient enrichment in U.S. EPA's National Nutrient Program [([U.S. EPA, 1998b](#)); [Appendix 7.1.6](#)]. The U.S. EPA is working with the states to develop numeric nutrient criteria to better define levels of N and P that affect U.S. waters. The numeric values include both causative (N and P) and response (chlorophyll *a*, turbidity) variables to assess eutrophic conditions. The U.S. EPA's National Nutrient Program to reduce eutrophication in water bodies developed recommended nutrient criteria for rivers and streams in 14 U.S. ecoregions for the states to use as a starting point to develop their own criteria ([U.S. EPA, 1998b](#)).

Surveys and fertilization experiments reported in the 2008 ISA show increased inorganic N concentration and aquatic ecosystem productivity, as quantified by chlorophyll *a* concentration, to be strongly related ([U.S. EPA, 2008a](#)). At the time of the 2008 ISA, increases in lake phytoplankton biomass (as chlorophyll *a*) with increasing N deposition were reported in several regions, including the Snowy Range in Wyoming ([Lafrancois et al., 2003b](#)) and across Europe ([Bergström and Jansson, 2006](#)). A meta-analysis of enrichment bioassays in 62 freshwater lakes of North America reported in the 2008 ISA found algal growth enhancement from N amendments to be common in slightly less than half of the studies ([Elser et al., 1990](#)). There was a mean increase in phytoplankton biomass of 79% in response to N enrichment ([Elser et al., 1990](#)). This meta-analysis was repeated, incorporating study sites from multiple countries and a much larger data set, with similar results ([Elser et al., 2007](#)). Chlorophyll *a* continues to be a common biological indicator of N nutrient enrichment in the research literature from 2008 to

present. [Dodds and Smith \(2016\)](#) conducted a review of N and P dynamics in stream ecosystems and concluded that both N and P are strongly correlated to chlorophyll and algal biomass. In the western U.S., [Elser et al. \(2009b\)](#) examined chlorophyll *a* response in Rocky Mountain, CO lakes where atmospheric deposition ranged from 2 to 7 kg N/ha/yr. Concentrations of chlorophyll were 2 to 2.5 times greater in high-deposition lakes relative to low-deposition lakes.

Since the 2008 ISA, nutrient threshold values for chlorophyll *a* responses have been identified for a subset of western mountain lakes. [Williams et al. \(2016a\)](#) calculated an average DIN threshold of 13  $\mu\text{g}$  DIN/L for increased chlorophyll *a* concentration across nine western mountain lakes (25  $\mu\text{g}$  DIN/L for increased chl *a* concentration beyond interannual variation). More than 25% of 207 lakes in Mount Rainier and the northern Cascades exceeded the 13  $\mu\text{g}$  DIN/L threshold. [Heard and Sickman \(2016\)](#) determined threshold values for phytoplankton growth for Sierra Nevada lakes. The doses of N that characterize the initial phytoplankton growth response (10% effective dose), rapid phytoplankton growth (50% effective dose), and saturating nutrient level (90% effective dose) in early- and late-season conditions within two high-elevation lakes were established. These doses were then compared with monitoring data from lakes within Yosemite, Sequoia, and Kings Canyon national parks. The range of threshold values for the 10–50% effective doses were in the range of 0.3 to 4  $\mu\text{mol}$  N/L (5–56  $\mu\text{g}$  N/L). The 50% effective doses were exceeded by 18% (late season) to 29% (early season) of monitored lakes, suggesting that N inputs via atmospheric deposition affect phytoplankton in many lakes in this region. The lakes that exceeded effective doses tended to be at high elevation on steep, north-facing slopes with limited vegetative growth.

Chlorophyll *a* can also be used as a bioindicator of lake response over decadal and longer periods. [Hundey et al. \(2014\)](#) took sediment cores from six remote alpine lakes in Utah to assess trends in lake productivity. In five of the six lakes, sedimentary chlorophyll *a* and percentage of organic matter was observed to be relatively constant from the beginning of the record (mid 1800s using  $^{210}\text{Pb}$  dating; 1200 to 1800 estimated by linear regression) until 1940–1960 when lake production progressively increased.

As reported in the 2008 ISA and discussed further in [Appendix 7.1.2.9](#), dissolved organic carbon (DOC) affects acidity and N cycling and is increasing in some U.S. surface waters ([Monteith et al., 2007](#); [Evans et al., 2006](#)). Recent studies indicate different phytoplankton responses to N and dissolved organic matter (DOM) inputs depending on nutrient status of the lakes and background DOC ([Deininger et al., 2017a](#); [Daggett et al., 2015](#)). [Daggett et al. \(2015\)](#) selected a low DOC, N and P colimited water body (Jordan Pond in Acadia National Park, ME) and an N limited lake with higher DOC (Sargent

Lake in Isle Royale National Park, MI) to assess the effects of an N gradient on algal biomass following addition of DOM. Both of these Class I areas have a similar N deposition rates (6–7 kg total inorganic N/ha/yr wet deposition). DOM addition stimulated phytoplankton biomass in both lakes regardless of nutrient limitation or background DOC concentration. Phytoplankton biomass in N limited Sargent Lake increased with both N and DOM inputs, while in N and P colimited Jordan Pond, algae were sensitive primarily to DOM addition. [Appendix 9.3.2.3](#) discusses a whole-lake N fertilization study along a gradient of DOC.

Not all studies have shown a positive relationship between N inputs and increased chlorophyll *a*. In the Canadian Rockies, [Murphy et al. \(2010\)](#) performed nutrient enrichment bioassays on 29 water bodies in Banff and Yoho national parks using 1 mg N/L additions. They found that N amendment did not significantly increase final total phytoplankton chlorophyll concentration across all of the water bodies sampled during either early or late summer 2007. Although phytoplankton collected from ponds showed several responses to nutrient amendment, the effect of N on total chlorophyll did not differ significantly between pond and lake communities. Harvested final total chlorophyll concentrations from the bioassays were significantly higher for ponds than lakes. In water bodies in Wapusk National Park, Manitoba, a significant linear relationship occurred between chlorophyll *a* and TP across all ponds but not between chlorophyll *a* and total N [TN; ([Symons et al., 2012](#))]. In another study in Colorado's Front Range in Green Lake Valley (part of the Niwot Ridge Long-Term Ecological Research Project), Green Lake 4, a well-studied lake in the area, was sampled weekly throughout the ice-free summer period to assess chlorophyll response ([Gardner et al., 2008](#)). Epilimnetic chlorophyll *a* concentrations peaked at 4 µg/L in late July. In the same study, NO<sub>3</sub><sup>-</sup> addition to an in situ mesocosm on the lake (930 µg/L NO<sub>3</sub><sup>-</sup>, for a final exposure of 1,240 µg/L NO<sub>3</sub><sup>-</sup> given background concentrations) did not increase algal biomass significantly in comparison with the control, while phytoplankton chlorophyll *a* increased in P and P + NO<sub>3</sub><sup>-</sup> additions, indicating the lake was P limited during the summer.

Although hypothesized to be driven by industrial point source emissions, an increase in aquatic primary production in some lakes in the Athabasca Oil Sands Region in Alberta, Canada appears to follow regional patterns of annual and seasonal changes in temperature. In a comparison of spectrally inferred chlorophyll profiles of lake sediments in 23 diverse undisturbed lakes, [Summers et al. \(2016\)](#) observed higher chlorophyll *a* concentrations in surface sediments compared with concentrations inferred for the period before oil sands development, irrespective of lake morphology, landscape position, N deposition, or other limnological characteristics. Spatial and temporal patterns in inferred chlorophyll *a* were positively correlated with annual and seasonal changes in temperature

and were consistent across the region, suggesting a regional impact on productivity rather than impacts associated with point source emissions.

Some research has been conducted regarding the biological impacts of changes in N retention. [Heini et al. \(2014\)](#) examined chlorophyll *a* at various depths in a lake in southern Finland and found that algae and cyanobacteria can affect water chemistry instead of just responding to it. Differences in phytoplankton strongly affected observed short-term differences in chemical properties. The chemical conditions in the deeper waters during summer were generally more stable than in the layers near the surface of the lake.

Since the 2008 ISA lake surveys, fertilization experiments and nutrient bioassays continue to show a strong correlation between N inputs and chlorophyll *a*. Determination of additional thresholds for chlorophyll *a* in remote high-elevation lakes have further linked this indicator to atmospheric inputs of N. The relative importance of DOC in modulating lake response to nutrients is better understood than at the time of the 2008 ISA ([Appendix 7.1.2.9](#)). The use of chlorophyll *a* as an indicator in national lake and stream assessments and for state numeric nutrient criteria ([Appendix 7.1.6](#)) is further supported by studies reported in this ISA.

**Table 9-2 Summary of additional evidence for nitrogen limitation on productivity of freshwater ecosystems that has been evaluated since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur—Ecological Criteria.**

Region	N Deposition	N Addition	Biological Effects	Reference
Sierra Nevada, CA	Not specified	Gradient of N (as KNO <sub>3</sub> and NaNO <sub>3</sub> ) ranging from 0 to 50 µmol/L (dose-finding study), then range used to model biological response was only up to about 18 µmol/L	10, 50, and 90% effective doses for excess phytoplankton growth were calculated for two high-elevation lakes. The modeled doses were compared with lake chemistry monitoring data to assess nutrient status. The 50% effective doses were exceeded by 18% (late season) to 29% (early season) of monitored lakes, suggesting that N inputs via atmospheric deposition affect phytoplankton in many lakes in this region. The threshold for stimulation of phytoplankton (10 to 50% ED) was 5–56 µg N/L.	<a href="#">Heard and Sickman (2016)</a>
Rocky Mountains, CO	2–7 kg N/ha	None	Atmospheric N deposition increased the stoichiometric ratio of N and P in lakes. Phytoplankton growth in 16 high N deposition lakes (~7 kg N/ha) was P limited whereas in 20 low N deposition lakes (~2 kg N/ha) growth was primarily N limited.	<a href="#">Elser et al. (2009a)</a>
Rocky Mountains, CO	High >6 kg N/ha/yr; low <2 kg N/ha/yr (NADP)	Enrichment of 7.5 µmol/L N (as NH <sub>4</sub> NO <sub>3</sub> ) for N, there was also a P and N + P treatment	Phytoplankton response to increased inputs of N was inferred from chlorophyll changes in bioassay data from 20 low N deposition lakes and 16 high N deposition lakes. Concentrations of chlorophyll and seston C were 2–2.5 times higher in the high N deposition lakes relative to the low N deposition lakes, while high-deposition lakes also had higher seston C:N and C:P (but not N:P) ratios.	<a href="#">Elser et al. (2009b)</a>
Rocky Mountains, CO	Not specified	Added 930 µg/L NO <sub>3</sub> <sup>-</sup> ; with background, exposure was 1,240 µg NO <sub>3</sub> <sup>-</sup> ; added 93 µg/L TDP	In in situ mesocosm experiments with water from Green Lake 4, chl <i>a</i> did not increase significantly with addition of NO <sub>3</sub> <sup>-</sup> in comparison with the control, while P and N + P treatments resulted in increases.	<a href="#">Gardner et al. (2008)</a>

**Table 9-2 (Continued): Summary of additional evidence for nitrogen limitation on productivity of freshwater ecosystems that has been evaluated since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur—Ecological Criteria.**

Region	N Deposition	N Addition	Biological Effects	Reference
Utah	Not specified	None	Using sediment core data from six remote alpine lakes, chl <i>a</i> and percentage of organic matter are relatively constant from the beginning of the record until 1940–1960 in five of six lakes, when production progressively increased. The authors found the limiting nutrient difficult to identify.	<a href="#">Hundey et al. (2014)</a>
Alberta, Canada	Not specified	None	TKN was a significant predictor of chl <i>a</i> in Baptiste Lake where chl <i>a</i> was independent of TP measured in the water column.	<a href="#">Adams et al. (2014)</a>
Wapusk National Park, Canada	Not specified	N (NH <sub>4</sub> NO <sub>3</sub> ) and P (KH <sub>2</sub> PO <sub>4</sub> ) were added to increase the nutrient concentrations by 10× mean ambient concentrations	Nutrient enrichment bioassays were conducted on water samples from 21 lakes and ponds with chl <i>a</i> concentrations from 1.2 to 10.8 µg/L. In total, 13% of the lakes and ponds were found to be N limited, 26% P limited, 26% colimited, and 38% did not respond to either N or P additions.	<a href="#">Symons et al. (2012)</a>
Sweden	Gradient rates of N deposition ranging from 100 to 1,000 kg N/km <sup>2</sup> /yr in four regions during summers of 2004–2006	N: 1 mg/L and/or the concentrations of P by 100 µg/L (molar N:P ratio, 23:1)	Phytoplankton were N limited in northern lakes (low N deposition), while in the southern lakes higher N deposition was accompanied by increased lake DIN concentrations and a switch from N to P limitation. N limitation was common during the summer. As summer progressed, P limitation in these systems switched to dual and colimitation of N and P, and to N limitation, due to exhaustion of the DIN pool in the lakes.	<a href="#">Bergström et al. (2008)</a>
Sweden	<1 kg N/ha/yr	Nutrients were added to increase [N] as NH <sub>4</sub> NO <sub>3</sub> by 100 µg/L (7.2 µmol/L) and/or [P] as KH <sub>2</sub> PO <sub>4</sub> by 10 µg/L (0.3 µmol/L)	In phytoplankton nutrient addition bioassays using water from high-elevation lakes, phytoplankton was subject to P limitation and became increasingly N and NP colimited at lower elevation. Chlorophyll concentrations in the bioassays were lower with increasing elevation and this pattern held over the whole growing season.	<a href="#">Bergström et al. (2013)</a>

**Table 9-2 (Continued): Summary of additional evidence for nitrogen limitation on productivity of freshwater ecosystems that has been evaluated since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur—Ecological Criteria.**

Region	N Deposition	N Addition	Biological Effects	Reference
Sweden	2 to 12 kg/ha/yr	None	N deposition positively related to total N and total P. The highest proportion of N fixing cyanobacteria (although only consisting of 5% of the algal biovolume) was found where N deposition was lowest. Epilithic periphyton N:P ratios increased with higher N availability from deposition.	<a href="#">Liess et al. (2009)</a>

C = carbon; chl = chlorophyll; ED = effective dose;  $\text{KH}_2\text{PO}_4$  = monopotassium phosphate; N = nitrogen; NADP = National Atmospheric Deposition Program;  $\text{NH}_4\text{NO}_3$  = ammonium nitrate;  $\text{NO}_3^-$  = nitrate; P = phosphorus; TDP = total dissolved phosphorus; TKN = total Kjeldahl nitrogen; TP = total phosphorus.

---

## 9.2.6 Potential Biological Indicators

In addition to widely used biological indicators of nutrient enrichment (chlorophyll *a*, periphyton/microbial biomass, diatoms), freshwater harmful algal blooms (HABs) and enzymes are altered by N availability. Formation of HABs are more relevant downstream where multiple sources of N contribute to elevated nutrient levels sufficient for bloom formation. Only a limited number of studies have used enzymes to date.

---

### 9.2.6.1 Harmful Algal Blooms

Freshwater HAB formation has become more prevalent in the U.S. in recent decades ([Lopez et al., 2008](#)), coinciding with increased N in surface waters. Although risk of bloom formation remains low for high-elevation oligotrophic water bodies with atmospheric N as the dominant source, atmospheric N may combine with other sources to contribute to total N loading in downstream lacustrine and riverine systems. Freshwater HABs can affect taste and odor of drinking water, lead to hypoxic conditions, impact recreational uses of surface waters, and produce toxins harmful to humans, domestic animals, and wildlife ([Lopez et al., 2008](#)). The major harmful algal group in freshwater environments are the cyanobacteria (blue-green algae). Cyanobacterial toxins are produced by several genera including *Microcystis*, *Anabaena*, *Nodularia*, *Aphanizomenon*, *Cylindrospermopsis*, and *Oscillatoria*. These toxins may target the liver (hepatotoxins such as cylindrospermopsins and microcystins), the nervous system (neurotoxins such as anatoxins and saxitoxins), or the skin (dermatotoxins).

There is evidence of the role for N in freshwater HABs in water bodies across the U.S. In western Lake Erie, cyanobacterial growth was N limited during bloom conditions in late summer, and the N fixing cyanobacterium *Anabaena* became dominant following the observed N limitation ([Chaffin et al., 2013](#)). In a survey of eutrophic midcontinent lakes, microcystins (common cyanobacterial toxins associated with HABs), were detected in all blooms ([Graham et al., 2010](#)). In another U.S. survey, TN was strongly correlated to microcystin concentration in lakes and reservoirs ([Beaver et al., 2014](#)). The highest cyanobacteria abundance was observed in the Midwest where agriculture is a dominant land use, and TN concentrations are higher. Using data from the U.S. EPA National Lakes Assessment ([U.S. EPA, 2009b](#)), [Yuan et al. \(2014\)](#) modeled a threshold for the probability of occurrence of *Microcystis*, a common non-N<sub>2</sub> fixing cyanobacterial genus. In their analysis, the frequency of occurrence of high microcystin concentrations depended most strongly on TN, with weaker associations to chlorophyll *a*. The calculated

threshold is based on the range of possible combinations of TN and chlorophyll *a* and the World Health Organization drinking water provisional guideline for microcystin of 1 µg/L (WHO, 1998). The recommended threshold ranges to protect against frequency of occurrence of high microcystin concentrations ( $0.1 \text{ MC} \leq 1 \text{ µg/L}$ ) were 570 or 1,100 µg/L TN paired with chlorophyll *a* concentrations of 37 and 3 µg/L, respectively (Yuan et al., 2014). Decreasing the frequency of microcystin occurrence to 5% gave TN concentrations of 250 or 400 µg/L paired with chlorophyll *a* concentrations of 14 and 1 µg/L. In the most recent U.S. EPA National Aquatic Resource Surveys, microcystin was detected in 12% of wetlands where water depth was sufficient to allow for microcystin sampling (U.S. EPA, 2016j) and in 39% of lakes (U.S. EPA, 2016h). The U.S. EPA has recently provided human health advisories on allowable limits of 0.3 µg/L microcystins and 0.7 µg/L cylindrospermopsin in drinking water over a 10-day exposure period (U.S. EPA, 2015a, b).

Since the 2008 ISA, additional studies have indicated that the availability and form of N influences algal bloom composition and toxicity, and inputs of inorganic N selectively favor some HAB species. A recent bloom in Lake Okeechobee in Florida was dominated by *Microcystis*, which depends on DIN for growth (Paerl and Scott, 2010). Multiyear monitoring data from western Lake Erie showed that microcystin concentration peaks coincided with inorganic N and that microcystin was significantly lower in years with less inorganic N loading (Gobler et al., 2016). In nutrient amendment experiments with water collected from Lake Agawam in New York, abundances of toxic strains of *Microcystis* were enhanced more than nontoxic strains by inorganic N, while nontoxic strains responded to organic N more frequently than inorganic N (Davis et al., 2010). *Microcystis* populations were stimulated more frequently by N than by P in the assays. Similarly, in a series of nutrient addition experiments using water from Sandusky Bay, Lake Erie, bloom growth and microcystin concentrations responded more frequently to the addition of inorganic and organic forms of N than to P addition, indicating that N inputs may affect bloom size and toxicity (Davis et al., 2015). Donald et al. (2011) reported differential responses of phytoplankton to various forms of N in mesocosm experiments in Wascana Lake, Saskatchewan. In this naturally P rich lake, addition of  $\text{NH}_4^+$  and urea promoted nonheterocystous cyanobacteria and algae, while increased chlorophytes and some cyanobacteria were observed with  $\text{NO}_3^-$  and urea. Microcystin production increased with added N, although the response varied by the form of N and the predominant algal taxon. In the same mesocosms, species-specific analyses indicated 144 individual taxa that exhibited distinct responses to N addition: 45 species showed stimulated growth, 93 species had a limited response, and 6 species had suppressed growth (Donald et al., 2013).

---

### 9.2.6.2 Enzymes

A recent study analyzed enzyme activity to characterize nutrient limitation in aquatic systems. Microbial enzyme response to changes in N and P was found to vary in terrestrial and aquatic compartments in Bear Brook watershed in Maine, the site of a whole-watershed N enrichment experiment ([Mineau et al., 2014](#)). Stronger effects were typically observed in aquatic habitats. Although not explicitly the focus of the study, the authors imply that P limitation is caused by N availability. Since 1989, ammonium sulfate ( $[\text{NH}_4]_2\text{SO}_4$ ) has been applied bi-monthly to the watershed by helicopter, (25.2 kg N/ha/yr). The activity of three enzymes (b-1,4-glucosidase [BG], b-1,4-N-acetylglucosaminidase [NAG], acid phosphatase [AP]) in soil, leaf litter in both terrestrial and stream habitats, and in stream biofilms were compared with the activities of these enzymes in a reference watershed. In both terrestrial and aquatic habitats in the Bear Brook watershed, BG and NAG activities were unaffected. Stream biofilms had fivefold higher AP activity, while stream litter had eightfold higher AP activity. Increased AP activity is indicative of enhanced P limitation in the treated watershed. Shorter experimental P enrichments were used to characterize potential P limitation under ambient and elevated N availability. In streams, the effects of acute P additions were strongest with reduced AP activity and increased BG activity.

---

## 9.3 Community Composition, Species Richness, and Diversity

Increased N deposition to water bodies, either directly or via N leaching from soils, increases available nutrients to aquatic biota and alters the balance of N and P. As reported in the 2008 ISA, differences in resource requirements allow some species to gain competitive advantage over others when nutrients are added, causing shifts in freshwater community composition and structure as N concentration increases ([Saros et al., 2005](#); [Lafrancois et al., 2004](#); [Wolfe et al., 2003](#)). In eutrophic systems, water quality changes associated with excess N nutrient inputs like lowered DO and algal blooms, which alter habitat by covering up substrate, can also lead to declines in biodiversity ([Hernández et al., 2016](#)). These pathways of N impacts have been identified as a threat for 50 aquatic invertebrate species (mollusks) and 14 fish species that are listed, or candidates for protection, under the U.S. Federal Endangered Species Act ([Hernández et al., 2016](#)). The authors did not consider the sources of N in their analysis of biota affected by N pollution.

Evidence for N effects on biodiversity in phytoplankton, zooplankton, and macroinvertebrates in the 2008 ISA included observations from paleolimnological studies, bioassays, and mesocosm and laboratory experiments. Community shifts and

decreased species richness of phytoplankton have been described in multiple studies while fewer studies have considered zooplankton. The new literature described below continues to report the effects of N enrichment on algal biodiversity and shows limited evidence of effects at higher trophic levels ([Table 9-3](#)).

---

### 9.3.1 Archaea and Bacterial Diversity

The recent identification of ammonia-oxidizing archaea (AOA) and the classification of these microbes in a distinct and novel phylum within Archaea (Thaumarchaeota) has led to a large research effort to characterize their prevalence, community dynamics, and ecological distribution ([Schleper and Nicol, 2010](#); [Spang et al., 2010](#)). Spatio-temporal dynamics and community structure of AOA appear to be affected by lake trophic status and form of N ([Mukherjee et al., 2016](#); [Bollmann et al., 2014](#); [Berdjeb et al., 2013](#)). In a survey of nitrifying microbes in Lake Erie and Lake Superior, AOA outcompeted ammonia-oxidizing bacteria (AOB) where ammonium concentrations are lower [i.e., oligotrophic Lake Superior 0.287  $\mu\text{M NH}_4^+$  versus 2.45  $\mu\text{M}$  in mesotrophic Lake Erie; [Mukherjee et al. \(2016\)](#)].

---

### 9.3.2 Phytoplankton Diversity

Survey data, paleolimnological studies, and fertilization experiments in the 2008 ISA reported species changes and reductions in plankton diversity in sensitive high-elevation lakes in the western U.S. in response to increased availability of N ([U.S. EPA, 2008a](#)). Available data reviewed in the 2008 ISA suggested that the increases in total N deposition do not have to be large to elicit an ecological effect. [Interlandi and Kilham \(2001\)](#) demonstrated that the highest species diversity was maintained at very low N levels ( $<3 \mu\text{M N}$ ) in lakes in the Yellowstone National Park region. A hindcasting exercise determined that a change in Rocky Mountain National Park lake algae occurred between 1850 and 1964 at only about 1.5 kg N/ha/yr wet N deposition ([Baron, 2006](#)). Similar changes inferred from lake sediment cores of the Beartooth Mountains of Wyoming also occurred at about 1.5 kg N/ha/yr deposition ([Saros et al., 2003](#)). Preindustrial inorganic N deposition is estimated to have been only 0.1 to 0.7 kg N/ha/yr based on measurements from remote parts of the world ([Holland et al., 1999](#); [Galloway et al., 1995](#)). In the western U.S., preindustrial, or background, inorganic N deposition was estimated by [Holland et al. \(1999\)](#) to range from 0.4 to 0.7 kg N/ha/yr.

**Table 9-3 Summary of studies on nitrogen effects on species composition and biodiversity that have been evaluated in the literature since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur—Ecological Criteria.**

Region	Endpoint	Deposition kg N/ha/yr	N Addition	Observation	Species	Ecosystem Type	Reference
Isle Royale National Park, MI and Acadia National Park, ME	Phytoplankton community structure	6–7 kg total inorganic N/ha/yr wet deposition	0, 5, 10, 20, or 40 µg/L	Chlorophytes had a reduced response to DOM addition when N was added to the N limited lake (Sargent Lake in Isle Royale National Park). Increase in abundance of diatoms ( <i>F. crotonensis</i> and <i>Tabellaria flocculosa</i> ) with DOM addition to the lake.	Multiple	Boreal lakes	<a href="#">Daggett et al. (2015)</a>
Lake Tahoe, CA and NV	Survey	Not specified	None	Endemic benthic invertebrate taxa have declined by 80 to 100% since a survey of Lake Tahoe was conducted in the 1960s. Changes in the density and assemblage structure of benthic invertebrates mirrors increases in nutrient enrichment and non-native species in the lake. Macrophyte occurrence has also declined.	Amphipods <i>Stygobromus laticolus</i> and <i>S. tahoensis</i> declined 99.9% No endemic turbellarians but abundant in 1960s. Endemic stonefly <i>Capnia lacustra</i> decreased 93.5% Endemic ostracods <i>Candona tahoensis</i> density decreased 83.4%	Subalpine, oligotrophic lake in California	<a href="#">Caires et al. (2013)</a>

**Table 9-3 (Continued): Summary of studies on nitrogen effects on species composition and biodiversity that have been evaluated in the literature since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur—Ecological Criteria.**

Region	Endpoint	Deposition kg N/ha/yr	N Addition	Observation	Species	Ecosystem Type	Reference
Bavaria, Germany	Phytoplankton community composition and abundance		0, 1, 2, 8, 16, and 32 mL of solution of 30 g/L NO <sub>3</sub> <sup>-</sup> and 10 mg/L NH <sub>4</sub> <sup>+</sup>	Increasing N enrichment gradient affected phytoplankton stoichiometry and community composition and heterotrophic nanoflagellate and ciliate abundances, indicating N load alters basal food web.	Dominant phytoplankton were Bacillariophyceae, dinoflagellates, Chrysophyceae, and Cryptophyceae. Only a few individuals of a few Chlorophyceae and Cyanophyceae (mainly <i>Anabaena</i> spp.) were observed. Bacillariophyceae's most abundant species were <i>Asterionella formosa</i> , <i>Cyclotella</i> spp., and <i>Fragilaria crotonensis</i> . Another abundant Chrysophyceae species <i>Dinobryon divergens</i> and the dinoflagellate <i>Ceratium hirundinella</i> .	Oligotrophic lake	<a href="#">Poxleitner et al. (2016)</a>

DOM = dissolved organic matter; KH<sub>2</sub>PO<sub>4</sub> = monopotassium phosphate; N = nitrogen; NaNO<sub>3</sub> = sodium nitrate; TN = total nitrogen; TDP = total dissolved phosphorus; TP = total phosphorus.

Some freshwater algae are particularly sensitive to the effects of added N and experience shifts in species diversity and community composition with increased N deposition. A general shift from chrysophytes that dominate lakes with low N to cyanophytes and chlorophytes in lakes with higher N has been observed in studies reported in the 2008 ISA ([Lafrancois et al., 2004](#); [Wolfe et al., 2003](#); [Jassby et al., 1994](#)) and newer studies ([Symons et al., 2012](#); [Pardo et al., 2011a](#); [Saros et al., 2010](#)). For example, in phytoplankton sampling from 21 lakes and ponds in Wapusk National Park, Canada, [Symons et al. \(2012\)](#) observed that the N limited lakes had significantly different phytoplankton community composition, with more chrysophytes and *Anabaena* spp. compared to all other lakes.

Using data from the U.S. Geological Survey National Water Quality Assessment, [Passy \(2008\)](#) assessed the responses of 2,426 benthic and 383 planktonic diatom communities from 760 and 127 distinct localities, respectively, to nutrient limitation. As more resources (basic cations, silica, iron,  $\text{NH}_3$ ,  $\text{NO}_3^-$ , and dissolved P) became limiting, benthic diatom richness declined while phytoplankton richness increased.

---

### 9.3.2.1 Paleolimnological Studies

In the 2008 ISA, changes in diatom species assemblages, increases in cell numbers, and pigment-inferred increases in whole-lake primary production were reported from paleolimnological studies of mountain lakes that have only been disturbed by atmospheric deposition and climate change. Sediment cores in oligotrophic lakes receiving  $<5$  kg N/ha/yr showed diatom community shifts that in part could be also related to climate change. As reported in the 2008 ISA and [Appendix 9.2.1](#) of this appendix, two opportunistic species of diatom, *A. formosa* and *F. crotonensis*, now dominate the flora of at least several lakes in the Rocky Mountains ([Slemmons et al., 2015](#); [Arnett et al., 2012](#); [Saros et al., 2010](#); [Saros et al., 2005](#); [Saros et al., 2003](#); [Wolfe et al., 2003](#); [Wolfe et al., 2001](#); [Interlandi and Kilham, 1998](#)). In the southern Rocky Mountains, this shift occurred in the 1950s in the south, with more recent shifts (1970s) in the central region ([Baron et al., 2011b](#)). In most, but not all, of these studies, the observed responses in phytoplankton were concordant with effects from increased atmospheric N deposition. Increased abundance of *A. formosa* is also linked to changes in lake temperature under conditions of declining N deposition and decreasing lake total N concentration ([Sivarajah et al., 2016](#)).

Studies available since the 2008 ISA (summarized here and in [Table 9-1](#)) provide additional evidence from historical records of lake sediments in assessing biological changes associated with N enrichment over time. In a survey of 28 lakes in national parks

across the western Great Lake region, 63% of study lakes experienced changes in the diatom community correlated with lake sediment  $\delta^{15}\text{N}$  (Hobbs et al., 2016). About 36% of sediment  $\delta^{15}\text{N}$  was statistically correlated to some form of deposited N. Sediment records from lakes in the Uinta Mountains, UT showed shifts in diatom community composition and increasing abundance of the nitrophilous diatom *A. formosa* linked to atmospheric deposition (Hundey et al., 2014). In sediment core sampling from high-elevation lakes from national parks in Washington, Sheibley et al. (2014) analyzed a total of 56 sediment samples for diatom presence and abundance over time. In the survey, over 250 diatom species were identified; however, only Hoh Lake in Olympic National Park showed clear evidence of impacts from N deposition based on changes in sediment diatom assemblages and the presence of *A. formosa*, *F. crotonensis*, and *Fragilaria tenera*. In high-elevation lakes in the Rocky Mountains with low atmospheric deposition (<2 kg N/ha/yr) and low to moderate surface water  $\text{NO}_3^-$  concentrations (<1  $\mu\text{g/L}$  [below detection] to 30  $\mu\text{g/L}$ ), Arnett et al. (2012) observed that diatom assemblages were already dominated by nitrophilous species like *A. formosa* or *F. crotonensis*. Because of the abundance of species indicative of moderate N enrichment even at  $\text{NO}_3^-$  concentrations below the detection limit, it was not possible to identify a threshold of reactive N response for diatom community change. In Baptiste Lake in Alberta, Canada, a general shift in diatom assemblages away from N intolerant species and proliferation of *Stephanodiscus hantzschii*, a nitrophilous diatom species, was observed (Adams et al., 2014). Paleolimnological analysis suggests that eutrophic conditions were present in the lake for at least 150 years.

N deposition, along with climate change, was identified as a driver of diatom compositional turnover (or beta diversity) in a synthesis of paleolimnological core samples of 52 Arctic, alpine, and boreal montane lakes in North America and western Greenland. Hobbs et al. (2010) stated that in all lakes, beta diversity was significantly greater during the 20th century than the 19th century, with only a small and nonsignificant difference in turnover between the 19th century and the 1550–1800 intervals ( $p = 0.86$ ). Compared with forested montane boreal sites, both alpine and Arctic lakes reveal greater diatom assemblage turnover in the 20th century. In Arctic lakes, temperature appears to be the main factor affecting diatom composition turnover, while in temperate lakes, N deposition appears to play a larger role. A meta-analysis of 200 lakes in Europe and North America showed diatom shifts in Arctic lakes around 1850 and temperate lakes around 1970 (Rühland et al., 2008). Observed changes were primarily attributed to warming trends. The authors examined the diatom record from one lake in detail (Whitefish Lake in Ontario) and reported that observations of diatom shifts in this lake were not explained by N deposition but rather corresponded to temperature changes.

New information on relative  $\text{NO}_3^-$  inputs from glacial versus snowpack meltwaters reported in [Appendix 7](#) indicates water of glacial origin has higher levels of  $\text{NO}_3^-$ , which may influence the interpretation of biological data from high-elevation lakes and streams in some regions of the U.S. ([Slemmons et al., 2015](#); [Slemmons et al., 2013](#); [Saros et al., 2010](#); [Baron et al., 2009](#)). In the central Rockies and Glacier National Park, fossil diatom richness in snowpack-fed lakes was found to be higher (34 to 54 taxa) relative to lakes fed by both glacial and snowpack meltwaters [12 to 26 taxa; [Saros et al. \(2010\)](#)]. In the central Rockies, N deposition was 1.4 to 2.5 kg Nr/ha/yr, with 10 to 20% of the lakes there receiving glacial meltwater. In Glacier National Park in the northern Rockies, approximately 50% of lakes receive glacial meltwater and deposition was 2.0 to 3.4 kg Nr/ha/yr. In another study comparing sedimentary fossil diatom assemblages in two adjacent lakes (one glacier-fed and the other snow-fed) in the central Rocky Mountains, increased abundances of *A. formosa*, and *F. crotonensis* were observed in the glacier-fed lake starting 1,000 years ago along with a decrease in diatom species richness ([Slemmons et al., 2015](#)). Shifts in the planktonic diatom communities occurred after 1970 in snow-fed lakes ([Slemmons et al., 2017](#)). These observations suggest increased N inputs associated with glacial meltwater have altered the fossil algal record and continue to affect algal communities in some glacier-fed lakes. No significant differences in phytoplankton biomass and community structure were observed between snowpack-fed and glacier and snowpack-fed lakes in the northern Cascade Mountains in Washington in a comparison of data collected in 1989 and 2013 ([Williams et al., 2016b](#)).

---

### 9.3.2.2 Bioassay, Mesocosm, and Laboratory Studies

Several experimental nutrient additions (mesocosm and bioassay studies) described in [Appendix 9.1.1.3](#) show that N limitation is common in freshwater systems ([Elser et al., 2009b](#); [Elser et al., 2009a](#); [Bergström et al., 2008](#)). Since the 2008 ISA, several N addition studies have explored the effects of increased nutrients on phytoplankton biomass and community structure ([Daggett et al., 2015](#); [Gardner et al., 2008](#)). In the Colorado Front Range, diatom abundance increased, and phytoplankton species composition shifted in nutrient-enriched mesocosms ([Gardner et al., 2008](#)). Principal component analysis suggested that 21% of the variance in phytoplankton community composition was related to added nutrients, while 34% of the variance was due to seasonal changes. In a bioassay comparison of phytoplankton community structure following N and DOM addition to a low DOC and N and P colimited water body (Jordan Pond in Acadia National Park, ME) and an N limited lake (Sargent Lake in Isle Royale National Park, MI), [Daggett et al. \(2015\)](#) observed increased chlorophytes following DOM inputs in both lakes. In the N limited lake, an increase in the abundance of *F.*

*crotonensis* and *Tabellaria flocculosa* was observed. There was a reduced response of chlorophytes to DOM addition when N was added to the N limited lake.

Most N addition studies of phytoplankton communities have focused on N limited systems. [Poxleitner et al. \(2016\)](#) conducted an N addition mesocosm experiment during the spring season in a P limited oligotrophic lake in Upper Bavaria, Germany. An increasing N enrichment gradient affected phytoplankton stoichiometry and community composition. Only small effects of N enrichment were documented using the biovolume of phytoplankton, the amount of particulate organic carbon, and the concentration of chlorophyll *a* as indicators. There was an effect, however, on phytoplankton community composition and heterotrophic nanoflagellate and ciliate abundances. Thus, changes in food web dynamics were suggested for P limited lakes when N levels are increased.

---

### 9.3.2.3 Whole Lake Studies

Altered phytoplankton community composition and increased phytoplankton biomass resulted from inorganic N fertilization of Reindeer Lake in northern Sweden ([Jansson et al., 2001](#)). In a whole-lake N fertilization study of three small boreal lakes in northern Sweden, [Deininger et al. \(2017a\)](#) observed that changes in community composition of phytoplankton were related to DOC rather than N addition. As DOC increased along a gradient, community composition shifted from nonflagellated toward high DOC-adapted flagellated autotrophs in the three fertilized lakes. In the same set of lakes, phytoplankton biomass increased but net zooplankton responses were modest, attributed by the authors to incompatible stoichiometry of food (phytoplankton) to consumers [zooplankton; [Deininger et al. \(2017b\)](#)].

---

### 9.3.3 Benthic Algal Diversity

Benthic algae are typically less sensitive than planktonic algae to nutrient inputs because the former are associated with nutrient-rich substrates where sunlight reaches the sediment surface ([Spaulding et al., 2015](#)). Periphyton is typically more abundant than phytoplankton in these shallow habitats ([Vinebrooke et al., 2014](#); [Nydick et al., 2004](#)). Several recent studies have considered the effects of N on benthic algae characteristic of shallow lakes and littoral zones where primary production is mainly controlled by the availability of light ([Vadeboncoeur et al., 2008](#)). In a stable isotope tracer study in Bull Trout Lake, a subalpine lake in Idaho, the largest portion of added N was retained within the periphyton ([Epstein et al., 2012](#)). A directional change in benthic diatom species after 1960 that correlates with atmospheric deposition was observed in lake sediment cores

from high-elevation shallow lakes in Grand Teton National Park ([Spaulding et al., 2015](#)). [Liess et al. \(2009\)](#) conducted a survey of periphyton along an N deposition gradient (2 to 12 kg N/ha/yr) in Sweden. Benthic algal composition in lakes in the northern part of the country where N deposition was lower had a higher contribution from N fixing cyanobacteria (5% of algal biovolume) than in the south. Overall, lakes were more N limited in the North and P limited in the South. In another study using nutrient-diffusing substrata in two small Alpine lakes in the Rhone Alps, France, N enriched substrata had a greater phytobenthic biomass, and the taxonomic composition of the phytobenthos was different between the treatment and control ([Lepori and Robin, 2014](#)).

In pond fertilization experiments in 12 fishless, nonglacial ponds in Snow Pass within the Cascade Valley catchment of Banff National Park, Alberta, periphyton outcompeted phytoplankton for limiting nutrients, indicating the importance of considering both benthic and pelagic primary producers ([Vinebrooke et al., 2014](#)). In these N limited ponds, phytoplankton biomass increased significantly only when N was applied in the absence of fairy shrimp. High grazing pressure by fairy shrimp appeared to suppress the effects of added nutrients on algal communities, suggesting that trophic interactions are important to consider to avoid missing the effects of N in alpine water bodies.

The algal assemblage response following 6 weeks of nutrient amendments in Wyoming streams indicated that both N and P altered community structure of epilithic biofilm ([Kunza and Hall, 2013](#)). Depending on which nutrient was added, N<sub>2</sub> fixers reacted differently than non-N<sub>2</sub> fixers; an increase in non-N<sub>2</sub> fixing diatoms in the N and N + P additions was observed compared to N<sub>2</sub> fixer dominance in control and P treatment.

Other studies consider how changes in benthic algal biodiversity affect ecosystem processes such as chemical uptake. NO<sub>3</sub><sup>-</sup>-N uptake differed among benthic algal assemblages on transplanted rocks in a stream in Boise National Forest in central Idaho ([Baker et al., 2009](#)). Uptake of NO<sub>3</sub><sup>-</sup> was highest in the green filamentous algae, (dominated by the chlorophytes *Spirogyra* spp. and *Rhizoclonium* spp.), lowest in the yellow patch type (dominated by the chlorophytes *Spirogyra* spp. and *Bulbochaete* spp.), and intermediate in the brown patch type (dominated by diatoms, including *Synedra* spp., *Cymbella* spp., *Fragilaria* spp., and *Epithemia* spp.). NO<sub>3</sub><sup>-</sup>-N uptake normalized to chlorophyll *a* increased with algal composition and species richness in the three patch types.

---

### 9.3.4 Zooplankton Diversity

Changes to aquatic food webs in response to N enrichment have not been as thoroughly explored as changes to algal assemblages, but a few studies in the 2008 ISA showed

declines in zooplankton biomass ([Lafrancois et al., 2004](#); [Paul et al., 1995](#)) in response to N related shifts in phytoplankton biomass toward less palatable taxa with higher C:P ratios ([Elser et al., 2001](#)). New studies provide additional evidence for N deposition effects on zooplankton through altered trophic interactions.

The nutritional status of zooplankton is influenced by the quantity and quality of food items ([Elser et al., 2001](#)). In lakes across an N deposition gradient in Norway, zooplankton feeding on seston (organisms and nonliving matter in the water column) were found to be affected by P limitation in phytoplankton ([Elser et al., 2010](#)). The seston in lakes with high N deposition had significantly higher C:P and N:P ratios due to phytoplankton P limitation. Using an assay to measure alkaline phosphatase activity (APA), which is overexpressed in animals with dietary P deficiency, [Elser et al. \(2010\)](#) observed that the biomass-specific APA value differed considerably among taxa and that N deposition was significantly associated with some species such as seston-feeding zooplankton but not others, leading the authors to conclude that P limitation was transferred up the food chain. In three P deficient lakes in Germany, N enrichment experiments showed declines in mesozooplankton density and biomass, especially cladocerans, with N additions in the range of projected increasing atmospheric deposition ([Trommer et al., 2017](#)). An increase in seston C:P ratios was observed in one of the three P deficient lakes in response to N enrichment.

A taxonomic shift from omnivorous, raptorial-feeding copepods to filter-feeding herbivorous daphnids was observed with warming and N addition in a growth chamber experiment ([Thompson et al., 2008](#)). The study was conducted with water and sediment collected from Pipit Lake in the Canadian Rockies in Banff National Park, Alberta. While warming and N fertilization increased phytoplankton abundance, herbivory by *Daphnia middendorffiana* decreased but only in the presence of sediment (pond conditions). Findings demonstrated that the effects of warming and N differ both among trophic levels and aquatic alpine habitats.

---

### 9.3.5 Macroinvertebrate Diversity

Macroinvertebrates such as aquatic insects, crustaceans, worms, and mollusks are commonly sampled to assess water quality in federal and state monitoring programs ([U.S. EPA, 2016j](#)). These organisms feed on algae and organic material and are an important food source for fish and other wildlife. Few studies have considered the effects of atmospheric N enrichment on biodiversity of freshwater macroinvertebrates. Due to the existence of a survey of benthic invertebrates in Lake Tahoe, NV conducted in the 1960s, it was possible to assess how the populations have changed with enrichment and the

introduction of non-native species. In this high alpine lake, atmospheric N contributions are a significant portion (approximately 57%) of the total N loading to the lake ([Sahoo et al., 2013](#)). [Caires et al. \(2013\)](#) resurveyed the lake in 2008–2009 and observed declines of 80 to 100% in endemic benthic invertebrate taxa and changes to the community structure of benthic invertebrate assemblages. Corresponding to these changes in lake biota, a decrease in water clarity over the four decades between studies has been associated with a shift in the bottom of the euphotic zone (1% light penetration) from 80 to 57 m ([Chandra et al., 2005](#)).

A recent study from Denmark suggests that macroinvertebrates may be poor indicators of N enrichment. [Friberg et al. \(2010\)](#) measured stream macroinvertebrate occurrence along gradients in organic pollution and eutrophication in 594 streams. They observed that the occurrence of many taxa showed a stronger relationship to habitat condition than to chemical variables. Overall, macroinvertebrate occurrence appeared to be related primarily to biological oxygen demand,  $\text{NH}_4^+\text{-N}$ , and TP rather than TN. In a principal component analysis using the United States Geological Survey (USGS) National Ambient Water Quality Assessment (NAWQA) data set, [Carlisle et al. \(2007\)](#) identified nutrients ( $\text{NH}_4^+$ ,  $\text{NO}_3^-$ , TP) as a factor affecting macroinvertebrate occurrence, although specific conductance, pH, and  $\text{SO}_4^{2-}$  explained the greatest effects on macroinvertebrate abundance. A 20% loss of macroinvertebrate taxa was identified as a threshold for degraded streams based on benthic macroinvertebrate sampling data from a subset of basins in the eastern and midwestern U.S. ([Carlisle and Meador, 2007](#)).

---

### 9.3.6 Macrophyte Diversity

No U.S. studies of N effects on macrophyte (aquatic plant) community biodiversity in atmospherically N enriched lakes and streams have been identified in the recent literature, although declines in total macrophyte occurrence were noted in a resurvey of Lake Tahoe that compared current samples with those from a lake survey conducted in the 1960s ([Caires et al., 2013](#)). Benthic invertebrate declines were most severe in sampling sites where macrophytes were present in the 1960s but now absent, suggesting that macroinvertebrate and macrophyte assemblages are closely associated in the lake. [Barker et al. \(2008\)](#) conducted a mesocosm experiment using water and sediment from a stream in Norfolk, U.K. Experimental tanks were planted with 11 macrophyte species from the local environment. Constant P loadings were given to all tanks (50  $\mu\text{g P/L}$ ). Nitrate loading varied from 1 to 10 mg  $\text{NO}_3^-\text{-N/L}$ . Macrophyte species richness decreased with increasing N during the first year of treatment, and decreased in all treatments above 1 mg  $\text{NO}_3^-\text{-N/L}$  during the second year. [Barker et al. \(2008\)](#) estimated a threshold of 1.5 mg N/L for maintaining a stable species richness.

---

### 9.3.7 Amphibian Diversity

No studies on N enrichment effects on amphibian diversity were reviewed in the 2008 ISA or identified in the current literature.

---

### 9.3.8 Fish Diversity

No studies of direct effects of N enrichment on freshwater fish diversity were reviewed in the 2008 ISA. Post-2007 literature includes several behavioral endpoints in fish. ([Appendix 9.4.1](#)).

---

## 9.4 Animal Behavior and Disease

In addition to changes in biological indicators (i.e., chlorophyll *a*, periphyton/microbial biomass, diatoms, nutrient limitation shifts) and altered biodiversity, there is increasing evidence for a role of N in behavior and disease in biota. These indirect responses may impact the fitness of organisms inhabiting nutrient-enriched waters.

---

### 9.4.1 Behavior

Nutrient enrichment of freshwater systems has recently been shown to alter behavioral endpoints in an invertebrate, an amphibian, and a fish species in laboratory exposures. NO<sub>3</sub><sup>-</sup> exposure (21.4, 44.9, 81.8, 156.1 mg NO<sub>3</sub><sup>-</sup>/L) was shown to decrease the velocity of movement in the aquatic snail *Potamopyrgus antipodarum* ([Alonso and Camargo, 2013](#)). Reproductive impairments (decreased number of newborns) were observed at all tested concentrations. The NO<sub>3</sub><sup>-</sup> concentrations used in this study are much higher than typically measured in remote freshwater catchments affected by atmospheric deposition.

In the presence of chemical cues of the predator nymphs of the dragonfly (*Anax imperator*), western spadefoot toad (*Pelobates cultripes*) tadpoles typically decrease swimming activity by 44% ([Polo-Cavia et al., 2016](#)). When predator chemical cues were added to water containing NH<sub>4</sub>NO<sub>3</sub> tadpoles did not alter swimming activity. The concentrations of NH<sub>4</sub>NO<sub>3</sub> used in the study (20 mg/L and 80 mg/L) were not lethal to the tadpoles, and no altered swimming activity was observed with the added N except in the presence of predator chemical cues.

In the three-spined stickleback *Gasterosteus aculeatus*, a fish that inhabits both freshwater and brackish habitats, changes to water quality associated with eutrophication

(i.e., turbidity associated with algal blooms) have impacted social and reproductive behaviors in laboratory studies. These studies are reviewed in [Appendix 10](#).

---

#### 9.4.2 Disease

The interactions of N enrichment and disease in biota is a relatively new area of research in N impacted freshwater systems. The interactions characterized to date are complex and involve indirect effects on host-parasite interactions ([Johnson et al., 2010](#); [Johnson et al., 2007](#)). A host-parasite relationship potentially impacted by increased N to aquatic systems is that of the fungal pathogen *Metschnikowia bicuspidata*, which is parasitic to crustacean zooplankton *Daphnia dentifera* ([Dallas and Drake, 2014](#)). In a series of bioassays designed to assess the effects of N on host and pathogen, *D. dentifera* were exposed to six  $\text{NO}_3^-$  concentrations (0.4, 2, 4, 8, 16, and 32 mg  $\text{NO}_3^-/\text{L}$ ) and then inoculated with *M. bicuspidata*.  $\text{NO}_3^-$  decreased *D. dentifera* population size and increased infection prevalence. Next, ambient levels of N (0.4 mg  $\text{NO}_3^-/\text{L}$ ) and a concentration representative of a moderately polluted system (12 mg  $\text{NO}_3^-/\text{L}$ ) were used to test the influence of  $\text{NO}_3^-$  on pathogen dose, infection prevalence, and host fitness (growth and fecundity). No effects were observed on the growth rate of *D. dentifera*; however, greater infection prevalence was associated with increased  $\text{NO}_3^-$ , and in general, both host fecundity and infection intensity decreased with increasing pathogen dose.

---

### 9.5 Summary of Thresholds, Levels of Deposition at Which Effects Are Manifested, and Critical Loads

Since the 2008 ISA, additional thresholds of response to N have been identified that are useful for critical load development in water bodies impacted by N nutrient effects. Critical loads for N nutrient enrichment in U.S. freshwater ecosystems are summarized in [Table 9-4](#). Factors contributing to uncertainty in N deposition estimates for assessment of critical loads according to [Pardo et al. \(2011a\)](#) include “(1) the difficulty of quantifying dry deposition of nitrogenous gases and particles to complex surfaces; (2) sparse data, particularly for arid, highly heterogeneous terrain (e.g., mountains); and (3) sites with high snowfall or high cloud water/fog deposition, where N deposition tends to be underestimated.” N deposition estimates at high-elevation sites such as those in the Rocky and Sierra Nevada mountains are associated with considerable uncertainty, especially uncertainty for estimates of dry deposition ([Appendix 2](#)). For sensitive receptors such as phytoplankton shifts in high-elevation lakes, N deposition model bias may be close to, or exceed, predicted critical load values ([Williams et al., 2017a](#)).

Physical, chemical, and ecological variability across lakes affect their response to N deposition and contribute to uncertainty of critical load estimates ([Appendix 9.1.1.2](#)). A review by [Bowman et al. \(2014\)](#) noted that current N critical loads for sensitive alpine systems may not be protective under future climate scenarios of warmer summer temperatures and a shorter duration of snow cover.

Available data from the 2008 ISA suggest that the increases in total N deposition do not have to be large to elicit an ecological effect in remote alpine lakes. A hindcasting exercise determined that the shift in Rocky Mountain National Park lake algae composition that occurred between 1850 and 1964 was associated with wet N deposition that was only about 1.5 kg N/ha/yr ([Baron, 2006](#)). Similar changes inferred from lake sediment cores of the Beartooth Mountains of Wyoming occurred at about 1.5 kg TN/ha/yr deposition ([Saros et al., 2003](#)).

**Table 9-4 Summary of critical loads for nitrogen eutrophication for surface water in the U.S. [adapted from [Pardo et al. \(2011c\)](#) with newer studies added].**

Ecosystem	Site	Critical Load for N Deposition kg N/ha/yr	Comments	Reference/ HERO ID
Alpine stream	Southern Rockies/Loch Vale Rocky Mtn. Nat. Park	2	Modeled	<a href="#">Baron et al. (1994)</a>
Alpine lake	Northern Rockies/Beartooth Mtns., WY	1.5	Paleolimnological, shifts in diatom assemblages with <i>Fragilaria crotonensis</i> and <i>Cyclotella bodanica</i> increasing to comprise approximately 30% each of total assemblage	<a href="#">Saros et al. (2003)</a>
Alpine lakes	Rocky Mountains	2.5	Surveys and references therein	<a href="#">Bergström and Jansson (2006)</a>

High-elevation lakes of western and eastern U.S.	Rocky Mountains, Sierra Nevada, Northeast	1.0 to 3.0 (western lakes) 3.5 to 6.0 (northeastern lakes)	Based on N deposition calculated in three different ways and on lake NO <sub>3</sub> <sup>-</sup> concentrations	<a href="#">Baron et al. (2011b)</a>

**Table 9-4 (Continued): Summary of critical loads for nitrogen eutrophication for surface water in the U.S. [adapted from Pardo et al. (2011c) with newer studies added]**

Ecosystem	Site	Critical Load for N Deposition kg N/ha/yr	Comments	Reference/ HERO ID
Remote lakes		2.0 (western lakes) 8.0 (eastern lakes)	Based on value of N deposition at which significant NO <sub>3</sub> <sup>-</sup> leaching begins to occur	<a href="#">Pardo et al. (2011c)</a>
Alpine lakes	Rocky Mountain National Park	>1.5	Based on NO <sub>3</sub> <sup>-</sup> threshold of 0.5 μM (concentration which elicits a growth effect in the diatom <i>A. formosa</i> )	<a href="#">Nanus et al. (2012)</a>
Alpine lake	Hoh Lake, Olympic National Park, WA	1.0–1.2	Increased relative abundances of <i>Asterionella formosa</i> and <i>Fragilaria tenera</i> Diatom assemblage shift	<a href="#">Sheibley et al. (2014)</a>
Alpine lakes	Greater Yellowstone area	<1.5 to >4.0 <sup>a</sup>	Modeled; based on threshold value of NO <sub>3</sub> <sup>-</sup> (0.5 to 2.0 μeq/L)	<a href="#">Nanus et al. (2017)</a>
Western U.S. lakes	Remote mountain lakes across the western U.S.	4.1 <sup>a</sup>	Based on phytoplankton biomass nutrient limitation shifts	<a href="#">Williams et al. (2017b)</a>
Western U.S. lakes	Remote mountain lakes across the western U.S.	2.0 <sup>a</sup>	Modeled to reduce occurrence of false negatives to near zero	<a href="#">Williams et al. (2017b)</a>

N = nitrogen; NO<sub>3</sub><sup>-</sup> = nitrate.

<sup>a</sup>total N

Since the release of the 2008 ISA, work has continued on identifying thresholds of response to N deposition that can be used to calculate critical loads in sensitive freshwater systems. Threshold values for phytoplankton biomass growth have been identified for nine western mountain lakes in North Cascades, Mount Rainier, and Olympic national parks [13 to 25 μg DIN/L; [Williams et al. \(2016a\)](#)] and in lakes in the Sierra Nevada [0.3 to 4 μmol N/L (5 to 56 μg N/L); ([Heard and Sickman, 2016](#))]. [Williams et al. \(2017b\)](#) identified nutrient limitation shift thresholds (21 to 53 μg N/L) for remote western U.S. mountain lakes. A nutrient threshold for surface water NO<sub>3</sub><sup>-</sup> for growth of the diatom *A. formosa* was developed for high-elevation lakes in the Rocky Mountains where N deposition is prevalent ([Nanus et al., 2012](#)). The NO<sub>3</sub><sup>-</sup> threshold of 0.5 μmol/L (31 μg/L) was then used to estimate areas in Rocky Mountain National Park that exceed critical load values.

Additional critical loads for nutrient enrichment of freshwaters developed since the 2008 ISA include those in the western and northeastern U.S. [Pardo et al. \(2011c\)](#) estimated a critical load of 2.0 kg N/ha/yr for western lakes and 8.0 kg N/ha/yr for eastern lakes based on the value of N deposition at which significant  $\text{NO}_3^-$  leaching begins to occur. Using data from 125 lakes in the Greater Yellowstone area, including sensitive lakes in both Grand Teton and Yellowstone national parks, [Nanus et al. \(2017\)](#) estimated aquatic critical load values and identified locations with predicted critical load exceedances based on a threshold value of  $\text{NO}_3^-$  concentration in lake water selected as indicative of biological harm (0.5 to 2.0  $\mu\text{eq/L}$  in this study). Critical loads of TN deposition ranged from  $<1.5 \pm 1.0$  kg N/ha/yr to  $>4.0 \pm 1.0$  kg N/ha/yr. Exceedance estimates were as high as 48% of the Greater Yellowstone area study region.

[Baron et al. \(2011b\)](#) found that in the western high-elevation lakes, increased primary productivity and changes to algal diversity can occur with only minimal inputs of N deposition. They estimated that the thresholds, or critical loads, for nutrient enrichment are 1.0 to 3.0 kg N/ha/yr for the western mountains (Sierra Nevada and Rocky mountains; [Table 9-5](#)). For minimally disturbed lakes in the Northeast, a critical load of 3.5 to 6.0 kg N/ha/yr was estimated, but independent biological measures for nutrient enrichment are lacking in this region. In another study from the eastern Sierra Nevada and Greater Yellowstone Ecosystem, [Saros et al. \(2011\)](#) determined a critical load of 1.4 kg N/ha/yr wet N deposition by modeling wet deposition rates from the period in which diatom shifts first occurred. The shifts were identified from sediment cores between 1960 and 1965 in the eastern Sierra Nevada, and starting in 1980, in the Greater Yellowstone Ecosystem. Using core samples, [Sheibley et al. \(2014\)](#) identified diatom changes corresponding to N inputs from 1969–1975 in Hoh Lake in Washington and established a critical load of  $1.0\text{--}1.2 \pm 0.01$  kg N/ha/yr for the lake.

Using phytoplankton biomass N to P limitation shifts as the basis for critical load calculations, [Williams et al. \(2017b\)](#) determined an empirical critical load of 4.1 kg/TN/ha/yr for remote high-elevation lakes across the western U.S. The critical loads were calculated as the total (wet + dry) N deposition rate at which point below the critical load, N limitation is more likely than P limitation and above the critical load, P limitation is more likely than N limitation. Modeled critical loads using DIN:TP and DIN response categories yielded an average critical load of 3.8 kg/TN/ha/yr for the lakes. Modeled critical loads ranged from 2.8 to 5.2 kg/TN/ha/yr and correctly predicted exceedances in 69% of lakes using  $\text{NO}_3^-$ -N. The authors conducted a performance evaluation using the  $\text{NO}_3^-$ -N univariate model and identified a critical load of 2.0 kg/TN/ha/yr to reduce the likelihood of false negatives to near zero.

**Table 9-5 Summary of mean lake nitrate (NO<sub>3</sub><sup>-</sup>) concentrations, inorganic nitrogen deposition amounts, and nutrient enrichment inflection points where lake NO<sub>3</sub><sup>-</sup> concentrations reflect increased nitrogen deposition. [from [Baron et al. \(2011b\)](#)].**

Region	Mean Lake NO <sub>3</sub> <sup>-</sup>	Mean 1997–2006 NADP N Deposition	Nutrient Enrichment Inflection Point (NADP)	Mean 1997–2006 (PRISM + NADP) Deposition	Nutrient Enrichment Inflection Point (PRISM + NADP)	2002 Total N Deposition	Nutrient Enrichment Inflection Point (Total N)
Sierra Nevada (n = 30)	2.7 (1.10)	1.5 (0.22)	1.5	2.5 (0.34)	1.5	3.4 (0.47)	2.0
Rocky Mountains (n = 285)	3.7 (1.90)	1.2 (0.27)	1.0	3.0 (0.28)	2.0	2.0 (0.24)	3.0
Northeast (n = 216)	14.4 (0.76)	4.7 (0.18)	3.5	5.2 (0.18)	3.5	3.5 (0.20)	6.0

N = nitrogen; NADP = National Atmospheric Deposition Program; NO<sub>3</sub><sup>-</sup> = nitrate; PRISM = Parameter-Elevation Regressions on Independent Slopes Model; PRISM + NADP = concentrations from NADP with PRISM precipitation values.

Note: Inorganic N deposition was calculated three ways, as was described in [Baron et al. \(2011b\)](#). Coefficients of variation are in parentheses.

Mean lake NO<sub>3</sub><sup>-</sup> (in micromoles per liter), inorganic nitrogen (N) deposition amounts (in kg N/ha/yr), and nutrient enrichment inflection points where lake NO<sub>3</sub><sup>-</sup> concentrations increase in response to increasing N deposition.

Source: [Aber et al. \(2003\)](#), [Sickman et al. \(2002\)](#), U.S. Forest Service's Air Resource Management online database ([www.fs.fed.us/ARMdata](http://www.fs.fed.us/ARMdata)).

## 9.6 Summary and Causal Determination

In the 2008 ISA, the body of evidence was sufficient to infer a causal relationship between N deposition and the alteration of species richness, community composition, and biodiversity in freshwater ecosystems. New evidence from 2008 to the present, from paleolimnological surveys, fertilization experiments, gradient studies, phytoplankton community responses, and indices of biodiversity continue to show effects of N loading to sensitive freshwater systems. As reported in the 2008 ISA, freshwater systems in which N has been observed to influence ecological processes either received extremely high inputs [e.g., ([Dumont et al., 2005](#))], or had very low initial N concentrations and responded rapidly to the additional inputs ([Bergström and Jansson, 2006](#); [Baron et al., 2000](#)). As summarized in the 2008 ISA and supported by data in newer studies, nutrient enrichment effects on freshwater ecosystems from atmospheric deposition of N are most likely to occur in lakes and streams that have low primary productivity and low nutrient levels and that are located in the most undisturbed areas with no local pollution sources.

Even small inputs of N in these water bodies can increase nutrient availability or alter the balance of N and P, which can stimulate growth of phytoplankton. As reported in the 2008 ISA and further strengthened with new evidence in this review, there is consistent and coherent evidence for species composition changes and reductions in diversity, especially for primary producers from high-elevation lakes in the western U.S., in response to increased availability of N. New information is consistent with the conclusions of the 2008 ISA that **the body of evidence is sufficient to infer a causal relationship between N deposition and changes in biota, including altered growth and productivity, species richness, community composition, and biodiversity due to N enrichment in freshwater ecosystems.**

New data have not appreciably changed the consistent and coherent evidence at the time of the 2008 ISA that freshwater systems that are likely to be most impacted by nutrient enrichment due to atmospheric deposition of N are remote, oligotrophic, high-elevation water bodies with limited local nutrient sources and with low N retention capacity. N inputs to these ecosystems are linked to changes in biota, especially increased algal growth and shifts in algal communities. Freshwater systems sensitive to N nutrient enrichment include those in the Snowy Range in Wyoming, the Sierra Nevada Mountains, and the Colorado Front Range. A portion of these lakes and streams where effects are observed are in Class I wilderness areas ([Williams et al., 2017b](#); [Clow et al., 2015](#); [Nanus et al., 2012](#)).

Recent research further supports the 2008 ISA findings that N limitation is common in oligotrophic waters in the western U.S. ([Elser et al., 2009b](#); [Elser et al., 2009a](#)). Shifts in nutrient limitation, from N limitation, to between N and P limitation, or to P limitation, were reported in some alpine lake studies reviewed in the 2008 ISA and in this review. Since the 2008 ISA, several meta-analyses have reported an increase in P deposition to water bodies ([Stoddard et al., 2016](#); [Brahney et al., 2015](#); [Tipping et al., 2014](#)) and highlight the need to account for how sustained P deposition can modify the effects of anthropogenically emitted N deposition on productivity. P addition delayed the shift to P limitation (prolonged N limitation) for phytoplankton.

The body of evidence for biological effects of N enrichment and altered N:P ratios in remote freshwater systems (where atmospheric deposition is the predominant source of N) is greatest for phytoplankton, the base of the freshwater food web. Lake surveys, fertilization experiments, and nutrient bioassays reported in the 2008 ISA and in this review show increased pelagic and benthic algal productivity (as indicated by chlorophyll *a* concentration) to be strongly related to increased N concentration. An increase in lake phytoplankton biomass with increasing N deposition was reported in several regions, including the Snowy Range in Wyoming and across Europe. New studies

in the Rocky Mountains of Colorado where atmospheric deposition ranged from 2 to 7 kg N/ha/yr support observations from the 2008 ISA which showed correlations between greater chlorophyll *a* response and higher rates of deposition ([Elser et al., 2009a](#)). Several recent studies have considered the effects of N on benthic algae characteristic of shallow lakes and littoral zones where availability of light is the main factor controlling primary production. A few studies have shown that periphyton outcompeted phytoplankton for limiting nutrients, indicating the importance of considering both benthic and suspended primary producers.

Changes in phytoplankton species diversity and community structure reported in the 2008 ISA ([Lafrancois et al., 2004](#); [Wolfe et al., 2003](#); [Jassby et al., 1994](#)) and newer studies ([Symons et al., 2012](#); [Saros et al., 2010](#)) show a general shift from chrysophytes that dominate lakes with low N to cyanophytes and chlorophytes in lakes with higher N. In the 2008 ISA, diatom assemblage shifts were reported from the literature at total N deposition as low as 1.5 kg N/ha/yr ([Saros et al., 2003](#)). This evidence was further supported by a hindcasting exercise that determined the change in Rocky Mountain National Park lake algae that occurred between 1850 and 1964 was associated with an increase in wet N deposition that was only about 1.5 kg N/ha/yr ([Baron, 2006](#)). Two nitrophilous species of diatoms, *A. formosa* and *F. crotonensis*, are dominant in lakes with higher N and serve as biological indicators of N enrichment; however, increased relative abundance of *A. formosa* has also been attributed to lake warming in some regions where N deposition is decreasing ([Sivarajah et al., 2016](#)). Some shifts in algal biodiversity observed in high-elevation waters are attributed to climate change or nutrient effects and climate as costressors ([Appendix 13](#)).

The role of N in freshwater HAB formation has been further researched since the 2008 ISA. Additional evidence continues to show that the availability and form of N influences algal bloom composition and toxicity and that inputs of inorganic N selectively favor some HAB species, including those that produce microcystin. Microcystin is prevalent in U.S. waters as reported in recent regional and national surveys. Although the risk of HAB formation is low in high-elevation oligotrophic water bodies where N deposition is the dominant source of N, transport of atmospheric inputs can exacerbate eutrophic conditions in downstream water bodies. Increased understanding of the role of N as a limiting nutrient in many freshwater systems has led to recommendations to consider both N and P in nutrient reduction strategies ([Dodds and Smith, 2016](#); [Gobler et al., 2016](#); [Paerl et al., 2016b](#); [Lewis et al., 2011](#); [Scott and McCarthy, 2010](#); [Conley et al., 2009](#); [Paerl, 2009](#); [Lewis and Wurtsbaugh, 2008](#)).

Since the 2008 ISA, empirical and modeled critical loads for the U.S. have been estimated based on surface water NO<sub>3</sub><sup>-</sup> concentration, diatom community shifts, and

phytoplankton biomass growth nutrient limitation shifts. A critical load ranging from 3.5 to 6.0 kg N/ha/yr was identified for high-elevation lakes in the eastern U.S. based on the nutrient enrichment inflection point [where  $\text{NO}_3^-$  concentrations increase in response to increasing N deposition; ([Baron et al., 2011b](#))]. Another critical load of 8.0 kg N/ha/yr for eastern lakes based on the value of N deposition at which significant increases in surface water  $\text{NO}_3^-$  concentrations occur was estimated by [Pardo et al. \(2011c\)](#). In both Grand Teton and Yellowstone national parks, critical loads for total N deposition ranged from  $<1.5 \pm 1.0$  kg N/ha/yr to  $>4.0 \pm 1.0$  kg N/ha/yr ([Nanus et al., 2017](#)). Exceedance estimates were as high as 48% of the Greater Yellowstone area study region, depending on the threshold value of  $\text{NO}_3^-$  concentration in lake water selected as indicative of biological harm.

Additional critical loads have been identified since the 2008 ISA for eastern Sierra Nevada lakes, Rocky Mountain lakes, the Greater Yellowstone Ecosystem, and Hoh Lake, Olympic National Park [[Table 9-4](#); ([Nanus et al., 2017](#); [Sheibley et al., 2014](#); [Pardo et al., 2011c](#); [Saros et al., 2011](#))]. The identified values fall near or within the range of 1.0 to 3.0 kg N/ha/yr for western lakes ([Baron et al., 2011b](#)). An empirical critical load of 4.1 kg/TN/ha/yr above which phytoplankton biomass P limitation is more likely than N limitation was identified by [Williams et al. \(2017b\)](#) for the western U.S. Modeled critical loads ranged from 2.8 to 5.2 kg/TN/ha/yr, and a performance analysis indicated that a critical load of 2.0 kg/TN/ha/yr would likely reduce the occurrence of false negatives to near zero.

The evidence for N effects on other freshwater biota is not as extensive as for phytoplankton. Since the 2008 ISA, new research on archaea and bacterial diversity in freshwater systems suggests that these organisms respond to lake trophic state and the form of N present. At higher trophic levels, zooplankton responses to N inputs are attributed to changes in food quality which can potentially alter food web interactions ([Deininger et al., 2017b](#); [Meunier et al., 2016](#); [Elser et al., 2009a](#)). A few studies in the 2008 ISA showed declines in zooplankton biomass ([Lafrancois et al., 2004](#); [Paul et al., 1995](#)) in response to N related shifts in phytoplankton biomass toward less palatable taxa with higher C:P ratios ([Elser et al., 2001](#)). Limited studies since the 2008 ISA suggest that atmospheric N inputs are linked to taxonomic shifts and declines in some invertebrates, although the effects attributed to N are difficult to separate from other stressors such as climate change and invasive species. Water quality changes associated with excess N nutrient inputs, such as lowered DO and algal blooms that alter habitat by covering up substrate, can also lead to declines in biodiversity in macroinvertebrates and fish including species listed under the federal Endangered Species Act ([Hernández et al., 2016](#)). Although little research has been conducted in freshwater systems, some evidence suggests that increased turbidity associated with algal blooms may affect reproductive

and social behaviors in fish ([Appendix 10](#)). Emerging research on disease in biota suggest that N enrichment may modify relationships such as host susceptibility to parasites and pathogens.

Since the 2008 ISA, further studies have shown that both trophic interactions and DOC modify ecosystem response to N loading. In a whole-lake N fertilization study, [Deininger et al. \(2017a\)](#) observed that changes in community composition of phytoplankton were related to DOC rather than N addition to small N limited boreal lakes. As DOC increased along a gradient, community composition shifted from nonflagellated toward high DOC-adapted flagellated autotrophs in the three fertilized lakes. In the same set of lakes, although phytoplankton biomass increased, net zooplankton responses were modest and attributed by the authors to incompatible stoichiometry of food (phytoplankton) to consumers [zooplankton; [Deininger et al. \(2017b\)](#)]. A study in Banff National Park, Canada indicated that grazing pressure on algae may have negated the effects of nutrient inputs on primary producers ([Vinebrooke et al., 2014](#)). Limited evidence suggests a decreased rate of leaf litter decomposition by microbial communities with N loading to streams.

New studies show that the N contribution from glacial meltwater (which has higher  $\text{NO}_3^-$  relative to water from melting snow) affects diatom community composition in high-elevation lakes and streams in some regions of the U.S. ([Slemmons et al., 2015](#); [Slemmons et al., 2013](#); [Saros et al., 2010](#)). N deposition to snow and glaciers are important sources of N to alpine lakes and streams that are fed by meltwaters. In a comparison of biological response in snowpack-fed lakes versus lakes with both glacial and snowpack meltwater in the Rockies, fossil diatom richness was higher in the snowpack-fed lakes (34 to 54 taxa) compared to lakes with both glacial and snow meltwater inputs [12 to 26 taxa; ([Saros et al., 2010](#))]. Characterizing diatom community responses to meltwater sources is important for interpreting the biological effects of N deposition in high-elevation systems with both glacial and snow inputs.

---

# APPENDIX 10 BIOLOGICAL EFFECTS OF NITROGEN ENRICHMENT IN ESTUARIES AND NEAR-COASTAL SYSTEMS

This appendix characterizes the biological effects of nitrogen (N) enrichment in estuaries (areas where freshwater from rivers meets the salt water of oceans), coastal lagoons, coral reef ecosystems, and open ocean areas near coastlines. An overview of N inputs to coastal systems, including characteristics and identification of areas of the U.S. sensitive to nutrient over-enrichment ([Appendix 10.1](#)) is followed by discussions of the indicators of nutrient enrichment ([Appendix 10.2](#)), its effects on biodiversity and ecosystem structure and function ([Appendix 10.3](#)), animal behavior, and disease ([Appendix 10.4](#)), and the role of N enrichment and acidification on calcifying organisms ([Appendix 10.5](#)). [Appendix 10.6](#) summarizes the thresholds of biological effects of N in coastal regions, and [Appendix 10.7](#) reviews the causal determination based on a synthesis of new information and previous evidence from prior N assessments.

---

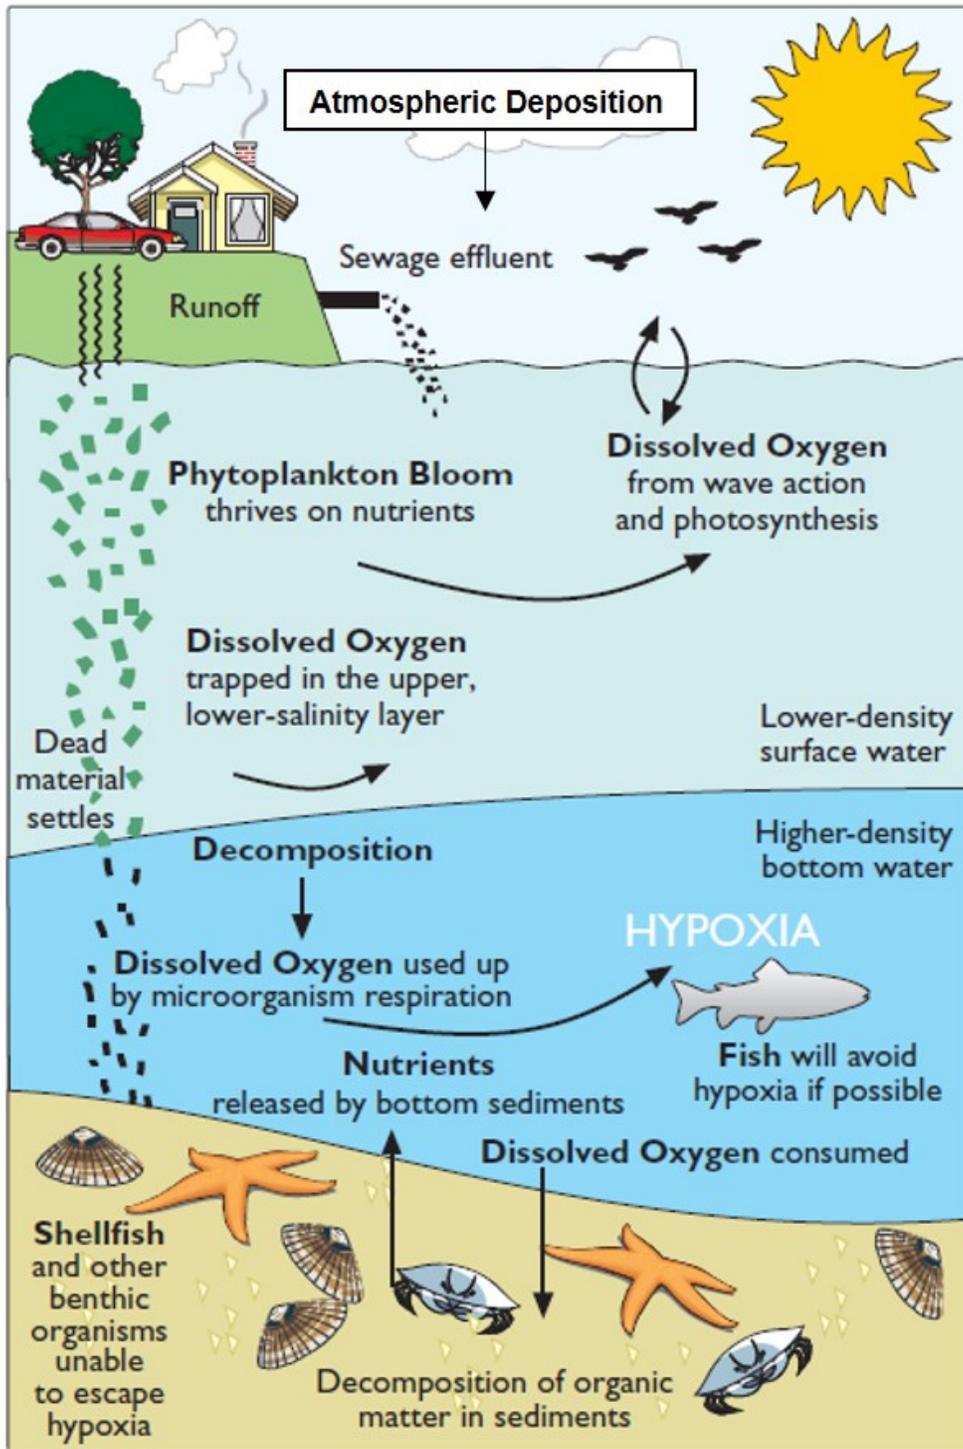

## 10.1 Introduction

In the *2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur-Ecological Criteria* (2008 ISA), the body of evidence was sufficient to infer a causal relationship between N deposition and the alteration of species richness, species composition, and biodiversity in estuarine systems ([U.S. EPA, 2008a](#)). Nitrogen pollution is the major cause of harm to the majority of estuaries in the U.S. ([Bricker et al., 2008](#); [NRC, 2000](#)). In estuaries, N from atmospheric and nonatmospheric sources contributes to increased primary productivity, leading to eutrophication ([Figure 10-1](#)). Estuary eutrophication is a process of increasing nutrient over-enrichment indicated by water quality deterioration, resulting in numerous adverse effects including areas of low dissolved oxygen (DO) concentration (hypoxic zones), species mortality, and harmful algal blooms (HABs). Eutrophic systems are characterized by an increase in the rate of supply of organic matter (primary production and organic carbon accumulation) in excess of what an ecosystem is normally adapted to processing ([Diaz et al., 2013](#); [Nixon, 1995](#)). In the 2008 ISA the strongest evidence for a causal relationship was from changes in biological indicators of nutrient enrichment including chlorophyll *a*, macroalgal “seaweed” abundance, HABs, DO, and submerged aquatic vegetation (SAV). Biological effects of increasing nutrient enrichment also include changes in biodiversity in these systems ([Section IS.2.2.4](#)). For this ISA, new information is consistent with the 2008 ISA and the causal determination

has been updated to reflect more specific categories of effects. **The body of evidence is sufficient to infer a causal relationship between N deposition and changes in biota, including altered growth, total primary production, total algal community biomass, species richness, community composition, and biodiversity due to N enrichment in estuarine environments.**

In the previous ISA, there was a strong scientific consensus that N is the principal cause of coastal eutrophication in the U.S. ([U.S. EPA, 2008a](#); [NRC, 2000](#)). On average, human activity has likely contributed to a sixfold increase in the N flux to the coastal waters of the U.S. over the past several decades, and excessive N represents the most significant coastal pollution problem ([Bricker et al., 2008](#); [Bricker et al., 2007](#); [Howarth and Marino, 2006](#); [Bricker et al., 2003](#); [Howarth et al., 2002](#); [NRC, 2000](#)). Many coastal areas receive high enough levels of N input from human activities to cause eutrophication ([Bricker et al., 2007](#); [Howarth et al., 1996a](#); [Vitousek and Howarth, 1991](#)). As reported in the 2008 ISA, N driven eutrophication of shallow estuaries has increased over the past several decades, and environmental degradation of coastal ecosystems is now a widespread occurrence ([Bricker et al., 2007](#); [Paerl et al., 2000](#)).

Coastal systems are linked to terrestrial N processes along the freshwater to ocean continuum as nutrients deposited to the watershed move downstream. As described in the 2008 ISA, in coastal ecosystems, the nutrients most commonly associated with phytoplankton growth are N, phosphorus (P), and silicon (Si). The relative proportions of these nutrients are important determinants of primary production, food web structure, and energy flow through the ecosystem ([Turner et al., 1998](#); [Justic et al., 1995b](#); [Justic et al., 1995a](#); [Dortch and Whitley, 1992](#)). In general, estuaries tend to be N limited [[D'Elia et al. \(1986\)](#); [Howarth \(1988\)](#); [Nixon \(1995\)](#); [NRC \(2000\)](#); [Howarth and Marino \(2006\)](#); [Elser et al. \(2007\)](#); [Paerl and Piehler \(2008\)](#); [Appendix 10.1.3](#)]; however, some estuaries are P limited, or colimited by N and P, or switch seasonally between N and P ([Howarth et al., 2011](#); [Paerl and Piehler, 2008](#); [Howarth and Marino, 2006](#)).

N = nitrogen.

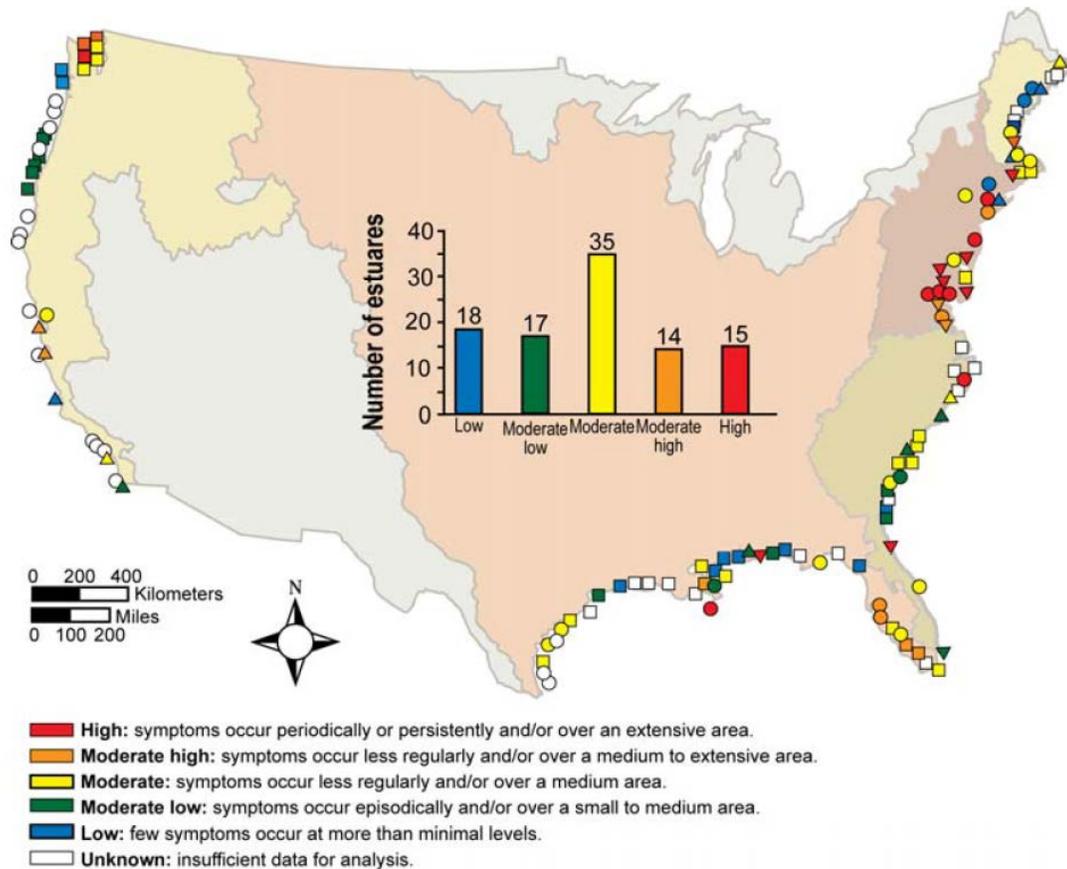

Notes: Atmospheric N deposition is one of the sources of nutrient enrichment to coastal areas.

Source: Modified from [U.S. EPA \(2012b\)](#).

**Figure 10-1 Eutrophication can occur when the availability of nutrients increases above normal levels.**

Altered biogeochemical processes associated with N loading ([Appendix 7](#)) may affect aquatic biota in a diversity of coastal habitats. Habitats associated with coastal areas include shallow open waters, sandy beaches, mud and sand flats, rocky shores, oyster beds, coral reefs, mangrove forests, river deltas, tidal pools, and seagrasses ([U.S. EPA, 2016g](#)). [Appendix 11](#) will cover wetland ecosystems, including those located on coasts in which soils and/or sediments are periodically inundated by tides or flooding. Estuaries in the U.S. are located on both coasts with varying levels of eutrophication occurring [[Bricker et al. \(2007\)](#); [Figure 10-2](#)]. SAV, including the eelgrass *Zostera marina*, are important ecological communities found within some coastal bays and estuaries that are sensitive to elevated nutrient loading ([Appendix 10.2.5](#)). Estuaries provide breeding grounds, nurseries, and shelter for aquatic biota. Near-coastal coral reefs have a more limited distribution in the U.S. occurring off south Florida, Texas, Hawaii, and U.S. territories in the Caribbean and Pacific. Elevated N loading appears to play a role in susceptibility of coral species to disease and bleaching ([Appendix 10.4.2](#)).

In the 2008 ISA and the National Estuarine Eutrophication Assessment (NEEA), a comprehensive survey of eutrophic conditions in the Nation's estuaries conducted by the National Oceanic and Atmospheric Administration (NOAA), the most eutrophic estuaries in the U.S. occurred in the mid-Atlantic region, and the estuaries with the lowest degree of eutrophication were in the North Atlantic [[Bricker et al. \(2007\)](#) and [Figure 10-2](#)]. In the NEEA, 65% of assessed estuaries had moderate to high overall eutrophic conditions ([Bricker et al., 2007](#)). In the U.S., Chesapeake Bay is perhaps the best-documented case study of the effects of human activities on estuarine eutrophication. Human disturbances, such as landscape changes, have exacerbated the negative impacts of N deposition by reducing N removal and retention in the upper watershed region. Anthropogenic N inputs have substantially altered the trophic condition of Chesapeake Bay over the last 50 to 100 years. Signs of eutrophication in the bay include high algal production, low biodiversity, and large hypoxic and anoxic zones. Other estuaries identified in the 2008 ISA where the extent of hypoxia and algal blooms have increased included Long Island Sound, the Pamlico Estuary in North Carolina, and along the continental shelf adjacent to the Mississippi and the Atchafalaya River discharges to the Gulf of Mexico ([U.S. EPA, 2008a](#)). This appendix updates the state of the science on N-nutrient enrichment, focusing on U.S. waters, since the release of the 2008 ISA.

**Figure 10-2 Overall eutrophication condition on a national scale.**

### 10.1.1 Nitrogen Sources to Estuaries and Coasts

Sources of N are described in detail in [Appendix 2](#). Briefly, coastal waters are influenced by N enrichment from upstream sources that may undergo biogeochemical transformations along the freshwater-to-ocean continuum as well as direct inputs from the atmosphere. In estuaries adjacent to areas of coastal upwelling, such as some locations along the Pacific coast of the U.S., oceanic inputs of nutrients may also represent an important source of N ([Brown and Ozretich, 2009](#)). N inputs can be attributed to point sources from a single outfall or discharge point and nonpoint sources, which are diffuse ([U.S. EPA, 2008a](#)). Both point and nonpoint sources have been identified as targets for control of N inputs in coastal systems ([Stephenson et al., 2010](#); [Paerl et al., 2002](#)).

---

### 10.1.2 Trends in Atmospheric Deposition of Nitrogen (N)

Trends in atmospheric deposition are discussed in [Appendix 2](#). In summary, in many parts of the U.S., including the Southeast, Mid-Atlantic, and Midwest, deposition of reduced N has increased relative to oxidized N in last few decades, shifting from a nitrate ( $\text{NO}_3^-$ ) dominated to an ammonium ( $\text{NH}_4^+$ ) dominated condition. This trend is expected to continue in the future under existing emission controls and current projections of atmospheric deposition ([Li et al., 2016d](#); [Ellis et al., 2013](#); [Pinder et al., 2008](#); [U.S. EPA, 2008a](#)). Wet deposition is now primarily  $\text{NH}_4^+$  at nearly 70% of U.S. air monitoring locations and reduced N dominates dry deposition in most parts of the country ([Li et al., 2016d](#)). This relative increase in  $\text{NH}_4^+$  is attributed to intensified industrial-scale animal operations, increased application of fertilizer, and successful  $\text{NO}_x$  emission controls ([Li et al., 2016d](#); [Xing et al., 2013](#)). Mobile source emissions, especially emissions from diesel vehicles, which increasingly use urea to control  $\text{NO}_x$  emissions, also contribute to total reduced N loading as well as near-road runoff in regions receiving heavy traffic ([Bettez et al., 2013](#)). The increase in highly bioreactive reduced N from deposition and other sources is often a preferred form of N for phytoplankton, including harmful species ([Appendix 10.3.3](#)). In coastal areas of the U.S., atmospheric inputs are heterogeneous ranging from <10 to approximately 70% of the N inputs ([Table 7-8](#)).

---

### 10.1.3 Nitrogen Limitation

As reported for several decades prior to the 2008 ISA, N enrichment of marine and estuarine waters can alter the ratios among nutrients such as P and Si and affect overall nutrient limitation. N is the most common limiting nutrient in estuarine and coastal waters and continued inputs have resulted in N over enrichment and subsequent alterations to the nutrient balance in these systems ([U.S. EPA, 2008a](#); [Elser et al., 2007](#); [Howarth and Marino, 2006](#); [NRC, 2000](#); [Paerl et al., 2000](#); [Nixon, 1995](#); [Howarth, 1988](#); [D'Elia et al., 1986](#)). As described in the 2008 ISA, nutrient limitation may shift along the estuarine to ocean continuum ([U.S. EPA, 2008a](#)). For example, Chesapeake Bay exhibits a shift in nutrient limitation with P most commonly limited at upstream freshwater locations. At the transition between fresh and salt water, N and P may be colimiting, whereas the saltwater environments in the lower bay and sound regions are usually N limited ([Fisher et al., 1998](#); [Rudek et al., 1991](#)). Levels of N limitations are affected by seasonal patterns in estuaries, with N limited conditions likely occurring during the peak of annual productivity in the summer ([U.S. EPA, 2008a](#)).

Since the 2008 ISA, N limitation in estuarine and marine systems has been further evaluated, with recognition of the shifting nature of nutrient limitation based on relative

nutrient inputs and other ecosystem conditions. The rate of nutrient delivery, especially N, to coastal waters is strongly correlated to primary production and phytoplankton biomass (Paerl and Piehler, 2008). Strong input controls causing low riverine P inputs have, in some cases, exacerbated N limitation downstream, with implications for estuarine eutrophication (Paerl, 2009). Likewise, if N inputs are high enough, some estuaries and coastal marine ecosystems can become P or Si limited (Howarth et al., 2011; Paerl and Justić, 2011; Paerl and Piehler, 2008). Under this scenario, if a system becomes P limited, the N input may travel farther away from its sources and contribute to eutrophication at greater downstream distances (Howarth et al., 2011).

The role of N inputs from upstream and the connectivity between freshwater and receiving estuarine and coastal waters have led to recommendations to reduce both N and P in upstream waters (Glibert and Burford, 2017; Paerl et al., 2016b; Woodland et al., 2015; Paerl et al., 2014; Conley et al., 2009; Paerl, 2009). Increased N inputs may be affecting N limitation in the open ocean as well as in near-coastal areas. Kim et al. (2014a) reported a detectable increase in  $\text{NO}_3^-$  concentration in the upper Pacific Ocean. The rate of increased N relative to P was highest near the source of anthropogenic emissions in northeastern Asia with rates decreasing eastward across the upper North Pacific Ocean. The authors suggest that increased N deposition may enhance primary production and potentially lead to a shift from N to P limitation in this region.

Additional studies support observations reported in the 2008 ISA of N and P dynamics in estuaries. P limitation can play an important role, particularly seasonally if the water body has a significant freshwater source (Kemp et al., 2005; Malone et al., 1996). P limited conditions often exist in the low salinity regions while N limitation is more common downstream in higher salinity waters (Paerl and Otten, 2013). Studies in the Chesapeake Bay and in Europe have shown that the phytoplankton community in coastal ecosystems can be P limited over several months in the spring and switch to N limitation for periods of time as short as 1 week later in the season (Trommer et al., 2013; Malone et al., 1996). In the low-nutrient waters of North Carolina's Alligator River estuary, phytoplankton primary productivity and biomass (chlorophyll *a*) increased with N additions, but both indicators showed the greatest increases after treatment with combined N and P, indicating that this system was colimited by N and P (Rossignol et al., 2011). N additions in this region are known to lead to poor water quality and related complications, such as algal blooms, hypoxia/anoxia (water with DO that is too low to support marine biota), fish kills, and to impact ecosystem services, including fisheries and recreation (Paerl and Piehler, 2008).

---

#### 10.1.4 Characteristics of Coastal Systems Sensitive to Eutrophication

Each coastal system has site-specific characteristics that influence ecological response to nutrient loading. A variety of factors that govern the sensitivity of estuaries and near-coastal marine waters to eutrophication from atmospheric N deposition are summarized in the 2008 ISA. Of critical importance is the total N input from all sources, including both atmospheric and nonatmospheric sources ([Appendix 10.1.1](#)). Other key elements include the flushing rate and dilution capacity of the watershed which reflects the volume of water available to dilute added N ([NRC, 2000](#); [Bricker et al., 1999](#)). The NEEA defined susceptibility as an estimate of the natural tendency of an estuary to retain or flush nutrients ([Bricker et al., 2007](#)). In estuaries that have longer residence times, nutrients are more likely to be taken up by algae and lead to eutrophic conditions.

As described in the 2008 ISA, the principal watershed features that control the amount of increased N flux to estuaries in the U.S. include human population, agricultural production, and the size of the estuary relative to its drainage basin ([Fisher et al., 2006](#); [Caddy, 1993](#); [Peierls et al., 1991](#)). A study included in the 2008 ISA reported a strong correlation between population density (persons/km<sup>2</sup>) and the total N loading from watershed to estuary ( $r^2 = 0.78$ ) for coastal watersheds in the U.S. ([Turner et al., 2001](#)). This finding is likely due to the prevalence of automobiles in heavily populated areas, along with their associated N emissions and deposition, plus the myriad of nonatmospheric sources of N from human activities, particularly wastewater discharges. The study authors also determined that direct atmospheric deposition becomes increasingly more important as a contributor to the total N loading to an estuary as the water surface area increases relative to total watershed area (terrestrial plus water surfaces). Because of human population growth and the preference for living in coastal areas, there is substantial potential for increased N loading to coastal ecosystems from both atmospheric and nonatmospheric sources.

Freshwater inputs to coastal areas and subsequent response to nutrient inputs depend on residence time of the nutrient-laden freshwater and the degree of tidal exchange within the estuary ([Zaldivar et al., 2008](#)). Residence time is defined by physical and hydrological characteristics of the watershed, such as surface area, volume, depth, and flushing rate ([Paerl et al., 2002](#)). In water bodies with short residence times, there is little opportunity for nutrients to be taken up and for algal blooms to develop ([Bricker et al., 2007](#)). For example, in the heavily N loaded lower Hudson River estuary, phytoplankton are flushed away as fast as they can grow due to high input of freshwater and high rates of flushing ([Howarth and Marino, 2006](#); [Howarth et al., 2000](#)). In the NEEA, systems with longer flushing times were considered more susceptible to eutrophication ([Bricker et al., 2007](#)).

Other factors within the highly variable estuarine environment ([Appendix 7.2.2](#)) that influence the composition of biological communities include salinity, DO, and suspended solids, which vary spatially and temporally along the estuary continuum ([Borja et al., 2012](#)). Mixing depth, temperature, and light penetration depth also affect biological response ([Paerl et al., 2002](#)). A stratified water column that separates well-oxygenated surface water from bottom water and sediments is generally required to form hypoxic zones ([Jewett et al., 2010](#)). In contrast to the seasonal or persistent nature of hypoxic zones, diel-cycling hypoxia typically occurs over hours to days and does not require stratification. Precipitation events like storms and floods or drought can also modulate nutrient effects [[Paerl and Piehler \(2008\)](#); [Appendix 13](#)].

In the 2008 ISA and NEEA, estuaries characterized as eutrophic were generally those that had large watershed-to-estuarine surface area, high human population density, high rainfall and runoff, low dilution, and low flushing rates ([U.S. EPA, 2008a](#); [Bricker et al., 2007](#)). In literature reviewed for this ISA, many studies have re-emphasized the important role that physical mixing and hydrologic factors play in determining which estuaries and coastal ecosystems are the most sensitive to N enrichment ([Hart et al., 2015](#); [Wilkerson et al., 2015](#); [Glibert et al., 2014](#); [Rothenberger et al., 2014](#); [Howarth et al., 2011](#); [Kennison et al., 2011](#)). The hydrodynamics of a system may play an overriding role in controlling phytoplankton growth ([Hart et al., 2015](#); [Yang et al., 2008](#)). These factors, which affect estuarine response to nutrient loading, should be taken into account when establishing N input thresholds so that eutrophication can be controlled for different ecosystem types, hydrologic conditions, and future climate scenarios ([Paerl et al., 2014](#)).

[Bricker et al. \(2014\)](#) evaluated N inputs to the Potomac River Estuary and found that despite some improvements in the upper estuary (i.e., increased DO and decreased chlorophyll *a* in the tidal fresh zone; continued regrowth of sea grasses), eutrophic conditions have worsened in the lower estuary since the early 1990s. Eutrophic conditions in the Potomac were found to be representative of the Chesapeake Bay region and other U.S. estuaries, with moderate to high levels of nutrient-related degradation, particularly compared with similar river-dominated low-flow systems ([Bricker et al., 2014](#)). These river-dominated watersheds with low flow (>10 days residence time), high population density (i.e., >100 people/km<sup>2</sup>), and >40% of land use classified as urban and/or agriculture were predicted to be likely impacted by eutrophication.

[Scavia and Liu \(2009\)](#) evaluated a nutrient-driven phytoplankton model that provides a first-order screening tool for estuarine susceptibility classification. Using data from 75 estuaries, they found that the susceptibility of an estuary to nutrient loading could be estimated based on the ratio of river inflow ( $Q$ ) to estuarine volume ( $V$ ). In this analysis, efficiency appeared to decrease roughly with the inverse square root of  $Q/V$ :

$\varepsilon = 0.908(Q/V)^{-0.47}$  ( $R^2 = 0.53$ ), where  $\varepsilon$  represents mean values arising from the 75 estimated normal distributions. Model results showed that estuaries with a  $Q:V$  value greater than 2.0/year are less susceptible to nutrient loads, and those with  $Q:V$  values between 0.3 and 2.0/year are moderately susceptible. Case studies showed that  $Q:V$ —and thus estuarine sensitivity to nutrient loading—can vary between seasons and with storm events due in part to fluctuations in river inflow.

In some estuaries, especially in the Pacific Northwest, upwelling and oceanic exchange caused by regional wind patterns likely control primary production rather than anthropogenic nutrient loading ([Brown and Ozretich, 2009](#); [Hickey and Banas, 2003](#)). Nutrient inputs from local and regional upwelling in these systems can be difficult to discern from anthropogenic sources. Upwelling-dominated areas are characterized by short water residence time and have a moderately low expression of eutrophication symptoms, although nutrient concentrations are high ([Kaldy et al., 2017](#); [Brown and Ozretich, 2009](#); [Bricker et al., 2008](#); [Bricker et al., 2007](#)). Transfer of hypoxic water from upwelling to estuaries can also occur but is not linked to anthropogenic nutrient additions ([Brown and Power, 2011](#)).

---

#### 10.1.4.1 Climate Modification of Ecosystem Response to Nitrogen

Climate-related changes including temperature, precipitation, wind patterns, extreme weather events, stronger estuary stratification, increased metabolism and organic production, and sea level rise are all expected to modify coastal habitats ([Altieri and Gedan, 2015](#); [Statham, 2012](#); [Rabalais et al., 2009](#)). These interacting factors will alter sensitivity to N loading and ecosystem response to nutrient inputs. For example, eutrophic conditions and the extent and duration of hypoxia are predicted to increase with changes in temperature and precipitation ([Altieri and Gedan, 2015](#); [Rabalais et al., 2009](#); [Boesch et al., 2007](#)). Freshwater and nutrient contributions to estuaries are expected to rise due to predicted increases in surface water flow and runoff from watersheds ([Rabalais et al., 2010](#); [Adrian et al., 2009](#); [Whitehead et al., 2009](#)). [Howarth et al. \(2012\)](#) demonstrated larger N fluxes (larger percent delivery of human N inputs) in wetter climates with more discharge, across 154 different watersheds in the U.S. and Europe. High organic loads and freshwater inputs associated with extreme weather events may enhance stratification and contribute to hypoxia ([Wetz and Yoskowitz, 2013](#)). Temperature modification leading to sea level rise and inputs of freshwater will likely alter salinity gradients and increase stratification within estuaries ([Statham, 2012](#); [Najjar et al., 2010](#)).

In estuaries affected by nutrient enrichment and climate-associated alterations described above, conditions favor a shift in phytoplankton toward greater abundance and distribution of toxic cyanobacteria associated with increased prevalence of HABs and declines in SAV ([Paerl et al., 2016a](#); [Najjar et al., 2010](#)). Research indicates that N and climate change will interact to drive losses in biodiversity that will be more than additive compared to each independent force ([Porter et al., 2013](#)). Decreases in pH associated with nutrient-enhanced coastal eutrophication combined with elevated atmospheric CO<sub>2</sub> could increase susceptibility of fauna to ocean acidification [[Cai et al. \(2011c\)](#); [Appendix 10.5](#)]. Coral reef ecosystems are particularly susceptible to combined effects of acidification, rising sea level, warming trends, and eutrophication. [Appendix 13](#) includes a more detailed discussion of how climate (e.g., temperature and precipitation) modifies ecosystem response to N loading.

---

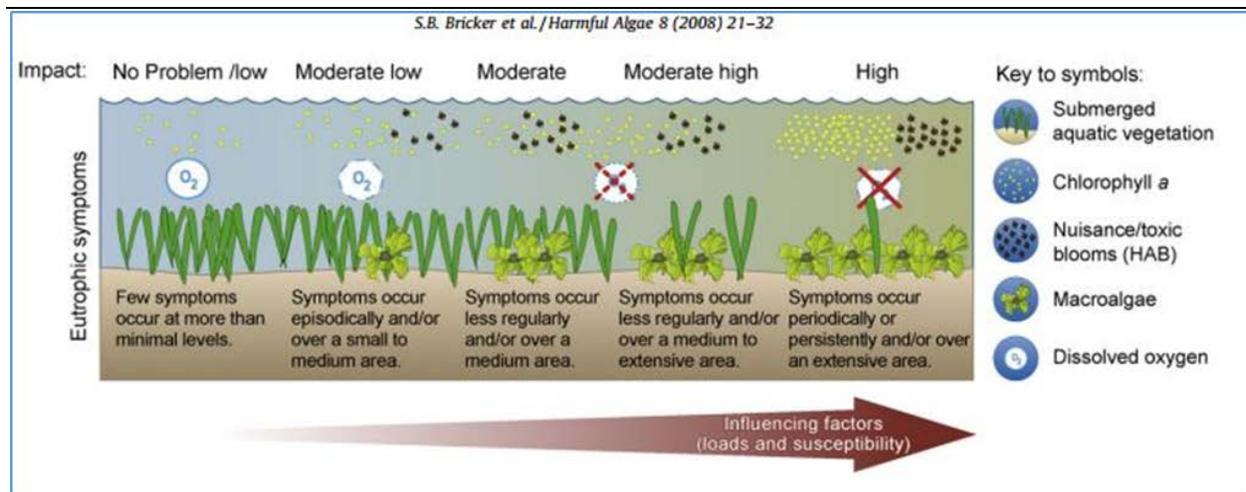

## 10.2 Indicators of Nutrient Enrichment

In the complex environment of the freshwater-to-ocean continuum there are many chemical and biological indicators of eutrophic conditions ([Table 7-8](#)). One approach is to measure total nutrient loading and concentrations; however, these data need to be interpreted in the context of the physical and hydrological characteristics that determine ecosystem response. Water quality measures (water clarity, DO) and quantification of nutrients along with biological indicators such as chlorophyll *a*, phytoplankton abundance, HABs, macroalgal abundance, SAV, and fish kills can all be used to assess responses to nutrient loading. Some biological indicators such as chlorophyll *a* are directly linked to nutrient enrichment and provide evidence of early response to added nutrients, while other indicators such as low DO and decreases in SAV indicate that the degree of eutrophication has progressed ([Borja et al., 2012](#)). A summary of key indicators of estuarine eutrophication is provided in [Table 10-1](#), and these indicators are discussed in the following sections. The 2008 ISA used the five ecological indicators shown in [Figure 10-3](#) (chlorophyll *a*, harmful/nuisance/toxic algal blooms, macroalgae, DO, and SAV) included in the Assessment of Estuarine Trophic Status (ASSETS) categorical Eutrophication Condition Index (ECI) in the NEEA to estimate the likelihood that an estuary is experiencing eutrophication or will experience eutrophication ([Bricker et al., 2007](#)).

**Table 10-1 Indicators of Estuarine Eutrophication.**

Indicator	Description
Chlorophyll <i>a</i>	Excess N input will stimulate primary productivity, and chlorophyll <i>a</i> concentration is an indicator of phytoplankton biomass. Phytoplankton biomass is strongly controlled in coastal waters by the availability and supply rates of nutrients, especially N ( <a href="#">Paerl and Piehler, 2008</a> ).
Harmful/nuisance/toxic algal blooms (HABs)	Excess N input can cause nuisance or toxic algal blooms, which release toxins in the water that can poison aquatic animals and threaten human health ( <a href="#">Baron et al., 2012</a> ). Problem occurrences of HABs increased 13% from 1997 to 2007 in Mid-Atlantic estuaries, the only region for which data were available, along with increasing N loading ( <a href="#">Bricker et al., 2008</a> ).
Macroalgal abundance	Macroalgal blooms can cause the loss of important submerged aquatic vegetation by blocking sunlight, and opportunistic macroalgae can outcompete many seagrass species ( <a href="#">Kennison et al., 2011</a> ). They can also cause hypoxia and smother seagrass, coral, clams/oysters, and other benthic organisms. High biomasses also cause “stinky beach” by rafting onto beaches and decaying.
Dissolved oxygen (DO)	Dissolved O <sub>2</sub> concentration decreases with increasing algal abundance under elevated N because microbes consume O <sub>2</sub> as they decompose dead algae. Oxygen depletion mainly occurs in bottom waters under stratified conditions. Increased atmospheric N deposition combined with N loading from other sources will likely affect the size, frequency, and severity of hypoxia events ( <a href="#">Rabalais et al., 2010</a> ). Hypoxia also contributes to ocean acidification, which is detrimental to the growth and development of calcifying organisms ( <a href="#">Howarth et al., 2011</a> ). The largest documented zone of hypoxic coastal water in the U.S. is located in the northern Gulf of Mexico ( <a href="#">Dale et al., 2010</a> ).
Submerged aquatic vegetation (SAV)	Excess N input stimulates algal growth, and opportunistic macroalgae may block the penetration of sunlight into the water column and outcompete seagrasses, leading to reduced SAV coverage. Increased epiphyte loads on the surface of macrophytes from nutrient enrichment may reduce biomass, shoot density, percentage cover, production and growth of SAV ( <a href="#">G.Nelson, 2017</a> ). Reduced extent of eelgrass was found to correspond to increased loading of N (from wastewater, fertilizer, and atmospheric deposition) to small to medium shallow estuaries in New England ( <a href="#">Latimer and Rego, 2010</a> ), and the distribution of SAV in Chesapeake Bay is used as an indicator of diversity and biological balance in the <i>U.S. EPA Report on the Environment (U.S. EPA, 2016k)</i> .

Chl = chlorophyll; DO = dissolved oxygen; EPA = Environmental Protection Agency; HAB = harmful algal blooms; N = nitrogen; O<sub>2</sub> = oxygen; SAV = submerged aquatic vegetation.

**Figure 10-3 Biological indicator responses to nutrient enrichment.**

### 10.2.1 Chlorophyll *a*

Chlorophyll *a* is part of the light harvesting complex (group of pigments) used by photosynthetic organisms to convert light energy into carbohydrates through a series of biochemical reactions. The concentration of chlorophyll *a* is often used as a proxy for phytoplankton biomass. Algae form the base of the coastal food web and excess algal growth is often directly linked to nutrient enrichment. This indicator can be easily quantified and linked to aircraft and satellite-based remote sensing and autonomous monitoring platforms to assess effects at the regional and ecosystem level ([Appendix 7.2.7](#)). Chlorophyll *a* is widely used to assess eutrophic conditions because of its sensitivity to nutrient inputs and was one of the indicators of overall eutrophic condition of U.S. coastal areas in the 2008 ISA ([U.S. EPA, 2008a](#)). Increased levels of chlorophyll *a* can signal an early stage of water quality degradation related to nutrient loading and measurements of chlorophyll *a* are incorporated into water quality monitoring programs ([Appendix 7.2.7](#) and [Appendix 7.2.10](#)). High concentration of chlorophyll *a* suggests that algal biomass is sufficiently high to contribute to low DO concentration from increased decomposition of dead algae. Due to the strength of hydrologic forces (i.e., freshwater inputs and tidal flushing) in some types of coastal systems, benthic chlorophyll *a* may be a more sensitive indicator of ecosystem response to N enrichment than planktonic chlorophyll *a* in well-flushed systems ([Paerl and Piehler,](#)

[2008](#)). Phytoplankton blooms can also be advected into estuarine systems from the coastal ocean ([Brown and Ozretich, 2009](#)).

Chlorophyll *a* concentrations are commonly included in standardized frameworks of eutrophic condition [[Appendix 10.2.6](#); [Borja et al. \(2012\)](#)]. Many of these indices define spatial extent and temporal sampling periods and statistical measures to determine representative concentrations. Several chlorophyll *a* thresholds have been identified for U.S. water bodies ([Table 10-2](#)). The U.S. EPA National Coastal Condition Assessment (NCCA; formally known as National Coastal Assessment) measures chlorophyll *a* from an annual index period (June to October) and compares the samples to reference conditions to determine a rating [ $>20$   $\mu\text{g/L}$ , poor;  $5\text{--}20$   $\mu\text{g/L}$ , fair;  $<5$   $\mu\text{g/L}$ , good; [U.S. EPA \(2016g\)](#); [U.S. EPA \(2012b\)](#)]. For the NEEA ASSETS, the 90th percentile of annual values for chlorophyll *a* combined with spatial coverage and frequency of occurrence of blooms are reported for distinct salinity zones (tidal fresh  $0\text{--}0.5$  ppt), mixing zone ( $0.5$  to  $25$  ppt), and seawater ( $>25$  ppt);  $0\text{--}5$   $\mu\text{g/L}$  is a water body with low risk of eutrophication,  $5\text{--}20$   $\mu\text{g/L}$  is moderate,  $>20$   $\mu\text{g/L}$  is high ([Bricker et al., 2007](#)).

**Table 10-2 Chlorophyll *a* thresholds used in methods to evaluate the status of phytoplankton in U.S. coastal and estuarine water bodies.**

Method/ Approach	Chlorophyll <i>a</i> Thresholds and Ranges ( $\mu\text{g/L}$ )	Sample Time Frame	Statistical Measure	Other Characteristics	Community Composition	Indicators in Overall Eutrophication Index
U.S. EPA NCCA	Poor $>20$ Fair $5\text{--}20$ Good $0\text{--}5$	Index period (June–Oct.)	Concentration percentage of coastal area in poor, fair, and good condition based on probabilistic sampling design for 90% conf. in areal result		No	Chlorophyll <i>a</i> , water clarity, DO, DIP, DIN
ASSETS (eutrophic condition component only)	Poor $>20$ Fair $5\text{--}20$ Good $0\text{--}5$	Annual	90th percentile chlorophyll <i>a</i> concentration of annual data	Spatial coverage, frequency occurrence	Nuisance and toxic bloom occurrence, frequency, duration	Chlorophyll <i>a</i> , macroalgae, DO, seagrasses, nuisance/toxic algal blooms

ASSETS = Assessment of Estuarine Trophic Status; conf. = confidence; DIN = dissolved inorganic nitrogen; DIP = dissolved inorganic phosphorus; DO = dissolved oxygen; EPA = Environmental Protection Agency; L = liter; NCCA = National Coastal Condition Assessment.

Source: [Borja et al. \(2012\)](#).

In the NEEA, elevated chlorophyll *a* concentration was the most widespread documented symptom of eutrophication ([Bricker et al., 2007](#)). Half of the estuaries for which data were available exhibited high chlorophyll *a* concentration ([Bricker et al., 2007](#)). In the 2008 ISA, San Francisco Bay, CA was an example of an estuary that has experienced considerable increases in chlorophyll *a* concentrations in recent years.

Phytoplankton biomass, as indicated by chlorophyll *a* concentration, is strongly controlled in estuaries by the availability and supply rates of nutrients, especially N ([Paerl and Piehler, 2008](#)). Bioassays conducted in the low-nutrient Alligator River estuary in North Carolina showed that N enrichment is directly related to increasing chlorophyll *a* concentration. Although the highest increase occurred in response to addition of both N and P, dissolved inorganic N (DIN) treatment alone stimulated chlorophyll *a* in some treatments ([Rossignol et al., 2011](#)). A 3-year data set from Raritan Bay, NJ indicates that nutrient loading contributed to high concentrations of chlorophyll *a* from 2010–2012 ([Rothenberger et al., 2014](#)). Winter and spring N loading to Mattawoman Creek estuary and other shallow estuaries in the Chesapeake Bay region was highly correlated to summer chlorophyll *a* concentrations ([Boynton et al., 2014](#)). However, after point source nutrient (N and P) reductions were enacted, a decrease in chlorophyll *a* was observed in Mattawoman Creek. In North Carolina's Neuse River estuary, which is part of the Albemarle-Pamlico estuary, it appears that the elevated loading of total N (TN) contributed to higher annual average chlorophyll *a* values from 2000–2009 ([Lebo et al., 2012](#)).

While recent research indicates that N loading remains a strong predictor of chlorophyll *a* concentrations under most conditions, there has been increasing discussion regarding the role of other factors in altering the strength of this relationship. The impact of nutrient inputs can at times be overtaken by hydrologic features, seasonal variations, climatic changes, and oscillations exerting greater control over phytoplankton dynamics ([Paerl et al., 2010](#)). In Buzzard's Bay, MA, both nutrient loading and shape of the embayment were factors in determining spatial and temporal water quality trends including the observation that chlorophyll *a* is increasing at a faster rate than N enrichment ([Rheuban et al., 2016](#)). It appears that more chlorophyll *a* per unit of TN was produced as the 22-year time series progressed. In Corpus Christi Bay, TX, rainfall events altered nutrient N:P ratios but did not affect chlorophyll *a* ([Turner et al., 2015](#)). Instead, chlorophyll *a* concentration in weekly samples mainly followed seasonal trends by increasing in spring and summer and decreasing in fall and winter. No significant relationships were observed between annual TN, total phosphorus (TP) load, and annual mean chlorophyll *a* concentrations in the Guana Tolomato Matanzas estuary in Florida, rather phytoplankton biomass in this well-flushed system was influenced by temperature, precipitation, water residence times, and tidal exchange ([Hart et al., 2015](#)). [Glibert et al. \(2014\)](#) found

significant increases in chlorophyll *a* over time at only three out of seven study areas in the Maryland/Virginia coastal lagoon, although regionally chlorophyll *a* concentrations increased due to increasing anthropogenic nutrient loads and increased freshwater flow in the early 2000s. In the Neuse River estuary, NC, which has a long residence time allowing for detection of nutrient stimulation, nutrient addition bioassays along the estuary indicated strong N limitation at the chlorophyll *a* maximum and downstream where there was a strong preference of  $\text{NH}_4^+$  over  $\text{NO}_3^-$  as a DIN source ([Paerl and Piehler, 2008](#)).

Using satellite and meteorological data from U.S. Atlantic coastal waters, [Kim et al. \(2014b\)](#) found that precipitation events were associated with increased levels of chlorophyll *a* in low nutrient areas (defined as having  $\text{NO}_3^-$  concentrations of less than 1  $\mu\text{M}$ ), but precipitation was correlated with lower chlorophyll *a* concentrations in high nutrient areas (defined as having  $\text{NO}_3^-$  concentrations greater than 1  $\mu\text{M}$ ). This is likely because in low nutrient areas, new N input from precipitation stimulated phytoplankton growth. In areas already high in nutrients, wind associated with precipitation events may have deepened the mixed layer and the resulting loss of light availability caused chlorophyll *a* concentrations to decline ([Kim et al., 2014b](#)). Two studies modeling historical data from Chesapeake Bay indicate that variation in climatic conditions dominated phytoplankton dynamics in the bay in recent years ([Harding et al., 2016a](#); [Harding et al., 2016b](#)). Much of the bay is producing more chlorophyll *a* per unit TN than in the past, leading Harding and others to suggest that return to the historical relationship between N and chlorophyll *a* is unlikely.

In four coastal estuaries that shifted from eutrophication to oligotrophication (reduction in nutrients), the degree of return of chlorophyll *a* to reference status varied, likely due to concurrent changes in the estuaries from costressors and the time elapsed from eutrophication to nutrient reduction ([Duarte et al., 2009](#)). Due to these shifting baselines the authors suggest that the current paradigm of nutrient reduction to a historical level needs to be replaced by targets that maintain key ecosystem functions in the context of changing conditions in the estuaries over time.

---

## 10.2.2 Harmful/Nuisance/Toxic Algal Blooms

Harmful algal blooms (HABs) reflect the proliferation of a toxic or nuisance algal species that negatively affects natural resources or humans. Blooms are increasing in outbreak frequency and extent in the U.S. and other countries, and N is one of the nutrients known to promote HAB formation ([Baron et al., 2012](#); [Heisler et al., 2008](#)). A concurrent increase in atmospheric sources of N to coastal areas and proliferation of harmful algal

bloom formation have been recognized for several decades ([Paerl et al., 2002](#); [Paerl and Whitall, 1999](#); [Paerl, 1997](#)). The form of N delivered to coastal regions of the U.S. from atmospheric and other sources is changing from primarily  $\text{NO}_3^-$  to an increase in reduced forms of N ([Appendix 10.1.2](#)), which are favored by some HAB forming species ([Glibert et al., 2016](#)). HABs caused by N enrichment can release toxins that are harmful to fish and shellfish and that may accumulate in predators and organisms higher in the food web ([Johnson et al., 2010](#)). For example, cyanobacteria blooms (cyanoHAB) have been documented in estuaries along the U.S. Mid-Atlantic and Southeast coasts as well as Gulf coast estuaries ([Preece et al., 2017](#)). Other blooms are not toxic but may cause low DO events due to very high biomass. In addition to effects on biota, HABs cause a range of responses in humans from direct dermatitis, such as swimmers itch, to severe food poisoning, liver and kidney toxicity, and paralysis ([Peel et al., 2013](#); [Johnson et al., 2010](#)).

The frequency and duration of algal blooms is one of five indicators used in the NEEA and was included as an indicator of eutrophic conditions in the 2008 ISA ([U.S. EPA, 2008a](#); [Bricker et al., 2007](#)). Of the 81 estuary systems for which data were available in the NEEA, 26 exhibited a moderate or high symptom expression for nuisance or toxic algae ([Bricker et al., 2007](#)). In the previous 2008 ISA review, the frequency of phytoplankton blooms and the extent and severity of hypoxia were documented to have increased in the Chesapeake Bay ([Officer et al., 1984](#)) and Pamlico Sound estuaries in North Carolina ([Paerl and Piehler, 2008](#)) and along the continental shelf adjacent to the Mississippi and Atchafalaya river discharges to the Gulf of Mexico ([Eadie et al., 1994](#)). New tools and monitoring approaches to further characterize HABs have become available since the 2008 ISA ([Appendix 7.2.7](#)). For example, solid phase adsorption toxin tracking (SPATT), a passive sampling tool which simulates the contamination of filter-feeding bivalves, has been used recently in the field to detect the presence of algal toxins with greater accuracy than grab-sampling methods ([Gibble and Kudela, 2014](#); [Kudela, 2011](#); [Lane et al., 2010](#)). Remote sensing systems are increasingly being used to forecast and monitor HABs in coastal waters ([Klemas, 2012](#)).

Harmful effects of HAB toxins on fish and wildlife are readily transferred through the food web and may persist even when the bloom conditions have passed. Microcystin, a class of toxins produced by many cyanoHABs is found in all trophic levels from shellfish to finfish to top level predators and can persist in the food web for months ([Preece et al., 2017](#)). [Wood et al. \(2014\)](#) found that microcystin persisted in overwintering populations of estuarine finfish, common wedge clam (*Rangia cuneata*), and blue crab (*Callinectes sapidus*) in the James River estuary, VA although the highest tissue concentrations and greatest percentage of individuals affected were observed when toxins in the water column were at maximum levels. The toxin was present in both muscle and viscera of

blue crabs at concentrations that have been shown to have physiological effects on other species of estuarine crab ([Wood et al., 2014](#)). Accumulation of microcystin measured over the course of 2 years in the James River estuary, near Chesapeake Bay, was found to be highest in suspension feeding animals while top predators (piscivores), scavengers, and benthic feeders all had lower levels of microcystin ([Bukaveckas et al., 2017](#)). In Monterey Bay, CA, deaths of 21 sea otters (*Enhydra lutris*), a federally listed threatened species, were attributed to hepatotoxic shellfish poisoning due to trophic transfer of microcystin observed in this study to have originated from nutrient-impaired lakes and rivers discharging to the bay ([Miller et al., 2010](#)). Other HAB toxins, such as domoic acid, are also known to be transferred up the food web ([Trainer et al., 2012](#)). Domoic acid from recent blooms of the diatom *Pseudo-nitzschia* along the U.S. West Coast has impacted razor clam (*Siliqua patula*) and Dungeness crab (*Metacarcinus magister*) fisheries, led to symptoms of domoic acid poisoning in California sea lions (*Zalophus californianus*), and was detected in additional marine mammals from southern California to northern Washington ([McCabe et al., 2016](#)).

Research on HAB-forming species have shown that the form of N supplied affects phytoplankton growth ([Glibert et al., 2016](#)). Generally,  $\text{NH}_4^+$  is considered to be the preferred form of N for some phytoplankton due to lower energy requirements for uptake and assimilation; however, diatoms specialize in use of oxidized N forms ([Glibert et al., 2016](#)). For example, the HAB-forming dinoflagellate species *Heterosigma akashiwo* is able to grow well with a pulsed supply of  $\text{NH}_4^+$ ,  $\text{NO}_3^-$ , and urea under low light conditions and assimilate stores of N nutrients, suggesting that this species could outcompete diatoms in silicate-limited, N enriched coastal areas ([Kok et al., 2015](#)). In *Pseudo-nitzschia* spp., laboratory experiments showed that both of the species studied were able to grow on  $\text{NH}_4^+$ ,  $\text{NO}_3^-$ , and urea, although urea was the preferred form of N ([Melliti Ben Garali et al., 2016](#)). These findings were supported by a field experiment in which chlorophyll *a* concentration significantly increased and exponential growth occurred in all N-enriched in situ microcosms until the end of the experiment, with specific growth rates highest in the urea and  $\text{NO}_3^-$  additions. The dinoflagellate *Akashiwo sanguinea* showed different growth profiles and N assimilation with form of N and concentration, growing faster in  $\text{NH}_4^+$  and with greater enzyme affinity for urea ([Liu et al., 2015](#)). Differential growth responses of HAB species to reduced N can alter phytoplankton community composition and biodiversity ([Appendix 10.3.3](#)).

There is also evidence, mostly from freshwater systems, that the form of N affects toxin production of some HAB species ([Appendix 9.2.6.1](#)). In nutrient amendment experiments with water collected from the tidally influenced Transquaking River, which flows into Chesapeake Bay, *Microcystis* was stimulated by N more frequently than P, and abundances of toxic and nontoxic strains were enhanced to different degrees by inorganic

and organic N ([Davis et al., 2010](#)). Response of *Alexandrium fundyense* to nutrient addition varied throughout the course of bloom events in Northport-Huntington Bay, NY ([Hattenrath et al., 2010](#)). Addition of  $\text{NH}_4^+$  to bloom water most frequently resulted in statistically significant increases of *A. fundyense* density and toxin concentration compared to other forms of N (glutamine,  $\text{NO}_3^-$ , and/or urea). [Davidson et al. \(2012\)](#) found that, in general, laboratory studies show that toxin production can be influenced by nutrient ratios, but extrapolation of those results to the specific species and conditions in the field is difficult.

Modeling studies have reported on potentially altered future scenarios of phytoplankton community changes and HAB formation, intensity, duration, and toxicity due to changes in N deposition ([Lee and Yoo, 2016](#); [Glibert et al., 2010b](#)). [Pinder et al. \(2008\)](#) reported on modeled scenarios that predict alterations in the frequency, intensity, toxicity, and species composition of algal blooms due to higher rates of N deposition and changes in the reduced N to oxidized N ratio. Future changes in HAB dynamics will be affected by climate change ([Appendix 10.1.4.1](#)) and increased N loading, and integrated ecosystem models that couple the atmosphere, land, and coastal ocean are needed to estimate these HAB responses ([Glibert et al., 2010a](#)). Long-term monitoring (1987–2005) of phytoplankton populations in the Bay of Fundy in southwestern New Brunswick, Canada did not link HABs to nutrients, rather many species abundances are explained by climate and weather patterns ([Martin et al., 2009](#)). For *A. fundyense* there was a negative relationship with cell density and  $\text{NO}_3^-$ .

[Table 10-3](#) summarizes new studies from U.S. waters on levels and forms of N at which effects are manifested in phytoplankton.

**Table 10-3 Levels and forms of nitrogen at which effects on phytoplankton are manifest in U.S. coastal waters evaluated in the literature since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur—Ecological Criteria.**

Study Site	Ambient N Deposition	N Additions	Ecological/Biological Effects	Species	Reference
Northport-Huntington Bay complex, NY		Addition of NH <sub>4</sub> <sup>+</sup> (10 μM–40 μM)	Addition of NH <sub>4</sub> <sup>+</sup> significantly increased <i>A. fundyense</i> densities compared to the control. The addition of NH <sub>4</sub> <sup>+</sup> (40 μM) yielded a significant increase in both <i>A. fundyense</i> densities and toxin concentrations four and 8×, respectively, compared to controls.	Phytoplankton ( <i>Alexandrium fundyense</i> )	<a href="#">Hattenrath et al. (2010)</a>
Raritan Bay, NJ		Ambient levels	Multivariate analyses of a 3-yr data set indicated that the abundance of HAB species <i>Heterosigma akashiwo</i> is positively associated with NO <sub>3</sub> <sup>-</sup> in Raritan Bay. Both climatic conditions and nutrient concentrations affect phytoplankton bloom composition in the bay.	Phytoplankton ( <i>Heterosigma akashiwo</i> and 13 other HABs identified)	<a href="#">Rothenberger et al. (2014)</a>
Raritan Bay, NJ		Nutrients (N and Fe) added alone or in combination to different treatments. N was added as a single pulse sodium nitrate (NaNO <sub>3</sub> ) to increase NO <sub>3</sub> <sup>-</sup> concentrations by approximately 10 μM. The N additions lowered the Si:N ratios from ~3 to <1	Dinoflagellates and HAB-forming taxa increased to a greater extent when NO <sub>3</sub> <sup>-</sup> levels were high (which led to a low Si:N ratio of less than one). Centric and chain-forming diatoms resulted from enriched NO <sub>3</sub> <sup>-</sup> concentrations, differing from the pennate diatoms and green flagellates that accompanied ambient NO <sub>3</sub> <sup>-</sup> concentrations. Dinoflagellates in the genus <i>Dinophysis</i> , which could be HAB-forming, also resulted from enriched NO <sub>3</sub> <sup>-</sup> and lowered Si:N.	Phytoplankton Dinoflagellates, diatoms	<a href="#">Rothenberger and Calomeni (2016)</a>

**Table 10-3 (Continued): Levels and forms of nitrogen at which effects on phytoplankton are manifest in U.S. coastal waters evaluated in the literature since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur—Ecological Criteria.**

Study Site	Ambient N Deposition	N Additions	Ecological/Biological Effects	Species	Reference
Ocean surface from 28°N to 44°N and from the East Coast of the U.S. to 60–70°W	Based on direct measurements of wet deposition along the East Coast of the U.S., the N supply through wet deposition was estimated to be 25–45 mmol N/m <sup>2</sup> /yr		Precipitation events in coastal waters of the eastern U.S. increased the chlorophyll <i>a</i> concentration up to 15% in low-nutrient areas (<1 μM NO <sub>3</sub> <sup>-</sup> ) but decreased the chlorophyll <i>a</i> concentration in nutrient-replete areas (>1 μM NO <sub>3</sub> <sup>-</sup> ). The authors suggested that in nutrient-depleted areas (south of 36°N), the added nutrients were a dominant factor increasing the chlorophyll <i>a</i> concentration, whereas in the nutrient-replete areas (north of 36°N), where phytoplankton growth was light limited, reduced light availability was the dominant factor determining reduced chlorophyll <i>a</i> concentration.	Phytoplankton	<a href="#">Kim et al. (2014b)</a>
Mattawoman Creek, Chesapeake Bay	Used atmospheric deposition data from <a href="#">Boynton et al. (2008)</a> , including N from both wet and dry deposition (0.81 mg N/L as an annual average concentration). Direct atmospheric deposition to surface waters of the creek contributed about 6,000 kg N/yr or about 16 kg N/day to the creek system.		Strong relationships were found between N loading and algal biomass and between algal biomass and water clarity. Winter–spring N loading and summer chlorophyll <i>a</i> were found to be highly correlated, a relationship which appears to be linear.	Phytoplankton and SAV	<a href="#">Boynton et al. (2014)</a>

**Table 10-3 (Continued): Levels and forms of nitrogen at which effects on phytoplankton are manifest in U.S. coastal waters evaluated in the literature since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur—Ecological Criteria.**

Study Site	Ambient N Deposition	N Additions	Ecological/Biological Effects	Species	Reference
Tidally influenced Transquaking River which flows into Chesapeake Bay		20 µM (NO <sub>3</sub> <sup>-</sup> ), 20 µM NH <sub>4</sub> <sup>+</sup> (NH <sub>4</sub> <sup>+</sup> ), 10 µM (= 20 µM N) urea, 10 µM (= 20 µM N), L-glutamine (GA), P (1.25 µM orthophosphate), or a combined treatment of NO <sub>3</sub> <sup>-</sup> and P	<i>Microcystis</i> was simulated by N more frequently than P, and abundances of toxic and nontoxic strains were enhanced to different degrees by inorganic N and organic N. Toxic <i>Microcystis</i> abundance increased more with inorganic N than organic N.	Toxic and nontoxic strains of <i>Microcystis</i>	<a href="#">Davis et al. (2010)</a>
Maryland and Virginia coastal bays	Measurements of atmospheric deposition since 2000, based on the NADP, suggest that NO <sub>3</sub> <sup>-</sup> is decreasing and NH <sub>4</sub> <sup>+</sup> from deposition is stable for the coastal bays.		N in the water column is dominated by reduced N (primarily NH <sub>4</sub> <sup>+</sup> ) with low concentrations of NO <sub>3</sub> <sup>-</sup> also present, resulting in phytoplankton community shifts to those species that can do well under such conditions. Submerged aquatic vegetation has decreased.	Phytoplankton and SAV	<a href="#">Glibert et al. (2014)</a>
Alligator River estuary, NC	Potential for atmospheric deposition of N from nearby farm (wet NH <sub>4</sub> <sup>+</sup> concentrations increased greatly close to farm).	DIN additions: 140 µg N-NH <sub>4</sub> <sup>+</sup> /L, 140 µg N-NO <sub>3</sub> <sup>-</sup> /L, and 70 µg N-NH <sub>4</sub> <sup>+</sup> /L plus 70 µg N-NO <sub>3</sub> <sup>-</sup> /L	Significant increase in phytoplankton biomass (chl <i>a</i> ) and rates of primary productivity due to N enrichment. DIN treatments alone significantly stimulated chl <i>a</i> in two out of five tests for all three DIN addition treatments, although DIN + DIP treatments provided the largest increase in chl <i>a</i> .	Phytoplankton	<a href="#">Rossignol et al. (2011)</a>
Neuse River estuary, NC		Ambient, acute DIN inputs via runoff from hydrologic pulses (hurricanes, tropical storms, heavy rainfall events)	Study noted increase in phytoplankton bloom frequency and magnitude (indicated by increasing chl <i>a</i> variability) over time in response to acute DIN inputs from hydrologic pulses. Control of algal bloom duration, thresholds, taxonomic composition, and spatial extent may be dictated by climatic changes and oscillations instead of nutrient inputs.	Phytoplankton	<a href="#">Paerl et al. (2010)</a>

**Table 10-3 (Continued): Levels and forms of nitrogen at which effects on phytoplankton are manifest in U.S. coastal waters evaluated in the literature since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur—Ecological Criteria.**

Study Site	Ambient N Deposition	N Additions	Ecological/Biological Effects	Species	Reference
New River estuary, NC		N addition to estuary water in the form of DIN, organic N from river water (with dissolved inorganic P) or urea	Varying the form of nutrients promoted growth of different phytoplankton groups based on photopigment analysis. Dinoflagellates, chlorophytes, and cyanobacteria responded to dissolved organic N while cyanobacteria increases were most frequent with inorganic N addition.	Phytoplankton	<a href="#">Altman and Paerl (2012)</a>
Four sites with tidal influence, South Carolina coast		NH <sub>4</sub> <sup>+</sup> , NO <sub>3</sub> <sup>-</sup> , and urea treatments applied separately to bioassays. N forms were added at Redfield ratios (N:P = 16:1)	Along a gradient from highly developed to undeveloped sites, phytoplankton communities at the more developed sites had higher biomass and growth rate with N (particularly urea) additions and potentially HAB forming species were more often found at the more developed sites.	Phytoplankton	<a href="#">Reed et al. (2016)</a>
Ten Mile Creek, Indian River Lagoon, FL		High median concentrations of total N (0.988 mg/L), NO <sub>3</sub> <sup>-</sup> -N (0.104 mg/L), NH <sub>4</sub> <sup>+</sup> -N (0.103 mg/L), and total Kjeldahl N (0.829 mg/L)	Chl a was negatively correlated with N concentrations and the highest chl a concentrations were related to the conditions of static and open water with long residence time. Hydrodynamics of a system may play an overriding role in controlling phytoplankton growth.	Phytoplankton	<a href="#">Yang et al. (2008)</a>
San Francisco Bay/estuary		NO <sub>3</sub> <sup>-</sup> and NH <sub>4</sub> <sup>+</sup> measured from two source estuaries	A comparison of N isotopes in cells of the HAB species <i>Microcystis aeruginosa</i> with N in rivers flowing into the bay suggested that NH <sub>4</sub> <sup>+</sup> , not NO <sub>3</sub> <sup>-</sup> was likely the primary source of N that supported the bloom.	Phytoplankton (cyanobacteria <i>Microcystis aeruginosa</i> )	<a href="#">Lehman et al. (2015)</a>

**Table 10-3 (Continued): Levels and forms of nitrogen at which effects on phytoplankton are manifest in U.S. coastal waters evaluated in the literature since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur—Ecological Criteria.**

Study Site	Ambient N Deposition	N Additions	Ecological/Biological Effects	Species	Reference
San Francisco Bay/estuary		Ambient nitrate ranged from 0.19 to 0.36 mg/L. Ambient ammonia ranged 0.02 to 0.06 mg/L.	The greatest chl <i>a</i> concentration and cell density occurred in the San Joaquin River estuary which had a high average nitrate concentration (0.36 mg/L). The second highest chl <i>a</i> concentration and cell density occurred in the Old River estuary which had relatively low N concentration (mean 0.19 mg/L). Differences in chl <i>a</i> were correlated with environmental conditions, particularly streamflow and water temperature and secondarily to nutrient concentrations and ratios.	Phytoplankton (cyanobacteria <i>Microcystis aeruginosa</i> )	<a href="#">Lehman et al. (2008)</a>

### 10.2.3 Macroalgal Abundance

The abundance of macroalgae, which are generally referred to collectively as “seaweed,” was an indicator of eutrophic condition in the 2008 ISA ([U.S. EPA, 2008a](#)). Macroalgae have been combined with other indicators to classify estuarine condition ([Borja et al., 2012](#)). For example, NEEA includes an assessment of macroalgae ([Bricker et al., 2007](#)). Macroalgal blooms can contribute to loss of important SAV by blocking the penetration of sunlight into the water column. Although macroalgal data for estuaries in the U.S. were generally sparse, the NEEA reported high macroalgal expression in 15 of the 64 estuaries evaluated ([Bricker et al., 2007](#)). In some lagoons with limited oceanic exchange, macroalgae may be a more sensitive biological indicator than phytoplankton [e.g., [Nobre et al. \(2005\)](#); [McLaughlin et al. \(2014\)](#)]. For example, in most estuaries of the Southern California Bight, macroalgae is the dominant primary producer and a key indicator of eutrophication ([McLaughlin et al., 2014](#)). Macroalgae may not be a good indicator of eutrophication in some upwelling-influenced estuaries in the Pacific Northwest because an increase in macroalgal biomass in these systems does not appear to be associated with temporal declines in eelgrass ([Hessing-Lewis et al., 2015](#); [Hessing-Lewis and Hacker, 2013](#); [Hessing-Lewis et al., 2011](#)).

Opportunistic, fast-growing macroalgae can exhibit very high rates of N uptake during periods of high N availability and can often outcompete or block out light for other macrophytes when N loads are high and variable ([Abreu et al., 2011](#)). This growth of macroalgae can also smother corals, clams, oysters, and other biota ([Bricker et al., 2007](#)) and contribute to declines in seagrasses ([Olyarnik and Stachowicz, 2012](#)). These macroalgae also tend to preferentially uptake N in the form of  $\text{NH}_4^+$ . In a Danish study, sea lettuce (*Ulva lactuca*), which is a common species of macroalgae in U.S. coastal waters, grew faster and exhibited greater biomass when subjected to  $\text{NH}_4^+$  as the N source compared to  $\text{NO}_3^-$  ([Ale et al., 2011](#)). This difference was thought to be due to reduced N being more easily assimilated and used by algae. Similarly, in experimental manipulations with *Gracilaria tenuistipitata*, an opportunistic macroalgal species from China, when both  $\text{NH}_4^+$  and  $\text{NO}_3^-$  were available,  $\text{NH}_4^+$  was assimilated more rapidly and algal biomass was higher than with  $\text{NO}_3^-$  addition alone ([Wang et al., 2014a](#)). Growth of *Caulerpa cylindracea*, an invasive macroalga in the Mediterranean Sea, was not inhibited by high  $\text{NH}_3$ , and was able to outcompete native macroalgae in experimental plots with nutrient addition ([Gennaro et al., 2015](#)).

Southern California estuaries, some of the most nutrient enriched in the world, have not been well studied in the past, but recent work is providing important information about macroalgal growth in response to N loading to these systems. Opportunistic macroalgae

(*Ulva intestinalis* and *Ulva expansa*) were shown to take up  $\text{NO}_3^-$  from the water very efficiently at many concentration levels, giving these species the ability to outcompete other algae in estuaries subject to varying nutrient loads ([Kennison et al., 2011](#)). Algae that were depleted in N took up  $\text{NO}_3^-$  at higher rates than enriched algae, and uptake rates slowed as the algae became saturated with N.

However, macroalgal abundance was not found to be directly related to water or sediment N concentrations in Southern California estuaries ([Kennison and Fong, 2014](#)). Rather, macroalgal blooms occurred throughout the year and appeared to be influenced by the unique physical and hydrological differences between estuaries. For instance, in one estuary with high nutrient levels in both water and sediment, little to no macroalgal biomass was present, possibly due to high water velocities that prevented young algal filaments from attaching ([Kennison and Fong, 2014](#)). In other estuaries, comparatively high algal biomass was found year-round even when nutrient supplies were lower than other sites (although still N enriched), perhaps due to low rates of tidal flushing and longer water residence times. Internal nutrient processing, variable hydrological regimes, and multiple external nutrient sources may all contribute to eutrophic conditions ([Kennison and Fong, 2014](#)).

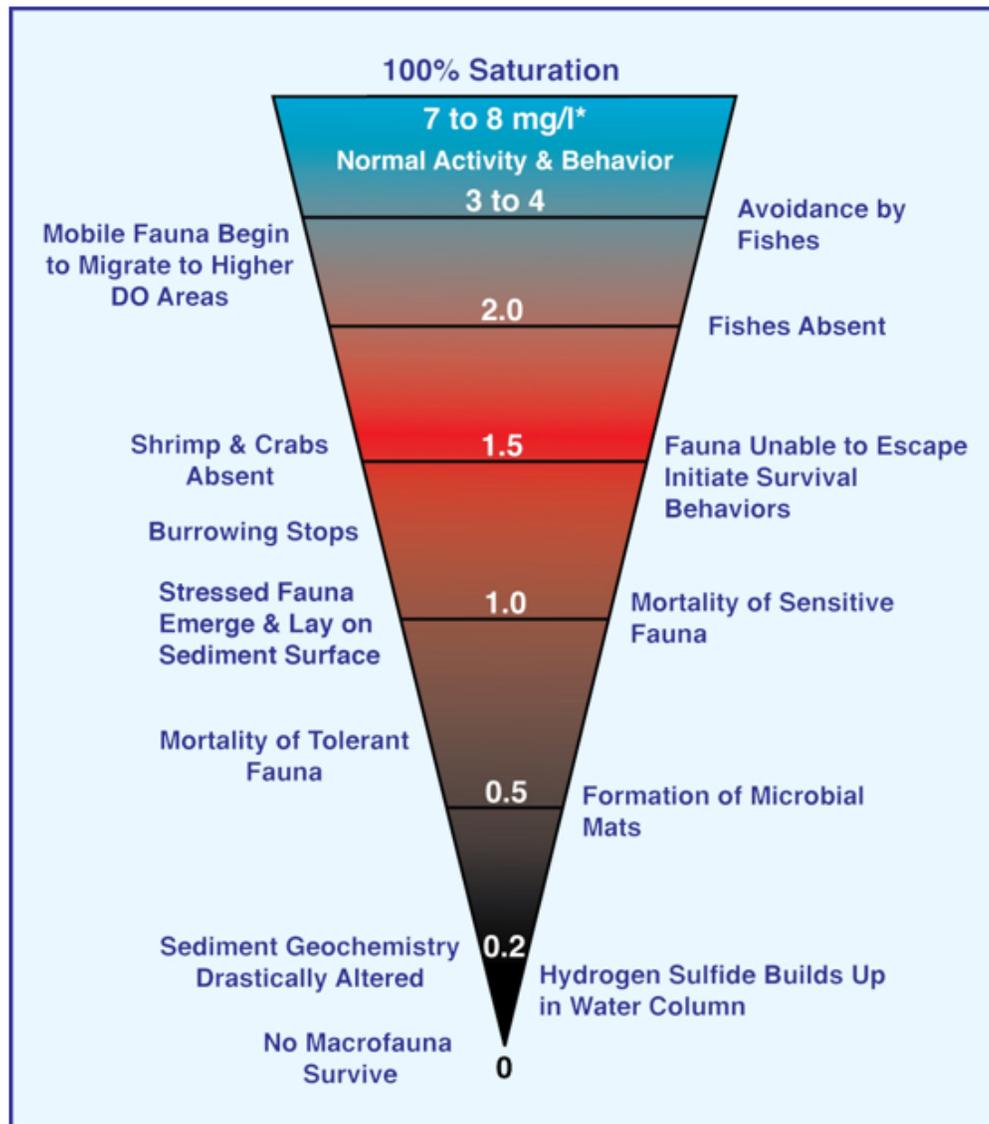

---

## 10.2.4 Dissolved Oxygen

DO was included in the 2008 ISA, the NCCA, and the NEEA as an indicator of eutrophic condition ([U.S. EPA, 2008a](#)). Additional information on DO is provided in [Appendix 7.2.3](#). Oxygen depletion largely occurs only in bottom waters under stratified conditions, not throughout the entire water column. The decomposition of organic matter associated with increased algal abundance consumes DO and can reduce DO concentrations in eutrophic waters to levels that cannot support aquatic life ([Jewett et al., 2010](#)). Respiration of microbes, macrophytes, and animal biota can also reduce DO to very low levels such as primary producers in the dark, deeper portions of the well-mixed Hudson River estuary ([Howarth et al., 1996b](#)) and as seen every night in a eutrophic seagrass-dominated system on Cape Cod ([Howarth et al., 2014](#)). In the Cape Cod seagrass system, hypoxia is common at dawn, following hours of darkness, yet oxygen levels are supersaturated at the end of the daylight period.

Generally, some biota are impacted at DO levels from 3 to 4 mg/L, and increasingly adverse effects are observed on biota at lower DO concentrations ([Figure 10-4](#)). Decreased DO can lead to the development of hypoxic or anoxic zones that are inhospitable to fish and other life forms and can impact ecosystem processes ([Diaz et al., 2013](#); [Levin et al., 2009](#); [Diaz and Rosenberg, 2008](#)). For example, in Chesapeake Bay,

[Sturdivant et al. \(2014\)](#) observed that macrobenthic production was 90% lower during hypoxic conditions, resulting in a biomass loss similar to 7,320–13,200 metric tons C over an area of 7,720 km<sup>2</sup>. The authors estimated this change represented a displacement of 20 to 35% of macrobenthic activity during the summer.

DO = dissolved oxygen; l = liter; mg = milligrams.

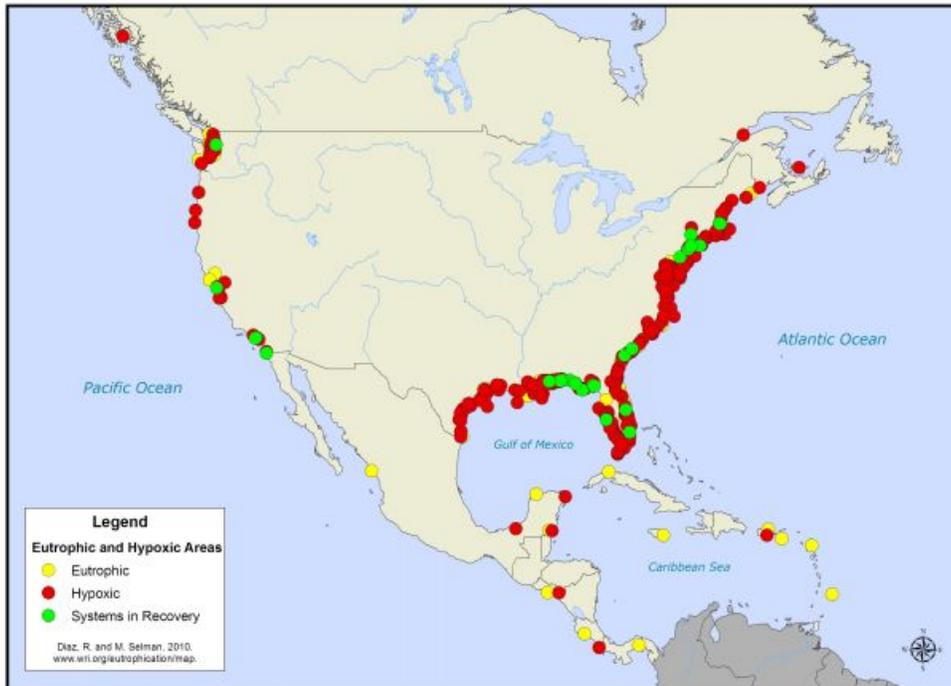

Source: [Diaz et al. \(2013\)](#).

**Figure 10-4** The range of ecological impacts exhibited as dissolved oxygen levels drop from saturation to anoxia.

In the U.S., the incidence of hypoxia has increased almost 30-fold from 1960 to 2008 and is now reported in more than 300 systems ([Jewett et al., 2010](#)). Climate change and increasing N loading to coastal ecosystems are both expected to widen the distribution and increase the size of areas affected by eutrophication-induced hypoxia, while also increasing the frequency and persistence of these events [[Rabalais et al. \(2010\)](#); [Appendix 13](#)]. Areas of eutrophication-related hypoxia are found on the U.S. East and West coasts and the Gulf of Mexico ([Figure 10-5](#)). Eutrophication-induced hypoxia, which has been documented globally, can be characterized by both the duration of the event and the ecosystem response ([Diaz et al., 2013](#); [Diaz and Rosenberg, 2008](#)). Summer hypoxia is most common, followed by periodic oxygen (O<sub>2</sub>) depletion that may occur in some systems more often than seasonally. In these hypoxic and anoxic areas (“dead zones”) only organisms that can live with little or no O<sub>2</sub> are present ([Diaz et al., 2013](#); [Jewett et al., 2010](#)). Once an ecosystem reaches severe seasonal hypoxia, there is a shift to benthic organisms with shorter life spans and smaller body size ([Diaz and Rosenberg, 2008](#)).

[Zhou et al. \(2014b\)](#) estimated the hypoxic volume of Chesapeake Bay over a 25-year period. The date of onset of hypoxia occurs earlier in the summer and the end of hypoxia also shifted to earlier in the fall with no trend in the seasonal-maximum hypoxia itself from 1985 to 2010. Nutrient loading from the Rappahannock, Susquehanna, and Potomac Rivers explains >85% of the seasonally averaged interannual variability in hypoxic volumes. [Testa and Kemp \(2012\)](#) investigated interactions between hypoxia and nutrient cycling in Chesapeake Bay, based on analysis of long-term monitoring data collected during two time periods: 1965 to 1980 and 1985 to 2007. They found that bottom water in the upper bay region, where seasonal hypoxia first develops, was enriched in NH<sub>4</sub><sup>+</sup> and PO<sub>4</sub><sup>3-</sup> relative to other regions of the bay. This might help explain the occurrence of extensive and persistent hypoxia during the month of June even during years of lower N loading.

## Eutrophic and Hypoxic Coastal Areas of North America and the Caribbean

Source: <http://www.wri.org/resources/maps/coastal-eutrophic-and-hypoxic-areas-north-america-and-caribbean> modified from [Diaz et al. \(2013\)](#).

**Figure 10-5 Coastal eutrophic and hypoxic areas of North America and the Caribbean.**

Recent research has shown that the duration of a hypoxic event is one of the most important factors affecting macroinvertebrate density and species composition. [Baustian and Rabalais \(2009\)](#) found that hypoxia duration (the number of days during which O<sub>2</sub> concentrations were below 1 mg/L) was highly correlated with both reduced species density and diversity in the northern Gulf of Mexico. Very low O<sub>2</sub> levels can be lethal to fish with no means of escape, and it has been suggested that even sublethal hypoxia may lower the breeding rate and affect fish populations ([Moran et al., 2010](#)). Hypoxia has been shown to act as an endocrine disruptor in Atlantic croaker (*Micropogonias undulatus*) in laboratory studies and biomarkers of reproductive function and endocrine disruption are observed in field-collected individuals ([Murphy et al., 2009](#); [Thomas and Rahman, 2009](#); [Thomas et al., 2007](#)). Hypoxic conditions increase nitric oxide and super oxide radicals in brain tissue in croakers, causing cellular oxidative damage and inhibited protein expression in the hypothalamus and leading to neuroendocrine effects ([Rahman and Thomas, 2015](#)). Low O<sub>2</sub> conditions have also been shown to alter animal behavior ([Appendix 10.4.1](#)). O<sub>2</sub> content influences hatching rate and parental effort among other

reproductive behaviors in three-spined sticklebacks (*Gasterosteus aculeatus*), so eutrophication-induced hypoxia may alter reproductive output in some fish populations (Candolin, 2009). However, hypoxia does not appear to negatively affect fisheries below what would be predicted from N loadings alone, except under circumstances in which raw sewage is released or when critical habitat is lost for very sensitive species (Breitburg et al., 2009). In a review of long-term chronic effects of hypoxia on commercially important fishery species Townhill et al. (2017) noted that effects range from positive to negative, and from physiological to ecosystem-level. Some fish can acclimate to hypoxic conditions and/or take advantage of more susceptible prey, affecting food web dynamics. Other species cannot avoid hypoxia (especially shellfish) and suffer physiological stress, mortality, and/or increased predation. Other species have been shown to move away from the area to avoid stress (Appendix 10.4.1), which also has cascading food web implications.

The effects of low DO are influenced by the presence of multiple stressors. For example, Gobler et al. (2014) examined concurrent effects of low DO and acidification on the early lifestages of bay scallops (*Argopecten irradians*) and hard clams (*Mercenaria mercenaria*). Observations in later lifestages of the clams indicated that growth rates decreased by 40% in combined exposures to hypoxia and acidification. Additional studies with earlier lifestages indicated effects were more severe with costressors than with either hypoxia or acidification alone. Juvenile oysters (*Crassostrea virginica*) grown under varying conditions of low pH and duration of hypoxia seemed to acclimate and were only negatively affected by the most severe pH experiment (Keppel et al., 2016). Growth rates were reduced 30–37% initially by both brief, repeated hypoxia and long moderate hypoxia events; however, at the end of the study most oysters were the same size regardless of treatment. This study also reported that the initial effects on oyster growth were more pronounced by constant moderate hypoxia (1.3 mg/L) than they were by severe but cyclical hypoxia (0.5 mg/L).

At the time of the last review, it was documented that the largest zone of hypoxic coastal water in the U.S., and the second largest in the world, was the northern Gulf of Mexico Hypoxic Zone on the Louisiana-Texas continental shelf (Dale et al., 2010; Jewett et al., 2010; U.S. EPA, 2008a). Since the 2008 ISA, observations continue to indicate a large zone of hypoxia in the northern Gulf of Mexico during the summer months associated with increased N loading from the Mississippi and Atchafalaya River Basins. The size of the midsummer bottom-water hypoxia area (<2 mg/L DO) in the northern Gulf of Mexico has varied considerably since 1985, with a long-term average of 13,751 km<sup>2</sup> [5,240 mi<sup>2</sup>; U.S. EPA (2015c)]. In the summer of 2017, the hypoxic zone in the Gulf was the largest ever measured at 14,123 km<sup>2</sup> [8,776 mi<sup>2</sup>; U.S. EPA (2017f)]. Alexander et al. (2008) used the SPARROW water quality model to show that atmospheric deposition to watersheds in

the Mississippi River Basin is the second largest source of N (16%) to the Gulf, after effluents from corn and soybean production (52%).

The Hypoxia Task Force (Mississippi River/Gulf of Mexico Watershed Nutrient Task Force) is a federal/state partnership (five federal agencies, the National Tribal Water Council and 12 states bordering the Mississippi and Ohio rivers) established in 1997 with the goal of reducing nutrient inputs and the size of the hypoxic zone in the Gulf of Mexico ([U.S. EPA, 2017e](#), [2015c](#)). The task force is working toward the goal of reducing the areal extent of the Gulf of Mexico hypoxic zone to less than 5,000 km<sup>2</sup> by 2035, with an interim target of 20% nutrient load reduction by 2025. This was revised from the 2001 action plan that called for the described reductions by 2015 ([U.S. EPA, 2001](#)). Each state in the task force has a nutrient reduction plan, and progress toward stated goals are reported in the Mississippi River/Gulf of Mexico Watershed Nutrient Task Force Report to Congress ([U.S. EPA, 2015c](#)) as required by the *Harmful Algal Bloom and Hypoxia Research and Control Amendments Act of 2014* ([HABHRC Act, 2014](#)). Other states not included in the Mississippi River/Gulf of Mexico Watershed Nutrient Task Force have nutrient reduction programs in place.

Hypoxic conditions are reported from other U.S. locations ([Figure 10-5](#)). For example, in the shallow estuary of Long Island Sound, atmospheric deposition is considered to comprise a significant fraction of total N loading [19%; [Whitall et al. \(2004\)](#)], and DO levels below 3 mg/L are common, with levels below 2 mg/L known to occur. During some years, portions of the Long Island Sound bottom waters become anoxic [DO <1 mg/L; [Latimer et al. \(2014\)](#)]. The maximum extent and duration of hypoxic events (<2 mg/L DO) in Long Island Sound has varied considerably since the 1980s ([U.S. EPA, 2016k](#)). Between 1987 and 2014, the average annual maximum extent was 98 km<sup>2</sup> (61 mi<sup>2</sup>). In 2014, the hypoxic area was 32 km<sup>2</sup> (20 mi<sup>2</sup>), with the lowest DO levels occurring in the western end of the Sound. The shortest hypoxic event occurred in 2014, lasting 2 days. The longest hypoxic event was 71 days in 1989. Over the full period of record (1987–2014), the average annual maximum duration was 31 days. Other estuaries identified in the 2008 ISA where hypoxic conditions occur included Chesapeake Bay and the Pamlico Estuary in North Carolina ([U.S. EPA, 2008a](#)). [Murphy et al. \(2011\)](#) analyzed a 60-year record of Chesapeake Bay hypoxic zone volumes and found a slight but significant decreasing trend in late summer hypoxia, which aligns with the decrease in N loading due to management controls. This analysis also showed a correlation between N loading and the duration of summer hypoxia events ([Murphy et al., 2011](#)). In a modeling study in Chesapeake Bay using analysis of monitoring data, nutrient loading was identified as the main mechanism driving interannual hypoxia variability ([Li et al., 2016b](#)). In upwelling regions such as along the West Coast, hypoxic events driven by

upwelling can be advected into estuaries from global ocean circulation rather than anthropogenic nutrient additions ([Brown and Power, 2011](#); [Brown and Ozretich, 2009](#)).

---

### 10.2.5 Submerged Aquatic Vegetation

SAV, rooted vascular plants that grow to the surface but do not emerge from the water, is important to the quality of coastal ecosystems because it provides habitat for a variety of aquatic organisms, serves as nursery grounds for estuarine invertebrates and fish, absorbs excess nutrients, and traps sediments ([Lefcheck et al.](#); [U.S. EPA, 2008a](#); [Handley et al., 2007](#)). Recently, the presence of seagrass beds was linked to decreased bacterial pathogens of humans, fishes, and invertebrates in the water column and a lower incidence of disease in adjacent coral reefs ([Lamb et al., 2017](#)). The loss of SAV can, therefore, have a cascade of effects on other ecosystem characteristics and ecosystem services. Water clarity is important for photosynthesis of SAV ([Handley et al., 2007](#)). Water quality changes associated with excess N nutrient inputs, such as excessive algal growth and hypoxia can impact SAV extent. For example, declines of Johnson's sea grass (*Halophila johnsonii*) which is currently listed as threatened under the U.S. Endangered Species Act has been linked to eutrophication of coastal waters, specifically low DO and algal blooms that alter habitat by covering up substrate ([Hernández et al., 2016](#)). Elevated levels of N tend to increase epiphytes on the surface of SAV, in the absence of other limiting factors, contributing to declines in seagrass biomass, shoot density, percentage cover, production, and growth ([G.Nelson, 2017](#); [Nelson, 2017](#)).

Seagrass loss is occurring globally with nutrient enrichment as a major driving factor contributing to declines in SAV coverage ([Latimer and Rego, 2010](#); [Waycott et al., 2009](#)). SAV is included as a biological indicator for estuarine condition for U.S. coastal waters in ASSETS-ECI in the NEEA and in U.S. EPA's *Report on the Environment* ([U.S. EPA, 2016k](#); [Bricker et al., 2007](#)). At the time of the 2008 ISA, estimates of historical losses of SAV and declines in habitat were available for some coastal regions of the U.S.; although, there were few data documenting the long-term response of SAV to N loading. In Waquoit Bay, MA, [Valiela et al. \(1992\)](#) reported a strong negative relationship between modeled N loading and measured eelgrass (*Zostera marina*) area based on measurements of eelgrass coverage from 1951 to 1990. In the NEEA report, only a small fraction of the estuary systems evaluated reported high severity of SAV loss from the 1990s to 2004 ([Bricker et al., 2007](#)), in part, because historical losses wiped out seagrasses in many estuaries, and recent changes do not seem of high severity.

Since the 2008 ISA, additional studies are available on the relationship between N loading and SAV abundance, including the development of thresholds of response to N

loading in seagrasses ([Table 10-4](#)). Seagrass dieback in Snug Harbor Cape Cod, MA in 2010 was linked to N loading, which stimulated growth of epiphytes on the seagrasses ([Howarth et al., 2014](#)). [Orth et al. \(2010\)](#) observed a consistent negative correlation between SAV abundance and N loading based on water quality data in Chesapeake Bay from 1984–2006. In the Potomac River, a major tributary to Chesapeake Bay, a reduction in total N from point and nonpoint sources was significantly correlated to increased SAV abundance and diversity using field data from 1990 to 2007 ([Ruhl and Rybicki, 2010](#)). Similarly, the reduction of N and P input from point sources into Mattawoman Creek, a tributary to Chesapeake Bay, led to large increases in SAV coverage and density ([Boynton et al., 2014](#)). [Benson et al. \(2013\)](#) identified a tidal-averaged total N concentration of <0.34 mg/L as a threshold for healthy eelgrass in a survey of 19 Massachusetts estuaries. Eelgrass coverage decreases markedly in shallow estuaries in New England with N loading rates  $\geq 100$  kg N/ha/yr (based on nitrogen loading model [NLM] estimates from wastewater, fertilizer, and atmospheric deposition inputs). Loading rates above 50 kg/ha/yr are likely to impact habitat extent ([Latimer and Rego, 2010](#)). These ranges were found to be comparable to loading thresholds identified in other East Coast estuaries ([Table 10-4](#)). In a modeling study using NLM applied to small- to medium-sized estuaries of southern New England, direct atmospheric deposition to the water surface made up an average of 37% of the N input, while indirect deposition via the watershed averaged 16% of N loading. The percentage, however, varied widely for individual estuaries ([Latimer and Charpentier, 2010](#)).

**Table 10-4 Nitrogen loading thresholds from multiple watershed sources versus eelgrass loss.**

Loading Threshold (kg/ha/yr)		Description			
>20		• Areal cover of eelgrass sharply reduced			
100		• Meadows disappeared [Cape Cod estuaries, n = 10; <a href="#">Bowen et al. (2007)</a> ]			
~30		• Substantial eelgrass loss (80–96% of bed area)			
≥60		• Total disappearance [Cape Cod estuaries, n = 7; <a href="#">Hauxwell et al. (2003)</a> ]			
≥64 <sup>a</sup>		• Threshold based on nonparametric change-point analysis [95% probability of change; Chesapeake Bay estuaries, n = 101; <a href="#">Li et al. (2007)</a> ]			
≥52		• Threshold based on nonparametric change-point analysis [95% probability of change; New England estuaries, n = 57; <a href="#">Latimer and Rego (2010)</a> ]			
Consensus of Literature		Percentage of Eelgrass Area Loss (n = 57)			
		Mean %	Median %	25th Percentile	75th Percentile
≤50		62	73	39	78
51–99		88	89	82	98
≥100		93	100	95	100

<sup>a</sup>This only includes point source inputs.

Source: [Latimer and Rego \(2010\)](#).

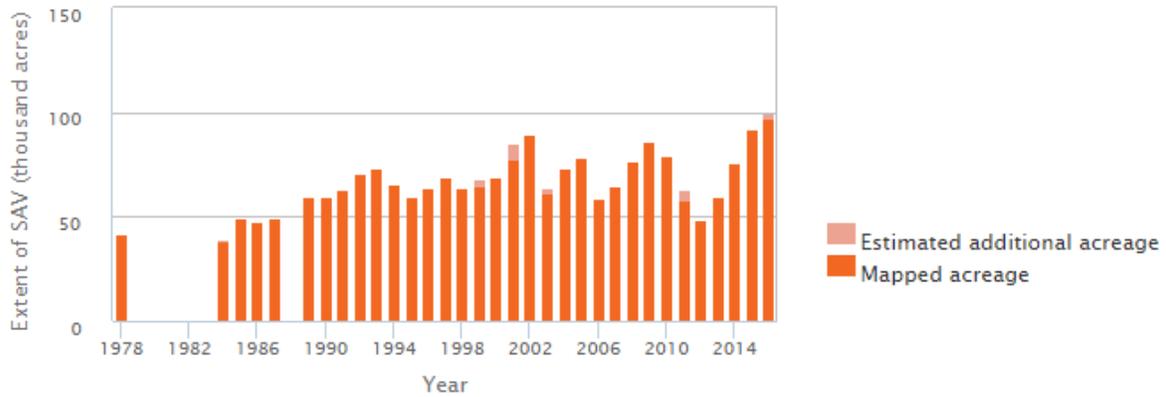

The extent of SAV is stable or increasing in some coastal areas of the U.S. In Chesapeake Bay, SAV coverage has increased from 41,000 acres (16,600 hectares) in 1978 to a peak of 97,000 acres (39,250 hectares) in 2016 based on data collected by the Virginia Institute of Marine Science [[VIMS \(2016\)](#); [Figure 10-6](#)] as reported in U.S. EPA’s *Report on the Environment* ([U.S. EPA, 2016k](#)). SAV acreage has fluctuated in the bay since 2002, covering an estimated 60,000 acres in 2013 then increasing in the most recent surveys conducted in 2015 and 2016. This estimate is based on black-and-white, 1:24,000-scale aerial photographs of the Chesapeake Bay. Aerial monitoring first occurred in 1978 and has occurred annually since 1984 (except during 1988). The SAV survey targets SAV species, which as a group are sensitive to disturbance, particularly from eutrophication and associated reductions in light availability. Pilots follow fixed flight routes to comprehensively photograph all tidal shallow water areas of the bay and its tidal

tributaries. [Orth et al. \(2010\)](#) reported a strong correlation between tributaries where nutrient reductions have occurred and increases in seagrass abundance; however, further reductions are necessary to meet SAV restoration targets. ([Lefcheck et al.](#)) project a catastrophic 95% loss of eelgrass *Z. marina* in Chesapeake Bay (and the associated ecosystem services provided by this habitat type) in the next 30 years given the conservative expectation of 2°C increase in temperature and continued trajectory of 40% decline in water clarity due to the additive effects of these stressors especially on shallow eelgrass beds. They report a 29% decline in eelgrass area in Chesapeake Bay since 1991 using high-resolution aerial imagery and water quality data. The authors note that eelgrass abundance has increased in recent years, but that recovery is limited to shallow, nearshore areas and represents only a fraction of pre-1970s distribution of this species. Despite extensive restoration efforts in the Chesapeake Bay watershed, water quality indicators (chlorophyll *a*, DO, and Secchi depth) and biotic metrics of ecological condition have shown little improvement during a 23-year period ([Williams et al., 2010](#)) The one exception to the pattern of no improvement in water quality was an observed increase in the amount of SAV. Overall, water quality has decreased and chlorophyll *a* levels have increased since 1986.

In Tampa Bay, FL (see [Appendix 16.4](#)), data on seagrass (primarily *Thalassia testudinum*) extent is available as far back as the 1950s. In the 1970s and early 1980s, the bay exhibited signs of increasing eutrophication including loss of seagrasses. Seagrass coverage has recovered to relatively predisturbed conditions (approx. 15,380 ha) following N controls implemented in the mid-1980s ([Greening et al., 2014](#); [Greening et al., 2011](#)). Although the nutrient-load hypothesis of [Brauer et al. \(2012\)](#) suggests that algae can outcompete or block out light for other macrophytes under high or variable nutrient loads, this is not always the case. For example, in Yaquina Bay in Oregon, distribution of eelgrass has remained stable despite high nutrient loads and algal blooms ([Kaldy, 2014](#)), and seagrass populations in Puget Sound, WA have also remained relatively stable for the last 40 years ([Shelton et al., 2017](#)).

In other U.S. coastal areas, SAV coverage has declined. SAV coverage in the coastal lagoon of Maryland and Virginia showed an increase with time until the early 2000s, and then a decrease in the past decade, likely due to increasing anthropogenic nutrient inputs that were accelerated by increased freshwater flow over the same time period ([Glibert et al., 2014](#)). In an analysis of 12 years of data for eelgrass areal coverage along the Massachusetts coastline, there was an overall decrease in seagrass abundance although the amount of change was highly variable between individual embayments ([Costello and Kenworthy, 2011](#)).

### Exhibit 1. Extent of submerged aquatic vegetation (SAV) in the Chesapeake Bay, 1978–2016

There were partial Bay-wide surveys from 1979 to 1983, and no survey in 1988.

Information on the statistical significance of the trend in this exhibit is not currently available. For more information about uncertainty, variability, and statistical analysis, view the technical documentation for this indicator.

**Data source:** Chesapeake Bay Program, 2017

SAV = submerged aquatic vegetation.

Source: [U.S. EPA \(2016k\)](#).

### Figure 10-6 Extent of submerged aquatic vegetation in the Chesapeake Bay 1978–2016.

SAV is often at a competitive disadvantage under N enriched conditions due to the fast growth of opportunistic macroalgae that preferentially take up  $\text{NH}_4^+$  and can block light from seagrass beds ([Abreu et al., 2011](#)). Eelgrass from the Pacific Northwest exhibited increased growth rates with increasing  $\text{NH}_4^+$  concentrations, but growth rate was not related to  $\text{NO}_3^-$  concentration ([Kaldy, 2014](#)). Temperature was found to significantly affect the response of eelgrass to nutrients, but the effects were not synergistic. A significant increase in leaf length and decreases in shoot density and aboveground and belowground biomass in eelgrass was observed concurrent with increased shading by algae in field studies of 12 estuaries in Atlantic Canada ([Schmidt et al., 2012](#)). In the same study, C and N storage (two ecosystem services provided by eelgrass) declined with increasing eutrophication.

A modeling framework to link variable freshwater inputs with seagrass (*Halodule wrightii*, *Thalassia testudinum*) biomass and timing of growth and chlorophyll *a* was

applied to the Caloosahatchee River estuary in southwest Florida ([Buzzelli et al., 2014](#)). The model predicted organic N in the upper estuary, and chlorophyll *a* in time and space reasonably well; however, there was more variation in  $\text{NH}_4^+$  while  $\text{NO}_x^-$  (nitrate-nitrite) was proportional to freshwater inflow. Overall, the model reflected variations in seagrass biomass, although timing and growth did not match the variability of field observations. A spatial model of coastal Australia was used to relate N loading from land to the extent of SAV ([Fernandes et al., 2015](#)). The largest N plume was associated with discharges from an industrialized estuary and a wastewater treatment plants. The location and size of the N plumes changed with seasonal influences. The results of spatial model analysis comparing the plume to seagrass distribution obtained from video surveillance showed that dense seagrass meadows only occurred in areas that were unaffected by N plumes, regardless of the seasonal influences on the plumes.

---

## 10.2.6 Indices of Estuarine Condition

Biological and chemical indicators have been used by the states to develop numeric nutrient criteria for estuaries ([Appendix 7.2.10](#)). Indicators may also be combined into an overall condition rating to measure ecosystem function, structure and processes in a standardized approach ([U.S. EPA, 2016g](#); [Borja et al., 2012](#); [U.S. EPA, 2012b](#); [Devlin et al., 2011](#); [Bricker et al., 2007](#)). Several assessment frameworks for eutrophic condition have been developed in the U.S. (e.g., U.S. EPA's NCCA and the NOAA NEEA ASSETS-ECI) and other countries (e.g., Trophic State Index [TRIX], *Institut français de recherche pour l'exploitation de la mer* [IFREMER], transitional water quality index [TWQI]); however, the applicability of a specific framework to areas outside of the region where they were originally developed may be limited ([McLaughlin et al., 2014](#); [Borja et al., 2012](#)). Within the same estuary, results of assessment of eutrophic condition may vary depending on the framework used for evaluation and the associated chemical and biological indicators ([McLaughlin et al., 2014](#); [Garmendia et al., 2012](#); [Devlin et al., 2011](#)). In a comparison of methods to assess nutrient enrichment impacts, [Devlin et al. \(2011\)](#) suggested that indices incorporating annual data, frequency of occurrence, spatial coverage, secondary biological indicators, and a multicategory rating scale are more robust and representative. Two of these methods that have been applied to U.S. waters are ASSETS-NCI ([Bricker et al., 2007](#)) and NCCA ([U.S. EPA, 2016g, 2012b](#)). ASSETS-NCI is only applied to nutrients and focuses on response indicators rather than chemical indicators, while the NCCA can be used for assessing other stressors to coastal areas and integrates both chemical and biological data.

The ASSETS ECI in the NEEA ([Bricker et al., 2007](#)) was used to estimate the likelihood that an estuary is experiencing or will experience eutrophication based on five ecological

indicators: chlorophyll *a*, macroalgae, DO, nuisance/toxic algal blooms, and SAV [Figure 10-3; Bricker et al. (2007)]. ASSETS uses the frequency and spatial extent of algal blooms combined with the 90th percentile of annual values for chlorophyll *a* (Table 10-2). Estuaries are divided into salinity zones, and ratings are combined as an area-weighted sum. Results from the NEEA were included in the 2008 ISA, and the biological indicators are the same in both reports for nutrient effects in estuarine systems.

The NCCA reports represent collaboration between U.S. EPA, NOAA, U.S. Fish and Wildlife Service, and coastal state agencies. The most recent sampling period was 2010 (U.S. EPA, 2016g). NCCAs use chlorophyll *a*, DO, and three additional indicators (DIN, DIP, water clarity) to determine a water quality index (U.S. EPA, 2016g, 2012b). The NCCA include data on water quality, sediment quality, benthic community composition, and fish tissue contaminants to determine the overall condition of the nation's coastal waters. In the most recent NCCA report, water quality was rated good in 36% of coastal and Great Lakes nearshore waters, fair in 48%, and poor in 14%, based on measures of the eutrophication parameters that make up the water quality index (P, N, water clarity, chlorophyll *a*, and DO concentrations).

Additional indices applied to U.S. waters include biological indicators of estuarine condition. Fertig et al. (2014) described a Eutrophication Index applied to Barnegat Bay-Little Egg Harbor Estuary, NJ using weighted indicators of water quality (temperature, DO, TN, TP), light availability (chlorophyll *a*, total suspended solids, Secchi depth, macroalgae percentage cover, percentage surface light, epiphyte biomass), and seagrass (*Zostera* spp.) response (aboveground biomass, belowground biomass, density, percentage cover and length). The biological condition gradient conceptual framework (Davies and Jackson, 2006) was applied to Greenwich Bay, RI to assess estuarine habitat over time (Shumchenia et al., 2015). Biological indicators included seagrass extent, benthic community, primary productivity, and shellfish. In a regional survey of 23 estuaries in southern California, 78% of estuaries were rated “moderate” or “worse” based on macroalgae, 39% based on phytoplankton, and 63% based on DO using the European Union Water Framework Directive (McLaughlin et al., 2014). With the ASSETS framework, 53% of surveyed areas were identified as impaired. The variability in categorizing estuarine condition was influenced by spatial and temporal scales as well as which indicators and thresholds were selected. Additional indices used in other countries for describing estuarine condition are reported in Zaldivar et al. (2008), Borja et al. (2008), Borja et al. (2012), Devlin et al. (2011), Garmendia et al. (2012), and Andersen et al. (2014).

A modeling indicator for ecosystem response to N uptake, which includes a measure of the loss of species richness, was used to create a marine eutrophication Ecosystem

Damage indicator [meED; [Cosme et al. \(2017\)](#)]. The indicator is based on the loss of species richness caused by hypoxia, which is in turn caused by eutrophication. The meED ecosystem damage indicator itself indicates the potential impact of eutrophication in the receiving habitat based on species density estimates. [Cosme et al. \(2017\)](#) supported the meED for inclusion in Life Cycle Impact Assessments (LCIA) when characterizing N emissions. Their paper describes the calculation of the meED indicator for 66 large marine ecosystems and maps risk of ecosystem damage due to eutrophication based on this indicator.

---

## 10.3 Effects on Biodiversity

Increased N loading to coastal areas can lead to shifts in community composition, reduced biodiversity, and mortality of biota. Biodiversity is important for ecosystem stability and function, including provision of ecosystem services ([Section IS.2.2.4](#)). Evidence for impacts to biodiversity include paleontological evidence ([Appendix 10.3.1](#)), altered phytoplankton community composition ([Appendix 10.3.2](#)), responses of phytoplankton to reduced versus oxidized N ([Appendix 10.3.3](#)), bacteria/archaea diversity ([Appendix 10.3.4](#)), benthic diversity ([Appendix 10.3.5](#)), and fish diversity ([Appendix 10.3.6](#)). The form of N supplied can significantly affect phytoplankton community composition in estuarine and marine environments ([Glibert et al., 2016](#); [Paerl et al., 2000](#); [Stolte et al., 1994](#)). In hypoxic areas, mortality of benthic biota and avoidance of low-O<sub>2</sub> conditions by mobile organisms lead to changes in biodiversity and loss of biomass ([Diaz and Rosenberg, 2008](#)). Energy transfer through the food web can also be altered by a decrease in predators and an increase in microbes from oxygenated areas to anoxic zones.

---

### 10.3.1 Paleontological Diversity

Sediment records from Chesapeake Bay showed alterations in producers and consumers correlated to land use change in the watershed ([Sowers and Brush, 2014](#); [Brush, 2009](#)). In this estuary, diatom community structure has shown a steady decrease in overall diversity since 1760 as estimated by sediment core analysis ([Cooper and Brush, 1993](#)). Diatom populations began to shift from benthic to planktonic in the early 1900s corresponding to the increased N flux and higher sediment inputs [which decreased light penetration; [Brush \(2009\)](#)]. Additional sediment cores from two distinct locations in the estuary show a shift to an estuarine food web that is predominately planktonic ([Sowers and Brush, 2014](#)). An increase in the abundance of the foraminifera *Ammobaculites* spp. and a decrease in the abundance of the polychaete *Nereis* spp. were observed along with the

change in primary producers. Paleontological evidence from England shows significant changes in benthic species composition and ecosystem functioning between periods of extremely low O<sub>2</sub> ([Caswell and Frid, 2013](#)). The evidence suggests that normal benthic functions are maintained during early hypoxia, but these functions collapse once thresholds of severely low O<sub>2</sub> are reached.

---

### 10.3.2 Phytoplankton Diversity

As reported in the 2008 ISA, excess N can contribute to changes in phytoplankton species composition ([U.S. EPA, 2008a](#)). High loadings of N and P can also increase the potential for Si limitation, with associated changes in diatoms. Such changes to the phytoplankton community and functional groups (e.g., diatoms, dinoflagellates, cryptomonads, cyanobacteria, chlorophytes) can also affect higher trophic levels because these organisms are the base of the estuarine food web. For example, if the nutrient mix favors species that are not readily grazed (e.g., cyanobacteria, dinoflagellates), trophic transfer will be poor, and relatively large amounts of unconsumed algal biomass will settle to the bottom, which could stimulate decomposition, O<sub>2</sub> consumption, and the potential for hypoxia ([Paerl et al., 2003](#)). Changes in phytoplankton species abundance and diversity have been further documented through in situ bioassay experiments, such as the results reported by [Paerl et al. \(2003\)](#) for the Neuse River estuary, North Carolina. Effects were species specific and varied dramatically depending on whether, and in what form, N was added. The findings illustrate the potential impacts of N additions on phytoplankton.

Several studies published since the 2008 ISA use shifts in diatoms as a measure of N enrichment effects on species diversity. In microcosm studies from Raritan Bay, centric and chain-forming diatoms resulted from enriched NO<sub>3</sub><sup>-</sup> concentrations, differing from the pennate diatoms and green flagellates that accompanied ambient NO<sub>3</sub><sup>-</sup> concentrations ([Rothenberger and Calomeni, 2016](#)). The Si:N ratio was identified as an important factor governing the phytoplankton community dynamics in the bay. Phytoplankton community structure was altered by eutrophication in the Skidaway River estuary, Georgia, as evidenced by a shift away from diatoms and towards nonsilicate nanoplankton ([Verity and Borkman, 2010](#)). There was a strong relationship between diatom taxon distribution and TN concentrations in Charlotte Harbor, FL ([Nodine and Gaiser, 2014](#)). Differences were noted in the phytoplankton community structure during the time periods before, during, and after eutrophication in the Black Sea ([Mikaelyan et al., 2013](#)). Diatoms and dinoflagellates especially were found to be dependent on high N and N:P ratios. While nutrient ratios are known to influence phytoplankton community structure, [Davidson et](#)

[al. \(2012\)](#) pointed out that these nutrient ratios are important only when at least one nutrient is low enough to limit growth.

Shifts in phytoplankton community structure are known to occur in estuaries due to N enrichment, but climatic changes may at times outweigh the impacts of eutrophication [[Paerl et al. \(2010\)](#); [Appendix 10.1.4.1](#)]. Thus, physical changes caused by climate change, such as water temperature, stratification, circulation, and hydrologic variability, must be taken into account when modeling phytoplankton community responses to N enrichment ([Paerl et al., 2014](#)). Likewise, [Glibert et al. \(2014\)](#) noted changes in phytoplankton community composition along with increased anthropogenic N input and a switch to long-term wet conditions in the coastal lagoons area of Maryland and Virginia. A 3-year data set from Raritan Bay indicates that both climatic conditions and nutrient concentrations affected phytoplankton composition from 2010–2012 ([Rothenberger et al., 2014](#)). The abundance of flagellates in the bay over time reflects a shift in dominance away from diatoms that is characteristic of eutrophic systems. Location and surrounding land cover, as well as the type of N input, are important factors in the response of the phytoplankton community to N addition ([Reed et al., 2016](#)). Phytoplankton community composition in four tidally influenced sites along a gradient from highly developed to undeveloped (natural) in coastal SC were influenced by surrounding land cover and the form of N, with cyanobacteria, dinoflagellates, and other potentially HAB-forming species most often found at the more developed sites.

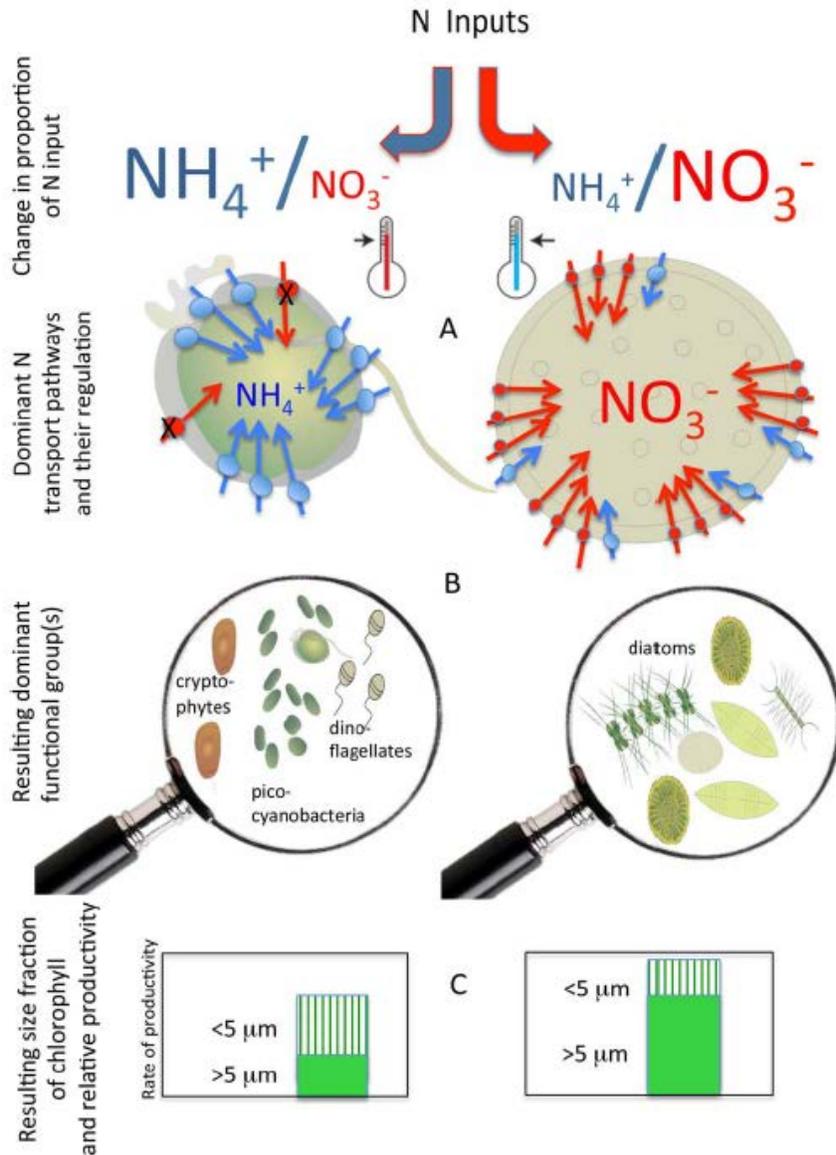

---

### 10.3.3 Diversity of Phytoplankton Under Different Forms of Nitrogen (Reduced vs. Oxidized)

Reduced forms of atmospheric N are increasing relative to oxidized N in the U.S. ([Appendix 10.1.2](#)) and play an increasingly important role in eutrophication and HAB dynamics in coastal areas. Specific phytoplankton functional groups have a preference for  $\text{NH}_4^+$  over  $\text{NO}_3^-$  ([Appendix 10.2.2](#)), perhaps leading to selective stimulation of primary production, especially in light-limited estuarine and coastal waters ([Glibert et al., 2016](#); [Paerl et al., 2000](#); [Stolte et al., 1994](#)). Increasing loads of  $\text{NH}_3/\text{NH}_4^+$  have been linked to the expansion of HABs ([Glibert et al., 2016](#); [Esparza et al., 2014](#); [Altman and Paerl, 2012](#); [Blomqvist et al., 1994](#)). For example, in San Francisco Bay, a comparison of N isotopes in cells of the cyanobacterial HAB species *Microcystis aeruginosa* with N in rivers flowing into the bay indicated the primary source of N that supported the bloom formation was likely  $\text{NH}_4^+$  ([Lehman et al., 2015](#)). Phytoplankton response to the form of N supplied ([Appendix 10.2.2](#), and [Table 10-3](#)) could lead to altered phytoplankton growth and community composition and have cascading effects on trophic structure and biogeochemical cycling ([Glibert et al., 2016](#); [Paerl et al., 2000](#)). Cyanobacteria, and many

chlorophytes and dinoflagellates may be better adapted to the use of  $\text{NH}_4^+$ , while diatoms generally thrive in environments with oxidized forms of N such as  $\text{NO}_3^-$ . [Figure 10-7](#) summarizes the dominant functional phytoplankton groups in primarily reduced N and in primarily oxidized N conditions.

Field studies indicate that HAB-forming dinoflagellates are often associated with enrichment of reduced N. In Maryland and Virginia coastal bays, [Glibert et al. \(2014\)](#) observed a regional shift in phytoplankton community composition to species that do well in reduced N conditions. Phytoplankton community dynamics varied with the form of N in nutrient enrichment experiments using water from the New River estuary, NC ([Altman and Paerl, 2012](#)). Photopigment analysis used to identify and quantify taxonomic groups revealed that the addition of riverine dissolved organic nitrogen (DON) promoted dinoflagellates, chlorophytes, and myxoxanthophyll (cyanobacteria) while zeaxanthin (cyanobacteria) was most frequently detected with inorganic N. In the Neuse River estuary, NC where  $\text{NH}_4^+$  concentrations have increased over time, the abundance of raphidophytes (including the potentially toxic dinoflagellate species *H. akashiwo*), haptophytes, chlorophytes, and the bloom-forming dinoflagellate *Heterocapsa rotundata* have also increased ([Rothenberger et al., 2009](#)). Incubation experiments carried out in the Neuse River estuary in spring, early summer, and late summer to test how the growth and community composition of phytoplankton responded to N availability and specific form of N ([Cira et al., 2016](#)). Phytoplankton community composition varied by season, and different taxa were found to be able to uptake both urea and  $\text{NO}_3^-$  when conditions were limiting, although the results varied by taxa. Seasonal experiments suggested that N was not the only factor controlling phytoplankton growth in the spring, as the experiment conducted in March showed that only growth rates of fucoxanthin-containing (brown algae) species were stimulated by N addition. In field studies along a gradient from highly developed to undeveloped (natural) study sites in the southeastern U.S., phytoplankton communities at the more developed sites showed higher biomass and growth rates with N (particularly urea) additions ([Reed et al., 2016](#)). In addition, cyanobacteria, dinoflagellates, and other potentially HAB-forming species were more often found at the more developed sites.

Source: [Glibert et al. \(2016\)](#).

**Figure 10-7** Summary conceptual schematic illustrating the effect of changes in the proportion of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  in the loads of N provided to a natural system. When  $\text{NH}_4^+$  is the dominant form, and when waters are warmer, flagellates, cyanobacteria, and chlorophytes among other classes may proliferate, leading to overall productivity dominated by the small size class of algae (e.g.,  $<5 \mu\text{m}$ ). In contrast, when  $\text{NO}_3^-$  is the dominant form provided, especially under cooler water conditions, diatoms more likely dominate, and their overall production will be more likely dominated by cells of a larger size class (e.g.,  $>5 \mu\text{m}$ ). Moreover, chlorophyll a yield and total production may be higher than under the  $\text{NH}_4^+$  enrichment condition.

In mesocosm studies in the P-limited Florida Bay ecosystem, chl *a* concentrations (phytoplankton biomass) increased with N + P treatment but did not increase with only N enrichment. However, N only enrichment (especially in the form of  $\text{NH}_4^+$ ) did change the phytoplankton assemblage in the direction of more picocyanobacteria ([Shangguan et al., 2017](#)). A shift of phytoplankton biomass toward diatoms making up a larger portion of the total biomass was observed when N in the form of  $\text{NO}_3^-$  was added, either alone or in combination with P. Using chlorophytes and diatoms from Suisun Bay, CA grown under controlled laboratory conditions [Berg et al. \(2017\)](#) found that the four diatoms species tested grew faster on  $\text{NH}_4^+$  than  $\text{NO}_3^-$  suggesting that diatoms were not under a competitive disadvantage under high  $\text{NH}_4^+$ . Only the chlorophyte *R. planktonicus* grew significantly faster on  $\text{NO}_3^-$ . None of the diatoms tested in controlled lab conditions were sensitive to  $\text{NH}_4^+$  at concentrations that would be found in the local environment. The results show that the responses are highly species specific in tolerance of  $\text{NH}_4^+$ .

Not all studies have found variation in algal response with the form of N. [Richardson et al. \(2001\)](#) examined the effects of different forms of N application ( $\text{NO}_3^-$ ,  $\text{NH}_4^+$ , urea) on the structure and function of estuarine phytoplankton communities in mesocosm experiments in the Neuse River estuary, NC. Even though  $\text{NH}_4^+$  is more readily taken up by phytoplankton in this estuary than is  $\text{NO}_3^-$  ([Twomey et al., 2005](#)), the results of the [Richardson et al. \(2001\)](#) study suggested that phytoplankton community structure was determined more by the hydrodynamics of the system than by the form of N available for growth. [Twomey et al. \(2005\)](#) measured Neuse River estuary phytoplankton uptake rates of  $\text{NH}_4^+$ ,  $\text{NO}_3^-$ , and urea.  $\text{NH}_4^+$  was the dominant form of N taken up, contributing about half of the total N uptake throughout the estuary. Uptake varied spatially; in particular,  $\text{NO}_3^-$  uptake declined from 33% of the total uptake in the upper estuary to 11 and 16% in the middle and lower estuary, respectively. Urea uptake contributed 45 and 37% of the total N uptake in the middle and lower estuary, showing the importance of regenerated N for fueling phytoplankton productivity in the mesohaline sections of the estuary. Therefore, N budgets based only on inorganic forms may seriously underestimate the total phytoplankton uptake ([Twomey et al., 2005](#)).

---

#### 10.3.4 Diversity of Bacteria, Archaea, and Microzooplankton

Since the 2008 ISA, a few studies have explored ammonia-oxidizing bacteria (AOB) and ammonia-oxidizing archaea (AOA) community responses in relation to N in coastal waters. These organisms play a key role in N cycling and the AOA were described relatively recently ([Könneke et al., 2005](#)). [Bouskill et al. \(2012\)](#) examined the distribution and abundance of AOA and AOB across a variety of aquatic environments, including two sites at different salinity levels in Chesapeake Bay. The AOB were dominate in the

freshwater end of the continuum, whereas AOA were more common in open ocean areas. The abundance of both groups was correlated with the concentration of  $\text{NH}_4^+$  in the water, especially relative abundance of AOB. A similar pattern was observed in the Sacramento-San Joaquin Delta where AOB were more abundant in the  $\text{NH}_4^+$ -rich Sacramento River compared to the San Joaquin River and Suisun Bay where AOA were prevalent ([Damashuk et al., 2015](#)). Community structure of benthic ammonia oxidizers differed across the region and appeared to be related to nutrient inputs. In the Puget Sound estuary, WA, AOA were generally more abundant, however, AOB increased relative to AOA during periods of high  $\text{NH}_4^+$  ([Urakawa et al., 2014](#)). Community structure of planktonic ciliates was found to be significantly related to the spatial distribution of  $\text{NO}_3^-$ -N concentrations across a gradient of sites in Jiaozhou Bay, China, suggesting the potential applicability of planktonic ciliate functional groups as a water quality indicator ([Xu et al., 2016a](#)).

---

### 10.3.5 Benthic Diversity

Invertebrates associated with bottom substrates of coastal systems are useful indicators of biological change for impacted waters. Several indices based on benthic invertebrates, macroinvertebrates, or macrophytes have been used to assess biological condition in response to the European Water Framework Directive ([Andersen et al., 2014](#); [Zaldivar et al., 2008](#)). A few of these indices have been tested in U.S. waters. [Borja et al. \(2008\)](#) compared the Benthic Index of Biotic Integrity (B-IBI), the AZTI Marine Biotic Index (AMBI), and its multivariate extension the M-AMBI in Chesapeake Bay. There was relative agreement between methodologies, and differences were related to spatial variability and habitat type. Comparable regional benthic indices for the Northeast/Acadian, northeast Virginian, southeast Virginian, southeast Carolinian, and Gulf Louisianan coasts were developed for the U.S. EPA's coastal assessments [[NCCA; U.S. EPA \(2016g\)](#)].

N enrichment has been shown to have significant but complex effects on suspension-feeding macroinvertebrates in estuaries. Shellfish species can respond positively to increased N loading and high phytoplankton biomass levels due to increased quantity and quality of food particles ([Carmichael et al., 2004](#)). A recent study in Long Island's Peconic Estuary suggested that eutrophication affects shellfish through changes in the quality of food and not the quantity ([Wall et al., 2013](#)). Select species (oysters [*C. virginica*] and clams [*Mercenaria mercenaria*]) in eutrophic areas experienced enhanced growth rates that were strongly correlated with high densities of autotrophic nanoflagellates and centric diatoms. Other species (scallops [*Argopecten irradians*] and slipper limpets) suffered negative effects and grew at the slowest rate at the most

eutrophic sites. Bay scallop growth was negatively correlated with densities of dinoflagellates, which were more abundant at the most eutrophic site ( $p < 0.001$ ). In rocky shore environments in Ireland, similar to those of the U.S. northeastern Atlantic coast, N enriched sites near industrial and sewage outfalls have been shown to have reduced total abundance and number of molluscan taxa and altered community composition compared with control sites ([Atalah and Crowe, 2012](#)). Nitrite and  $\text{NH}_3$  levels explained the highest percentages of variation in the molluscan assemblage structure (13 and 12.5%, respectively), owing in large part to the absence of three rare species at contaminated sites. The observed shift in community structure caused by different levels of molluscan tolerance to N enriched conditions has been suggested for use as a biological indicator of eutrophication ([Atalah and Crowe, 2012](#)). The role of benthic invertebrates in coastal N cycling and the use of shellfish for coastal N remediation is discussed in [Appendix 7.2.6.11](#).

---

### 10.3.6 Fish Diversity

A few studies have recently reported effects on fish biodiversity in nutrient-impacted estuaries. Comparison of trophic organization of fish in estuarine reaches of nine rivers in Victoria, Australia showed that inorganic N loading was an important factor explaining trophic diversity of fish assemblages. There was greater trophic diversity of fish assemblages with mid to high inorganic N loading suggesting that DIN influences not only estuary primary productivity but is transmitted upward through the food chain ([Warry et al., 2016](#)). In Prince Edward Island estuaries, adult and young-of-the-year abundance of pollution-tolerant mummichogs (*Fundulus heteroclitus*) increased in estuaries with greater intensity of N loading from agricultural land use ([Finley et al., 2013](#)). In this study, eutrophication was associated with changes in habitat variables, which were linked to mummichog abundance. In an estuary in the southern Gulf of St. Lawrence in Canada, loss of eelgrass was linked to declines in fish diversity, but the loss did not change the positions of organisms within the food chain ([Schein et al., 2013](#); [Schein et al., 2012](#)).

---

### 10.3.7 Trophic Interactions

Altered trophic transfer following nutrient-associated changes in phytoplankton community composition were reported in the 2008 ISA. Phytoplankton that are not readily grazed, such as cyanobacteria and dinoflagellates, are not transferred to higher trophic levels as efficiently as diatoms [more readily grazed by zooplankton which are then consumed by fish; [Paerl et al. \(2003\)](#)]. Since the 2008 ISA, studies have further

characterized the effects of nutrient enrichment on trophic interactions. In the Skidaway River estuary, GA, increasing nutrient concentrations and changes in nutrient ratios led to increases in eukaryotic organisms (heterotrophic and mixotrophic flagellates, dinoflagellates, ciliates, and metazoan zooplankton) but not diatoms, potentially altering food web predator-prey relationships ([Verity and Borkman, 2010](#)). In an experimental study in Chesapeake Bay, [Reynolds et al. \(2014\)](#) demonstrated that a reduction of crustacean grazers controlling algal growth on seagrasses resulted in 65% reduced seagrass biomass and nearly sixfold increased epiphytic algae. In experimental plots where grazers were removed, aboveground eelgrass biomass was reduced following fertilization. In the presence of grazers, eelgrass biomass increased with fertilization. When predators were excluded, mesograzers were able to limit epiphytic algal growth even when nutrients were added. Based on these findings, the researchers suggested that it is unlikely that reducing nutrient pollution alone would restore seagrass meadows where alterations to food webs have already reduced populations of algae-feeding mesograzers. Similar results were reported in [McSkimming et al. \(2015\)](#) from *Posidonia angustifolia* meadows in Australia where mesograzers responded to nutrient addition by increasing grazing per capita, resulting in greater consumption of epiphytic algae.

A review of nutrient addition studies from the North Atlantic suggests that, overall, the addition of nutrients caused the biomass of opportunistic macroalgae to approximately double. Higher numbers of midlevel predators has the same effect because they lead to a smaller population of grazers eating the macroalgae ([Ostman et al., 2016](#)). Analysis of review data indicated that the effect of midlevel predators on green macroalgae biomass increased with eutrophication. Recovery of sea otter (*Enhydra lutris*) populations in California appear to control algal growth on eelgrass by increased predation of crabs (*Cancer* spp. and *Pugettia producta*) which, in turn, decrease predation of mesograzers such as sea slugs (*Phyllaplysia taylori*) that feed on the algae ([Hughes et al., 2013](#)). Newer literature has provided evidence for complex interactions between eutrophication and other stressors and subsequent effects on trophic interactions. For example, [Burnell et al. \(2013\)](#) used mesocosms to demonstrate the effect of eutrophic conditions on plant-herbivore grazing interactions between the sea urchin *Amblypneustes pallidus* and the seagrass *Amphibolis antarctica* affected by warming and acidification. Nutrient enrichment offset increased grazing associated with acidification and warming; however, it did not fully counter the additive effects of these two stressors.

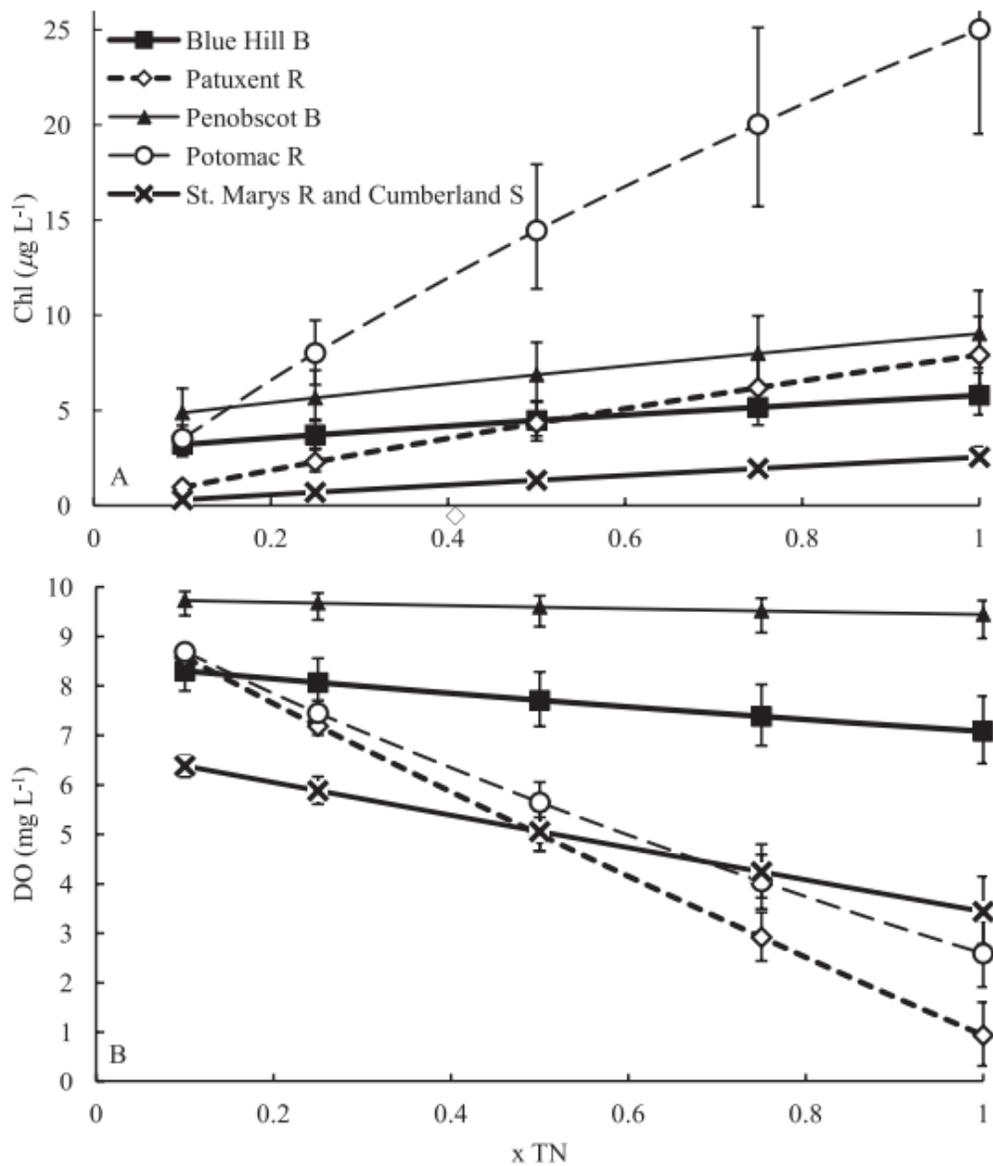

---

### 10.3.8 Models Linking Indicators to Nitrogen Enrichment

Process-oriented models such as nutrient-phytoplankton-zooplankton (NPZ) models are used to predict the response of organisms such as HABs to various known and/or

predicted nutrient conditions ([Swaney et al., 2008](#)). A nutrient-driven phytoplankton model developed by [Scavia and Liu \(2009\)](#) was expanded by [Evans and Scavia \(2013\)](#) to test the sensitivity of the response of chlorophyll *a* levels and DO levels to N enrichment. Results indicated that separate processes control chlorophyll *a* and DO sensitivity (estuary flushing time and relative mixing depth, respectively), and that these sensitivities vary among estuaries ([Figure 10-8](#)).

Using the European regional Seas Ecosystem Model for an area of the Japan Sea, [Lee and Yoo \(2016\)](#) showed that the phytoplankton community there will shift to smaller phytoplankton, and the food web structure will likely be altered if atmospheric deposition continues to intensify in the region as predicted. For the study period 2001–2012, the model estimated that the atmospheric N deposition in the Ulleung Basin would increase the annual net primary production by an average of 4.58% (range from 3.77–10.58%).

chl = chlorophyll; DO = dissolved oxygen; TN = total nitrogen.

The x-axis shows river total nitrogen load relative to the 1992 SPARROW total nitrogen load for each estuary. In the figure legend, R = river, B = bay, and S = sound.

Source: [Evans and Scavia \(2013\)](#).

---

## 10.4 Animal Behavior and Disease

In addition to changes in biological indicators (i.e., chlorophyll *a*, HABs, macroalgal abundance, SAV) and altered species diversity there is increasing evidence for a role of N in behavior and disease in coastal biota. These indirect responses may affect the fitness of organisms inhabiting nutrient-enriched waters.

---

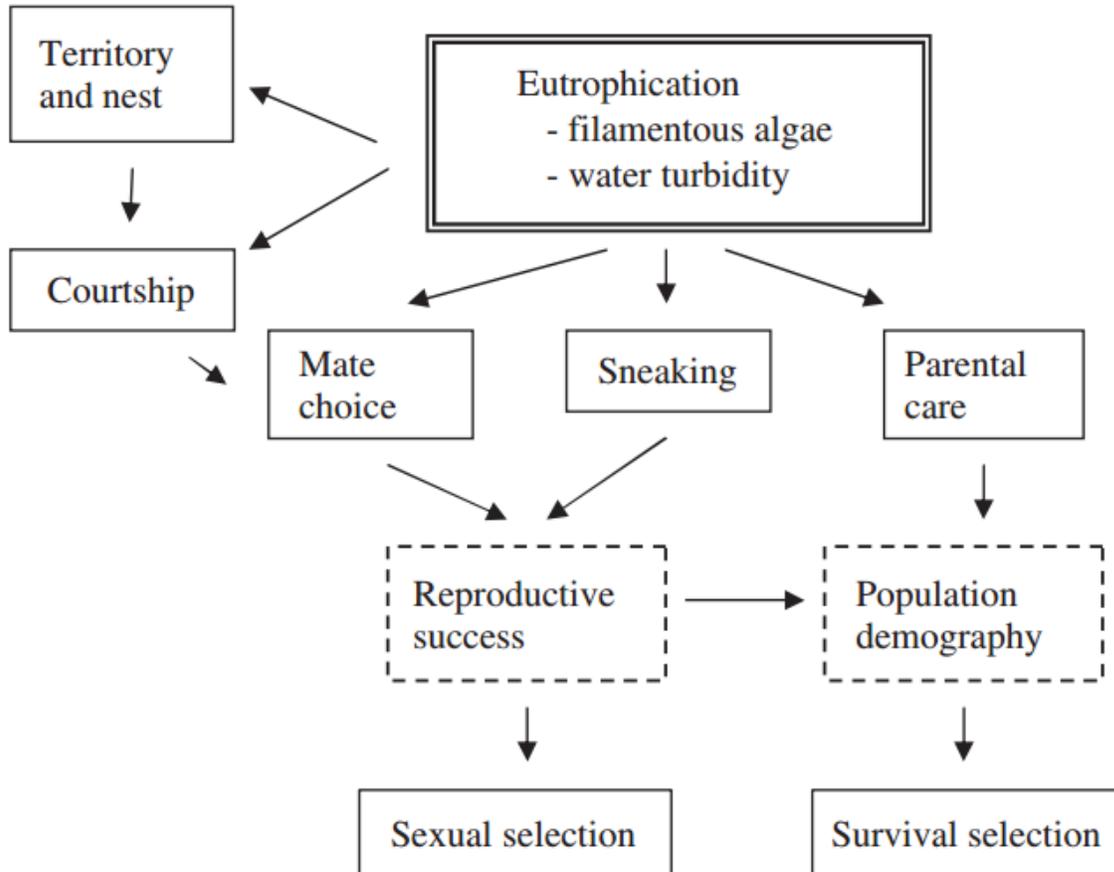

### 10.4.1 Behavior

Coastal biota exhibit behavioral responses to hypoxic conditions, including acclimation or avoidance ([Townhill et al., 2017](#); [Levin et al., 2009](#)). Some fish have the ability for aquatic surface respiration, a behavior in which the fish swims to the surface and is able to take advantage of the relatively higher levels of DO in the water there. [Dixon et al. \(2017\)](#) assessed four common species of shallow estuarine finfish for their reactions to episodic hypoxic conditions and altered pH levels. Severe hypoxia induced surface respiration behavior of three of the four fish species, but all were unaffected by diel variations in pH.

Turbidity caused by excess algae in the water, a secondary effect of eutrophication, has been shown in laboratory studies to potentially alter some fish behaviors, with implications for mate selection and offspring survival rates. It is not known whether some of these behavior changes will be adaptive or if they will have positive or negative effects on the fish populations. For instance, when the strength of sexual selection on several traits is relaxed, the relative importance of survival selection may increase ([Candolin, 2009](#)). The color contrast created by increased turbidity may lead to a heightened feeding response in some fish larvae such as California yellowtail (*Seriola lalandi*), which exhibited elevated growth and survival rates compared to larvae raised in clear (oligotrophic) water ([Stuart and Drawbridge, 2011](#)).

Several studies of the three-spined sticklebacks (*Gasterosteus aculeatus*) indicate that observed alterations of reproductive behaviors are linked to eutrophic conditions ([Figure 10-9](#)). Laboratory manipulations suggest that turbidity caused by eutrophication may affect mate selection and breeding success in this euryhaline fish species ([Heuschele et al., 2012](#); [Heuschele and Candolin, 2010](#)). When given the choice between dense or sparse algae, male sticklebacks preferred to nest in dense algae (which simulated eutrophic conditions). The nests of those males were more likely to be parasitized by other males; however, the males nesting in dense algae also acquired more eggs, and thus, had a higher probability of reproduction ([Heuschele and Candolin, 2010](#)). This may be because reduced visibility leads to reduced mate selectivity searching by females,

although it is unknown whether these behavior changes would have positive or negative impacts on the population ([Heuschele et al., 2012](#)).

Source: [Candolin \(2009\)](#).

**Figure 10-9** The pathway of effects of eutrophication on different reproductive behaviors and selection forces in *Gasterosteus aculeatus*.

Simulated turbidity has also been shown to impair visual mate choice in an eastern Atlantic species of marine pipefish, *Syngnathus typhle* ([Sundin et al., 2010](#)). A follow-up study in the same species allowed other factors to occur, namely mating competition and mate encounter rates which counteracted the effects of lack of visual cues and led to increased sexual selection in turbid waters ([Sundin et al., 2017](#)). In the same species, the latency period between courting and copulation was prolonged in low-O<sub>2</sub> conditions,

although other measures of reproductive behavior (total time spent courting, probability of mating, dancing, male pouch-flap behavior) were unaffected ([Sundin et al., 2015](#)).

Other types of fish mating behaviors are also affected by eutrophication. Male sticklebacks engage in an opportunistic mating behavior called “sneaking” which is less successful under more turbid (eutrophic) conditions ([Vlieger and Candolin, 2009](#)).

Eutrophication has so far been found to have conflicting impacts on nest building behavior in male sticklebacks, with varying implications for the survival rate of stickleback offspring. Male sticklebacks built smaller nests with wider openings during eutrophic (algal bloom) conditions ([Wong et al., 2012](#)). These males also took longer to complete the nest than did males that built during nonbloom conditions. However, under normal water conditions in a laboratory setting, male sticklebacks that had been collected from eutrophic waters built their nests faster than those collected from noneutrophic waters, although the nests did not differ in structure or composition between the two groups ([Tuomainen and Candolin, 2013](#)). In European sand gobies (*Pomatoschistus minutus*), another species that exhibits paternal care of eggs, algal turbidity altered male behaviors ([Järvenpää and Lindström, 2011](#)). Males spent more time away from the nest and exhibited less fanning of the eggs with their pectoral and tail fins. Goby egg survival rates were actually found to be higher under turbid conditions. Although the mechanism for this outcome is unknown, it was proposed that males may have increased other forms of care in the presence of eutrophic conditions, leading to higher egg survival.

Under normal conditions, it is beneficial for sticklebacks to live in larger groups where they gain protection from predators, are able to forage more efficiently, and are able to find a mate more easily than in smaller groups. However, in eutrophic (turbid) water, sticklebacks did not show a preference for joining a larger shoal as they did under normal conditions ([Fischer and Frommen, 2013](#)). This lack of exhibited shoal preference under turbid conditions could eventually reduce individual stickleback fitness. In addition, sticklebacks changed shoals less frequently in turbid water than observed under normal conditions, leading to a decrease in the transfer of important social information, such as the location of foraging routes. Therefore, increased turbidity may reduce social learning opportunities for sticklebacks and may, in turn, impair their foraging efficiency ([Fischer and Frommen, 2013](#)).

---

#### 10.4.2 Disease

Diel-cycling hypoxia in estuaries is a natural phenomenon that can be exacerbated by increased biomass and productivity associated with anthropogenic nutrient loadings ([Tyler et al., 2009](#)). [Tyler et al. \(2009\)](#) observed that upper areas of four Delaware

estuaries experienced increased incidence of severe hypoxia ( $DO \leq 2$  mg/L) where nutrient loading was greater. The duration and spatial extent of diel-cycling hypoxia in the estuaries were primarily associated with water temperature, previous day's insolation, hours of morning ebb tide, and daily stream flow. Oysters (*C. virginica*) exposed to periods of diel-cycling hypoxia were demonstrated to have increased incidence and progression of *Perkinsus marinus* infection (Dermo) in field and laboratory experiments ([Breitburg et al., 2015](#)). Field experiments were conducted in Chesapeake Bay. The authors suggest that the likely mechanism is negative effects of hypoxia on host immune response.

Seagrass meadows were recently shown to decrease pathogens harmful to both human health and marine organisms. In field studies adjacent to islands in Indonesia affected by wastewater pollution, bacterial pathogens were reduced by up to 50% in seagrass meadows and coral reefs adjacent to seagrass beds had reduced disease incidence ([Lamb et al., 2017](#)). Several recent studies have suggested that seagrasses may be more susceptible to wasting disease caused by the marine slide mold (genus *Labyrinthula*) under conditions of elevated  $NO_3^-$  loading ([Hughes et al., 2017](#); [Kaldy et al., 2017](#)).

Nutrient enrichment is one of several factors linked to increased disease susceptibility and bleaching in corals ([D'Angelo and Wiedenmann, 2014](#); [Vega Thurber et al., 2014](#); [Wiedenmann et al., 2013](#)). Coral bleaching occurs when the symbiotic relationship between the coral host and microalgae (*Zooxanthellae* spp.) breaks down. Although most research on nutrient loading on corals includes both N and P several studies have isolated effects of N which impacts corals via distinct pathways from P ([Shantz and Burkepile, 2014](#)). [Wiedenmann et al. \(2013\)](#) reported that the coral-algae symbiosis can be interrupted by elevated inorganic N concentration rather than both N and P. In a meta-analysis of nutrient impacts on corals, N reduced coral calcification 11% on average, while increasing photosynthetic rate ([Shantz and Burkepile, 2014](#)). Increased DIN decreases the temperature threshold at which coral bleaching occurs ([Wooldridge, 2009](#)). The threatened status of staghorn coral (*Acropora cervicornis*) and elkhorn coral (*Acropora palmata*) under the U.S. Endangered Species Act has been linked to indirect N pollution effects, specifically low DO and algal blooms that alter habitat, and other non-nutrient stressors ([Hernández et al., 2016](#)).

---

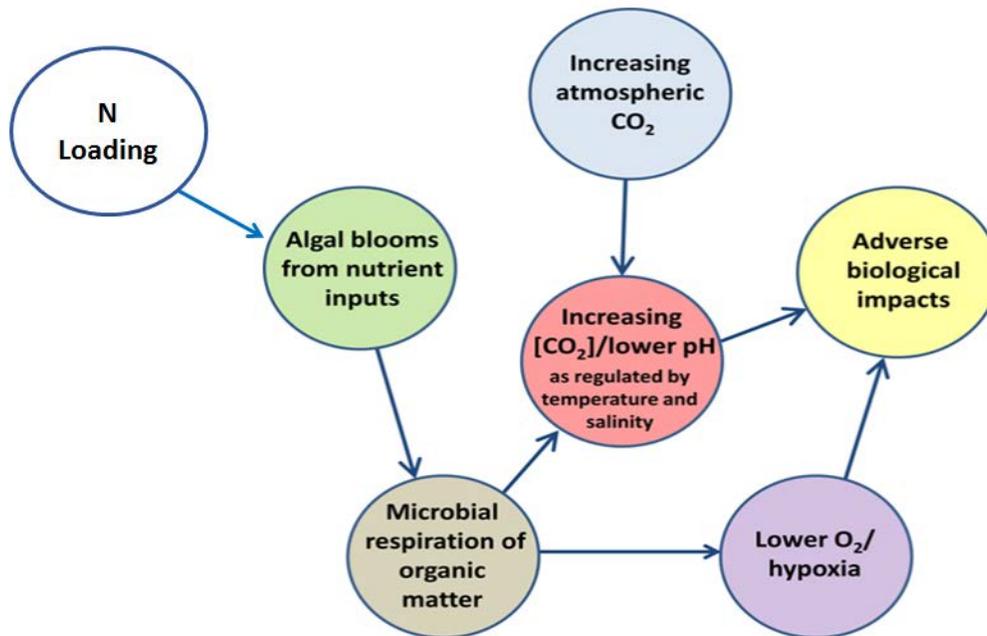

## 10.5 Nitrogen Enrichment and Acidification Effects on Calcifying Organisms

Eutrophication and acidification are complex biogeochemical processes that are driven by the same hydrological (stratification) and biological (production/respiration) processes,

that can result in hypoxia and enhanced organic matter loading ([Wallace et al., 2014](#); [Cai et al., 2011c](#)). Ocean acidification, which can be exacerbated by elevated N input, is projected to alter marine habitat, have a wide range of effects at the population and community level, and affect food web processes ([Mostofa et al., 2016](#); [Andersson et al., 2015](#); [Gaylord et al., 2015](#); [Sunda and Cai, 2012](#); [Doney et al., 2009](#)).

Dissolution of atmospheric anthropogenic carbon dioxide (CO<sub>2</sub>) into the ocean has caused increasing acidification of some coastal waters, resulting in long-term decreases in pH [[Orr et al. \(2005\)](#); [Wallace et al. \(2014\)](#); [Appendix 7.2.7.2](#)]. Decreased alkalinity can impact buffering and influence system response to nutrient inputs ([Cai et al., 2017b](#)). A major finding of The West Coast Ocean Acidification and Hypoxia Science Panel was that, while the dominant cause of ocean acidification in the region is global CO<sub>2</sub> emissions, local discharge of nutrients and organic C is a factor exacerbating ocean acidification and hypoxia ([Chan et al., 2016](#)). Acidification due to direct CO<sub>2</sub> dissolution is more likely observable in open ocean environments but may be masked by enhanced primary production (eutrophication) leading to basification in surface waters. Nutrient-driven eutrophication can trigger algal blooms, which upon decomposition in bottom waters, further reduce oxygen levels in the water column and thus also lower the pH. Consequently, nutrient enhanced acidification is a result of the synergistic input of CO<sub>2</sub> from the atmosphere plus the decomposition of organic matter stimulated by anthropogenic nutrients (e.g., eutrophication). It can be further exacerbated by warming ([Baumann and Smith, 2018](#)) as well as changes in buffering capacity (alkalinity) of freshwater inputs.

Increased respiration of particulate organic matter stimulated by N enrichment exacerbates coastal ocean acidification, which coupled with reduced buffering capacity, leads to an alteration of the carbonate biogeochemistry ([Appendix 7.2.4](#)). Specifically, N enrichment is expected to worsen this acidification because degradation of excess organic matter from blooms generates CO<sub>2</sub> in the water column, which in turn increases acidity [[Figure 7-8](#), [Figure 10-10](#); [Cai et al. \(2011c\)](#); [Howarth et al. \(2011\)](#); [Sunda and Cai \(2012\)](#); [Wallace et al. \(2014\)](#)]. Allochthonous organic matter inputs, which have been increasing in many coastal watersheds from changing land use ([Wilson et al., 2016](#); [Wetz and Yoskowitz, 2013](#)), are an important additional source of organic matter leading to overall increases in acidity. N-driven eutrophication and anthropogenically enhanced allochthonous organic matter loading, as well as reduced buffering capacity operate simultaneously to alter carbonate biogeochemical cycling.

CO<sub>2</sub> = carbon dioxide; N = nitrogen; O<sub>2</sub> = oxygen.

Modified from: [Sunda and Cai \(2012\)](#).

**Figure 10-10 Pathway from nitrogen loading to biological effects of nutrient-enhanced coastal acidification. Both microbial respiration of organic matter and increasing atmospheric carbon dioxide lower pH of coastal waters.**

Acidification of coastal waters may cause varying degrees of harm to marine organisms that produce calcium carbonate shells or skeletons, including oysters, clams, sea urchins, shallow water corals, and calcareous plankton ([Mostofa et al., 2016](#); [Gledhill et al., 2015](#); [Pfister et al., 2014](#); [Kroeker et al., 2013](#); [Sunda and Cai, 2012](#)). The acidifying process decreases the saturation state of the two minerals (aragonite and calcite) that most bivalves use to form their shells ([Barton et al., 2015](#); [Barton et al., 2012](#)). Lower pH of seawater can also potentially impair physiological energetics and spawning capacity of shellfish ([Xu et al., 2016b](#)). Commercially important species from the New England coastal region have shown biological responses to changes in the carbonate system associated with ocean and coastal acidification ([Gledhill et al., 2015](#)). Already, there are declines in oyster production on the U.S. West Coast due to the inability of oysters to create shells due to acidification ([Chan et al., 2016](#); [Barton et al., 2015](#); [Hettinger et al., 2012](#)). However, other factors can confound the response of these sensitive organisms.

More research is needed to accurately determine the interactions and combined impact of ocean acidification and N enrichment and other stressors on U.S. ecosystems like coral reefs and estuaries with sensitive shellfish populations ([Kroeker et al., 2013](#)).

In a recent modeling study of risk of food web and fisheries to ocean acidification in the California current nearshore, invertebrates and associated fishery revenues are expected to be impacted to a greater extent than pelagic species ([Marshall et al., 2017](#)). Although this modeling study did not take N inputs or other measures into account, invertebrates that live in or on the benthic layer (crabs, shrimps, bivalves) will experience the strongest effects of ocean acidification, followed by those species that consume benthic invertebrates such as demersal fish and Dungeness crabs (*Metacarcinus magister*). However, the model also showed that different species of groundfish reacted differently to the changing pH, so some species and associated fishery dynamics may be impacted to a greater degree than others.

Research on costressors associated with conditions of coastal acidification and eutrophication suggest that interactions between elevated CO<sub>2</sub>, increasing acidity, decreasing alkalinity, and nutrient inputs are complex. In macroalga *Ulva pertusa* grown under conditions of low pH and high NH<sub>4</sub><sup>+</sup>, both growth rate and NH<sub>4</sub><sup>+</sup> uptake were significantly higher than in treatments with higher pH and lower nutrient enrichment ([Kang and Chung, 2017](#)). [Young and Gobler \(2016\)](#) tested the effects of elevated concentrations of CO<sub>2</sub> alone, and in combination with elevated nutrient (N + P) levels, on the growth rates of two common species of opportunistic macroalgae, the rhodophyte *Gracilaria* and the chlorophyte *Ulva*. Results showed that higher levels of pCO<sub>2</sub> significantly enhanced the growth rates of both types of macroalgae, and the combination of enriched N + P and pCO<sub>2</sub> did appear capable of synergistically promoting the growth of *Ulva*. Given that eutrophication can yield elevated levels of pCO<sub>2</sub>, this study suggests that the overgrowth of macroalgae in eutrophic estuaries can be further promoted by acidification.

Eelgrass productivity and growth are predicted to increase under conditions of elevated CO<sub>2</sub> because photosynthesis in these plants is thought to be currently limited by CO<sub>2</sub> ([Koch et al., 2013](#); [Alexandre et al., 2012](#); [Palacios and Zimmerman, 2007](#)). However, seagrass productivity responses to combined stressors of pCO<sub>2</sub> and NO<sub>3</sub><sup>-</sup> were found to be variable between different species ([Ow et al., 2016](#)). In mesocosm experiments with the seagrass *Zostera noltii*, photosynthesis increased under enriched CO<sub>2</sub>, but NO<sub>3</sub><sup>-</sup> and NH<sub>4</sub><sup>+</sup> uptake and growth rate were not significantly affected, indicating that seagrass production may be limited by N availability under increased CO<sub>2</sub> ([Alexandre et al., 2012](#)).

Combined effects of  $\text{NO}_3^-$  enrichment, acidification, and temperature resulted in the highest reproductive success for the green tide-forming algae *Ulva rigida*, pointing to potentially more severe green tides under future scenarios than under present conditions, especially in areas where eutrophication is a concern (Gao et al., 2017). A decline in calcification of the coral *Marginopora rossi* was observed at a pH of 7.6 alone or in combination with nutrients (Reymond et al., 2013). In  $\text{NO}_3^-$  enriched seawater, the number of zooxanthellae cells in the host coral increased but with no observable benefits on coral growth. A threshold for ocean acidification at pH 7.6 alone or in combination with eutrophication will lead to a decline in *M. rossi* calcification.

Models show that while the impact of each acidification pathway (N enrichment and atmospheric  $\text{CO}_2$  dissolution) may be moderate, the combined effect of the two may be much larger than would be expected by just adding the effects of each pathway together (Sunda and Cai, 2012; Cai et al., 2011c). These models, which incorporate the expected future higher atmospheric  $\text{CO}_2$  levels and current levels of eutrophication, show dramatic increases in acidification of coastal waters below the pycnocline. Model predictions agreed well with pH data from hypoxic zones in the northern Gulf of Mexico and both the modeled and the measured decreases in pH are well within the range shown to impact marine fauna (Sunda and Cai, 2012). Data from the northern Gulf of Mexico revealed a significant positive correlation between subsurface water pH and  $\text{O}_2$  concentration, linking acidification to low  $\text{O}_2$  levels from organic matter decomposition (Cai et al., 2011c). Results from a coupled physical-biogeochemical model in the Gulf of Mexico point to eutrophication driven by river nutrient input as an important factor in acidification and hypoxia generation (Laurent et al., 2017). Findings from the model showed that acidified waters are predicted in a thin layer close to the bottom of the Gulf, similar to the vertical distribution of the seasonal hypoxia zone.

The increase in atmospheric  $\text{CO}_2$  dissolution is also expected to alter the N cycle in the ocean, with implications for the entire ecosystem. Acidification will result in decreased rates of nitrification, which combined with expected increasing N deposition, is expected to cause the  $\text{NH}_4^+$  concentration of the water to rise (Lefebvre et al., 2012). A study of the coccolithophore *Emiliana huxleyi*, which plays a major role in the global carbon cycle by regulating the exchange of  $\text{CO}_2$  across the ocean-atmosphere interface, found that higher levels of  $\text{NH}_4^+$  can affect the morphology and calcification of the coccolithophore. The combined effect of higher  $\text{NH}_4^+$  levels and greater acidification could reduce calcification rates, suggesting a greater alteration to the ocean's carbon cycle due to the combined effect of increased  $\text{NH}_4^+/\text{NO}_3^-$  and acidification (Lefebvre et al., 2012).

---

## 10.6 Summary of Thresholds and Levels of Deposition at Which Effects Are Manifested

Studies linking changes in estuary nutrient status to atmospheric deposition have been limited, although some states are addressing atmospheric inputs as part of their development of total maximum daily loads [TMDLs; [Linker et al. \(2013\)](#)]. Since the 2008 ISA, additional thresholds of response to N have been identified for biological indicators. In general, the identification and application of indicators and thresholds to assess eutrophication in coastal areas is more highly developed in Europe than in the U.S. due to the implementation of the EU's Water Framework Directive ([Zaldivar et al., 2008](#)). Here we limit discussion to indicators and thresholds that have been applied to U.S. water bodies.

For chlorophyll *a*, both NEEA ASSETS and U.S. EPA NCCA have a similar range for categorizing eutrophic conditions; however, ASSETS uses the 90th percentile chlorophyll concentration of annual data and U.S. EPA NCCA uses growing season (June–October) values [[Borja et al. \(2012\)](#); [Table 10-2](#)]. For ASSETS, chlorophyll concentrations of 0–5 µg/L is a water body with low risk of eutrophication, 5–20 µg/L is moderate, >20 µg/L is high with >60 µg/L indicating hypereutrophic conditions. NCCA identified chlorophyll concentration of >20 µg/L as an indicator of an estuary in poor condition. Chlorophyll concentrations between 5–20 µg/L are classified as fair and chlorophyll concentration 0–5 µg/L was good for sites located in the Northeast, Southeast, Gulf, West Coast, and Alaska ([U.S. EPA, 2012b](#)). Values were lower for sites in Hawaii, Puerto Rico, U.S. Virgin Islands, American Samoa, and Florida Bay (0.5 µg/L good, 0.5–1 µg/L fair, >1 µg/L, poor).

For DO, ASSETS uses the 10th percentile of annual data. DO concentrations of 0 mg/L are anoxic, 0–2 mg/L are indicative of hypoxic conditions, and 2–5 mg/L are biologically stressful conditions ([Devlin et al., 2011](#); [Bricker et al., 2007](#)). Spatial coverage (range of 0–10% [low] to >50% [high]) and frequency of occurrence (persistent, periodic, episodic) are also included in determining reference thresholds for DO with ASSETS. For U.S. EPA NCCA, the cutpoint used for poor DO condition is <2 mg/L in bottom waters ([U.S. EPA, 2016g, 2012b](#)). Because many states use higher concentrations, the NCCA considers concentrations between 2 and 5 mg/L as fair, and >5 mg/L as good.

Under the U.S. Clean Water Act, states are in the process of developing numeric nutrient criteria to better define levels of N and P that affect estuaries and coastal marine waters ([Appendix 7.2.10](#)). The numeric values include both causative (N and P) and response (chlorophyll *a*, biocriteria) variables to assess eutrophic conditions. For progress toward state development of numeric criteria for N see <http://cfpub.epa.gov/wqsits/nnc->

[development/](#). Atmospheric deposition as a source of N may represent a potential target for remediation such as TMDL, nutrient budgets, and allocations.

The Chesapeake Bay 2010 TMDL load reductions include atmospheric deposition. This is the first time atmospheric N loads to tidal waters have been included in a TMDL for reduction ([U.S. EPA, 2010](#)). For Chesapeake Bay, a numerical chlorophyll criteria ranging from 1.4 to 15 mg/m<sup>3</sup> (µg/L) based on seasonal mean across salinity zones was proposed as a restoration goal with 90th percentile compliance limits ranging from 4.3 to 45 mg/m<sup>3</sup> [µg/L; [Harding et al. \(2014\)](#)]. These values were based on relationships of chlorophyll *a* concentrations to DO, water clarity, and presence of toxic algae. Chlorophyll *a* concentration ranges of 7.2 to 11 mg/m<sup>3</sup> (µg/L; May–August mean) in the bay and 9 to 14 mg/m<sup>3</sup> (µg/L; annual mean) in the tributaries would be protective of low DO conditions. For SAV growth, a mean chlorophyll *a* concentration of 7.9–12 mg/m<sup>3</sup> (µg/L) with a threshold of 19–28 mg/m<sup>3</sup> (µg/L) during the growing season would allow for sufficient light conditions. For decreased risk for toxic cyanobacteria, a mean summer chlorophyll *a* concentration of 15 mg/m<sup>3</sup> and a threshold of 25 mg/m<sup>3</sup> (µg/L) was recommended.

For seagrasses in New England estuaries, a threshold of N loading (N export of wastewater, fertilizer, and atmospheric deposition from the watershed combined with direct atmospheric deposition to waters)  $\geq 100$  kg N/ha/yr was identified. Eelgrass is essentially absent in areas with these levels of N loading, and levels above 50 kg N/ha/yr are likely to impact habitat extent [[Table 10-4; Latimer and Rego \(2010\)](#)]. These values were based on literature threshold values from [Bowen and Valiela \(2001a\)](#), [Hauxwell et al. \(2003\)](#), [Li et al. \(2007\)](#), and [Latimer and Rego \(2010\)](#). [Greaver et al. \(2011\)](#) identified the range of 50–100 kg N/ha/yr total N loading as the empirical critical load for loss of eelgrass based on [Latimer and Rego \(2010\)](#). These threshold levels for seagrasses were developed in shallow, poorly flushed systems that may not be universally representative of all estuaries.

---

## 10.7 Summary and Causality Determination

In the 2008 ISA, the body of evidence was sufficient to infer a causal relationship between N deposition and the alteration of species richness, species composition, and biodiversity in estuarine systems ([U.S. EPA, 2008a](#)). The strongest evidence for a causal relationship was from changes in biological indicators of nutrient enrichment (chlorophyll *a*, macroalgal abundance, HABs, DO, SAV) and N was recognized as the major cause of harm to the majority of estuaries in the U.S. ([Bricker et al., 2008](#); [NRC, 2000](#)). Phytoplankton are the base of the coastal food web, and increases in primary

producer biomass and altered community composition associated with increased N can lead to a cascade of direct and indirect effects on higher trophic levels. For this ISA, new information is consistent with the 2008 ISA, and the causal determination has been updated to reflective more specific categories of effects. **The body of evidence is sufficient to infer a causal relationship between N deposition and changes in biota, including total primary production, altered growth, total algal community biomass, species richness, community composition, and biodiversity due to N enrichment in estuarine environments.**

Since the 2008 ISA, additional evidence has shown that reduced forms of atmospheric N play an increasingly important role in estuarine and coastal eutrophication and HAB dynamics. In many parts of the U.S., especially the Southeast, Midwest, and Mid-Atlantic, deposition of reduced N has increased relative to oxidized N in last few decades. The form of N delivered to some coastal areas of the U.S. is shifting from primarily  $\text{NO}_3^-$  to an increase in reduced forms of N. The increase in highly bioreactive reduced N from deposition and other sources is often a preferred form of N for specific phytoplankton functional groups (e.g., cyanobacteria, dinoflagellates) including harmful species ([Glibert et al., 2016](#); [Paerl et al., 2000](#)). Atmospheric inputs to estuaries are heterogeneous across the U.S., ranging from <10 to approximately 70% of the N inputs ([Table 7-9](#)), so deposition may play a significant role in altering nutrient dynamics in some coastal systems (i.e., Mid-Atlantic, Southeast) that support an increasing human population and spatial expansion of industrial scale animal operations ([Li et al., 2016d](#)).

Chlorophyll *a* is a broadly applied indicator of phytoplankton biomass and used as a proxy for assessing effects of estuarine nutrient enrichment. It can signal an early stage of water quality degradation related to nutrient loading and is incorporated into water quality monitoring programs and national-scale assessments, including U.S. EPA's NCCA and the NEEA. In general, 0–5  $\mu\text{g/L}$  chlorophyll concentration is considered to be good, chlorophyll concentrations between 5–20  $\mu\text{g/L}$  are classified as fair, and >20  $\mu\text{g/L}$  indicates an estuary in poor condition. Phytoplankton sampling and sediment core analysis have shown changes in phytoplankton community structure in estuaries with elevated N inputs. These shifts at the base of the food web to species that are not as readily grazed (e.g., cyanobacteria, dinoflagellates) have a cascade of effects that include poor trophic transfer and an increase in unconsumed algal biomass, which could stimulate decomposition,  $\text{O}_2$  consumption, and the potential for hypoxia ([Paerl et al., 2003](#)). Although availability of N is an important factor for productivity in estuaries, many newer studies have emphasized the role of physical and hydrologic factors in increase of chlorophyll *a* and other indicators of N enrichment ([Hart et al., 2015](#); [Turner et al., 2015](#); [Wilkerson et al., 2015](#); [Glibert et al., 2014](#); [Kennison and Fong, 2014](#); [Rothenberger et al., 2014](#); [Paerl et al., 2010](#); [Yang et al., 2008](#)).

Incidence of HAB outbreaks continues to increase in both freshwater and coastal areas, a problem that has been recognized for several decades ([U.S. EPA, 2008a](#); [Bricker et al., 2007](#); [Paerl et al., 2002](#); [Paerl and Whittall, 1999](#); [Paerl, 1997](#)). Of the 81 estuary systems for which data were available in the NEEA reported in the 2008 ISA, 26 exhibited a moderate or high symptom expression for nuisance or toxic algae ([Bricker et al., 2007](#)). HAB bloom conditions and effects of HAB toxins on coastal biota have been further characterized since the 2008 ISA ([Wood et al., 2014](#); [Miller et al., 2010](#)). The form of N affects phytoplankton growth and toxin production of some HAB species. CyanoHAB presence has been documented in estuaries along the U.S. Mid-Atlantic and Southeast coasts as well as Gulf coast estuaries ([Preece et al., 2017](#)).

In addition to phytoplankton, macroalgae growth is also stimulated by increased N inputs. Macroalgal blooms can smother benthic organisms and corals and contribute to the loss of important SAV by blocking the penetration of sunlight into the water column. Studies published since the 2008 ISA provide further evidence that macroalgae respond to the form of N, with some species showing greater assimilation and growth rates with  $\text{NH}_4^+$  than with  $\text{NO}_3^-$  ([Wang et al., 2014a](#); [Ale et al., 2011](#)).

Since the 2008 ISA, seagrass coverage is improving or stable in some estuaries like Tampa Bay and Chesapeake Bay, while many areas continue to see declines in seagrass extent. Loss of SAV habitat can lead to a cascade of ecological effects because many organisms are dependent upon seagrasses for cover, breeding, and as nursery grounds. SAV is often at a competitive disadvantage under N enriched conditions due to the fast growth of opportunistic microalgal epiphytes and macroalgae competitors that preferentially take up  $\text{NH}_4^+$  and can block light from seagrass beds. Since the 2008 ISA, additional studies are available on the relationship between N loading and SAV abundance ([Boynton et al., 2014](#); [Orth et al., 2010](#); [Ruhl and Rybicki, 2010](#)), and several studies have identified specific regional thresholds [[Latimer and Rego \(2010\)](#); [Benson et al. \(2013\)](#); [Table 10-4](#)]. [Greaver et al. \(2011\)](#) identified the range of 50–100 kg/N/ha/yr total N loading as the empirical critical load for loss of eelgrass based on [Latimer and Rego \(2010\)](#).

Increased algal biomass associated with nutrient over-enrichment leads to increased decomposition of organic matter, which decreases DO. Oxygen depletion largely occurs only in bottom waters under stratified conditions, not throughout the entire water column. A variety of ecological impacts are associated with low DO ([Figure 10-4](#)), and this indicator has been used in national assessments of coastal condition including U.S. EPA's NCCA and the NEEA. DO concentrations of 0 mg/L are anoxic, 0–2 mg/L are indicative of hypoxic conditions, and 2–5 mg/L are biologically stressful conditions ([Devlin et al., 2011](#); [Bricker et al., 2007](#)). For example, many fishes are absent at DO levels below

2 mg/L, and mortality of tolerant organisms can occur at approximately 0.5 mg/L. Hypoxia has recently been shown to affect reproductive parameters in fish which may lead to effects at the population level. In laboratory conditions, increased turbidity associated with eutrophic conditions has been shown to alter fish reproductive behaviors ([Candolin, 2009](#)). Macroinvertebrate community structure is also affected by the duration and severity of hypoxia. A shift to benthic organisms with shorter life spans and smaller body size has been observed in coastal areas that experience severe seasonal hypoxia ([Diaz and Rosenberg, 2008](#)). Reduced species density and diversity in the northern Gulf of Mexico are linked to the duration of hypoxic events ([Baustian and Rabalais, 2009](#)).

Post-2007 literature includes additional information on the extent and severity of eutrophication and hypoxia in sensitive regions. [Diaz et al. \(2013\)](#) assessed global patterns in hypoxia from the 1960s to 2011. Areas of eutrophication-related hypoxia are found on the U.S. East and West Coasts and the Gulf of Mexico ([Figure 10-5](#)). Overall, the extent of hypoxia is increasing globally with some areas showing signs of improvement. In the 2008 ISA, the largest zone of hypoxic coastal water in the U.S. was the northern Gulf of Mexico on the Louisiana-Texas continental shelf ([U.S. EPA, 2008a](#)). This area, which forms annually between May and September, continues to be the largest in the U.S. and the second largest in the world, averaging about 16,500 km<sup>2</sup> (10,250 mi<sup>2</sup>) in size ([Dale et al., 2010](#); [Jewett et al., 2010](#)). In the summer of 2017, the hypoxic zone in the Gulf was the largest ever measured at 14,123 km<sup>2</sup> [8,776 mi<sup>2</sup>; [U.S. EPA \(2017f\)](#)]. Atmospheric deposition from watersheds in the Mississippi/Atchafalaya River basins contributes approximately 16 to 26% of the total N load in the Gulf of Mexico ([Robertson and Saad, 2013](#); [Alexander et al., 2008](#)). Long Island Sound also experiences periods of anoxia in some years. In other U.S. coastal systems, the incidence of hypoxia is increasing; however, the severity of DO impacts are relatively limited temporally and spatially ([Jewett et al., 2010](#); [U.S. EPA, 2008a](#); [Bricker et al., 2007](#)). In the Pacific Northwest, coastal upwelling can be a large source of nutrient loads, and advection of upwelled water can introduce into estuaries hypoxic water that is not related to anthropogenic sources.

The indicators described above (chlorophyll *a*, HABs, macroalgal abundance, DO, SAV, and benthic diversity) have been incorporated into indices that describe eutrophic conditions in coastal areas. In the 2008 ISA, the ASSETS ECI developed for the NEEA was used as an assessment framework for eutrophic conditions in coastal U.S. estuaries ([Bricker et al., 2007](#)). The NCCA incorporates indicators that include chlorophyll *a* and DO to assess U.S. waters ([U.S. EPA, 2016g, 2012b](#)). Additional indices of overall condition of estuarine functioning that incorporate biological indicators of eutrophication have since been developed both in the U.S. and other countries ([Borja et al., 2012](#); [Devlin et al., 2011](#); [Borja et al., 2008](#)). Comparisons of these frameworks have led to the

identification of more robust and representative methods to measure estuarine response, including incorporation of annual data, frequency of occurrence, spatial coverage, secondary biological indicators, and a multicategory rating scale ([Devlin et al., 2011](#)).

In addition to having effects on biota in estuarine environments, N enrichment is one of several factors linked to increased disease susceptibility, bleaching, and reduced calcification rate in corals ([Appendix 10.4.2](#)). Near-coastal coral reefs in the U.S. occur off southern Florida, Texas, Hawaii, and U.S. territories in the Caribbean and Pacific. The threatened status of staghorn coral (*Acropora cervicornis*) and elkhorn coral (*Acropora palmata*) under the U.S. Endangered Species Act has been linked to indirect N pollution effects, specifically low DO and algal blooms that alter habitat, and to other non-nutrient stressors ([Hernández et al., 2016](#)).

Increased N enrichment is a contributing factor to coastal acidification under certain conditions such as in systems with strong thermal stratification or with spatial or temporal decoupling of production and respiration processes ([Appendix 7.2.4](#)). Acidification is projected to alter marine habitat, have a wide range of effects at the population and community level, and impact food web processes ([Marshall et al., 2017](#); [Mostofa et al., 2016](#); [Andersson et al., 2015](#); [Gaylord et al., 2015](#); [Sunda and Cai, 2012](#); [Doney et al., 2009](#)). Organisms that produce calcium carbonate shells such as calcareous plankton, oysters, clams, sea urchins, and coral may be affected by long-term decreases in pH [[Pfister et al. \(2014\)](#); [Sunda and Cai \(2012\)](#); [Kroeker et al. \(2013\)](#); [Mostofa et al. \(2016\)](#); [Appendix 10.5](#)]. Although the interactions between elevated CO<sub>2</sub>, increasing acidity, and nutrient inputs are complex, changes in the carbonate system, including decreased pH, have been shown to elicit biological responses in commercially important species from the New England coast and there are documented declines in oyster production on the U.S. West Coast linked to ocean acidification.

---

# APPENDIX 11 NITROGEN ENRICHMENT EFFECTS IN WETLANDS

This appendix describes the effects of N deposition on wetland ecosystems. The introduction contains an overview of the relationship between N deposition and wetland endpoints, as well as the wetland classification system used in this appendix ([Appendix 11.1](#)). Regional sensitivity in wetlands is related to position within the watershed ([Appendix 11.2](#)). N deposition causes changes to biogeochemical pools and processes in wetlands, specifically to N ([Appendix 11.3.1](#)) and C cycling ([Appendix 11.3.2](#)). Nitrogen eutrophication affects wetland primary producers via alteration of aboveground plant biomass ([Appendix 11.4](#)), plant stoichiometry and physiology ([Appendix 11.5](#)), plant architecture ([Appendix 11.6](#)), and plant demography ([Appendix 11.7](#)). Nitrogen eutrophication also alters wetland biodiversity via changes to plant community composition ([Appendix 11.8.1](#)) and to consumer communities ([Appendix 11.8.2](#)). There are a number of critical loads published for wetland ecosystems ([Appendix 11.9](#)).

---

## 11.1 Introduction

The 1993 Oxides of Nitrogen Air Quality Criteria document (hereafter referred to as the 1993 AQCD) and the 2008 ISA for Oxides of Nitrogen and Sulfur—Ecological Criteria (hereafter referred to as the 2008 ISA) evaluated the effects of nitrogen deposition on wetland ecosystems. The 1993 AQCD found that the three main ecological effects of N deposition on wetland ecosystems were reduced biodiversity, modified microbial processes, and increased primary production. The 2008 ISA supported and extended the conclusions in the 1993 AQCD, especially with regard to the effects of N deposition on species diversity, and also found evidence for alterations of ecosystem nitrogen and carbon cycling. The 2008 ISA found that the evidence was sufficient to infer a causal relationship between N deposition to wetland ecosystems and the alteration of biogeochemical cycling, as well as the alteration of species richness, species composition, and biodiversity. New evidence published between 2008–2015 from observational studies, experimental N additions in the field and in mesocosms, and reanalysis of large data sets supports and extends the conclusions of the 2008 ISA. **The body of evidence is sufficient to infer a causal relationship between N deposition and the alteration of biogeochemical cycling in wetlands.** In addition to new information on species biodiversity, there is recently published evidence of N deposition effects on endpoints not covered in the 2008 ISA, including alterations to plant physiology and plant architecture.

**The body of evidence is sufficient to infer a causal relationship between N deposition and the alteration of growth and productivity, species physiology, species richness, community composition, and biodiversity in wetlands.**

Wetland vegetative communities are adapted to high levels of natural organic acidity, so S and N deposition are unlikely to cause any acidification-related effects at levels of acidic deposition commonly found in the U.S. ([U.S. EPA, 2008a, in Annex B, in Annex B, in Annex B, in Annex B](#)). Sensitivity of wetlands to N deposition as a nutrient are well documented in the 2008 ISA ([Appendix 11.2](#)). Hydrologic pathways are often the same pathways of N input; therefore, they are useful for discussing the N sources and sensitivity to atmospheric N deposition. In general, wetland types ([Table 11-1](#)) that receive most of their total N input from the atmosphere are most sensitive to atmospheric deposition. Nearly all new N comes from atmospheric deposition in ombrotrophic bogs because these wetlands only receive water inputs via precipitation. They develop where precipitation exceeds evapotranspiration and where there is some impediment to drainage of the surplus water ([Mitsch and Gosselink, 1986](#)). Freshwater fens, marshes, and swamps are characterized by ground and surface water inputs that are often on the same order of magnitude as precipitation ([Koerselman, 1989](#)). Lastly, estuarine and coastal wetlands receive water from precipitation, ground/surface water, and marine/estuarine sources. Therefore, bogs (and presumably vernal pools) are among the most vulnerable wetlands to the nutrient-enrichment effects of N deposition ([Krupa, 2003](#)).

**Table 11-1 Wetland classification used in the Integrated Science Assessment.**

Wetland Term	Definition [adapted from <a href="#">Wakeley (2002)</a> ; <a href="#">Mitsch and Gosselink (2000)</a> ; <a href="#">Cowardin et al. (1979)</a> ]
<b>Soil-based classification</b>	
Peat	Substrate consisting of partially decomposed plant litter. In bryophyte-dominated wetlands (bogs and fens), this layer is composed of dormant or dead moss. In marshes and swamps, peat consists of dead litter, including plant leaves, stems, and roots, as well as undifferentiated soil organic matter and sediments.
Peatland	Any wetland that accumulates or has historically accumulated organic C stores in the substrate. Net primary productivity and accumulation of fixed C exceed decomposition rates. In Europe, the synonymous term "mire" is used.
<b>Hydrology-based classification</b>	
Permanent wetland	Wetland where a zone of the soil profile or peat profile remains saturated with water. The deeper soil profile is typically saturated, anoxic, and often has a high percentage of organic matter.
Intermittent wetland	Wetland where soils are saturated with water for short periods of time, annually or every few years; soils tend to have higher mineral contents than do permanent wetland soils.

**Table 11-1 (Continued): Wetland classification used in the Integrated Science Assessment.**

<b>Wetland Term</b>	<b>Definition [adapted from <a href="#">Wakeley (2002)</a>; <a href="#">Mitsch and Gosselink (2000)</a>; <a href="#">Cowardin et al. (1979)</a>]</b>
Intertidal wetland	Wetlands where soils or sediments are inundated with water at high tide and are exposed to air at low tide. This includes salt marshes, mangroves, and unvegetated mudflats.
<b>Soil-, hydrology-, and vegetation-based classification</b>	
<b>Bog or peat bog</b>	Defined by vegetation. A wetland with high moss cover and a depth profile with high organic content (peat), sometimes comprised of compressed senesced mosses. Ericaceous shrubs and certain graminoids are also particularly adapted for bog conditions.
Ombrotrophic or oligotrophic bog	A peatland dominated by acidophilic mosses, particularly <i>Sphagnum</i> mosses. Water is derived entirely from precipitation, with high [DOC], low pH, and low nutrient concentrations.
Mesotrophic, poor, or intermediate fen	A peatland that supports herbaceous and woody plant species with a wetland surface composed of moss species. Water sources include precipitation, surface water, and groundwater. Water pH (acidic to circumneutral) and nutrient concentrations are intermediate between ombrotrophic bog and minerotrophic fen.
Minerotrophic, rich, eutrophic, or calcareous fen	A peatland dominated by herbaceous graminoid species typical of marshes, with a mat composed of moss species. Water sources include precipitation, surface water, and groundwater. Water has higher pH (circumneutral to alkaline), as well as higher concentrations of calcium ions and other nutrients, than other bog types.
<b>Swamp</b>	Defined by vegetation. A wetland dominated by woody plants, particularly tree and shrub species with physiological adaptations to occasional or constant soil inundation.
Mangrove	An intertidal swamp. A subtropical or tropical swamp dominated by halophytic trees and shrubs. Tidal inundation by ocean or estuarine waters is frequent. In the U.S., dominant species are trees in the <i>Avicennia</i> and <i>Rhizophora</i> genera. Mangroves are important nursery habitats for marine animal species.
<b>Marsh</b>	Defined by vegetation. A wetland dominated by herbaceous plants with physiological adaptations to occasional or constant soil inundation.
Freshwater marsh	Marsh dominated by herbaceous plant community composed of species with physiological adaptations to soil inundation. Includes marshes in lakes, rivers, and nonsaline regions of estuaries. Salt- and sulfide-intolerant marsh plant species are common. Soils may be peat or mineral sediments.
Pothole	A type of freshwater marsh. A shallow pond with herbaceous and submerged aquatic vegetation, common in the prairie ecosystems of the Dakotas and central Canadian plains. A pothole is often not connected by surface water flow to its watershed; water sources include precipitation and groundwater.
Tidal marsh	An estuarine marsh. Used in this document to describe estuarine marshes in which water level fluctuates in response to ocean tides but marsh water has low or no salinity (i.e., water sources are freshwater). Depending on physical location in the estuary, occasional saltwater intrusion may alter biogeochemistry and plant community. A mix of saline-tolerant and saline-intolerant plant species is common.
Salt or coastal marsh	Halophytic herbaceous species are dominant. Tidal inundation by ocean water structures the plant community, which typically forms zones of single species monocultures or low-diversity communities of plants with similar tolerances for salt and water stress. Plant roots trap alluvial sediments to build and maintain the elevation of the marsh surface, or platform. Salt marshes are important nursery habitats for marine animal species.

**Table 11-1 (Continued): Wetland classification used in the Integrated Science Assessment.**

<b>Wetland Term</b>	<b>Definition [adapted from <a href="#">Wakeley (2002)</a>; <a href="#">Mitsch and Gosselink (2000)</a>; <a href="#">Cowardin et al. (1979)</a>]</b>
<b>Intermittent</b>	Defined by hydrology and vegetation. Wetland where soils are saturated, with soil processes typical of aquatic sediments, for short periods annually or every few years; inundation occurs with sufficient frequency to prevent persistence of flooding-intolerant plant species.
Vernal pool	An area with mineral soils which is flooded by rainwater or rising water tables and then isolated from surface water flow as it slowly dries up. These seasonally inundated areas are important nursery habitat for a number of invertebrate and vertebrate species.
Riparian wetland	An area with mineral soils, and a high water table due to close proximity to a river, stream, or lake. Periodic inundation occurs when water levels rise. Vegetation is a mix of terrestrial plants and plants with physiological adaptations to occasional soil inundation.

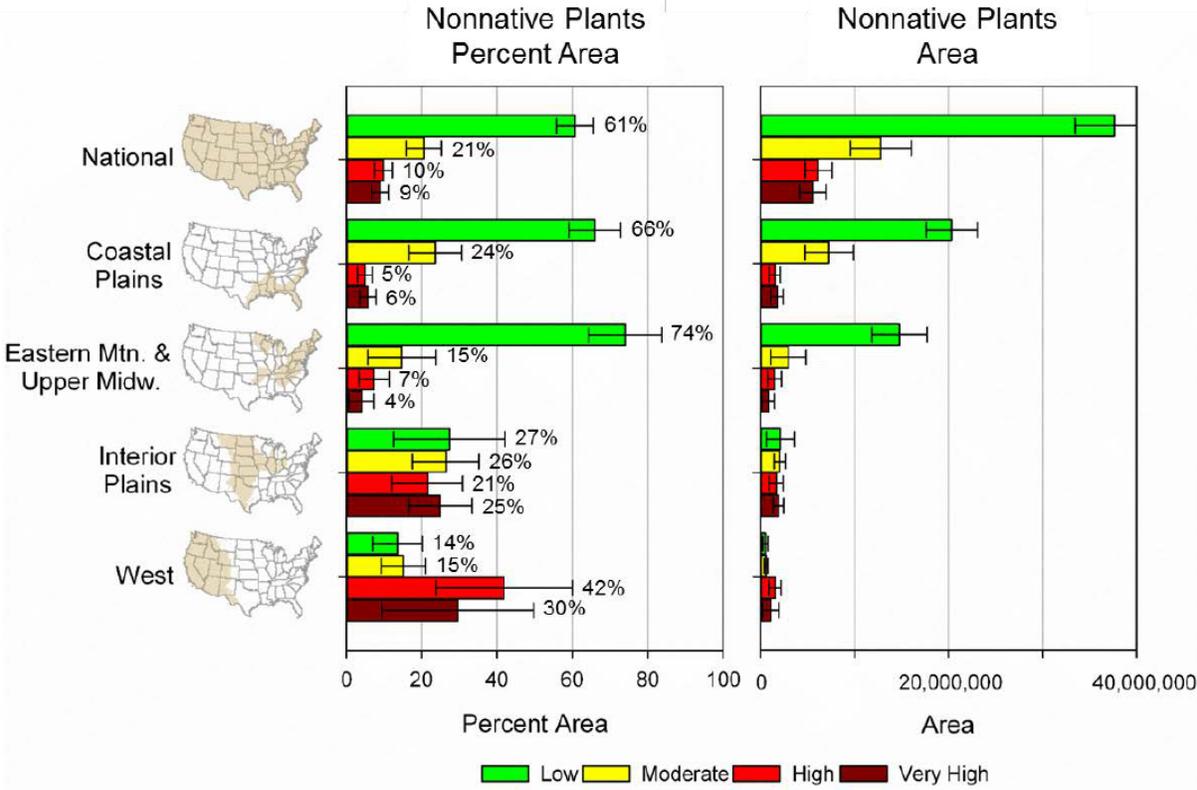

C = carbon; DOC = dissolved organic carbon.

## 11.2 Regional Sensitivity

There is no new information on regional sensitivity of wetlands to N deposition, and models of sources of N to wetland ecosystems are not yet available. In the 2008 ISA, wetlands were described in order of sensitivity to N deposition. Bogs and fens are among the most sensitive wetland ecosystems to N deposition. In the U.S., peat-forming bogs and fens are most common in glaciated areas, especially in portions of the Northeast and Upper Midwest ([U.S. EPA, 1993](#)). N deposition was projected to drastically change species composition based on experimental results in European fens ([Pauli et al., 2002](#); [Aerts and de Caluwe, 1999](#)). N input and output rates of freshwater or riparian marshes and swamps are intermediate between bogs and coastal marshes. N deposition increased primary productivity 30% and increased methane emissions in freshwater marshes. Atmospheric N inputs contribute to eutrophication problems in coastal marshes at many locations through direct deposition to the marsh, indirect deposition to the watershed, or direct deposition to estuaries or coastal waters followed by tidal delivery of aqueous N loads to wetlands (see [Table 7-9](#) for estimates of N deposition to estuaries). However, marine inputs of N are typically higher than direct atmospheric input to coastal wetlands.

The National Wetlands Condition Assessment (NWCA) was conducted by U.S. EPA in 2011 to characterize the condition of North American wetlands under multiple anthropogenic stressors and to provide a baseline for future assessments. The final report did not provide soil N or surface water ammonia, nitrate-nitrite, or total N, although these data were collected as part of the survey and are available ([U.S. EPA, 2016j](#)). Ecological endpoints that the NWCA identified as correlated with total N loading are the Nonnative Plant Stressor Indicator (NPSI; see [Appendix 11.8.1.3](#) for an explanation of the link

between N loading and non-native plants) and microcystin concentrations (see [Appendix 9](#)), although the dataset includes a number of other metrics that may respond to N deposition. Nationally, 39% of wetland area was estimated to experience moderate to very high stress based on the NPSI, with stresses particularly high in wetlands of the Interior Plains and West (see [Figure 11-1](#)). Microcystin, a toxin produced by cyanobacteria in response to available N, was detected in low concentrations in surface water at 12% of national wetland sites, with particularly high detection rates (34%) in the Interior Plains ([U.S. EPA, 2016j](#)).

Source: [U.S. EPA \(2016j\)](#).

**Figure 11-1** Estimated extent of wetlands stressed by nonnative plants as determined by Nonnative Plant Stressor Indicator, at a national or regional level.

---

## 11.2.1 Climate Modification of Ecosystem Response to Nitrogen

Changes in mean annual temperature and frequency and magnitude of precipitation will affect the responses of all wetlands to N loading; changes in sea level will affect the response of salt marsh, mangroves, and freshwater tidal wetlands. Temperature effects on wetlands have been demonstrated in European bog ecosystems, where increased temperatures increased cover of woody species and decreased *Sphagnum* moss cover just as N deposition does ([Hedwall et al., 2017](#)). In metaregressions of *Sphagnum* moss response to N addition and temperature, the two factors synergistically depressed *Sphagnum* production, with an 1°C increase in summer temperature having an impact on *Sphagnum* equivalent to an additional 40 kg N/ha/yr ([Limpens et al., 2011](#)). Increasing temperatures may strengthen N effects upon wetland ecosystems.

Hydrologic regimes are important controls on wetland cycling and productivity, so changes in the magnitude and frequency of precipitation can have strong effects on ecosystem N retention and C storage. The same metaregression of *Sphagnum* mosses referenced above found that increased precipitation also increased *Sphagnum* sensitivity to N addition-induced decreases in production ([Limpens et al., 2011](#)). Experimental mesocosms modelling changes in precipitation to salt marshes found that precipitation delivered in infrequent, heavy storm events decreased N retention and plant productivity, even though storm events delivered a higher N deposition load to the marsh ([Hanson et al., 2016](#); [Oczkowski et al., 2016](#)). Shifts in precipitation towards less frequent, more intense rain events may strengthen N deposition-induced decreases in salt marsh N retention while weakening N deposition-induced increases in plant productivity.

Sea level rise will affect tidal wetlands through salt water intrusion into tidal freshwater wetlands ([Barendregt and Swarth, 2013](#)) and through increasing inundation of salt marshes, both of which have the potential to change community composition and decrease wetland extent. Experimental sea level rise of 10 cm increased N stimulation of belowground and aboveground plant biomass in Kirkpatrick Marsh (see ([Langley et al., 2013](#)) in [Appendix 11.3.2.1.2](#) and [Appendix 11.4.1](#)), but the response was species-specific, with only one species responding to the N deposition. Sea level rise effects on marsh response to N deposition are not well understood and may vary by species.

---

## 11.3 Soil Biogeochemistry

The 2008 ISA described the relationship between N deposition and the alteration of biogeochemical cycling in wetlands. N deposition alters N cycling by altering microbial

communities, the rates at which they transform N between pools, ecosystem retention or release of transformed N, and the emissions of the greenhouse gas nitrous oxide ([Appendix 11.3.1](#)). N deposition alters C cycling by altering soil processes such as decomposition and respiration (resulting in emissions of the greenhouse gases carbon dioxide and methane), as well as by altering soil pools such as belowground biomass and soil organic matter ([Appendix 11.3.2](#)). There is new evidence since 2008 of N deposition effects upon biogeochemical cycling across wetlands, as well as in salt marshes, mangroves, bogs, and riparian wetlands. **The body of evidence is sufficient to infer a causal relationship between N deposition and the alteration of biogeochemical cycling in wetlands.**

---

### 11.3.1 Nitrogen Pools and Processes

Water table depth tends to fluctuate more in wetlands than terrestrial ecosystems. The variable depth creates dynamic anoxic-oxic boundaries and many varied niches for different microbial communities. As a result, wetlands are important disproportionately to their spatial area on the landscape (i.e., hotspots) for the microbial transformation of nitrogen between oxidized and reduced forms. These nitrogen transformations can improve water quality of downstream streams, lakes, and estuaries by removing N in the soil or water of an ecosystem into the atmosphere. However, these transformations can result in emissions of the potent greenhouse gas nitrous oxide. Alteration to N cycling or N cycling microbial endpoints indicate changes to the important wetland function of improving water quality.

N deposition contributes to total N load in wetlands. The chemical indicators that are typically measured include  $\text{NO}_3^-$  and  $\text{NH}_4^+$  leaching, DON leaching, N mineralization, and denitrification rates, including  $\text{N}_2\text{O}$  emissions produced by incomplete denitrification. N dynamics in wetland ecosystems are variable in time and among types of wetlands and environmental factors, especially water availability ([Howarth et al., 1996a](#)). A wetland can act as a source, sink, or transformer of atmospherically deposited N ([Devito et al., 1989](#)), and these functions can vary with season and hydrological conditions. Vegetation type, physiography, local hydrology, and climate all play significant roles in determining source/sink N dynamics in wetlands ([Mitchell et al., 1996](#); [Arheimer and Wittgren, 1994](#); [Koerselman et al., 1993](#); [Devito et al., 1989](#)).

N mineralization (microbial transformation of organic N to inorganic forms of N) has been shown to increase with N addition, and this can cause an increase in wetland N export to adjacent surface water ([Groffman, 1994](#)). In general, ecosystem leaching losses of  $\text{NO}_3^-$  from wetlands to downstream aquatic systems are small, although recent

research suggests that N addition to peatlands increases export of N in both inorganic and organic forms ([Edokpa et al., 2015](#)). Bogs and fens in the Marcell Experimental Forest that receive 2.8–4.7 kg N/ha/yr as atmospheric deposition export 0.26 (bogs) and 1.34 kg N/ha/yr (fens), respectively ([Hill et al., 2016](#)). Wetlands tend to have low N export to surface water because anoxic zones within wetlands are favorable for microbial denitrification of N from  $\text{NO}_3^-$  to gaseous N forms. Elevated N inputs to wetlands will often increase the rate of denitrification ([Duffy and Kahara, 2011](#); [Cooper, 1990](#); [Broderick et al., 1988](#); [Dierberg and Brezonik, 1983](#)), because N additions to aquatic environments with high organic C increase denitrifier abundance, activity, and denitrification rates ([Kim et al., 2015b](#)). This mitigates environmental effects associated with increased N supply to soils and drainage waters; however, increased denitrification may also increase the emissions of greenhouse gases (e.g.,  $\text{N}_2\text{O}$ ) to the atmosphere. Denitrification appears to be negligible in wetland environments that are typically nutrient (including N) poor, such as some bogs and fens ([Morris, 1991](#)). Incomplete denitrification and emission of  $\text{N}_2\text{O}$  tend to be higher in freshwater tidal wetlands than in saline wetlands like mangroves or salt marshes ([Welti et al., 2017](#)). In salt marshes, dissimilatory nitrate reduction to ammonium (DNRA) is an important process that cycles N while retaining N within marsh sediments (see also [Appendix 7.2.6.5](#)). N addition decreases DNRA while increasing nitrification and denitrification rates ([Peng et al., 2016](#)), decreasing N retention in salt marshes, and increasing  $\text{N}_2\text{O}$  emissions ([Chmura et al., 2016](#); [Moseman-Valtierra et al., 2011](#)).

New studies summarized below in salt marsh, mangrove, peat bog, and riparian wetlands have evaluated the effects of N loading/N addition on endpoints related to N cycling. In addition, there is a new study on wetland N removal, synthesizing information across wetland types.

---

### 11.3.1.1 Across Wetlands

N removal, defined as the sum of denitrification, plant uptake, and burial in sediments, was evaluated by analyzing data from 109 wetlands distributed globally, including agricultural wetlands, freshwater marshes, freshwater swamps, and coastal marshes ([Jordan et al., 2011](#)). Total N loads to these wetlands ranged from 0.2–90,480 kg N/ha/yr; however, the sources of reactive N were not identified by the authors. Across this global data set, wetland N removal as measured in outflow is proportional to wetland N load. N removal efficiency was 26% higher in nontidal wetlands than in tidal wetlands.

The 2008 ISA found evidence that N deposition alters the emission of nitrous oxide ( $\text{N}_2\text{O}$ ) and methane ( $\text{CH}_4$ ), which contribute to global warming. A meta-analysis of

19 N addition observations, ranging from 15.4 to 300 kg N/ha/yr, found that N enrichment increased wetland N<sub>2</sub>O emissions by 207% ([Liu and Greaver, 2009](#)).

---

### 11.3.1.2 Salt Marsh

New studies have evaluated the effects of N loading/N addition on tidal export, N mineralization, nitrification, and microbial community structure in salt marshes. Tidal export of N from salt marshes was studied in a long-term (>30 years) fertilization experiment in Massachusetts ([Brin et al., 2010](#)) in which tidal export of N increased with increasing N load. Tidal export of ammonia increased linearly with increasing annual N load, and tidal export of nitrate increased exponentially with increasing annual load (see [Table 11-2](#) for equations). Likewise, a linear relationship was documented between increasing N and decreasing potential N mineralization after 7 months of N addition to three salt marshes in California [see [Table 11-2](#) for equation; ([Vivanco et al., 2015](#))]. In this same study, there was no relationship between N addition and net nitrification rates; however, the nitrification rates differed among the marsh sites.

In Kirkpatrick Marsh, MD, N addition decreased N retention in marshes dominated by native plants and by the invasive lineage of *Phragmites australis*. N addition of 250 kg N/ha/yr decreased ecosystem N retention by 55%, driven largely by a 57% decrease in N retention belowground, in roots, rhizomes, and soil ([Pastore et al., 2016](#)). N addition also altered the relative allocation of N to pools in marsh plants. N addition increased the total pool of N stored in aboveground biomass through stimulatory effects on biomass production (see [Appendix 11.4.1](#)), but decreased the total pool of N stored in belowground biomass by 6%. N addition decreased the pool of N in belowground biomass but also shifted the distribution of root N higher in the soil profile than in control plots (to 15–25 cm depth from 40–50 cm depth), making it more vulnerable to leaching and to microbial transformation: N addition increased pore water NH<sub>4</sub><sup>+</sup> concentrations 120% and N<sub>2</sub>O flux out of soils by 220% ([Pastore et al., 2016](#)). The invasive species *P. australis* established roots at depths below the native plant community (see [Appendix 11.3.2.1.2](#)), which increased mineralization deep in the peat profile to increase pore water [NH<sub>4</sub><sup>+</sup>] 9–72% at 40–70 cm ([Mozdzer et al., 2016](#)). Like many terrestrial invasive species, *P. australis* may respond to N loading by creating a positive feedback loop of increasing soil N availability and expanding invasion. Increasing reactive N may change the diversity and composition of microbial communities responsible for denitrification and nitrification. Change in the microbial communities could change the rate of the chemical reactions that microbes perform in the wetland. Increasing N loads alter the abundance of denitrifying bacteria.

In the long-term marsh fertilization experiment in a salt marsh in Massachusetts, *nirS* DNA sequences were amplified to assess denitrifying bacteria ([Bowen et al., 2013](#)). The plots sampled were fertilized with sewage sludge, which contained other nutrients, metals, and organic material in addition to N, and N addition rates were 221, 655, or 1,966 kg N/ha/yr. With the addition of N, denitrifying bacteria communities became more dissimilar, as widely distributed bacteria declined, and abundance and richness of unique denitrifiers increased ([Bowen et al., 2013](#)). [Lage et al. \(2010\)](#) sampled sediments associated with *Spartina patens* in a New England salt marsh. This study used the *amoA* DNA sequence in sediments to sample the ammonia-oxidizing bacteria, which produce nitrites from ammonia in the first step of nitrification. The majority of species affected by N addition were within a clade of *Nitrosospira*-like sequences found in other salt marshes. N addition decreased evenness of distribution and altered composition, specifically the relative abundance of taxa within the marine and estuarine *Nitrosospira*-like clade, suggesting that there are fine-scale genetic differences to the bacteria's ability to use nitrogen.

An incubation experiment of soils collected from different zones of salt marsh in Yancheng Nature Reserve added ammonium or nitrate in equal amounts of N to assess what effects N chemical species had on microbial cycling of N. N addition increased net N mineralization in all marsh zones, with oxidized N increasing net N mineralization 16–29%, and reduced N increasing net mineralization 58–69% ([Zhang et al., 2016c](#)). N forms had similar rates upon net nitrification rates, as  $\text{NO}_3^-$  addition increased nitrification rates 34–54%, and  $\text{NH}_4^+$  addition increased nitrification rates 65–94%. N addition also increased the temperature sensitivity of N mineralization ( $Q_{10}$ ) in low marshes ([Zhang et al., 2016c](#)), suggesting a synergistic stimulation between increased N loading and temperature upon N release from salt marshes to the marine environment.

---

### 11.3.1.3 Mangrove

In mangrove ecosystems, N addition suppressed N fixation and increased denitrification ([Whigham et al., 2009](#)). Laboratory incubations showed that the denitrification rate was 15 times higher in soils that had received 100 kg N/ha/yr than in control soils (N load on N deposition in control soils not reported). However, field measurements of  $\text{N}_2\text{O}$  emissions were 5.6 times higher in fertilized than in control soils, indicating incomplete denitrification in fertilized soils. Nitrogen fixation rates were suppressed by 88% in fertilized plots ([Whigham et al., 2009](#)).

---

#### 11.3.1.4 Freshwater Tidal Marsh

The Madisonville Nutrient Plots on the Tchefuncte River, LA, have received N addition of 0, 50, 200, or 1,200 kg N/ha/yr for 11 years. There was no measurable effect of N addition upon total N, microbial N, soluble N, denitrification rates, or C cycling in the top 10 cm of soil ([Steinmuller et al., 2016](#)), although there were effects upon aboveground productivity, plant stoichiometry, and plant community (see [Appendix 11.4.2](#), [Appendix 11.5.3](#), and [Appendix 11.8.1.2](#)).

---

#### 11.3.1.5 Riparian or Intermittent Wetlands

New studies on riparian wetlands include N addition relationships to denitrification rates and bacterial community composition. In a riparian wetland in Durham, NC, wetland species' potential denitrification activity increased linearly with increasing soil total inorganic N [see [Table 11-2](#) for equation; ([McGill et al., 2010](#))]. In freshwater riparian wetlands along the James River, VA, soils were collected and incubated with added nitrogen. Nitrogen addition increased the abundance of denitrifying bacteria—quantified as copies of the *nirS* sequence—by 541% when labile organic matter was also added ([Morrissey et al., 2013](#)). When N addition occurred simultaneously with the addition of recalcitrant organic matter, denitrifying bacterial abundance decreased 96% with increased N. Community composition of denitrifying bacteria shifted in response to N addition, as did the composition of bacteria capable of dissimilatory nitrate reduction to ammonia [quantified as copies of *nrfA* sequence; ([Morrissey et al., 2013](#))].

In riparian forests, increased N loads altered the symbiotic association between *Alnus incana* ssp. *tenuifolia* (grey alder) and *Frankia* (actinorhizal, N-fixing bacteria). N addition of 100 kg N/ha/yr decreased the density of *Frankia*-hosting root nodules by 62% compared with nodules from unamended control plots. Nodule respiration rates were 28% lower under N fertilization, indicating lower rates of *Frankia* metabolism, and N fixation in nodules was 31% lower than in controls ([Ruess et al., 2013](#)).

A recent study of an alpine meadow and intermittent wetland on the Tibetan Plateau found that adding 30 kg N/ha/yr changed the wetland from a net sink to a net source of N<sub>2</sub>O emissions to the atmosphere, suggesting N addition stimulated microbial denitrification ([Wang et al., 2017c](#)).

---

### 11.3.1.6 Bog and Fen

In peat bog ecosystems, N addition decreases ecosystem retention of N and increases N exports in surface water from hydrologically connected bogs. In Mer Bleue Bog, Ontario, N addition decreased the N retention efficiency of the ecosystem, as measured by the recovery of an  $^{15}\text{N}$  tracer. When N was added at the rate of 16 kg N/ha/yr from 2000–2007, a pulse of added  $^{15}\text{N}$  was recovered at lower rates from fertilized plots than from unamended control plots (N deposition was 8 kg N/ha/yr), indicating a 71% reduction in average retention efficiency across biomass pools (Xing et al., 2011). A recent study (samples taken in 2014) in this bog found increases in nitrate and ammonium concentrations in response to N addition in peat, with N addition increasing  $[\text{NO}_3^-]$  71–169% and  $[\text{NH}_4^+]$  90–269%, suggesting that the living *Sphagnum* moss is no longer retaining N but leaching it into the peat below (Pinsonneault et al., 2016).

A European study of N pools in bogs found that N deposition changes the retention of N within vascular plants and peat soil. Under N treatment equivalent to deposition of 2 kg N/ha/yr,  $^{15}\text{N}$  recovery was 66% for mosses, 3.8% for shrubs, and 1.8% for graminoids. Deposition of 47 kg/ha/yr changed  $^{15}\text{N}$  recovery to 12% for shrubs as well as increasing the total N stored in shrubs by 360% compared to mesocosms receiving 2 kg N/ha/yr.  $^{15}\text{N}$  recovery also declined in peat under N deposition, with  $^{15}\text{N}$  recovery of 60% under 2 kg N and  $^{15}\text{N}$  recovery of 36% under 47 kg N (Zajac and Blodau, 2016). Increases in plant N uptake along with decreasing efficiency of plant N retention (see Appendix 11.5.5) can lead to increases in dissolved organic N exports from bogs. A study in a NPK-fertilized and limed (addition of  $\text{CaCO}_3$ ) peatland catchment in the U.K. found high levels of N export (14 kg N/ha watershed/yr) from the wetland to the Kinder River, with over half of the exported N in the form of dissolved organic nitrogen (Edokpa et al., 2015).

The Whim bog experiment in Scotland added N as either ammonium or nitrate to simulate wet deposition, which with ambient N deposition of 8 kg N/ha/yr resulted in treatment N loads of 16, 32, and 64 kg N/ha/yr. Increasing  $\text{NO}_3^-$  loading increased concentrations of dissolved organic nitrogen (DON) in pore water, while increasing  $\text{NH}_4^+$  loading increased cation leaching from moss into pore water, and increased DIN in pore water at the highest N addition level (Chiwa et al., 2016). N addition impaired the ability of the *Sphagnum* moss mat to absorb and retain N, beginning at 32 kg N/ha/yr for oxidized N and 64 kg N/ha/yr for reduced N addition. This study illustrates the different effects of reduced and oxidized N upon bog ecosystems (see also, Appendix 11.5.5). However, a recent analysis by (Wieder et al., 2016) suggested that North American and European *Sphagnum* species have different tolerances for and responses to N loading, so critical loads for North American bogs should be inferred with caution from European bogs.

Recent studies have documented high rates of nitrogen fixation by microbial diazotrophs living on and in dead *Sphagnum* cells (Vile 2014 and Larmola 2014 in [van Den Elzen et al., 2017](#)). Microbial N fixation rates were observed at N deposition of 25 kg N/ha/yr, and added another 6 kg N/ha/yr to moss and peat ([van Den Elzen et al., 2017](#)).

### 11.3.1.7 Summary Table

**Table 11-2 New studies on nitrogen addition effects on nitrogen cycling in wetlands.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Agricultural wetlands; intertidal marshes; freshwater bogs and marshes; freshwater swamps; other wetlands	0.02–90,480 kg N/ha/yr as N load, mean load for each wetland class: agricultural: 426, intertidal: 211, freshwater bogs and marshes: 890, freshwater swamps: 69, other: 280 kg N/ha/yr Deposition = not reported	Removal: wetland N removal ( $N_{\text{removal}}$ ) is proportional to N load ( $N_{\text{load}}$ ): $\log(N_{\text{removal}}) = 0.943 \times \log(N_{\text{load}}) - 0.033$ . N removal efficiency is 26% higher in nontidal than tidal wetlands.	Global	Reanalysis of data from 109 global wetlands	<a href="#">Jordan et al. (2011)</a>
Wetlands (natural and agricultural)	N addition experiments, N addition of 15.4 to 300 kg N/ha/yr Deposition = not reported	N addition increases $N_2O$ emissions 207% across wetlands ( $n = 19$ ).	Global	Meta-analysis of data collected from North America, South America, Europe, and Asia	<a href="#">Liu and Greaver (2009)</a>
Salt marsh	Addition = 180 kg N/ha/yr (as Milorganite, NPK 10-6-4), 520 kg N/ha/yr (as urea or as Milorganite), 1,560 kg N/ha/yr (as Milorganite)	Tidal export of N increases with increasing N addition ( $N_{\text{add}}$ as kg N/ha/yr). For $NH_4^+$ export ( $NH_{\text{export}}$ , in kg N/season): $NH_{\text{export}} = 0.00083 \times N_{\text{add}} + 0.432$ . For $NO_3^-$ export ( $NO_{\text{export}}$ , in kg N/season): $NO_{\text{export}} = 0.122 \times e^{-0.0018N_{\text{add}}}$	Great Sippewissett Marsh, MA	<i>Spartina alterniflora</i> , <i>Spartina patens</i> , and <i>Distichlis spicata</i>	<a href="#">Brin et al. (2010)</a>

**Table 11-2 (Continued): New studies on nitrogen addition effects on nitrogen cycling in wetlands.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Salt marsh	Addition = 0, 100, 200, 400, 800, 1,600, 3,200 kg N/ha/yr as urea N deposition = 3–5 kg N/ha/yr as reported in <a href="#">Tonnesen et al. (2007)</a>	Mineralization: potential net N mineralization ( $N_{min}$ ) decreases in a linear response to added N ( $N_{add}$ , in g N/m <sup>2</sup> /yr): $N_{min} = -0.0015 \times N_{add} + 0.022$ . Nitrification: no significant relationship.	Morro Bay National Estuary, Carpinteria Salt Marsh Reserve, Tijuana River Reserve Estuary, CA	<i>Salicornia depressa</i> ( <i>Salicornia virginica</i> ) stands	<a href="#">Vivanco et al. (2015)</a>
Salt marsh	Addition: 50 mg N/kg soil, as (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub> or NaNO <sub>3</sub> Ambient deposition = not specified	N addition increased net N mineralization in all three marsh zones. NO <sub>3</sub> <sup>-</sup> addition increased net N mineralization 16–29%, and NH <sub>4</sub> <sup>+</sup> addition increased net N mineralization by 58–69%. The most predictive soil parameter for net N mineralization was labile C:labile N ( $r = -0.85$ ) N addition increased net nitrification in all three marsh zones. NO <sub>3</sub> <sup>-</sup> addition increased net nitrification 34–54%, and NH <sub>4</sub> <sup>+</sup> addition increased net nitrification by 65–94%. The most predictive soil parameter for net nitrification was labile C:labile N ( $r = -0.81$ ). N addition increased Q <sub>10</sub> values (stimulatory effect of temperature upon net N mineralization) in <i>P. australis</i> and <i>S. alterniflora</i> marsh zones.	Aerobic soil incubations constructed from core samples from Yancheng National Nature Reserve, China	Monospecific stands across marsh elevation gradient: <i>Suaeda salsa</i> (native) in high marsh, <i>Phragmites australis</i> (native) in low marsh, <i>Spartina alterniflora</i> (invasive, native to North America) in previously unvegetated mud flats	<a href="#">Zhang et al. (2016c)</a>

**Table 11-2 (Continued): New studies on nitrogen addition effects on nitrogen cycling in wetlands.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Intertidal marsh	Addition = 250 kg N/ha/yr (as NH <sub>4</sub> Cl) since 2006 Ambient deposition = not reported Average N loads to Chesapeake Bay are 140 kg N/ha/yr <sup>15</sup> N tracer applied 2006, measure AG 2005–2013, measured BG 2014	Total marsh retention (AG biomass, BG biomass, soil) of <sup>15</sup> N label was 55% lower in N treatment, because belowground (BG biomass + soil) N retention was 57% lower in N treatment. Across elevated CO <sub>2</sub> treatments, belowground N retention was 51% lower in N treatment. N addition increased N mass in AG biomass for C4 grasses. N addition increased N mass in total plant biomass for the first 6 yr, but not for the last 2 yr of measurement. N addition decreased N mass of fine roots. N addition decreased total N BG by 6% by shifting N mass across the soil profile: N addition increased BG N mass at depths of 15–25 cm, but decreased BG N mass at depths of 40–50 cm. N addition increased N <sub>2</sub> O flux from plots by 220% and pore water NH <sub>4</sub> <sup>+</sup> concentrations increased 120%.	Kirkpatrick Marsh, Rhode River, Edgewater, MD	C3 <i>Schoenoplectus americanus</i> ; C4 <i>Spartina patens</i> and <i>Distichlis spicata</i>	<a href="#">Pastore et al. (2016)</a>
Intertidal marsh	Addition = 250 kg N/ha/yr (as NH <sub>4</sub> Cl) Ambient deposition = not reported	N addition increased pore water concentrations of NH <sub>4</sub> <sup>+</sup> by 9 and 72% at depths of 40 and 80 cm, respectively. <i>P. australis</i> increased SOM decomposition in recalcitrant peat 1.8–1.9 times over rates in unvegetated peat. DNF = denitrification; DNRA = dissimilatory nitrate reduction to ammonium; fert = fertilizer; ha = hectare; kg = kilogram; KNO<sub>3</sub> = potassium nitrate; LTER = Long-Term Ecological Research; N = nitrogen; NH<sub>4</sub><sup>+</sup> = ammonium; NH<sub>4</sub>NO<sub>3</sub> = ammonium nitrate; NPK = nitrogen, phosphorus, potassium; S = sulfur; yr = year.

### 11.3.2 Soil Carbon Cycling

Wetlands can be hotspots for emissions of carbon dioxide and methane. High water levels in wetland soils prevent the rapid decomposition of dead roots and fallen stems by aerobic bacteria or fungi. Over long time periods (decades, centuries, or millennia), these conditions result in large stores of carbon belowground in wetland systems. Methanogens are able to decompose some of these anaerobic, saturated carbon stores to produce methane, and in severe droughts, a larger microbial community can produce large pulses of carbon dioxide by decomposing freshly aerated older organic carbon. Endpoints of

methane and carbon dioxide emissions have important implications for the wetland function of long-term carbon storage and regulation of atmospheric composition.

A meta-analysis that included wetlands with other nonforest ecosystems indicated no effect of N deposition on overall net ecosystem exchange of carbon (see [Appendix 11.3.2.2.1](#)). In other words, any gain in carbon capture by photosynthesis was offset by ecosystem respiration and C leaching. There were not enough studies to evaluate wetlands as a separate category.

---

### **11.3.2.1 Belowground Decomposition, Respiration, and Biomass**

Respiration includes the release of carbon dioxide that can be measured in the air. Soil respiration may be the result of root or microbial activity. The process of decomposition often releases carbon dioxide from organic matter. Decomposers feed on dead organic matter, breaking it down into smaller compounds such as carbon dioxide or methane, water, and nutrients. Nitrogen may change the rate of respiration and decomposition.

Low decomposition in wetlands results in the buildup of dead plant material in the soil. In relatively closed systems, such as rain-fed bogs, a nutrient-poor, high-organic-acid ecosystem is produced. In open systems where flowing surface water supplies additional nutrients and sediments, the growth of new root systems on top of undecomposed roots can trap sediment and increase the height of the soil surface. This accretion of new wetland soil depends on both plant growth and maintenance of old carbon stored in soil organic matter. Wetland existence depends on the sum of these processes: if the sum of new plant growth does not exceed the decomposition of the soil organic matter, the wetland may subside until water levels rise above the soil surface. In this case, the drowned wetland area converts to an aquatic system. Wetland accretion is particularly important in estuarine and marine systems, where wave action and tides regularly wash sediment and dead plant material out of the wetland into aquatic systems, where the material nourishes aquatic food webs. Belowground endpoints, such as bulk density, soil organic matter, and root and rhizome production, are all indicators of wetland health and continued existence ([Table 11-3](#)).

#### **11.3.2.1.1 Across Wetlands**

A new study of 90 wetlands around the Gulf Coast from Florida to Texas found that higher N in the soil correlated with lower soil bulk density [see [Table 11-3](#) for equation; ([Nestlerode et al., 2014](#))]. Wetlands included both tidal and nontidal marshes and swamps. Reactive N or atmospheric N deposition loads were not quantified. This result

suggests that higher N in wetlands correlates with a reduction in wetland soil stability, making wetlands more susceptible to erosion.

#### 11.3.2.1.2 Salt Marsh

A new study confirms N loading increases carbon dioxide production from salt marsh soils. The new study uses an older model developed by [Wigand et al. \(2003\)](#), the Nitrogen Loading Model (NLM) for wetlands and estuaries of Narragansett Bay, RI, to determine annual N loads for different watersheds (sum of  $N_r$  from runoff, deposition, and municipal waste, 10.3–6,727 kg N/ha/yr) within the bay. Sampling of cordgrass marshes [*Spartina alterniflora* and *Spartina patens*; ([Wigand et al., 2009](#))] within these watersheds showed that soil respiration of CO<sub>2</sub> increased linearly and at similar rates with increasing annual N load in stands of *S. alterniflora* and *S. patens*. Decreases in sediment soil %C and %N and in belowground biomass were also observed as soil respiration increased ([Wigand et al., 2009](#)). Two additional experiments evaluated how N addition affects soil respiration ([Anisfeld and Hill, 2012](#)) and general CO<sub>2</sub> [see [Wigand et al. \(2015\)](#)]. In both cases, N addition increased these rates; however, the amount of N was over 1,000 kg/ha/yr, too high a level to evaluate the effects of N deposition.

In the Great Sippewissett Marsh fertilization experiment, fertilization with 520 kg N decreased long-term carbon storage in substrates by 31% ([Turner et al., 2009](#)). The stability of the marsh substrate (measured as the physical resistance to force) decreased 60% in urea-only fertilized plots. In contrast, N addition to *S. alterniflora* marshes located in Cocodrie, LA did not affect the physical resistance of the surface marsh substrate, and no changes at any profile were detected with the addition of 1,200 kg N/ha/yr ([Turner, 2011](#)). This study found negative effects upon marsh physical resistance at high rates of N addition (2,300–18,600 kg N/ha/yr) not relevant to evaluating the effects of N deposition.

The stability of marsh peat soils depends in part upon coarse roots and rhizomes, which marsh plants produce for physical support and as perennial storage organs. A long-term study at Goat Island, SC found stimulatory effects of N addition upon *Spartina alterniflora* coarse roots and rhizomes, and organic matter in peat ([Wigand et al., 2015](#); [Davey et al., 2011](#)), but the experimentally added N load was 4,200 kg N/ha/yr, too high to infer N deposition effects. Each year, marsh plants produce a new set of fine roots to acquire nutrients from the sediment and pore water. In Kirkpatrick Marsh, vegetation consisted of *Schoenoplectus americanus*, *Spartina patens*, and *Distichlis spicata*. N addition (250 kg N/ha/yr) decreased fine root production by 42 and 84% compared to control plots in the 3rd and 4th years of the experiment ([Langley and Megonigal, 2012, 2010](#)). When *S. americanus* and *S. patens* were planted in mesocosms for a sea level by

nitrogen fertilization factorial experiment, results were different. There was no belowground response in mesocosms at current sea levels to nitrogen addition ([Langley et al., 2013](#)). However, in a mesocosm mimicking a 10 cm rise in sea level, N addition increased belowground biomass by 130%. In a mesocosm mimicking a productive marsh elevated 15 cm above current sea level, N addition increased fine roots in mesocosms by 20–40% ([Langley et al., 2013](#)). The long-term study at Goat Island found inhibitory effects of N addition upon fine root mass ([Davey et al., 2011](#)), but the experimentally added N load was too high to infer N deposition effects.

North American salt marshes are currently being invaded by the European lineage of *Phragmites australis*, which is identified as a noxious weed or banned from sale or transport by six states ([USDA, 2015b](#)). A Kirkpatrick Marsh study compared establishing *P. australis* mesocosms to mesocosms of the native plant community described by [Langley et al. \(2013\)](#), and found that 250 kg N/ha/yr increased belowground biomass of the invasive species ([Mozdzer et al., 2016](#)). The invasive species had a greater rooting depth than the native community, and N addition increased root biomass 23–69% at depths of 10 to 40 cm, giving *P. australis* a competitive advantage over the native species. *P. australis* roots primed microbial activity and increased decomposition of buried peat by 1.8–1.9 times rates in uncolonized peat ([Mozdzer et al., 2016](#)), creating a positive feedback loop between increasing N and invasive species expansion. A large scale eutrophication experiment conducted at Plum Island Estuary, MA added nitrogen and phosphorus to tidal inflows to raise tidal nitrate concentrations to 15 times the background N load ([Deegan et al., 2012](#)). Although the annual nitrogen load cannot be calculated, the results of this experiment illustrate the mechanisms by which N addition destabilizes salt marshes. Belowground biomass decreased 33% compared to control marshes, and this in turn altered drainage, resulting in 4% higher water content in creek banks in enriched marshes. Creek bank with decreased stabilizing root mats and increased water content were less stable, with increasing numbers and lengths of creek bed fractures over time (see [Table 11-3](#) in [Appendix 11.3.2.1.6](#) for equation). Creek banks were so destabilized by N addition that the number of slumps, or creek edges sliding into creek beds, was 113% higher in enriched than control marsh, which increased the creek channel width:depth ratio by 28%. The unvegetated area of exposed mud was 200% higher in the enriched marsh as a consequence of the marsh destabilization ([Deegan et al., 2012](#)).

#### **11.3.2.1.3 Freshwater Tidal Marsh**

In marshes, coarse roots and rhizomes are produced by plants to serve as physical supports and as storage organs for nutrients and carbohydrates. In a freshwater tidal

marsh dominated by *Zizaniopsis miliacea* in the Altamaha River Estuary, GA, addition of 500 kg N/ha/yr decreased the biomass of live rhizomes by 71%, and the mass of macro-organic matter (living + dead roots) decreased 33% ([Ket et al., 2011](#)). An N-loading experiment added 50, 200, or 1,200 kg N/ha/yr to a freshwater tidal marsh on the Tchefuncte River, LA ([Graham and Mendelssohn, 2016](#)). Researchers used two different sampling methods to assess belowground biomass. Addition of 200 or 1,200 kg N/ha/yr reduced biomass of established roots by 51%. Addition of 1,200 kg N/ha/yr also increased growth of new roots into empty soil 106% over control ([Graham and Mendelssohn, 2016](#)). This suggests that high and very high levels of N loading to tidal freshwater marshes may destabilize existing marshes, while very high N loading may accelerate establishment or expansion of new marshes. However, N addition in this experiment had no measurable effect upon organic matter content, bulk density, total C, total P, or N cycling in the top 10 cm of soil [see [Appendix 11.3.1.4](#); [Steinmuller et al. \(2016\)](#)].

#### **11.3.2.1.4 Intermittent Wetland**

An N addition study was established on the Tibetan Plateau in an alpine meadow that is also an intermittent wetland. N addition of 30 kg N/ha/yr increased belowground biomass 26%. N addition also stimulated CO<sub>2</sub> uptake 25% ([Wang et al., 2017c](#)), which offset the concurrent stimulation of N<sub>2</sub>O emissions (see [Appendix 11.3.1.5](#)).

#### **11.3.2.1.5 Bog and Fen**

In the 2008 ISA, soil respiration in bogs had been studied in European countries under a natural gradient of atmospheric N deposition from 2 to 20 kg N/ha/yr. Studies found enhanced decomposition rates for material accumulated under higher atmospheric N supplies resulted in higher carbon dioxide emissions. There are three new studies on an Ontario bog and two new studies from European systems.

The Mer Bleue Bog in Ontario is the site of two concurrent fertilization experiments. In one experiment, treatments were initiated in 2000 with nitrogen addition of 16 kg N/ha/yr. The second experiment was initiated in 2005 in separate plots, where nitrogen-only treatments of 32 kg N/ha/yr and 64 kg N/ha/yr were applied. Each experiment had separate control plots. N addition at the rate of 16 kg N/ha/yr decreased the concentrations of CO<sub>2</sub> in peat substrate in the 8th year of N addition (2007), decreasing CO<sub>2</sub> by 19% at a 5-cm depth and 14% at a 25-cm depth ([Wendel et al., 2011](#)). N addition at the rate of 64 kg N/ha/yr did not significantly alter ecosystem respiration when assessed 7 years after fertilization started (2011), but due to changes in

photosynthesis and declines in cover (see [Appendix 11.5.5](#) and [Appendix 11.8.1.5](#)), net ecosystem exchange in the growing season was 46% lower than in unamended bog plots ([Larmola et al., 2013](#)).

In the Mer Bleue ombrotrophic peat bog, 16 kg N/ha/yr added from 2000 to 2007 increased peat biomass 17% in the top 10 cm of the substrate. In addition, median temperature at a 5-cm depth in the peat was 19% lower in plots that received 16 kg N/ha/yr than in control plots ([Wendel et al., 2011](#)), which the authors posited was due to increased shading by increasingly productive shrub species. In contrast, soil temperatures were elevated deeper in the peat substrate; at 20-cm depth, average daily temperature was 0.6°C higher in plots with 16 kg N/ha/yr added than in control plots ([Wendel et al., 2011](#)). More recently, peat samples from Mer Bleue suggest that N addition of 16 kg N/ha/yr, along with the resultant increase in shrub production, has increased soluble phenolics 17% in peat, with peat C:K ratio increasing 45% ([Pinsonneault et al., 2016](#)), indicating a shift towards more recalcitrant C in the peat as well as K limitation of the bog (see [Appendix 11.5.5](#)). In terms of the microbial community responsible for decomposition and respiration in the peat, N addition in all amounts increased P and K limitation, as indicated by increasing soluble C:P and C:K ratios and increasing activity of P and K acquiring enzymes. However, N addition also increased microbial breakdown of carbon, as indicated by 62–97% increases in the activity of  $\beta$ -D-glucosaminidase ([Pinsonneault et al., 2016](#)). A recently initiated addition experiment in the same bog added 64 kg N/ha/yr as either  $\text{NH}_4^+$  or  $\text{NO}_3^-$  and found that reduced N resulted in 15% higher soluble phenolics and suppressed enzyme activities compared to oxidized N ([Pinsonneault et al., 2016](#)). This result suggests that oxidized N is more likely to enhance microbial decomposition of peat than an equivalent amount of reduced N.

A recent study of mesocosms collected from European bogs under a natural gradient of N deposition from 2 to 24 kg N/ha/yr showed that increasing N deposition correlated with increased respiration (and increased gross primary productivity, and increased net C uptake; see [Appendix 11.4.5](#)) up to 15 kg N/ha/yr, but that all C fluxes decreased by 40% between 15 and 24 kg N/ha/yr ([Estop-Aragones et al., 2016](#)). Importantly, N stimulation of respiration continued under drought conditions, although there was no relationship during drought between N deposition and GPP or net carbon uptake. Inference from this study is limited by sample size; there was only one mesocosm per bog ([Estop-Aragones et al., 2016](#)). In a study of decomposition rates conducted in Eastern Europe, N deposition altered decomposition rates in bogs. When a standard cellulose substrate was placed in all bogs, decomposition mass loss was higher at the high N deposition (20–25 kg N/ha/yr) Jizera Mountains site, 170% higher when placed in areas dominated by *Sphagnum rubrum*, and 510% higher mass loss in areas dominated by *S. magellanicum*, than in the

low N deposition (12.5 kg N/ha/yr) Jeseníky Mountains site ([Jirousek et al., 2015](#)). When *S. rubrum* samples were collected from both sites and decomposed in a common site, moss collected from the high N site decomposed more slowly, with 30% less mass lost than from moss collected at the low N site, indicating that N deposition increased the recalcitrance of moss to decomposition ([Jirousek et al., 2015](#)). In contrast, at the Whim Bog N addition experiment, there was no effect of added N as either ammonium or nitrate (treatment N loads of 16, 32, and 64 kg N/ha/yr) upon decomposition of senesced *Sphagnum* moss ([Manninen et al., 2016](#)), although there were effects upon living moss and water quality (see [Appendix 11.5.5](#) and [Appendix 11.3.1.5](#)).

### 11.3.2.1.6 Summary Table

**Table 11-3 Loading effects upon belowground carbon cycling.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Estuarine marsh, estuarine shrub swamp, palustrine marsh, palustrine swamp	N dep = not reported S dep = not reported	Soil total N ( $N_{soil}$ , as %N) increased as soil bulk density (SBD, as g/cc) decreased, $\ln(N_{soil}) = -1.9233 \times SBD + 0.4165$ .	90 Gulf Coast wetlands, Texas to Florida	Marsh community, soil and pore water chemistry	<a href="#">Nestlerode et al. (2014)</a>
Salt marsh	Watershed total N load (10.3, 11.5, 27.4, 37.4, 2,729.9, 3,661, and 6,727 kg N/ha/yr) using nitrogen loading model in <a href="#">Wigand et al. (2003)</a> N dep = not reported S dep = not reported	In <i>S. alterniflora</i> stands, soil respiration ( $y$ ) increased linearly with N loading ( $x$ ) ( $y = 0.0006x + 2.04$ ). Soil %C and %N decreased as soil respiration increased.	Narragansett Bay, RI	Bare sediments in <i>Spartina patens</i> and <i>Spartina alterniflora</i> stands, additional <i>S. patens</i> marshes from <a href="#">Wigand (2008)</a> ; <a href="#">Wigand et al. (2003)</a>	<a href="#">Wigand et al. (2009)</a>

**Table 11-3 (Continued): Loading effects upon belowground carbon cycling.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Salt marsh	Addition: 1,050 kg N/ha/yr (low) as NaNO <sub>3</sub> , 2,100 kg N/ha/yr (medium) as NH <sub>4</sub> NO <sub>3</sub> or NaNO <sub>3</sub> , 4,200 kg N/ha/yr (high) as NH <sub>4</sub> NO <sub>3</sub> in same plots in over several years N dep = not reported S dep = not reported	Medium N increased annual sediment respiration (g C/m <sup>2</sup> /yr) by 53%.	Hoadley Creek Marsh, Guilford, CT	<i>Spartina alterniflora</i>	<a href="#">Anisfeld and Hill (2012)</a>
Salt marsh	520 kg N/ha/yr in U (N as urea treatment), UP (urea + 208 kg P/ha/yr as phosphate), and HF (milorganite, 10-6-4 NPK) plots, as reported by <a href="#">Brin et al. (2010)</a> N dep = not reported S dep = not reported	Fertilization decreased the organic:inorganic ratio by 31% in older, deeper (pre-1963) marsh substrate, and decreased the physical resistance of the marsh substrate (shear vane strength) by 60% in U plots, 36% in UP plots, and 35% in HF plots.	Great Sippewissett Marsh, MA	<i>Spartina alterniflora</i> , <i>Spartina patens</i> , and <i>Distichlis spicata</i>	<a href="#">Turner et al. (2009)</a>
Coastal salt marsh	Addition: 4,200 kg N/ha/yr as NH <sub>4</sub> NO <sub>3</sub> or (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub> N dep = not reported S dep = not reported	N addition increased coarse root volume 63% in the top 10 cm, or 61% in the top 20 cm of sediment. Organic matter increased 20% in the top 21 cm of sediment. CO <sub>2</sub> emission increased 41%.	Goat Island, SC (measured 2008)	<i>Spartina alterniflora</i> and associated sediments	<a href="#">Wigand et al. (2015)</a>
Salt marsh	4,200 kg N/ha/yr as NH <sub>4</sub> NO <sub>3</sub> N dep = not reported S dep = not reported	N addition increased peat mass fraction by 28% and root/rhizome mass fraction by 58% in wet shallow (<10 cm) sediments. Fine root mass decreased 39% in shallow sediments.	Goat Island, SC (measured 2008)	<i>Spartina alterniflora</i>	<a href="#">Davey et al. (2011)</a>

**Table 11-3 (Continued): Loading effects upon belowground carbon cycling.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Estuarine salt marsh	250 kg N/ha/yr N dep = not reported S dep = not reported	Total fine root production decreased by 42 and 84% in the 3rd and 4th yr.	Kirkpatrick Marsh, MD (measured in 3rd and 4th yr, 2008–2009)	<i>Schoenoplectus americanus</i> (C3), <i>Spartina patens</i> (C4), and <i>Distichlis spicata</i> (C4)	<a href="#">Langley and Megonigal (2012, 2010)</a>
Estuarine salt marsh	NH <sub>4</sub> Cl solution injected into mesocosm peat at root-level, 250 kgN/ha, increases N by 40% above annual average background concentration Deposition not reported	At increased marsh elevation (15 cm above current sea level), N addition increased total fine root mass by 20–40%. At 10 cm sea level rise, N addition increases BG biomass by 130% under ambient [CO <sub>2</sub> ].	Kirkpatrick Marsh, MD	Factorial mesocosm experiment with varying sea levels: 35 or 15 cm rise in marsh elevation; current sea level; 10, 20, or 30 cm rise in sea level.  Mesocosms planted with 2 rhizomes <i>Schoenoplectus americanus</i> and 10 stems <i>Spartina patens</i> ; harvested each year	<a href="#">Langley et al. (2013)</a>
Salt marsh	Addition = 250 kg N/ha/yr (as NH <sub>4</sub> Cl) Ambient deposition = not reported	N addition did not significantly affect the rooting depth of <i>Phragmites australis</i> , which was significantly deeper than rooting depth of native community. N addition increased belowground biomass of <i>P. australis</i> 37–69% between 10 and 40 cm depth, with peak increases at 10 cm depth. N addition increased pore water concentrations of NH <sub>4</sub> by 9 and 72% at depths of 40 and 80 cm, respectively. <i>P. australis</i> increased SOM decomposition in recalcitrant peat 1.8–1.9x over rates in unvegetated peat.	Mesocosms of invasive (from seeds) or native (from rhizome fragments) plants in Kirkpatrick Marsh, Rhode River, Edgewater, MD	Invasive <i>Phragmites australis</i> ; native community of <i>Spartina patens</i> , <i>Schoenoplectus americanus</i>	<a href="#">Mozdzer et al. (2016)</a>

**Table 11-3 (Continued): Loading effects upon belowground carbon cycling.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Salt marsh	<p>Nitrate and phosphate dissolved in tidal inflows to raise aqueous NO<sub>3</sub><sup>-</sup> concentrations to 70–100 μM and raise PO<sub>4</sub><sup>3-</sup> to 5–7 μM.</p> <p>Background load in tides: 5 μM NO<sub>3</sub><sup>-</sup>, 1 μM PO<sub>4</sub><sup>3-</sup>.</p> <p>N dep = not reported</p> <p>S dep = not reported</p>	<p>Marsh stability (F, as creek bank fractures) decreases with cumulative N enrichment (y, in years of N enrichment): F = 0.42y + 0.79. Creek fractures were 4.4x as long in enriched as in control marsh.</p> <p>Water content in creek bank increases 4%.</p> <p>Number of bank slumps into creek bed is 2.1x higher in enriched marsh. Channel width:depth increased 28%.</p> <p>Belowground biomass decreases 33%.</p> <p>Area of unvegetated exposed mud increased 200%.</p>	Plum Island Estuary, MA	Primary tidal creeks with <i>Spartina alterniflora</i> in low marsh along creeks, and <i>Spartina patens</i> in high marsh platforms	<a href="#">Deegan et al. ### 11.3.2.2 Methane Emissions

Methane (CH<sub>4</sub>) is an important greenhouse gas that is over 20 times more effective at trapping heat than carbon dioxide. The primary biological source of methane is microbial (methanogens in the domain Archaea), as is the primary biological sink (methanotrophs among the Bacteria and Archaea). N addition can stimulate methane flux from wetlands by increasing methanogen activity when dissolved labile organic C is abundant ([Kim et al., 2015b](#)), or by decreasing methane oxidation by methanotrophs, as was recently observed in a boreal peatland ([Lozanovska et al., 2016](#)). Therefore, understanding the controls on these microorganisms is important for predicting methane flux from ecosystems. In terms of carbon emissions, the 2008 ISA reported that N deposition alters CH<sub>4</sub> flux in wetland and forested ecosystems. A meta-analysis of 25 N addition observations (N addition 30 to 240 kg N/ha/yr) found that N addition increased CH<sub>4</sub> emissions by 95% from wetlands and grasslands [see [Table 11-4](#) for other nonsignificant results; ([Liu and Greaver, 2009](#))].

There is new evidence that N loading increases methane production in soils. In the N addition experiments replicated in three California marshes ([Vivanco et al., 2015](#); [Irvine et al., 2012](#)), field-measured methane flux from soils increased linearly with increasing N load (0, 100, 200, 400, 800, 1,600, 3,200 kg N/ha/yr), such that CH<sub>4</sub> flux from soils increased by 1.23 µg CH<sub>4</sub>/m<sup>2</sup>/day for each 10 kg N/ha/yr added  $R^2 = 0.23$  and  $P = 0.025$  ([Vivanco et al., 2015](#); [Irvine et al., 2012](#)). Methane flux increased from low or nearly negative to net positive values above ~100 kg N/ha/yr, showing that the effect of added N on methanogenesis, the final step in anaerobic decomposition, offset any increase in methanotrophy. Differential effects of N on both methanogenesis and methanotrophy have been documented in other ecosystems ([Irvine et al., 2012](#); [Liu and Greaver, 2009](#)). The linearity of the trend became less robust when the exposure time increased to 14 months.

Soils were collected from the Tijuana River Reserve near the sites used in [Vivanco et al. \(2015\)](#) and incubated in a laboratory microcosm experiment with factorial C and N additions ([Irvine et al., 2012](#)). Adding C and N together increased methane production by 44% above controls ([Irvine et al., 2012](#)), suggesting that N loading will increase microbial methane production disproportionately when accompanied by pulses of labile C. The authors concluded that temperate salt marshes generally emit low levels of methane, but these values are also highly spatially and seasonally variable ([Cheng et al., 2010](#); [Magenheimer et al., 1996](#); [Bartlett et al., 1985](#); [King and Wiebe, 1978](#)). Despite the high variability observed, however, the field experiments suggest that increased N availability

stimulated methanogenesis and increased methane emissions in southern California salt marshes, as in other ecosystems ([Liu and Greaver, 2009](#)).

A study of a salt marsh in the Yellow River Delta, China, added N loads in different chemical forms to the marsh to determine the effects of N form upon microbial communities involved in C cycling. N was added as 50 kg N/ha/yr as  $\text{NH}_4^+$ , 50 kg N/ha/yr as  $\text{NO}_3^-$ , or 100 kg N/ha/yr as  $\text{NH}_4\text{NO}_3$ . All three forms of N increased the abundance of archaeal methanogens as well as the abundance of bacteria that form syntrophies that stimulate methanogen metabolism ([Xiao et al., 2017](#)). Ordination of bacterial community composition suggested that all forms of N shifted the microbial community in the same direction, but that reduced N had much stronger effects on community composition than did oxidized N. N form also affected methane production and fluxes: all N forms increased methane in pore water, but only  $\text{NH}_4^+$  and  $\text{NH}_4\text{NO}_3$  additions increased methane emissions from the plots ([Xiao et al., 2017](#)). Reduced forms of N have stronger effects on microbial C cycling than do equivalent amounts of oxidized N.

#### 11.3.2.2.1 Summary Table

**Table 11-4 Nitrogen loading effects upon methane emissions.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Wetlands (natural and agricultural)	N addition experiments, N addition of 10 to 562 kg N/ha/yr Deposition = not reported	No effect across wetlands (n = 6) of N addition on net ecosystem exchange. N addition increased $\text{CH}_4$ emissions by 95% across grass + wetland + anaerobic agricultural systems (n = 25). No effect across drained wetlands of N addition (n = 6) upon biological $\text{CH}_4$ uptake.	Global	Meta-analysis of data collected from North America, South America, Europe, and Asia	<a href="#">Liu and Greaver (2009)</a>
Salt marsh	100, 200, 400, 800, 1,600, and 3,200 kg N/ha/yr as granular urea	Methane flux (y, as $\text{mg CH}_4/\text{m}^2/\text{day}$ ) increased linearly with N addition ( $N_{\text{add}}$ , as $\text{g N}/\text{m}^2/\text{yr}$ ): $y = 0.00123 \times N_{\text{add}} - 0.0122$ .	Morro Bay, Carpinteria Salt Marsh, Tijuana River Reserve, CA	Marsh dominated by <i>Salicornia depressa</i> (formerly <i>Salicornia virginica</i> )	<a href="#">Irvine et al. (2012)</a>

**Table 11-4 (Continued) Nitrogen loading effects upon methane emissions.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Salt marsh	0, 100, 200, 400, 800, 1,600, 3,200 kg N/ha/yr as urea  N dep = 3–5 kg N/ha/yr as reported in <a href="#">Tonnesen et al. (2007)</a>	CH <sub>4</sub> flux from soils increased by 1.23 µg CH <sub>4</sub> /m <sup>2</sup> /day for each 10 kg N/ha/yr added	Morro Bay National Estuary, Carpinteria Salt Marsh Reserve, Tijuana River Reserve Estuary, CA	Stands of <i>Salicornia depressa</i> (formerly <i>Salicornia virginica</i> )	<a href="#">Vivanco et al. (2015)</a>
Salt marsh	Addition of 50 kg reduced N/ha/yr as NH <sub>4</sub> Cl, 50 kg oxidized N as KNO <sub>3</sub> , or 100 kg N/ha/yr as NH <sub>4</sub> NO <sub>3</sub>  Ambient deposition = not specified	Addition of any form of N increased bacterial abundance of <i>Geobacillus</i> and <i>Clostridium</i> , and increased archaeal abundance of <i>Methanocellaceae</i> .  Reduced-N and NH <sub>4</sub> NO <sub>3</sub> additions decreased bacterial abundance of <i>Flavobacterium</i> , <i>Bacillus</i> , <i>Gillisia</i> , <i>Marinobacter</i> , and <i>Desulfosarcina</i> .  Redundancy analysis found positive correlations between ammonium-N measured in sediment, methane flux, pore water methane concentrations, <i>Geobacillus</i> abundance, <i>Clostridium</i> abundance, and <i>Methanocellaceae</i> abundance.  In dry season, only 50 kg reduced N addition plots are methane sources; all other plots are methane sinks.  In wet season, 50 kg oxidized N increased pore water CH <sub>4</sub> . 50 kg reduced N and 100 kg N increased pore water CH <sub>4</sub> as well as CH <sub>4</sub> emissions from plots.	Marsh of <i>Phragmites australis</i> and <i>Suaeda heteroptera</i> in the Yellow River Delta, China	Bacterial and archaeal communities assessed by bacterial primers <i>Ba338f</i> and <i>Ba806r</i> , and archaeal primers <i>Ar515f</i> and <i>Ar907r</i>	<a href="#">Xiao et al. (2017)</a>

## 11.4 Production and Aboveground Biomass

Aboveground biomass is a measure of how much carbon is fixed by wetland plants. Changes in this endpoint can affect food webs within the wetland, including dependent migratory species. Changes in aboveground biomass will also be important for food webs in rivers, lakes, or estuaries connected by surface water flow, because plant litter from wetlands is an important base for food webs downstream. In the 2008 ISA, evidence from Canadian and European peatlands showed that N deposition had negative or mixed effects on *Sphagnum* productivity, depending on history of deposition. In Canadian ombrotrophic peatlands experiencing deposition of 2.7–8.1 kg N/ha/yr, peat accumulation increased with N deposition, but accumulation rates had slowed by 2004, indicating a degree of N saturation. Coastal wetlands responded to N enrichment with increased primary production, shifting microbial and plant communities and altering pore water chemistry, although many of the studies in coastal wetlands used N enrichment levels more similar to those of wastewater than atmospheric deposition. The new studies published from 2008–2015 include work on tidal marsh, mangroves, and ombrotrophic bogs.

---

### 11.4.1 Salt Marsh

In the 2008 ISA, primary production of plant species in coastal wetlands typically increased with N addition; however, most studies applied fertilizer treatments that were several orders of magnitude larger than atmospheric deposition ([Darby and Turner, 2008](#); [Tyler et al., 2007](#); [Wigand et al., 2003](#); [Mendelsohn, 1979](#)). N fertilization experiments in salt marsh ecosystems show biomass stimulation from 6 to 413% with application rates ranging from 7 to 3,120 kg N/ha/yr ([U.S. EPA, 1993](#)).

A number of new studies have evaluated N effects on production and biomass in coastal wetlands. In Elkhorn Slough, the largest coastal marsh in California, addition of 150 kg N/ha/yr increased *S. pacifica* biomass in two of the six experimental sites ([Goldman Martone and Wasson, 2008](#)); a 36% increase over unamended plots occurred in a site with unrestricted tidal flow, and a 53% increase occurred in a marsh where impoundments restricted regular tidal exchange. [Darby and Turner \(2008\)](#) reported on a nitrogen addition experiment at Cocodrie, LA, in which five loads of nitrogen were applied to *S. alterniflora* marshes. Aboveground biomass increased linearly with increases in N load, although the regressions were not reported. Additions of 230 and 465 kg N/ha/yr did not significantly raise aboveground (AG) biomass above unamended marsh biomass, but 930 kg N/ha/yr increased AG biomass 122%, 1,860 kg N/ha/yr

increased AG biomass 124%, and 3,720 kg N/ha/yr increased AG biomass 141%. A nitrogen addition experiment with seven different N loads (0, 100, 200, 400, 800, 1,600, and 3,200 kg N/ha/yr) was replicated at three different California estuarine reserves [Morro Bay, Carpinteria Salt Marsh, and Tijuana River Marsh Reserve; ([Vivanco et al., 2015](#))]. Aboveground biomass of existing *S. depressa* increased linearly in response to N addition across all three marshes and N addition levels starting at 100 kg N/ha/yr (see [Table 11-5](#) for equation,  $R^2 = 0.58$ ). When harvested plots were resampled, the regrowth of aboveground biomass increased in a saturating response to increasing N load, with no significant increases in biomass in response to N above 1,600 kg N/ha/yr ([Table 11-5](#) for equation). Similar saturation of plant response occurred in N tissue (see [Appendix 11.5](#)).

In the eutrophication experiment at Plum Island, MA, tidal nitrate enriched to 15 times background concentrations, along with P additions, increased aboveground shoot biomass and specific mass of the vascular plant community by 16 and 9%, respectively ([Deegan et al., 2012](#)). When the tidal N enrichment was repeated in later years without P additions, added loads of 620 kg N/ha/yr or 1,200 kg N/ha/yr increased low marsh *Spartina alterniflora* shoot specific mass 3 and 12%, respectively ([Johnson et al., 2016a](#)). In the high marsh at this site, added N loads were smaller: at 140 kg N/ha/yr, *S. alterniflora* and *Distichlis spicata* increased shoot-specific mass 14 and 8% ([Johnson et al., 2016a](#)). There were also changes in plant architecture in the same plots (see [Appendix 11.6.1](#)), but no effects on plant community. The Kirkpatrick Marsh in Maryland is the site of a nitrogen fertilization experiment in a tidal marsh community consisting of *Schoenoplectus americanus*, *Spartina patens*, and *Distichlis spicata*. Over the 4 years of the experiment, nitrogen addition of 250 kg N/ha/yr increased total aboveground biomass by 47–79% ([Langley and Megonigal, 2010](#); [Langley et al., 2009](#)). When the biomass response was partitioned by carbon fixation mechanism (C3 or C4 plants), biomass of C3 plants declined with N addition to 81% in the 3rd year and 55% in the 4th year of initial fertilized *S. americanus* biomass. Biomass of C4 plants *S. patens* and *D. spicata* increased 2–51 times the control over the 4 years of the experiment (see [Appendix 11.8.1](#)), or increased 129% in the 4th year over initial fertilized C4 biomass.

In a related experiment at Kirkpatrick Marsh, mesocosms were constructed to mimic marshes at different sea levels, planted with *Schoenoplectus americanus* and *Spartina patens*, and subjected to the same nitrogen treatment ([Langley et al., 2013](#)). In this experiment, sea level had the strongest impact on biomass. In mesocosms set at the current sea level, N addition increased total AG biomass by 25–75%. The effects of N addition were stronger at other sea levels, but responses at those marsh surface elevations were species-specific. In a scenario of a 10-cm sea level rise, N addition increased total AG biomass 85–570% above biomass of similarly inundated unfertilized mesocosms. This strong response was driven almost entirely by the response of *S. americanus*, which

at a 10-cm sea level rise increased its biomass 150–533% in response to N addition. In mesocosms that mimicked a 15- or 35-cm increase in marsh elevation above sea level (as can occur in a highly productive marsh where productivity + accretion > decomposition + export), total AG biomass increased only 15–95%. This community response was driven by the response of *S. patens*, which at a 15- to 35-cm marsh elevation increase responded to nitrogen addition with 55–145% increases in AG biomass ([Langley et al., 2013](#)). These responses reflect the tolerance of these plants for inundation by tides and suggest that N addition may increase the productivity only of plants growing squarely within the range of their physiological tolerance.

Several other studies have evaluated N addition levels over 1,000 kg N/ha/yr; in all cases, N addition increased biomass, but the high levels of experimental N addition exponentially exceed N loading from deposition, limiting the scope of inference from this literature ([Anisfeld and Hill, 2012](#); [Nelson and Zavaleta, 2012](#); [Ryan and Boyer, 2012](#)).

---

#### 11.4.2 Mangrove

Mangrove ecosystems are ecologically and economically important because they provide habitat not just to a diversity of resident species but also serve as nurseries to the juvenile lifestages of many marine fish species. As slow-growing tree species, mangroves are rarely destructively sampled in order to estimate productivity and aboveground biomass. The mangroves at Indian River Lagoon, FL are the site of several nitrogen addition experiments. [Whigham et al. \(2009\)](#) added 100 kg N/ha/yr to plots of dwarf *Avicennia germinans*, black mangrove, which increased productivity by increasing the number of new branches 150% above control plots.

In a long-term (since 1997) N addition experiment that added approximately 11,200 kg N/yr to each tree, growth rate of *Rhizophora mangle*, quantified by measuring shoot elongation rates increased 290% in the shoreline fringe zone and increased 1,340% in the interior scrub zone ([Feller et al., 2009](#)). At Merritt Island National Wildlife Refuge, N addition of 1,400 kg N/ha/yr in the ecotone where mangroves and cordgrasses grow in competition increased *A. germinans* seedlings' production of new leaves by 42%, which increased total leaf biomass by 72% over unamended trees ([Simpson et al., 2013](#)) and altered above- and below-ground stoichiometry (see [Appendix 11.5.2](#)).

---

#### 11.4.3 Freshwater Tidal Marsh

In a freshwater tidal marsh on the Tchefuncte River, LA, [Graham and Mendelssohn \(2010\)](#) conducted an N loading experiment that added 50, 200, or 1,200 kg N/ha/yr to a

plant community dominated by *Sagittaria lancifolia*, *Eleocharis fallax*, and *Persicaria punctata* (formerly *Polygonum punctatum*). The aboveground net primary productivity of the community increased with increasing N in a negative quadratic function, with Aboveground Net Primary Productivity (ANPP) not increasing above 200 kg N/ha/yr ([Graham and Mendelsohn, 2010](#)).

At the Altamaha River Estuary, GA, N addition experiments were conducted in tidal freshwater marshes dominated by giant cutgrass *Zizaniopsis miliacea*. Addition of 500 kg N/ha/yr increased aboveground biomass 1.4–3.8 times control biomass in the 2nd through 5th years of fertilization ([Ket et al., 2011](#); [Frost et al., 2009](#)). A nitrogen experiment conducted in estuarine marshes and swamps on the Nanticoke River in the Chesapeake Bay found that while an added load of 670 kg N/ha/yr did not significantly change total herbaceous plant community aboveground biomass, it did increase biomass of the invasive *Typha* spp. by 47% ([Baldwin, 2013](#)). There are several other new studies on the effects of N loading on aboveground biomass of freshwater tidal ecosystems; however, the addition rates are greater than 500 kg N/ha/yr.

---

#### 11.4.4 Intermittent Wetland

An N addition study was established in an alpine meadow, which is also an intermittent wetland on the Tibetan Plateau. N addition of 30 kg N/ha/yr increased ANPP of the graminoid and herbaceous plant community by 11.5% ([Wang et al., 2017c](#)), which also affected C and N fluxes of the system (see [Appendix 11.3](#)).

---

#### 11.4.5 Bog and Fen

In Sphagnum-dominated ombrotrophic bogs, higher N deposition resulted in higher tissue N concentrations and greater NPP ([Aldous, 2002a](#)), but lower bulk density. A study of 23 ombrotrophic peatlands in Canada with deposition levels ranging from 2.7 to 8.1 kg N/ha/yr showed peat accumulation increasing linearly with N deposition; however, in later years of the study, the rate had begun to slow, indicating limited capacity for N to stimulate accumulation ([Turunen et al., 2004](#)). A study of European bogs under a deposition gradient of 2 to 24 kg N/ha/yr found that gross primary productivity and net carbon uptake of *Sphagnum fallax* mesocosms were positively correlated with increasing N deposition up to 15 kg N/ha/yr, but that the mesocosm collected from a bog receiving 24 kg N/ha/yr had 40% lower GPP and net C uptake than the mesocosm receiving 15 kg N/ha/yr ([Estop-Aragones et al., 2016](#)). However, there was N stimulation of GPP and net C uptake at deposition levels below 15 kg N/ha/yr when mesocosms were subject to

drought conditions. Inference from this study is limited by sample size; there was only one mesocosm per bog ([Estop-Aragones et al., 2016](#)).

In the Mer Bleue ombrotrophic peat bog, 8 years of N addition at the rate of 16 kg N/ha/yr increased biomass of mosses (*Sphagnum magellanicum*, *Sphagnum capillifolium*, and *Polytrichum strictum*) by 30% of moss biomass in control plots ([Xing et al., 2011](#)).

In oligotrophic bogs in Gogebic County, MI, N addition of 60 kg N/ha/yr increased total plant community productivity by 82% over unamended plot productivity, resulting in 2.6 times as much biomass in fertilized plots as biomass in unamended plots ([Iversen et al., 2010](#)). The plant community trends reflected the responses of the dominant vascular shrub *Chamaedaphne calyculata*, which increased its productivity by 87%, thus increasing its biomass in N addition plots 105% over its biomass in control plots ([Iversen et al., 2010](#)).

In general, vascular plants are able to respond more rapidly to N deposition than are moss species. A stable isotope N addition study in Bourtanger Moor, Germany, showed that grass *Lolium multiflorum* and sedge *Eriophorum vaginatum* responded to increasing N addition of approximately 30–55 kg N/ha/yr with linear increases in aboveground biomass ([Hurkuck et al., 2015](#)). Plant interception of N deposition also varied between species and with size for *L. multiflorum* (see [Appendix 5](#)).

Relative changes in biomass can lead to plant community changes. Model results from [Logofet and Alexandrov \(1984\)](#) suggest 7 kg N/ha/yr is the threshold for an oligotrophic bog to become a mesotrophic fen dominated by trees, as found in the 1993 Oxides of Nitrogen AQCD. In freshwater-rich fens in Gogebic County, MI, N addition of 60 kg N/ha/yr increased productivity of dominant grass *Calamagrostis canadensis*, which increased the species' biomass to 600% over its biomass in unamended fen plots ([Iversen et al., 2010](#)).

In many bogs and fens, N addition increases biomass and then abundance of vascular plants and N-tolerant moss species, while N-sensitive species decline. A study of purple pitcher plant, *Sarracenia purpurea*, growing in bogs across a deposition gradient of 3.4–5.0 kg N/ha/yr in the Adirondack Mountains, NY, identified a threshold for plant response to N ([Crumley et al., 2016](#)), with plant growth depressed 8–21% at deposition levels above 4.1 kg N/ha/yr, and with other negative effects on plant physiology (see [Appendix 11.5.5](#)). In a European mesocosm study of four moss species, elevated N concentrations typical of rainwater in the fen depress growth rates 18% compared to mosses growing in N concentrations typical of the fen groundwater ([Andersen et al., 2016](#)). Additional experimental N loading further decreases growth rate of all four

species. Two rare moss species, with declining abundance over the last 100 years, show high sensitivity to N, with more growth rate variation explained by N addition (18–23%) than for the growth rate in the more common moss species [5–7%; [Andersen et al. \(2016\)](#)].

Recent research has addressed differential responses of bogs and fens to reduced or oxidized forms of N addition. In an Irish fen dominated by peat moss *Sphagnum contortum* and brown moss *Scorpidium revolvens*, 50 kg N/ha/yr was applied as NO<sub>3</sub><sup>-</sup> in one treatment and as NH<sub>4</sub><sup>+</sup> in another treatment ([Paulissen et al., 2016](#)). Reduced N decreased *S. revolvens* biomass 67% compared to control plots, while oxidized N had no measurable effect on *S. revolvens* biomass. *S. contortum* biomass was not affected by reduced or oxidized N additions, although the plant's physiology did change in response to both treatments (see [Appendix 11.5.5](#)).

## 11.4.6 Summary Table

**Table 11-5 Nitrogen loading effects upon production and biomass.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Coastal high marsh	Addition: 150 kg N/ha/yr as urea S dep = not reported N dep = not reported	At two sites with unrestricted and restricted tidal flow, fertilization increased <i>S. pacifica</i> biomass by 36 and 53%, respectively.	Six sites at Elkhorn Slough, Watsonville, CA	Marsh community dominated by <i>Sarcocornia pacifica</i> , also contained <i>Jaumea carnosa</i> , <i>Frankenia salina</i> , <i>Spergularia salina</i> , <i>Distichlis spicata</i> , and <i>Atriplex californica/triangularis</i>	<a href="#">Goldman Martone and Wasson (2008)</a>
Estuarine salt marsh	Addition: 100, 200, 400, 800, 1,600, 3,200 kg N/ha/yr as urea N dep = 3–5 kg N/ha/yr as reported in <a href="#">Tonnesen et al. (2007)</a>	Aboveground biomass (AGB) increases in a linear response to N addition (N <sub>add</sub> , as g N/m <sup>2</sup> /yr), AGB = 0.001 × N <sub>add</sub> + 1.117 (R <sup>2</sup> = 0.58), while biomass regrowth (AGR) increases in a saturating response to N, AGR = -1.16 × e <sup>(-0.01N<sub>add</sub>)</sup> + 1.89.	Morro Bay National Estuary, Carpinteria Salt Marsh Reserve, Tijuana River Reserve Estuary, CA	<i>Salicornia depressa</i> ( <i>Salicornia virginica</i> ) stands	<a href="#">Vivanco et al. (2015)</a>

**Table 11-5 (Continued): Nitrogen loading effects upon production and biomass.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Salt marsh	Nitrate and phosphate dissolved in tidal inflows to raise aqueous NO <sub>3</sub> <sup>-</sup> concentrations to 70–100 μM and raise PO <sub>4</sub> <sup>3-</sup> to 5–7 μM. Background load in tides: 5 μM NO <sub>3</sub> <sup>-</sup> , 1 μM PO <sub>4</sub> <sup>3-</sup> . N dep = not reported S dep = not reported	Vascular plant shoot biomass increased 16%, shoot specific mass increased 9%.	Plum Island Estuary, MA	Primary tidal creeks with <i>Spartina alterniflora</i> in low marsh along creeks, and <i>Spartina patens</i> in high marsh platforms	<a href="#">Deegan et al. (2012)</a>
Salt marsh	Addition of nitrate dissolved in incoming tide 2011–2012, addition of N at 70–100 μM NaNO <sub>3</sub> <sup>-</sup> in tide for added load of 620–1,200 kg N/ha/yr in low marsh and 70–140 kg N/ha/yr in high marsh Ambient deposition = not specified	Low marsh <i>S. alterniflora</i> in enriched creeks received an additional N load of 1,200 kg N/ha/yr in 2011. That year, N addition increased shoot-specific mass 12% above <i>S. alterniflora</i> in reference creek plots. Low marsh <i>S. alterniflora</i> in enriched creeks received an additional N load of 620 kg N/ha/yr in 2012. That year, N addition increased shoot-specific mass 3%. High marsh <i>S. alterniflora</i> and <i>D. spicata</i> in enriched creeks received an additional N load of 140 kg N/ha/yr in 2011. N addition increased <i>S. alterniflora</i> shoot-specific mass 14%. In <i>D. spicata</i> , N addition increased shoot-specific mass 8%.	Plum Island Sound Estuary, MA	<i>Spartina alterniflora</i> , <i>Distichlis spicata</i> , and <i>Spartina patens</i> (high marsh); <i>Spartina alterniflora</i> (low marsh)	<a href="#">Johnson et al. (2016a)</a>
Estuarine marsh	Addition: 1,337 kg N/ha/yr as urea. S dep = not reported N dep = not reported	In <i>S. pacifica</i> , biomass increased 54–185% across habitats.	China Camp State Park, CA	<i>Sarcocornia pacifica</i> dominant (C3 succulent shrub), <i>Distichlis spicata</i> (C4 grass), and <i>Jaumea carnosa</i> (C3 semisucculent forb)	<a href="#">Ryan and Boyer (2012)</a>

**Table 11-5 (Continued): Nitrogen loading effects upon production and biomass.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Coastal salt marsh	Addition: 3,000 kg N/ha/yr as NH <sub>4</sub> NO <sub>3</sub> S dep = not reported N dep = not reported	AG biomass increased 28 and 216% in successive summers, and increased shoot-to-root ratio 249%.	Elkhorn Slough, Monterey Bay, CA	<i>Sarcocornia pacifica</i> dominant, <i>Distichlis spicata</i> , <i>Frankenia salina</i> , and <i>Jaumea carnosa</i>	<a href="#">Nelson and Zavaleta (2012)</a>
Coastal salt marsh	230, 465, 930, 1,860, or 3,720 kg N/ha/yr as (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub> S dep = not reported N dep = not reported	AG biomass increased linearly with N load (regression not given). Aboveground live biomass increased 122, 124, and 141% in response to 930, 1,860, and 3,720 kg N.	LUMCON, Cocodrie, LA	<i>Spartina alterniflora</i>	<a href="#">Darby and Turner (2008)</a>
Coastal salt marsh	1,050 kg N/ha/yr (low) as NaNO <sub>3</sub> , 2,100 kg N/ha/yr (medium) as NH <sub>4</sub> NO <sub>3</sub> or NaNO <sub>3</sub> , 4,200 kg N/ha/yr (high) as NH <sub>4</sub> NO <sub>3</sub> in same plots in over several years S dep = not reported N dep = not reported	ANPP increased by 132% in low, 130% in medium, and 120% in high N treatments.	Hoadley Creek Marsh, Guilford, CT	<i>Spartina alterniflora</i>	<a href="#">Anisfeld and Hill (2012)</a>
Estuarine salt marsh	Addition: 250 kg N/ha/yr S dep = not reported N dep = not reported	<i>S. americanus</i> aboveground biomass decreased by 19 and 45% in the 3rd and 4th yr, respectively. Biomass of <i>S. patens</i> and <i>D. spicata</i> increased 129% in the 4th yr over initial fertilized C4 biomass.	Kirkpatrick Marsh, MD (measured in 3rd and 4th yr, 2008–2009)	<i>Schoenoplectus americanus</i> (C3), <i>Spartina patens</i> (C4), and <i>Distichlis spicata</i> (C4)	<a href="#">Langley and Magonigal (2012, 2010)</a>
Estuarine salt marsh	Addition: 250 kg N/ha/yr S dep = not reported N dep = not reported	In the first two growing seasons, fertilization increased aboveground biomass in the second season by 57%.	Kirkpatrick Marsh, MD (measured in 1st and 2nd years, 2006–2007)	<i>Schoenoplectus americanus</i> , <i>Spartina patens</i> , and <i>Distichlis spicata</i>	<a href="#">Langley et al. (2009)</a>

**Table 11-5 (Continued): Nitrogen loading effects upon production and biomass.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Estuarine marsh	NH <sub>4</sub> Cl solution injected into mesocosm peat at root level, 250 kgN/ha, increases N by 40% above annual average background concentration Deposition not reported	At current sea level, N addition increased total AG biomass by 25–75% in 1st yr. With sea level rise 10 cm, <i>S. americanus</i> AG biomass increases 150–230% in 1st yr, 110–533% in 2nd yr. Total AG biomass at 10 cm increased 85–95% in 1st yr, 100–570% in 2nd yr. At increased marsh elevation (15 and 35 cm above sea level 1st yr, 15 cm 2nd yr), <i>S. patens</i> AG biomass increases 55–145% in 1st yr, 60–90% in 2nd yr. Total AG biomass at these elevations increased 15–95% in 1st yr, 30–35% in 2nd yr.	Kirkpatrick Marsh, MD	Factorial mesocosm experiment with varying sea levels: 35- or 15-cm rise in marsh elevation; current sea level; 10-, 20-, or 30-cm rise in sea level. Mesocosms planted with 2 rhizomes <i>Schoenoplectus americanus</i> and 10 stems <i>Spartina patens</i> ; harvested each year.	<a href="#">Langley et al. (2013)</a>
Mangrove/marsh ecotone	Addition: 1,400 kg N/ha/yr S dep = not reported N dep = not reported	Mangrove leaf production increased by 42% and leaf biomass increased by 72%.	Merritt Island National Wildlife Refuge, FL (Impoundment T9)	<i>Avicennia germinans</i>	<a href="#">Simpson et al. (2013)</a>
Mangrove	Addition: 1,400 kg N/ha/yr S dep = not reported N dep = not reported	Fertilization increases growth rate (shoot elongation) by 290% in the fringe zone and by 1,340% in the scrub zone.	Indian River Lagoon, FL (impoundment MI23)	<i>Rhizophora mangle</i>	<a href="#">Feller et al. (2009)</a>
Mangrove	100 kg N/ha/yr	N addition increased the number of new branches 150% in <i>Avicennia</i> .	Indian River Lagoon, FL (impoundment SLC-24)	<i>Avicennia germinans</i> and associated sediments	<a href="#">Whigham et al. (2009)</a>

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Ombrotrophic peatland	Ambient deposition of NO <sub>x</sub> , NH <sub>y</sub> , and SO <sub>x</sub> : 1.95–24.07 kg N/ha/yr and 3.18–36.90 kg S/ha/yr Deposition estimates from EMEP (European Monitoring and Evaluation Programme)-based IDEM (Integrated Deposition Model) from <a href="#">Pieterse et al. (2007)</a>	N and S deposition rates are correlated across these sites ( $r = 0.87$ ). Gross primary productivity (GPP, as g C/m <sup>2</sup> /day) increased with N deposition (N <sub>dep</sub> , as kg N/ha/yr) up to 15 kg N/ha/yr: $GPP = 1.262 + 0.219N_{dep}$ ; $R^2 = 0.65$ . There was no relationship between N deposition and GPP during drought and post-drought periods. Net carbon uptake by <i>Sphagnum</i> (C <sub>uptake</sub> , as g C/m <sup>2</sup> /day) was positively correlated with N deposition (N <sub>dep</sub> , as kg N/ha/yr) up to levels of 15 kg/ha/yr: $C_{uptake} = 0.76 + 0.155 \times N_{dep}$ ; $R^2 = 0.52$ . There was no relationship between N deposition and GPP during drought and post-drought periods. Respiration, GPP, and net carbon uptake were all 40% lower in the mesocosm from the 24 kg N/ha/yr than from the 15 kg N/ha/yr site.	Lab incubations of 14 <i>Sphagnum</i> mesocosm collected in saturated hollows in European bogs: U.K. and Ireland (n = 9), Poland (n = 4), and Slovakia (n = 1). Mesocosms were maintained at a high water table (0–5 cm depth) for 40 days, then were subject to drought for 100 days, then were rewetted to high water table (0–5 cm depth) for 200 days.	<i>Sphagnum fallax</i>	<a href="#">Estop-Aragones et al. (2016)</a>
Ombrotrophic peat bog	16 (low), 32 (medium), or 64 (high) kg N/ha/yr as N (NH <sub>4</sub> NO <sub>3</sub> ) or NPK (NH <sub>4</sub> NO <sub>3</sub> and KHPO <sub>4</sub> )	In high NPK, shrub biomass increased, with 40% higher leaf biomass, and 86% higher woody biomass.	Mer Bleue Bog, Ontario, Canada	Bog plant community: dwarf shrub species and mosses <i>Sphagnum magellanicum</i> , <i>Sphagnum capillifolium</i> , and <i>Polytrichum strictum</i>	<a href="#">Juutinen et al. (2010)</a>
Ombrotrophic peat bog	Addition: 16 kg N/ha/yr as NH <sub>4</sub> NO <sub>3</sub> N dep = 8 kg N/ha/yr as quantified by <a href="#">Turunen et al. (2004)</a>	N addition decreased aboveground moss biomass by 30%.	Mer Bleue Bog, Ontario, Canada (measured 2007)	Bog plant community: dwarf shrub species and mosses <i>Sphagnum magellanicum</i> , <i>Sphagnum capillifolium</i> , and <i>Polytrichum strictum</i>	<a href="#">Xing et al. (2011)</a>

## 11.5 Plant Stoichiometry and Physiology

N addition alters the stoichiometry of plant tissue. When inorganic N stores increase in the soil matrix due to N deposition, one of the first plant responses may be to increase N uptake and storage. As a result, the concentration of N in plant tissue (often reported as [N] or %N) is one of the earliest indicators of changing bioavailability of N within an ecosystem. Plants may store the additional N in proteins, use it for further growth if other nutrients and abiotic conditions are not limiting, or curtail growth of belowground,

nutrient-acquiring roots. Plant tissue [N] also has important implications for consumers, as many insect and vertebrate consumers preferentially graze on high N tissues, and plant [N] can also affect decomposition rates. In systems in which N availability increases while other nutrient cycles are unaltered, such as in nutrient-poor bogs, nutrient imbalances develop and plant [K] and [P] decline. This section will consider the effects of N deposition upon plant tissue [N] as a sensitive indicator of plant response, as well as the effects of N deposition upon other elements in plant tissue, which would indicate more detrimental effects of increased N availability upon plant growth.

Plant stoichiometry theory considers the balance of multiple chemical elements in living tissues. The stoichiometry of plant tissue is often connected to its physiological function. Most new studies on physiology and stoichiometry are for bogs and freshwater marshes. There are a few studies on saltwater marshes and fens. The new literature is summarized in the following sections.

---

### 11.5.1 Salt Marsh

There are several studies on the effects of N addition on salt marsh plant stoichiometry. In three California salt marshes, N addition at seven different levels (0, 100, 200, 400, 800, 1,600, and 3,200 kg N/ha/yr) showed that the succulent forb *Salicornia depressa* increased leaf %N in a saturating response, with no statistically significant increases in response above 800 kg N/ha/yr ([Vivanco et al., 2015](#)). There are several N addition studies at addition levels greater than 500 kg N/ha/yr [([Baldwin, 2013](#); [Nelson and Zavaleta, 2012](#); [Ryan and Boyer, 2012](#)); see [Table 11-6](#)].

---

### 11.5.2 Mangrove

The N addition levels in all new studies on mangroves are generally higher (greater than 500 kg N/ha/yr) than would be relevant to the effects of N deposition. As perennial plants, mangroves respond to increasing N loads by altering tissue storage of N as well as by increasing productivity ([Appendix 11.4.3](#)). In salt-marsh mangrove ecotone, *Avicennia germinans* seedlings responded to addition of 1,400 kg N/ha with 62% higher leaf tissue %N, as well as increased N in belowground biomass ([Simpson et al., 2013](#)). In more mature mangrove ecosystems receiving higher N loads (11,200 kg N/yr per tree), N addition decreased the efficiency with which *Rhizophora mangle* resorbed N from senescing leaves by 7%, which resulted in 39% higher %N in senesced leaves than in unfertilized trees ([Feller et al., 2009](#)).

---

### 11.5.3 Freshwater Marsh

N addition is documented to alter plant stoichiometry and physiology in freshwater marshes. This topic was not addressed in the 2008 ISA. Five new studies have been published since 2008.

In freshwater marsh mesocosms planted with wetland obligate graminoid *Bolboschoenus maritimus* [cosmopolitan bulrush, multiple synonyms including *Schoenoplectus maritimus*, listed as Special Concern by Connecticut and Rhode Island, and as endangered by Illinois, New Jersey, and New York; ([USDA, 2015b](#))] N addition increased N stored in plant tissues. Aboveground tissue %N increased 31–114% of %N in control plants with increasing N loads (32, 65, 108 kg N/ha/yr) added in fall 2009, and increased 33–67% with increasing N loads (59, 119, 198 kg N/ha/yr) added in the summer and fall of 2010 ([Duguma and Walton, 2014](#)). N addition also increased tissue N in belowground tissues. In fall 2009, addition of 32 kg N/ha/yr did not affect BG %N, but the addition of 65 kg N/ha/yr increased BG %N by 26%, and the addition of 108 kg N/ha/yr increased BG %N by 126 to 1.29% tissue N. In summer and fall 2010, the addition of 119 and 198 kg N/ha/yr increased BG %N 47 and 37%, with a tissue N value of 1.34 and 1.25% N, respectively ([Duguma and Walton, 2014](#)).

In tidal freshwater marshes of the Tchefuncte River, LA, experimentally added N loads of 50, 200, 1,200 kg N/ha/yr did not alter the relative dominance of *Sagittaria lancifolia* but did alter N storage in plant tissues. Plant tissue N (mg N/g leaf) increased 0.02 mg for every 10 kg N/ha/yr of N load. The change in plant N shifted the N:P ratio of plant tissue, 0.04 N:1 P increase for every additional 10 kg N/ha/yr ([Graham and Mendelssohn, 2010](#)). N addition also decreased the efficiency with which plants resorbed nutrients from senescing leaves for use in future growth. N addition decreased N resorption efficiency (%) by 0.1% for every additional 10 kg N/ha/yr, and decreased P resorption efficiency (%) by 0.09% for every additional 10 kg N/ha/yr ([Graham and Mendelssohn, 2010](#)).

In freshwater marsh mesocosms at the Smithsonian Environmental Research Center (SERC), native and introduced haplotypes of graminoid *Phragmites australis* were grown in a nitrogen addition experiment. The species *P. australis* includes haplotypes (genetic lineages) native to North America, as well as invasive haplotypes capable of forming monocultures that exclude native plant species. Nitrogen fertilization of 250 kg N/ha/yr increased the construction cost (grams of glucose invested in synthesizing a gram of biomass) of leaves for the native F haplotype of *P. australis* by 5% ([Caplan et al., 2014](#)). Nitrogen addition did not significantly alter construction costs of the invasive M haplotype [listed as a noxious weed, banned invasive, or plant pest by Alabama, Connecticut, Massachusetts, South Carolina, Vermont, and Washington; ([USDA, 2015b](#); [Caplan et al., 2014](#))]. These results suggest that N enrichment favors the invasive

haplotype over the native haplotype and may facilitate invasion; this is of concern because *P. australis* tolerates brackish conditions and invades North American wetlands all along the freshwater-freshwater tidal-salt marsh continuum.

In tidal freshwater marshes in the Altamaha River Estuary, GA, N addition of 500 kg N/ha/yr in the 2nd year stimulated productivity ([Appendix 11.4.2](#)) to the extent of diluting N and phosphorus (P) in plant tissues, decreasing leaf N (%) by 22%, and decreasing leaf P ( $\mu\text{g/g}$ ) by 25% ([Frost et al., 2009](#)). In the later years of the experiment, N addition increased leaf N (%) above control plot leaf N by 25–43% ([Ket et al., 2011](#)), and this increase altered leaf nutrient ratios, decreasing leaf C:N 18–28% and increasing leaf N:P 25–61% over leaves from control plots. The increases in productivity combined with alterations in leaf tissue nutrients altered total nutrient pools stored in aboveground biomass, increasing total aboveground N by 236% and total aboveground P by 169% ([Ket et al., 2011](#)).

---

#### 11.5.4 Riparian Wetland

In developing riparian forests at Bonanza Forest LTER, Alaska, N addition of 100 kg N/ha/yr increased leaf N 10% in tree species *Alnus incana* ssp. *tenuifolia* growing in late successional riparian forest, but not in recently colonized or midsuccessional sand bars ([Ruess et al., 2013](#)). N addition also altered *A. incana* ssp. *tenuifolia*'s internal P cycling efficiency, decreasing resorption of P from senescing leaves by 21% in midsuccessional forest ([Ruess et al., 2013](#)).

---

#### 11.5.5 Bog and Fen

Carnivorous plants grow optimally under low-N conditions, and many are limited in their distribution to bogs and fens. Recent research suggests that N deposition can disrupt their N-acquisition strategy of digesting the invertebrates they trap. Purple pitcher plants (*Sarracenia purpurea*) were measured and sampled across a narrow N deposition gradient (3.4–5.0 kg N/ha/yr) across bogs in the Adirondack Mountains ([Crumley et al., 2016](#)). Plant architecture, plant tissue N, and stable isotope N data suggested a growth and carnivory optima for plants in bogs receiving 3.8–4.1 kg N/ha/yr. At higher deposition rates of 4.4–4.9 kg N/ha/yr, there was no change in plant tissue N, but there were negative effects upon growth (see [Appendix 11.4.4](#)) and a 40% decrease in carnivory ([Crumley et al., 2016](#)). The wetland obligate pitcher plants have previously been shown to experience detrimental impacts of N deposition at physiological and population levels [([Gotelli and Ellison, 2002](#)) in 2008 ISA]. [Bott et al. \(2008\)](#) reciprocally

transplanted *Sarracenia purpurea* ssp. *purpurea* [listed as exploitably vulnerable in New York, threatened in New York, and endangered in Georgia and Illinois; ([USDA, 2015b](#))] between ombrotrophic Sapa bog and the rich Cedarburg fen, both in Wisconsin. Leaf %N was positively and linearly correlated with surface water  $\text{NO}_3^-$  concentration at the site where the plants were transplanted (leaf %N =  $0.9581 + 0.1667 \times \mu\text{M NO}_3^-$ ), confirming Gotelli's designation of pitcher plants as sensitive indicators of N deposition ([Bott et al., 2008](#)).

A deposition-induced shift away from insectivory can lead to deficiency in other nutrients for carnivorous plants. Across a natural deposition gradient in Sweden, the carnivorous plant *Drosera rotundifolia* experienced significant declines of insectivory-derived N at 3.81 and 11.30 kg N/ha/yr ([Millett et al., 2012](#)). Across a broader deposition gradient of European bogs (0.5–27.0 kg N/ha/yr), *D. rotundifolia* insectivory declined in a linear relationship with increasing N deposition, and plants experienced increasing P limitation as evidenced by increasing N:P tissue concentrations ([Millett et al., 2015](#)). These studies support previous research showing negative effects of N deposition upon *D. rotundifolia* populations (see [Appendix 11.7](#)).

Research conducted in European fens and reviewed in the 2008 ISA has shown that N addition favors the growth of grass and sedge species over peat-forming moss species ([U.S. EPA, 2008a](#)). New research suggests that North American sedge and grass species experience positive effects of N loading, and that their responses can alter N dynamics of North American bogs and fens. In a bog in Gogebic County, MI, where sedge *Carex oligosperma* [listed as Special Concern in Connecticut, threatened in Ohio and Pennsylvania, and endangered in Illinois, Massachusetts, and North Carolina; ([USDA, 2015b](#))] was dominant in the plant community, the obligate wetland species responded to 60 kg N/ha/yr addition by decreasing N use efficiency by 89% and N response efficiency by 84% ([Iversen et al., 2010](#)). The response of the sedge altered ecosystem responses in the bog, increasing plant community N uptake by 125% over uptake in unamended plots ([Iversen et al., 2010](#)). These changes increased N stored in biomass pools 171% above biomass N in control plots and increased the concentration of N in vascular plant tissues by 19% ([Iversen et al., 2010](#)). Similarly, the grass *Calamagrostis canadensis* [classified as wetland facultative or obligate in different U.S. regions by ([USDA, 2015b](#))], which was dominant in a closely adjacent rich fen, responded to N addition of 60 kg N/ha/yr by increasing N uptake. Along with increased productivity ([Appendix 11.4.5](#)), this response expanded the total pool of N stored in biomass by 300% ([Iversen et al., 2010](#)). A similar mesocosm study of bogs in western Europe across a deposition gradient of 2 to 47 kg N/ha/yr found that at the highest deposition level, plant tissue N of grasses and sedges was 120% higher than grasses and sedges at the lowest deposition level ([Zajac and Blodau, 2016](#)).

In the same set of experiments in Gogebic County, MI, woody plants increased their productivity in response to N loading, but their efficiency in using N declined, suggesting a mechanism by which N loading lowers N retention of bogs and fens ([Appendix 11.3.1.5](#)). The wetland obligate shrub *Chamaedaphne calyculata* (threatened in Illinois and Maryland) responded to 60 kg N/ha/yr addition by increasing plant N uptake by 75%, which increased productivity ([Appendix 11.4](#)) and increased the pool of N stored in aboveground biomass by 100%. However, nitrogen addition decreased the efficiency of photosynthesis and metabolism in *C. calyculata*, as N use efficiency was 81% lower and N response efficiency was 91% lower in fertilized plots ([Iversen et al., 2010](#)). In an intermediate fen, tree species *Alnus incana* ssp. *rugosa*, speckled alder [hereafter referred to as *A. rugosa*, endangered in Illinois; ([USDA, 2015b](#))], responded to an added 60 kg N/ha/yr with a 45% decline in N response efficiency [net primary productivity relative to available soil N; ([Iversen et al., 2010](#))]. A European study of mesocosms collected across a deposition gradient of bogs found that 12 kg N/ha/yr decreased N retention of shrub species, and 47 kg N/ha/yr increased ecosystem total N stored in shrub biomass ([Zajac and Blodau, 2016](#)).

A long-term fertilization experiment at the Mer Bleue Bog in Ontario, Canada, has documented the effect of more than a decade of elevated N inputs on the same species in an ombrotrophic peat bog. *Chamaedaphne calyculata* responded to 32 g N/ha/yr by increasing P resorption by 42%, and responded to 64 kg N/ha/yr by increasing P resorption by 33% ([Wang et al., 2014b](#)). N Plots that had received 64 kg N/ha/yr for 6 years decreased leaf calcium 22% ([Wang et al., 2014b](#)), and leaf Ca was 34% lower in *C. calyculata* from plots that received 9 years of 16 kg N/ha/yr than in leaves from control plots ([Bubier et al., 2011](#)). An observational study across a deposition gradient in the Adirondack Mountains found effects on *C. calyculata* stoichiometry at much lower deposition levels. There was a 27% increase in plant tissue N in *C. calyculata* when deposition increased from a range of 3.4–3.6 kg N/ha/yr to 4.9–5.0 kg N/ha/yr ([Crumley et al., 2016](#)).

After 9 years of N addition at Mer Bleue, leaf C:N ratios were 15% lower in *C. calyculata* leaves that received 16 kg N/ha/yr than in leaves from control plots, with dependent increases in leaf alanine and  $\gamma$ -aminobutyric acid (GABA; see [Table 11-6](#) for equations), amino acid pools that indicate N saturation in the plant ([Bubier et al., 2011](#)). Leaf aluminum concentrations were 44% lower in these leaves than in leaves from control plots ([Bubier et al., 2011](#)). In plots that received 64 kg N/ha/yr, there was no change in leaf C:N, but there were increases in proteins indicative of increased plant N uptake. *C. calyculata* leaf total chlorophyll was 84% higher than in control leaves, and there were 115% increases in leaf alanine and 94% increases in leaf GABA, indicating N saturation. Leaf manganese was 45% lower in these leaves than in control plot *C.*

*calyculata*, indicating that shrub productivity may be limited by micronutrients in a N-fertilized bog ([Bubier et al., 2011](#)).

At Mer Bleue, the wetland obligate shrub *Rhododendron groenlandicum* (synonym: *Ledum groenlandicum*, rare in Pennsylvania, threatened in Connecticut, and endangered in Ohio) responded to 4 years of 64 kg N/ha/yr with a 16% increase in leaf N and a dependent increase in leaf glutamic acid ([Bubier et al., 2011](#)). Leaf P declined by 54% of control leaf P after 4 years of 64 kg N/ha/yr ([Bubier et al., 2011](#)). After 7 years of 64 kg N/ha/yr, *R. groenlandicum* responded with a 23% decrease in leaf magnesium (Mg) and a 186% decrease in Mg resorption from senescing leaves ([Wang et al., 2014b](#)), indicating increasing limitation by magnesium, which could negatively affect photosynthesis and enzyme activity within the plant. After 7 years of 32 and 64 kg N/ha/yr addition, *R. groenlandicum* increased P and K resorption from senescing leaves; P resorption increased 12–12.2 times the rate of resorption in leaves from unamended plots, and increased K resorption by 92–123% ([Wang et al., 2014b](#)).

In the same experiment, after 7 years, N addition shifted the seasonality of gross photosynthesis, with addition of 64 kg N/ha/yr reducing C uptake 29–45% of control rates in early summer (May–July), and increasing C uptake 25% above rates in control plots in September ([Larmola et al., 2013](#)). After 9 years of 16 kg N/ha/yr addition, *R. groenlandicum* exhibited altered leaf physiology, doubling maximum carboxylation capacity ( $V_{\text{cmax}}$ ) on a per-leaf-mass basis ([Bubier et al., 2011](#)). There was no significant effect of 4 years of 64 kg N/ha/yr upon  $V_{\text{cmax}}$  measured during the same growing season (2008). The study authors posited that plants responded to this level of N availability with a stress response, allocating N to storage in glutamic acid ( $\text{nmol glutamic acid/g leaf} = 37.914 + 252.2 \times \text{leaf \%N}$ ) instead of using it in photosynthetic enzymes ([Bubier et al., 2011](#)).

At Mer Bleue, the wetland facultative shrub *Vaccinium myrtilloides* (designated sensitive in Washington, special concern in Connecticut, threatened in Ohio and Iowa, and endangered in Indiana) responded to nitrogen addition with declines in other leaf nutrients. Leaf calcium declined 23% in response to 9 years of 16 kg N/ha/yr and declined 56% in response to 4 years of 64 kg N/ha/yr ([Bubier et al., 2011](#)), indicating that increasing N will increasingly limit leaf Ca and by extension decrease signaling and structural integrity of plant tissues. Leaf P decreased by 55% after 9 years of 16 kg N/ha/yr and by 68% after 4 years of 64 kg N/ha/yr. Leaf manganese (Mn) decreased 57% under 64 kg N/ha/yr ([Bubier et al., 2011](#)), which could affect photosynthesis or N assimilation because Mn is a component of enzymes involved in these processes. *V. myrtilloides* leaf potassium also declined: 47% in response to 9 years of 16 kg N/ha/yr and 34% in response to 4 years of 64 kg N/ha/yr ([Bubier et al., 2011](#)). Leaf potassium

regulates stomatal movement, activates enzymes, and balances electrical charges associated with ATP production, so K deficiency can decrease photosynthesis and slow growth. Leaf aluminum decreased 45% of control leaf aluminum concentrations in plots receiving 64 kg N/ha/yr for 4 years ([Bubier et al., 2011](#)).

N addition can alter tissue nutrients in nonvascular plants as well. In the Mer Bleue bog, N addition of 32 kg N/ha/yr decreased moss [Ca] by 34%; N addition of 64 kg N/ha/yr increased moss [P] by 39%, and decreased moss [Ca] by 42% ([Wang et al., 2016a](#)). These results are consistent with N addition effects of Ca deficiencies in vascular plants (see above) and ecosystem P limitation (see [Appendix 11.3.2.1.3](#)) within this bog experiment. Surveys of two European bogs located in different mountain ranges found that N deposition altered the stoichiometry of *Sphagnum* moss species. *Sphagnum* tissue K concentrations were lower in samples collected from the high N deposition (20–25 kg N/ha/yr) Jizera Mountains, 64% lower in *S. rubrum* and 62% lower in *S. magellanicum*, than in samples from the lower deposition (12.5 kg N/ha/yr) Jeseníky mountain range. *S. magellanicum* [Mg] was also 45% lower at the high N deposition site than at the lower N deposition site ([Jirousek et al., 2015](#)). [Fritz et al. \(2014\)](#) performed a peat mesocosm study to test how a history of atmospheric N deposition alters the N uptake rates of *Sphagnum magellanicum*, a widely distributed peat-forming species. The researchers collected blocks of living *S. magellanicum* from a pristine bog in Argentina, which received an annual load of 1–2 kg N/ha/yr, and also from a polluted bog in the Netherlands, which received an annual load of 20–30 kg N/ha/yr. Under controlled conditions, nitrogen solutions of 1, 10, or 100  $\mu\text{mol N/L}$  were added to the block. Rates of N uptake were significantly different among bog samples (Argentine or Dutch) for the 10 or 100  $\mu\text{mol}$  solutions, with the pristine (Argentine) *Sphagnum* absorbing nitrogen at 1.4–2.6 times the rate of the uptake rate of the Dutch bog, which receives a higher annual N load ([Fritz et al., 2014](#)). A mesocosm study of four European moss species found that applying rainwater (elevated N and P) rather than groundwater increases moss tissue [N] and [P], while applying additional N in controlled treatments decreases moss tissue [P] ([Andersen et al., 2016](#)). A different European mesocosm study found that *Sphagnum* spp. plant tissue N increased across a N deposition gradient of 2 to 47 kg N/ha/yr, such that C:N ratio declined as a linear function of the natural log of increasing N deposition ([Zajac and Blodau, 2016](#)).

Recent research has addressed differential responses of bogs and fens to reduced or oxidized forms of N addition. In an Irish fen dominated by *Sphagnum contortum* and brown moss *Scorpidium revolvens*, 50 kg N/ha/yr was applied as  $\text{NO}_3^-$  in one treatment and  $\text{NH}_4^+$  in another treatment ([Paulissen et al., 2016](#)). Reduced N forms elicited stronger responses in tissue chemistry for each moss species. In *S. contortum*, oxidized N increased tissue N 29%, tissue P 28%, and concentrations of alanine (a free amino acid

hypothesized to be a mechanism of N storage) 31%; an equivalent addition of reduced N decreased tissue N 13%, tissue K 49%, and dramatically increased (by half to 66 times the control) the concentrations of five free amino acids storing excess N in plant tissue. In the more sensitive species *S. revolvens*, reduced N increased tissue N 76% but decreased tissue K 53%, and increased concentrations of arginine (a free amino acid) 7.3 times concentrations in control plots; these same metrics were unaffected by the equivalent oxidized N treatment (Paulissen et al., 2016). The stronger effects of reduced N on plant chemistry in *S. contortum* than *S. revolvens* may represent species-level differences in N tolerance, as *S. contortum* biomass did not change in response to N addition (see Appendix 11.4.4).

The Whim Bog experiment in Scotland added N as either ammonium or nitrate to simulate wet deposition, which with ambient N deposition of 8 kg N/ha/yr resulted in treatment N loads of 16, 32, and 64 kg N/ha/yr. As in other wetlands, the bog had divergent responses to oxidized and reduced N addition. *Sphagnum capillifolium* plant tissue N and N:P increased in response to increasing oxidized N in a saturating function, but responded to increasing reduced N in a linear function (Chiwa et al., 2016). Reduced N addition also resulted in increasing cation concentrations in pore water, suggesting cation leaching by the moss species as a result of N uptake. These results indicate a stronger effect of reduced N upon *Sphagnum* growth or P limitation, and these physiological changes also affected N cycling and water quality within the bog (see Appendix 11.3.1.5).

## 11.5.6 Summary Table

**Table 11-6 Nitrogen loading effects upon plant stoichiometry and physiology.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Coastal salt marsh	Addition: 100, 200, 400, 800, 1,600, 3,200 kg N/ha/yr as urea N dep = 3–5 kg N/ha/yr as reported in <a href="#">Tonnesen et al. (2007)</a>	<i>Salicornia</i> leaf %N increases in a saturating response to added N ( $N_{add}$ , as g N/m <sup>2</sup> /yr), leaf $N = -0.73 \times e^{-0.024 N_{add}} + 2.99$ .	Morro Bay National Estuary, Carpinteria Salt Marsh Reserve, Tijuana River Reserve Estuary, CA	<i>Salicornia depressa</i> ( <i>Salicornia virginica</i> ) stands	<a href="#">Vivanco et al. (2015)</a>

**Table 11-6 (Continued): Nitrogen loading effects upon plant stoichiometry and physiology.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Coastal salt marsh	3,000 kg N/ha/yr as NH <sub>3</sub> NO <sub>3</sub> N dep = not reported S dep = not reported	Plant [N] increased by 224 and 33%, and N pools in AG vegetation increased by 60 and 84% in successive summers.	Elkhorn Slough, Monterey Bay, CA	<i>Sarcocornia pacifica</i> dominant, <i>Distichlis spicata</i> , <i>Frankenia salina</i> , and <i>Jaumea carnosa</i>	<a href="#">Nelson and Zavaleta (2012)</a>
Estuarine salt marsh	1,337 kg N/ha/yr as urea N dep = not reported S dep = not reported	In <i>S. pacifica</i> , tissue N increased 28–46%. <i>D. spicata</i> tissue N increased 19%. <i>J. carnosa</i> tissue N increased by 54%.	China Camp State Park, CA	<i>Sarcocornia pacifica</i> dominant, <i>Distichlis spicata</i> , and <i>Jaumea carnosa</i>	<a href="#">Ryan and Boyer (2012)</a>
Mangrove/salt marsh ecotone	1,400 kg N/ha/yr N dep = not reported S dep = not reported	Mangrove leaf production increased by 42%. Leaf tissue %N increased 62%. Root %N increased 9% and root C:N decreased 25%.	Merritt Island National Wildlife Refuge, FL	<i>Avicennia germinans</i>	<a href="#">Simpson et al. (2013)</a>
Mangroves	No areal rate reported; 11,200 kg N/yr per tree N dep = not reported S dep = not reported	Fertilization increases growth rate (shoot elongation) by 290% in the fringe zone and by 1,340% in the scrub zone. In the fringe zone, fertilization decreases resorption efficiency of N from dying leaves by 7%, resulting in senesced leaves containing 39% more N than control senesced leaves.	Indian River Lagoon, FL	<i>Rhizophora mangle</i>	<a href="#">Feller et al. (2009)</a>
Freshwater marsh	Fall 2009: 32 (low), 65 (medium), 108 (high) kg N/ha/yr as (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub> ; summer 2010: 59 (low), 119 (medium), or 198 (high) kg N/ha/yr as (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub> N dep = not reported S dep = not reported	N addition increased <i>S. maritimus</i> %N of aboveground tissue 31–114% in 2009 and 33–67% in 2010. N addition (medium, high) increased <i>S. maritimus</i> %N of belowground tissue 26–126% in 2009 and 37–47% in 2010.	Mesocosms at UC Riverside research station, CA	<i>Schoenoplectus maritimus</i> , <i>Culex tarsalis</i> , and <i>Anopheles hermsi</i>	<a href="#">Duguma and Walton (2014)</a>

**Table 11-6 (Continued): Nitrogen loading effects upon plant stoichiometry and physiology.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Freshwater tidal marsh (growth chamber)	250 g N/ha/yr as NH <sub>4</sub> Cl solution N dep = not reported S dep = not reported	Nitrogen increases construction cost of leaves by 5% in native <i>Phragmites</i> . Nitrogen under elevated [CO <sub>2</sub> ] increases construction costs by 6% in invasive <i>Phragmites</i> .	Mesocosms at Smithsonian Environmental Research Center, MD	<i>Phragmites australis</i> (native F haplotype and invasive M haplotype)	<a href="#">Caplan et al. (2014)</a>
Freshwater tidal marsh	500 kg N/ha/yr as NH <sub>4</sub> Cl or urea	N addition decreased leaf [N] by 99% and leaf [P] by 25%.	Altamaha River, GA	<i>Zizaniopsis miliacea</i>	<a href="#">Frost et al. (2009)</a>
Freshwater marsh	500 kg N/ha/yr as NH <sub>4</sub> Cl or urea N dep = not reported S dep = not reported	In <i>Z. miliacea</i> , leaf %N increased 25–43% so that leaf C:N decreased 18–28% and leaf N:P increased 25–61%. Total N and total P in aboveground pools increased 236 and 169%, respectively.	Altamaha Estuary, GA	<i>Zizaniopsis miliacea</i> , <i>Pontederia cordata</i> , and <i>Sagittaria lancifolia</i>	<a href="#">Ket et al. (2011)</a>
Freshwater tidal marsh	50, 200, or 1,200 kg N/ha/yr as Nutralene methylene urea N dep = not reported S dep = not reported	In <i>S. lancifolia</i> , N addition (N <sub>add</sub> as kg N/ha/yr) increased plant tissue [N], [N] = 0.00226 × N <sub>add</sub> + 23.271; and N:P ratio, N:P = 0.00404 × N <sub>add</sub> + 16.853.  In <i>S. lancifolia</i> , resorption efficiencies (RE) declined with increasing N addition, for nitrogen: NRE = -0.01048 × N <sub>add</sub> + 31.796, for phosphorus: PRE = -0.00915 × N <sub>add</sub> + 62.778.	Tchefuncte River, Madisonville, LA	Oligohaline plant community dominated by <i>Sagittaria lancifolia</i> , <i>Eleocharis fallax</i> , and <i>Polygonum punctatum</i>	<a href="#">Graham and Mendelssohn (2010)</a>
Freshwater tidal marsh	Addition: 670 kg N/ha/yr S dep = not reported N dep = not reported	Foliar N increased in <i>A. calamus</i> (by 23%) and <i>Typha</i> spp. (by 47%).	Nanticoke River, MD and DE	Plant community	<a href="#">Baldwin (2013)</a>

**Table 11-6 (Continued): Nitrogen loading effects upon plant stoichiometry and physiology.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Riparian floodplain successional forest	100 kg N/ha/yr N dep = not reported S dep = not reported	Specific leaf mass decreased by 12 and 11% in early and late successional forest. Leaf N increased 10% in late successional forest. Leaf P resorption decreased 21%.	Bonanza Forest LTER, AK	<i>Alnus incana</i> ssp. <i>tenuifolia</i> and associated <i>Frankia</i> strains	<a href="#">Ruess et al. (2013)</a>
Ombrotrophic bog	Ambient deposition = 3.4–5.0 kg N/ha/yr across the region, divided for this study into the following ranges: 3.4–3.6, 3.8–4.1, 4.4–4.9, 4.9–5.0 kg N/ha/yr	Pitcher plant foliar N content increased 78% between low N deposition (3.4–3.6 kg N) and medium N deposition (3.8–4.1 kg N). There was no difference in foliar N between medium and higher deposition rates.  Stable isotope ( $\delta^{15}\text{N}$ ) and mass balance suggest that 68% of pitcher plant N was derived from carnivory under low N (3.4–3.6 kg N), 92% under medium N (3.8–4.1 kg N), and 55% under higher N (4.4–4.9 kg N). Increase from medium to higher N deposition decreased pitcher plant carnivory by 40%.  <i>Chamaedaphne calyculata</i> foliar N increased 27% from the lowest (3.4–3.6 kg N) to the highest deposition (4.9–5.0 kg N) sites.	Adirondack Mountains, NY (11 sites)	<i>Sarracenia purpurea</i>	<a href="#">Crumley et al. (2016)</a>
Bog	N deposition gradient: 1.94, 3.81, and 11.30 kg N/ha/yr	N from insectivory decreases with deposition: 55% from insects under 1.94 kg N/ha/yr, 20–30% under 3.81 and 11.30 kg N/ha/yr.	Three bogs in Sweden	<i>Drosera rotundifolia</i>	<a href="#">Millett et al. (2012)</a>

**Table 11-6 (Continued): Nitrogen loading effects upon plant stoichiometry and physiology.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Ombrotrophic bog	N deposition gradient: 0.5–27.0 kg N/ha/yr	N derived from insectivory decreases with increasing N deposition ( $N_{dep}$ as g N/m <sup>2</sup> /yr) in a linear relationship: $\delta^{15}N = -2.090 \times N_{dep} - 0.199$ , $R^2 = 0.43$ .  Plant tissue N:P increases with increasing N deposition in a logarithmic relationship: tissue N:P = $1.29 \times \ln(N_{dep}) + 10.00$ , $R^2 = 0.62$ .	13 bogs across Europe	<i>Drosera rotundifolia</i>	<a href="#">Millett et al. (2015)</a>

**Table 11-6 (Continued): Nitrogen loading effects upon plant stoichiometry and physiology.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Ombrotrophic peat bog	16 (low), 32 (medium), or 64 (high) kg N/ha/yr as N (NH <sub>4</sub> NO <sub>3</sub> ) or NPK (NH <sub>4</sub> NO <sub>3</sub> and KH <sub>2</sub> PO <sub>4</sub> ) N dep = 8 kg N/ha/yr S dep = not reported	In <i>R. groenlandicum</i> , leaf %N increased by 25% (low N) and 16% (high N), and leaf C:N ratios decreased by 19% (low N) and 15% (high N). Leaf P declined by 54% (high N). In low N addition, <i>R. groenlandicum</i> V <sub>cm</sub> max increased by 76% on a per-area basis or doubled on a per-mass basis. In <i>C. calyculata</i> , leaf C:N ratios decreased by 15% (low N) and 33% (high N), and total chlorophyll increased by 84% (high N), just as concentrations of leaf alanine increased 115% (high N) and GABA increased 94% (high N). Leaf Ca declined 34% (low N) and 17% (high N), leaf Mn declined 45% (high N), and leaf Al declined 44% (low N). In <i>V. myrtilloides</i> , leaf Ca declined 23% (low N) and 56% (high N), leaf P declined by 55% (low N) and 68% (high N), leaf Mn declined 57%, leaf K declined 47% (low N) and 34% (high N), and leaf Al declined 45% (high N). Amino acid leaf concentrations (y, as nmol/g) increased with leaf N (x, as %N): in <i>R. groenlandicum</i> , glutamic acid increased $y = 252.2x + 37.914$ ; in <i>C. calyculata</i> , alanine increased $y = 221.07x - 52.931$ , and GABA increased $y = 276.82x - 98.682$ .	Mer Bleue Bog, Ontario, Canada	Three ericaceous shrubs: <i>Vaccinium myrtilloides</i> , <i>Rhododendron groenlandicum</i> (formerly <i>Ledum groenlandicum</i> ), and <i>Chamaedaphne calyculata</i>	<a href="#">Bubier et al. (2011)</a>

**Table 11-6 (Continued): Nitrogen loading effects upon plant stoichiometry and physiology.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Ombrotrophic peat bog	16 (low), 32 (medium), or 64 (high) kg N/ha/yr as N (NH <sub>4</sub> NO <sub>3</sub> ) or NPK (NH <sub>4</sub> NO <sub>3</sub> and KH <sub>2</sub> PO <sub>4</sub> )	Under high N, gross PSN declined 29–45% in May–July but increased 25% in September.	Mer Bleue Bog, Ontario, Canada	Shrub species ( <i>Vaccinium myrtilloides</i> , <i>Rhododendron groenlandicum</i> , <i>Chamaedaphne calyculata</i> ), and mosses ( <i>Sphagnum magellanicum</i> , <i>Sphagnum capillifolium</i> , <i>Polytrichum strictum</i> )	<a href="#">Larmola et al. (2013)</a>
Ombrotrophic peat bog	16 (low), 32 (medium), or 64 (high) kg N/ha/yr as N (NH <sub>4</sub> NO <sub>3</sub> ) or NPK (NH <sub>4</sub> NO <sub>3</sub> and KH <sub>2</sub> PO <sub>4</sub> ) N dep = 5–6 kg N/ha/yr S dep = not reported	High N decreased leaf Ca (mg/cm <sup>2</sup> ) by 22% in <i>C. calyculata</i> and decreased leaf Mg (mg/cm <sup>2</sup> ) by 23% in <i>R. groenlandicum</i> . In <i>C. calyculata</i> , medium N increased P resorption by 42% as high N increased it by 33%. In <i>R. groenlandicum</i> , N addition (medium N, high N) increased P resorption by 12–12.2x, and increased K resorption by 92–123%. High N decreased Mg resorption 186% in <i>R. groenlandicum</i> .	Mer Bleue Bog, Ontario, Canada	<i>Chamaedaphne calyculata</i> and <i>Rhododendron groenlandicum</i> (formerly <i>Ledum groenlandicum</i> )	<a href="#">Wang et al. (2014b)</a>
Rich fen and ombrotrophic bog	No addition N dep = not reported S dep = not reported	Leaf N ( <i>y</i> , as %N) was positively correlated with surface water NO <sub>3</sub> <sup>-</sup> concentration ( <i>x</i> ): $y = 0.1667x + 0.9581$	Cedarburg fen and Sapa bog, WI	<i>Sarracenia purpurea</i> ssp. <i>purpurea</i>	<a href="#">Bott et al. ## 11.6 Plant Architecture

Plant architecture (plant height, branching) in wetlands is an important endpoint because the architecture of the dominant plants determines the availability of nesting habitats or refugia from flooding and predators. Plant architecture is defined as the three-dimensional organization of the plant body. For the parts of the plant that are aboveground, this includes the branching pattern, as well as the size, shape, and position of leaves and flower organs ([Table 11-7](#)). The 2008 ISA did not have sufficient data on N addition effects on wetland plant architecture to consider plant architecture as a specific endpoint.

### 11.6.1 Salt Marsh

There are several new studies on salt marsh plant architecture. [Darby and Turner \(2008\)](#) reported that for *Spartina alterniflora*, stem height increased linearly with N load starting at 230 kg N/ha/yr, although regression equations were not included. Stem density was

significantly higher than in unamended plots only for the highest N load, 3,720 kg N/ha/yr, which increased stem density by 43%. There are two other addition studies with N addition rates above 500 kg N/ha/yr that evaluated effects in U.S. salt marshes ([Ryan and Boyer, 2012](#); [Davey et al., 2011](#)).

The Plum Island tidal eutrophication experiment added nitrate and phosphate to salt marsh tidal creeks to achieve nitrate concentrations 15 times the concentrations of unamended creeks. In the last 2 years of this experiment, there was N but no P enrichment, and 620 kg N/ha/yr increased *Spartina alterniflora* plant height 4% in low marsh ([Johnson et al., 2016a](#)). In the high marsh, 140 kg N/ha/yr decreased *Distichlis spicata* height 4% ([Johnson et al., 2016a](#)). Across the course of the N and P addition, alterations in plant carbon allocation decreased vascular plant root:shoot biomass ratio by 31% ([Deegan et al., 2012](#)). With the decrease in belowground support and the decreases in shoot lignin (which provides structural support in plant shoots, see Stoichiometry section), a 5% increase in shoot height made plants top-heavy. As a result, lodging (plant stems collapsing to marsh substrate where they are inundated by tides), which was not observed in control marshes, affected 41% of the marsh area in enriched marsh ([Deegan et al., 2012](#)).

---

## 11.6.2 Mangrove

In Florida mangroves, [Whigham et al. \(2009\)](#) added 100 kg N/ha/yr to plots of dwarf *Avicennia germinans*, black mangrove, which increased the number of new branches produced 150% above control plots.

---

## 11.6.3 Freshwater Tidal Marsh

There are several new studies on freshwater tidal wetlands. In freshwater tidal marshes of Altamaha River Estuary, GA, N addition (500 kg N/ha/yr) increased the number of leaves per m<sup>2</sup> 52% and increasing plant height by 25–40% over the course of the 5-year experiment ([Ket et al., 2011](#)). [Duguma and Walton \(2014\)](#) constructed freshwater wetland mesocosms at UC Riverside, planting *Bolboschoenus maritimus* (formerly *Schoenoplectus maritimus*) and alkali bulrush, and monitoring plant responses as well as the use of mesocosms by mosquito species ([Appendix 11.8.2](#)). N addition of 32 kg N/ha/yr increased plant height 23% with no effect upon plant height when 65 or 108 kg N/ha/yr were added in 2009. However, in 2010 when the experiment was initiated earlier in the year (5 August start date in 2009, 22 March start date in 2010), all N addition

levels (59, 119, 198 kg N/ha/yr) increased plant height 28–44% above control plants ([Duguma and Walton, 2014](#)).

#### 11.6.4 Riparian Wetland

In developing riparian forests at Bonanza Forest LTER, AK, N addition of 100 kg N/ha/yr altered leaf structure of the tree species *Alnus incana* ssp. *tenuifolia* ([Ruess et al., 2013](#)). In the mostly recently colonized sand bars, N addition decreased specific leaf mass (SLM) of *A. incana* ssp. *tenuifolia* 12%, and in midsuccessional riparian forest SLM decreased 11% with N addition.

#### 11.6.5 Summary Table

**Table 11-7 Nitrogen loading effects upon architecture.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Coastal salt marsh	4,200 kg N/ha/yr as NH <sub>4</sub> NO <sub>3</sub> S dep = not reported N dep = not reported	N addition increased rhizome diameter by 1% in shallow and 5% in deep (10–20 cm) sediments.	Goat Island, SC	<i>Spartina alterniflora</i>	<a href="#">Davey et al. (2011)</a>
Coastal salt marsh	230, 465, 930, 1,860, or 3,720 kg N/ha/yr as (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub> S dep = not reported N dep = not reported	Stem density and stem height increased linearly with N load (regressions not given). Stem densities increased 43% in response to 3,720 kg N.	LUMCON, Cocodrie, LA	<i>Spartina alterniflora</i>	<a href="#">Darby and Turner (2008)</a>
Estuarine marsh	Addition: 1,337 kg N/ha/yr as urea. S dep = not reported N dep = not reported	In <i>S. pacifica</i> , height increased 207%, number of branches increased 135–283%. <i>J. carnososa</i> height increased 504%.	China Camp State Park, CA	<i>Sarcocornia pacifica</i> dominant (C3 succulent shrub), <i>Distichlis spicata</i> (C4 grass), and <i>Jaumea carnosa</i> (C3 semisucculent forb)	<a href="#">Ryan and Boyer (2012)</a>

**Table 11-7 (Continued): Nitrogen loading effects upon architecture.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Salt marsh	Nitrate and phosphate dissolved in tidal inflows to raise aqueous NO <sub>3</sub> <sup>-</sup> concentrations to 70–100 μM and raise PO <sub>4</sub> <sup>3-</sup> to 5–7 μM. Background load in tides: 5 μM NO <sub>3</sub> <sup>-</sup> , 1 μM PO <sub>4</sub> <sup>3-</sup> . N dep = not reported S dep = not reported	Root:shoot ratio decreases 31%. Shoot height increases 5%. Lodging affects 41% of area in enriched marshes, is not observed in control marsh.	Plum Island Estuary, MA	Primary tidal creeks with <i>Spartina alterniflora</i> in low marsh along creeks, and <i>Spartina patens</i> in high marsh platforms	<a href="#">Deegan et al. (2012)</a>
Salt marsh	Addition of nitrate dissolved in incoming tide 2011–2012, addition of N at 70–100 μM NaNO <sub>3</sub> <sup>-</sup> in tide for added load of 620–1,200 kg N/ha/yr in low marsh and 70–140 kg N/ha/yr in high marsh Ambient deposition = not specified	Low marsh in enriched creeks received an additional N load of 620 kg N/ha/yr in 2012. That year, N addition increased shoot height 4% above <i>S. alterniflora</i> in low marsh at reference creeks. High marsh in enriched creeks received an additional N load of 140 kg N/ha/yr in 2011. In <i>D. spicata</i> , N addition decreased shoot height 4%.	Plum Island Sound Estuary, MA	<i>Spartina alterniflora</i> , <i>Distichlis spicata</i> , and <i>Spartina patens</i> (high marsh); <i>Spartina alterniflora</i> (low marsh)	<a href="#">Johnson et al. (2016a)</a>
Mangrove	100 kg N/ha/yr	N addition increased the number of new branches 150% in <i>Avicennia</i> .	Indian River Lagoon, FL (impoundment SLC-24)	<i>Avicennia germinans</i> and associated sediments	<a href="#">Whigham et al. (2009)</a>
Freshwater marsh	Fall 2009: 32 (low), 65 (medium), 108 (high) kg N/ha/yr as (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub> ; Summer 2010: 59 (low), 119 (medium), or 198 (high) kg N/ha/yr as (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub> N dep = not reported S dep = not reported	N addition increased <i>S. maritimus</i> height 23% in 2009 (low N), and 28–44% in 2010.	Mesocosms at UC Riverside research station, CA	<i>Schoenoplectus maritimus</i> , <i>Culex tarsalis</i> , and <i>Anopheles hermsi</i>	<a href="#">Duguma and Walton (2014)</a>

## 11.7 Demography

Plant demography is the change in plant population size and structure through time. Changes to plant demography will determine the long-term stability of wetlands. Information on the effect of N loading on wetland plant demography, including establishment, survival, and reproduction is sparse. Evidence from salt marsh ecosystems shows mixed responses to N loading: two pre-2008 studies found negative effects of N addition upon reproduction in invasive *Spartina foliosa* and *Spartina* hybrids ([Tyler et al., 2007](#)), and a positive effect upon reproduction of native *Salicornia bigelovii* ([Boyer and Zedler, 1999](#)). Work reviewed in the 2008 ISA on *Sarracenia purpurea*, or northern pitcher plant, found that increases in N deposition increased population extinction risk ([Gotelli and Ellison, 2006, 2002](#)), which serves as the scientific basis for the wetland critical load values ([Appendix 11.9](#)). Additionally, an older study of *Drosera rotundifolia* in a Swedish bog found that N addition levels of 20 and 40 kg N/ha/yr significantly

decreased survivorship in comparison to control plots or N addition of 5 or 10 kg N/ha/yr ([Redbo-Torstensson, 1994](#)). The sections below describe two new studies that find negative impacts of high N upon the demography of wetland plants.

---

### 11.7.1 Mangrove

[Lovelock et al. \(2009\)](#) considered a global data set of mangrove responses to N fertilization experiments conducted for 3–12 years. N addition (900–2,700 kg N/tree/yr) decreased survival probability by 10%, with trees growing on the land side in hypersaline conditions particularly vulnerable when rainfall was low.

---

### 11.7.2 Riparian Wetland

The Great Salt Lake is an inland salt lake ecosystem that provides an important food source for migrating bird species as well as an economically important fishing industry by providing habitat for *Artemia franciscana*, brine shrimp. [Carling et al. \(2013\)](#) studied impounded and floodplain wetlands along the rivers that feed into the GSL, and found that increasing nitrate and nitrite concentrations in water flowing through the wetlands decreased reproduction of the submerged aquatic plants *Ruppia cirrhosa* and *Stuckenia* spp. (equations in [Table 11-8](#)).

### 11.7.3 Summary Table

**Table 11-8 Nitrogen loading effects upon demography.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Mangrove	No areal rate given; 900 kg/yr to 2,700 kg N/yr per tree as urea	Mangrove survival probability decreased 10% with N addition.	12 global sites, including Indian River Lagoon, FL	Mangrove species	<a href="#">Lovelock et al. (2009)</a>
Riparian wetlands and floodplain wetlands	Not reported	Reproduction (Repro, g/m <sup>2</sup> drupelets) declines with increasing surface water nitrate (NO <sub>3</sub> in mg/L): Repro = -4.15 × ln(NO <sub>3</sub> ) + 4.03, R <sup>2</sup> = 0.51; as well as with increasing surface water NO <sub>2</sub> <sup>-</sup> (NO <sub>2</sub> <sup>-</sup> in mg/L): Repro = -13.43 × ln(NO <sub>2</sub> <sup>-</sup> ) -25.27, R <sup>2</sup> = 0.54).	Great Salt Lake, UT	Submerged aquatic vegetation: <i>Ruppia cirrhosa</i> and <i>Stuckenia</i> spp.	<a href="#">Carling et al. (2013)</a>

g = gram; ha = hectare; kg = kilogram; L = liter; m = meter; mg = milligram; N = nitrogen; NO<sub>2</sub><sup>-</sup> = nitrite; NO<sub>3</sub><sup>-</sup> = nitrate; yr = year.

## 11.8 Biodiversity/Community

High biodiversity is a characteristic of wetlands. Fluctuating water levels in open systems such as riparian strips and tidal marshes create zones with distinct abiotic characteristics and multiple niches for microbes, plants, and animals with different biotic and abiotic requirements. More closed systems, such as bogs and fens, are nutrient-poor, high-organic-acid ecosystems that contain rare species including carnivorous plants, ericaceous plants, and bryophytes characterized by low growth rates. Most wetlands contain species with a range of N tolerance and N-acquisition strategies, and one result of eutrophication is to shift the composition and relative abundance of species so that nitrogen-tolerant species become more common as species that are adapted to low nitrogen availability become less common or disappear from the system. Thus, plant cover (percentage of the total wetland area occupied by a particular species) is an important metric of biodiversity. Similarly, communities of aquatic producers contain both nitrogen-tolerant and low-nitrogen-adapted species, and changes in phytoplankton species composition represents a change in biodiversity important for dependent food

webs (see [Appendix 9.3.2](#), [Appendix 10.3.2](#), and [Appendix 10.3.3](#)). Changes in the abundance of herbivorous, omnivorous, or predatory invertebrates are indicative of alterations to trophic interactions and effects, which could cascade up the food web towards economically or culturally important fish, bird, and mammal species.

The 2008 ISA found that the evidence was sufficient to infer a causal relationship between N deposition and the alteration of species richness, species composition, and biodiversity in wetland ecosystems. The 2008 ISA noted there are 4,200 native plant species in U.S. wetlands, 121 of which are federally endangered. Wetlands provide habitat to a disproportionately high number of rare plants given their relative area; for example, fens occupy 0.01% of the land area of northeast Iowa, yet contain 17% of the endangered, threatened, or listed species of concern in the area. Wetland species have evolved under N limited conditions, including endangered species in the *Isoetes* (three endangered species) and *Sphagnum* (15 endangered species) genera, as well as the endangered insectivorous plants *Sarracenia oreophila* and *Drosera rotundifolia*.

The 2008 ISA provided evidence from American bogs and fens that showed that *Sarracenia purpurea* (purple pitcher plant) responded to N deposition with changes in morphology and projected population extinction under N deposition levels of 4.5–6.8 kg N/ha/yr. Coastal wetlands responded to N enrichment with increased primary production, shifting microbial and plant communities, and altering pore water chemistry, although many of the studies in coastal wetlands used N enrichment levels more similar to that of wastewater than of atmospheric deposition.

---

## 11.8.1 Plants

---

### 11.8.1.1 Salt Marsh

Nitrogen was an important factor driving plant diversity in a study on the Patuxent River, where marsh soil  $\text{NO}_3^-$ -N and pore water salinity best explained the variation in plant species richness out of all factors considered, with  $\text{NO}_3^-$ -N accounting for 26% of the variation in the richness of all species. Presence-absence data for all species were used to determine the geographic range for each species, and the 50% of species per river with the smallest range was designated as a “restricted-range” subset. On the Patuxent River, the best model of variation in species richness of restricted range species contained only soil  $\text{NO}_3^-$ -N as an explanatory variable, with a positive relationship between  $\text{NO}_3^-$ -N and species richness [see [Table 11-9](#); ([Sharpe and Baldwin, 2013](#))].

Several new field addition studies further confirm N addition alters plant community composition in salt marshes. In Kirkpatrick Marsh, MD, a limited plant community and resampling of fixed plots allowed researchers to measure the biomass of plots as a proxy for plant cover. C4 plants *Spartina patens* and *Distichlis spicata* plot cover increased over the course of the 4-year fertilization experiment so that C4 biomass was 129% higher in the 4th year than in the 1st year of receiving 250 kg N/ha/yr, while C4 biomass in the control plots remained unchanged over 4 years. The C3 plant species *Schoenoplectus americanus* declined in biomass in the control plots by 8–22% of that produced in the 1st year, but decreased to a greater extent in N addition plots, declining after 4 years by 52% compared to the 1st year plot biomass ([Langley and Megonigal, 2010](#)). In the long-term nutrient addition experiment at Great Sippewissett Marsh, MA, 30 years of addition of sewage sludge altered community composition. Nitrogen addition at 170, 520, and 1,560 kg N/ha/yr altered the relative composition of *Spartina alterniflora* and *Distichlis spicata*, with percentage cover of *S. alterniflora* decreasing 3% with every additional 100 kg N/ha/yr, and percentage cover of *D. spicata* increasing 3% with every additional 100 kg N/ha/yr of total N load ([Fox et al., 2012](#)).

In Elkhorn Slough, CA, marsh community was assessed at six sites. At one site, where impoundment restricted tidal exchange, N addition of 150 kg N/ha/yr altered community composition, decreasing cover of native marsh plants by 52% and increasing cover of non-native upland plants by 80% ([Goldman Martone and Wasson, 2008](#)). There were two studies with N addition above 500 kg N/ha/yr ([Baldwin, 2013](#); [Ryan and Boyer, 2012](#)), but this N addition level was not useful in inferring effects of N deposition upon ecosystems.

---

### 11.8.1.2 Freshwater Tidal Marsh

In a freshwater tidal marsh on the Tchefuncte River, LA, N addition shifted the relative dominance of the perennial wetland-obligate monocots dominant at the site ([Graham and Mendelssohn, 2010](#)). Increasing N loads increased the relative dominance of *Persicaria punctata* (formerly *Polygonum punctatum*) with a 0.13% increase (percentage of total biomass consisting of *P. punctata*) for every 10 kg N/ha/yr added. Increasing N loads decreased the relative dominance of *Eleocharis fallax*, with a 0.08% decrease (percentage of total biomass consisting of *E. fallax*) for every 10 kg N/ha/yr added ([Graham and Mendelssohn, 2010](#)). N loading did not affect the relative dominance of *Sagittaria lancifolia*, but did alter its storage of N in plant tissues ([Appendix 11.5](#)).

---

### 11.8.1.3 Freshwater Wetland

There are two new studies of N loading in freshwater systems; they do not quantify N deposition or N loading in terms of an areal rate, but rather find correlations between surface water or soil N and changes in plant community diversity across a gradient of N loads. Nitrogen loading is often correlated with invasions of non-native plants and associated reductions in native species abundance and richness ([Green and Galatowitsch, 2002](#)). An observational study of 48 wetlands along the coasts of the Great Lakes found 7 floristically distinct plant communities: 1 *Sphagnum*-dominated wetland, 3 marsh types dominated by native plants, and 3 marsh types dominated by invasive species. A classification and regression tree that successfully classified 79% of the sites to the correct plant community used surface water total N, conductivity, and pH as explanatory variables: one of the invasive plant communities (dominated by the invasive *Typha* spp.) was associated with high total N ([Johnston and Brown, 2013](#)).

In a similar observational study of 28 restored wetlands in Illinois, soil nitrogen significantly correlated with plant invasion and a decline in native plant species richness ([Matthews et al., 2009](#)). There were linear, positive correlations of soil nitrate with relative percentage cover of non-native plants, and with relative percentage cover of invasive *Phalaris arundinacea* (see [Table 11-9](#) for full equations). For each 0.1 ppm increase in soil nitrate, non-native plant cover increased 4%, and *P. arundinacea* cover increased 5%. The surveyed wetlands were diverse communities: there were 483 vascular plant species across all 20 wetlands, and each wetland contained 40–100 native species. For every 0.1 ppm increase in soil ammonium across the wetlands, seven native species disappeared; and for every 0.1 ppm increase in soil nitrate, three native species disappeared ([Matthews et al., 2009](#)).

In addition to these studies, the National Wetlands Condition Assessment (NWCA), conducted by U.S. EPA in 2011, collected soil and water chemistry data as well as plant biodiversity data. In California wetlands sampled for this project, higher surface water nitrate + nitrite concentrations correlated with lower wetland condition scores as measured by the California Rapid Assessment Method [CRAM; [U.S. EPA \(2016j\)](#)].

---

### 11.8.1.4 Intermittent Wetland

Vernal pools are intermittent wetlands, which typically flood in the late winter and spring, and serve as important habitat for amphibians and endemic invertebrates. California vernal pools host a number of endangered and threatened animal species during their wet phase, as well as a high diversity of plant species during their dry phase.

There are no studies published that directly test the effect of N deposition or N addition to vernal pools, but there is a mesocosm study, which may allow some inference of N effects on vernal pools. This study added combined N and P solutions to mesocosms and found increased algal biomass, which decreased vascular plant cover and richness in vernal pool mesocosms ([Kneitel and Lessin, 2010](#)). N and P additions were not quantified in areal rates.

---

#### 11.8.1.5 Bog and Fen

In Mer Bleue Bog, Ontario, N addition decreased the dominance of *Sphagnum* mosses in the northern ombrotrophic peat bog. After 4 years of N fertilization at the rate of 64 kg N/ha/yr, cover of *Sphagnum* species (of *Sphagnum magellanicum* and *Sphagnum capillifolium*) in fertilized plots was 43% of *Sphagnum* cover in control plots ([Juutinen et al., 2010](#)). At year 12, cover of *Sphagnum* species in 16 kg N/ha/yr fertilized plots was 64% of cover in control plots ([Larmola et al., 2013](#)). Plots measured in the same growing season (2011) that had received 7 years of elevated N at higher N addition rates also experienced declines in *Sphagnum* cover: 26% decline in cover at 32 kg N/ha/yr and 54% decline in cover at 64 kg N/ha/yr ([Larmola et al., 2013](#)). The following year, moss species (*Sphagnum* spp. and *Polystrichum strictum*) cover was 63% lower in 64 kg N/ha/yr plots than in control plots, while the percentage of cover of the vascular plant *Chamaedaphne calyculata* was 202% higher in 32 kg N/ha/yr plots than in control plots ([Wang et al., 2016a](#)). These declines in peat-forming species corresponded to changes in ecosystem C fluxes ([Appendix 11.3.2](#)).

N deposition or addition effects upon plant community composition have been studied in European systems. In an Irish fen, which was also the site of a N addition experiment (see [Appendix 11.4.4](#) and [Appendix 11.5.5](#)), researchers observed plant community composition shifts in control plots over 4 years ([Paulissen et al., 2016](#)). Under ambient deposition of 7–10 kg N/ha/yr, cover of the N-sensitive brown moss *Scorpidium revolvens* decreased 25%, while cover of peat moss *Sphagnum contortum* increased 20% and cover of vascular plants increased qualitatively ([Paulissen et al., 2016](#)). N addition increases vascular plant cover in multiple systems. In an Italian fen, N addition altered plant cover of 4 of the 17 species documented in the marsh ([Gerdol and Brancaloni, 2015](#)). Vascular species cover did not shift in response to 10 kg N/ha/yr; but in response to 30 kg N/ha/yr addition, cover of shrub *Calluna vulgaris* increased 96% and cover of grass *Molinia caerulea* increased 5.6 times that of control plots. Like the vascular plants, moss species *Sphagnum fuscum* (native in the U.S., listed as endangered by North Carolina) did not respond to 10 kg N addition, but its cover decreased 45% in response to 30 kg N addition. The moss species *Polytrichum strictum* (native in the U.S., listed as

endangered in Kentucky) increased in response to both 10 or 30 kg N addition, with cover 190–240% higher after 8 years of N addition. Researchers continued to monitor the plots for 3 years after ceasing N addition treatments to assess wetland recovery: vascular plants and *P. strictum* remained dominant, while *S. fuscum* cover continued to decline, and a different moss species, *Sphagnum magellanicum*, increased its coverage in plots recovering from elevated N addition ([Gerdol and Brancaleoni, 2015](#)).

### 11.8.1.6 Summary Table

**Table 11-9 Nitrogen loading effects upon plant biodiversity and communities.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Coastal high marsh	Addition: 150 kg N/ha/yr as urea S dep = not reported N dep = not reported	At a site where tidal inflow was restricted, fertilization increased cover of non-native upland plants by 80% and decreased cover of native marsh plants by 52%.	Six sites at Elkhorn Slough, Watsonville, CA	Marsh community dominated by <i>Sarcocornia pacifica</i> , also contains <i>Jaumea carnosa</i> , <i>Frankenia salina</i> , <i>Spergularia salina</i> , <i>Distichlis spicata</i> , and <i>Atriplex californica/triangularis</i>	<a href="#">Goldman Martone and Wasson (2008)</a>
Estuarine salt marsh	Addition: 1,337 kg N/ha/yr as urea S dep = not reported N dep = not reported	<i>S. pacifica</i> cover increased at 6.2x the rate of increase in control. <i>J. carnosa</i> cover declined 5.4x as fast as in control.	China Camp State Park, CA	<i>Sarcocornia pacifica</i> dominant (C3 succulent shrub), <i>Distichlis spicata</i> (C4 grass), and <i>Jaumea carnosa</i> (C3 semisucculent forb)	<a href="#">Ryan and Boyer (2012)</a>
Estuarine salt marsh	Addition: 250 kg N/ha/yr S dep = not reported N dep = not reported	<i>S. americanus</i> aboveground biomass decreased by 19 and 45% in the 3rd and 4th yr, respectively.	Kirkpatrick Marsh, MD (measured in 3rd and 4th yr, 2008–2009)	<i>Schoenoplectus americanus</i> (C3), <i>Spartina patens</i> (C4), and <i>Distichlis spicata</i> (C4)	<a href="#">Langley and Megonigal (2012, 2010)</a>

**Table 11-9 (Continued): Nitrogen loading effects upon plant biodiversity and communities.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Coastal salt marsh	Addition: 170 kg N/ha/yr, 520 kg N/ha/yr, 1,560 kg N/ha/yr, all added as sewage sludge (10% N, 6% P <sub>2</sub> O <sub>5</sub> , 4% K <sub>2</sub> O) S dep = not reported N dep = not reported Background total N load = 2 kg/ha/yr (as reported in <a href="#">Bowen and Valiela (2001b)</a> ).	<i>S. alterniflora</i> cover ( $y$ , as % cover) declines in plots with increasing N load ( $N_{add}$ , as kg N/ha/yr), $y = -0.0292 \times N_{add} + 64.6$ . <i>D. spicata</i> cover ( $z$ , as % cover) increases in plots with increasing N load, $z = 0.0327 \times N_{add} + 3.04$ .	Great Sippewissett Salt Marsh, MA	Salt marsh community, dominated by <i>Spartina alterniflora</i> , <i>Spartina patens</i> , <i>Distichlis spicata</i> , and <i>Iva frutescens</i> .	<a href="#">Fox et al. (2012)</a>
Estuarine tidal marsh	Addition: none S dep = not reported N dep = not reported	On the Patuxent River, pore water NO <sub>3</sub> <sup>-</sup> -N and salinity best explained plant species richness (model $R^2 = 0.67$ ), with NO <sub>3</sub> <sup>-</sup> -N accounting for 26% of variation in the full data set and for 5% of variation in widely distributed species. In species with more restricted geographic ranges, NO <sub>3</sub> <sup>-</sup> -N alone best predicted plant species richness (positive relationship, model $R^2 = 0.71$ ).	Nanticoke River and Patuxent River, Chesapeake Bay, MD and DE	Plant community	<a href="#">Sharpe and Baldwin (2013)</a>
Estuarine tidal marsh	Addition: 670 kg N/ha/yr S dep = not reported N dep = not reported	<i>Typha</i> spp. cover increased by 120%.	Nanticoke River, MD and DE	Plant community	<a href="#">Baldwin (2013)</a>
Freshwater estuarine marsh	50, 200, or 1,200 kg N/ha/yr as Nutralene methylene urea S dep = not reported N dep = not reported	N addition ( $N_{add}$ as kg N/ha/yr) decreased the dominance of <i>E. fallax</i> ( <i>Efa</i> , as % biomass) $Efa = -0.00812 \times N_{add} + 15.410$ . Addition increased the dominance of <i>P. punctatum</i> ( <i>Ppu</i> , as % of biomass) $Ppu = 0.03144 \times N_{add} + 9.353$	Tchefuncte River, Madisonville, LA	Oligohaline plant community dominated by <i>Sagittaria lancifolia</i> , <i>Eleocharis fallax</i> , and <i>Polygonum punctatum</i>	<a href="#">Graham and Mendelssohn (2010)</a>

**Table 11-9 (Continued): Nitrogen loading effects upon plant biodiversity and communities.**

Type of Ecosystem	Additions or Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Restored freshwater wetlands	Ambient deposition; rates not reported	Soil available N (ppm ammonium, abbreviated as $N_{NH4}$ , or ppm nitrate, as $N_{NO3}$ ) correlated with decreasing native species richness (number of species, $y$ ): $y = -73.8N_{NH4} + 122$ , $r^2 = 0.41$ $y = -30.9N_{NO3} + 97.4$ , $r^2 = 0.18$ Soil available N (as ppm nitrate, or $N_{NO3}$ ), correlated with increasing cover by all nonnative plants (relative % cover all non-natives, $z$ ): $z = 41.7N_{NO3} - 3.5$ , $r^2 = 0.31$ Soil available N (as ppm nitrate, or $N_{NO3}$ ), correlated with increasing cover by invasive <i>Phalaris arundinacea</i> (relative % cover, abbreviated PHAR): $PHAR = 52.7N_{NO3} - 29.6$ , $r^2 = 0.58$	28 wetlands restored or created in 1992–2002, Illinois All wetlands surveyed summer 2006	Vascular plant community: 483 species across all wetlands, including 109 non-native species	<a href="#">Matthews et al. (2009)</a>

## 11.8.2 Consumers

Increased reactive N can alter dynamics among consumers in wetlands. Studies show that increasing N load increases parasitism, decreases overall health condition, and increases the abundance of mosquitos (vectors for zoonotic diseases). There is also a new meta-analysis evaluating consumer behavior in coastal wetlands. [He and Silliman \(2015\)](#) conducted a meta-analysis of herbivory in globally distributed coastal wetlands (marshes and mangroves) and found that N and N + P additions generally increased herbivore abundance and herbivory across salt marsh studies, but not across mangrove studies.

In a survey of the native mud snail *Ilyanassa obsoleta* collected from 15 New England salt marshes, increased N correlated with increasing parasitism of *I. obsoleta*. Sediment N correlated positively with parasitic trematode prevalence ( $R^2 = 0.41$ ) and with infection by the parasitic flatworm *Stephanostomum* spp. ( $R^2 = 0.42$ ).

[Wigand et al. \(2010\)](#) developed a metric for marsh condition using the Nitrogen Loading Model ([Wigand et al., 2003](#)) and data collected on abundance and richness of plants, invertebrates, and soil conditions of 10 coastal marshes in Narragansett Bay, RI. Marsh condition declined as annual N load to the marsh increased.

[Ialeggio and Nyman \(2014\)](#) collected plants dominant in freshwater (*Panicum hemitomon*), freshwater-brackish (*Sagittaria lancifolia*), and brackish (*Spartina patens*) marshes, fertilized the plants with 619 kg N/ha/yr in mesocosms, and then offered the plants along with unfertilized controls in feeding trials to the introduced aquatic rodent *Myocastor coypus* (nutria). Fertilization increased plant tissue N by 140%, from 0.9% N to 2.2% N by mass, and nutria preferentially fed on fertilized plants. N loading increased plant mass loss due to nutria herbivory by 750% ([Ialeggio and Nyman, 2014](#)).

N addition increases the abundance of mosquito species *Culex tarsalis* and *Anopheles hermsi*, which act as vectors for zoonotic diseases. [Duguma and Walton \(2014\)](#) constructed freshwater wetland mesocosms at UC Riverside, planting *Schoenoplectus maritimus* in all mesocosms and monitoring plant growth as well as colonization of mesocosms by mosquito species. N loads were 0, 32, 65, and 108 kg N/ha in 2009, and 0, 59, 119, and 198 kg N/ha in 2010. Sampling retrieved elevated numbers of *Culex tarsalis* (western encephalitis mosquito) larvae and pupae in elevated nitrogen treatments in both 2009 and 2010, and of *Anopheles hermsi* in 2010. In 2009, immature mosquito counts were 56–100% higher in fertilized treatments than in control treatments, but there were no differences among different N loads in mosquito counts. In 2010, total mosquito counts were similar in unenriched mesocosms and in mesocosms receiving 59 kg

N/ha/yr, but increased by 64% with 119 kg N/ha/yr, and by 129% with 198 kg N/ha/yr ([Duguma and Walton, 2014](#)).

---

## 11.9 Critical Loads

In the 2008 ISA, no critical loads studies had been published. Since then, critical loads have been published for wetlands in the U.S. ([Greaver et al., 2011](#)).

---

### 11.9.1 Freshwater Wetland

There are two published critical loads for North American freshwater wetlands. [Greaver et al. \(2011\)](#) determined that the critical load for altered peat accumulation and NPP is between 2.7 and 13 kg N/ha/yr, based on observations from [Aldous \(2002a\)](#), [Moore et al. \(2004b\)](#), [Rocheffort et al. \(1990\)](#), and [Vitt et al. \(2003\)](#). The upper end of this critical load range is based on measurements of wet deposition only [10 to 13 kg N/ha/yr; ([Aldous, 2002a, b](#))] and, therefore, does not reflect total N loading from all sources. There is evidence showing that N deposition alters both the morphology and population dynamics of the purple pitcher plant. The empirical evidence suggests a critical load to protect the population of purple pitchers of 10–14 kg N/ha/yr ([Gotelli and Ellison, 2006](#)), while matrix modeling to forecast long-term population sustainability based on observations of population demographics suggests a lower value of 6.8 kg N/ha/yr ([Gotelli and Ellison, 2002](#)).

---

### 11.9.2 Coastal Wetlands

Coastal wetlands have open hydrologic and nutrient cycles that receive N loads from sources other than atmospheric deposition, so a critical load for atmospheric N deposition has been difficult to establish ([Greaver et al., 2011](#)). Typically, the amount of N added in experimental treatments in these systems simulates total N input and, therefore, far exceeds the atmospheric deposition received by U.S. coastal wetlands. Only two studies have considered N loads below 100 kg N/ha/yr. Based on the results of [Wigand et al. \(2003\)](#), a critical load to protect the community structure of salt marshes is likely to be 63 to 400 kg N/ha/yr. [Caffrey et al. \(2007\)](#) provided additional evidence that 80 N/ha/yr alters microbial activity and biogeochemistry. [Greaver et al. \(2011\)](#) also established a critical load for eelgrass growing in estuarine and marine waters associated with coastal wetlands (see [Appendix 10.6](#)). The critical load for coastal wetlands is based on total N loading to salt marshes. Total loading includes N deposition directly to the marsh surface,

N deposited to the watershed and transported via surface or groundwater, and runoff from agriculture, urban areas, or other sources. Additional experimental evidence on ecosystem response to N loads more similar to N loading from atmospheric deposition is needed to improve the critical load calculation for coastal wetlands in the U.S.

---

### 11.9.3 Comparison to Critical Loads from Europe

An assessment of N critical loads in Europe was published in 2003 and designated critical loads for multiple types of wetlands, including raised and blanket bogs, poor fens, rich fens, mountain rich fens, and intertidal wetlands ([Bobbink et al., 2003](#)). There are numerous publications on N effects to wetlands in Europe compared to the U.S. In general, documented responses include effects on growth and species composition, competition among species, peat and peat water chemistry, decomposition, and nutrient cycling. A brief summary of the European critical loads for wetlands is presented here.

[Bobbink et al. \(2003\)](#) assigned a critical load of 5 to 10 kg N/ha/yr for bog ecosystems, based on plant community and species responses to N deposition, and indicated that precipitation and P limitation should be used to assign critical loads to individual sites. The observed changes in the plant communities of ombrotrophic bogs included the replacement of *Sphagnum*-forming species with nitrophilous moss species [20 to 40 kg N/ha/yr in Dutch bogs; ([Greven, 1992](#))] and the absence of characteristic *Sphagnum* species in British bogs [30 kg N/ha/yr; ([Lee and Studholme, 1992](#))]. A recent study along a deposition gradient in Alberta, Canada, compared *Sphagnum* bog and fen responses in that region to previously published European bog and fen responses to N and S deposition. Similar N deposition gradients elicited significant *Sphagnum* and water chemistry responses in European peatlands but no responses in Albertan peatlands ([Wieder et al., 2016](#)). This suggests that critical loads for European *Sphagnum* species, which have experienced a longer history of higher N deposition than North American wetlands, may not be applicable in North American bogs and fens. [Bobbink et al. \(2003\)](#) also suggested a critical load for the carnivorous bog plant roundleaf sundew [10 kg N/ha/yr in Swedish bogs; ([Bobbink et al., 2003](#); [Redbo-Torstensson, 1994](#))] that may be relevant to American bogs where this species also grows. The European critical load for this carnivorous plant is similar to the range of critical loads suggested for freshwater wetlands in the U.S.

There are European critical loads for fens, but they are based on moss decline, and the amount of N causing ecological effects may not be directly relevant to U.S. ecosystems for the reasons outlined by [Wieder et al. \(2016\)](#). European poor fens have a critical load of 10 to 20 kg N/ha/yr based on increased sedge and vascular plants and negative effects

on mosses. The critical load for rich fens in Europe is 15 to 35 kg N/ha/yr based on increased tall graminoids and decreased diversity. The critical load for montane rich fens in Europe was 15 to 25 kg N/ha/yr based on increased vascular plants and decreased bryophytes. These community changes are similar to the increasing vascular plant and declining moss cover observed in American N addition experiments (see [Appendix 11.10](#)), although there has been no critical load established for American bogs and fens based on these community composition changes. In Europe, changes in the vegetation composition and structure likely affect fauna species assemblages, such as ground-breeding birds, spiders, and beetles, living in the originally open bog vegetation. Increased nutrient availability results in an increase of the nutrient content of plant material ([Limpens et al., 2003a](#); [Tomassen et al., 2003](#)) and algal growth ([Limpens et al., 2003b](#); [Gulati and Demott, 1997](#)), which affects herbivorous, detritivorous, and carnivorous invertebrates ([van Duinen et al., 2004](#)).

The European critical load for salt marshes, based on expert judgment, is 30 to 40 kg N/ha/yr ([Bobbink et al., 2003](#)), but studies of European salt marshes are limited. There are no European wetland systems composed of native plants directly equivalent to North American low salt marshes; in European systems, these zones consist of unvegetated mud flats, or of monocultures of invasive plants. High levels of N input (65 to 70 kg N/ha/yr) significantly increased biomass production in the Netherlands ([van Wijnen and Bakker, 1999](#)); however, no changes in species composition and in diversity have been observed at deposition of 15 to 25 kg N/ha/yr at sites in the Netherlands and Germany ([Bobbink et al., 2003](#)). The critical load for N deposition in North American coastal wetlands may be close to these values when considered as part of the total N load that these systems receive.

---

## 11.10 Summary

There are chemical and biological effects of N deposition in wetlands. Wetland vegetative communities are adapted to high levels of natural organic acidity, so it is unlikely that S or N deposition would cause any acidification-related effects at levels of acidic deposition commonly found in the U.S. [([U.S. EPA, 2008a](#)), in Annex B]. Wetlands can be sensitive to eutrophication caused by N deposition. These effects were documented in the 2008 ISA. In this appendix, new information published since 2008 is integrated with the information published in the 2008 ISA. Synthesis is made across wetland types for causality statements. Information is also synthesized for freshwater and coastal wetlands because saltwater and estuarine wetlands are typically adapted to much higher N loading.

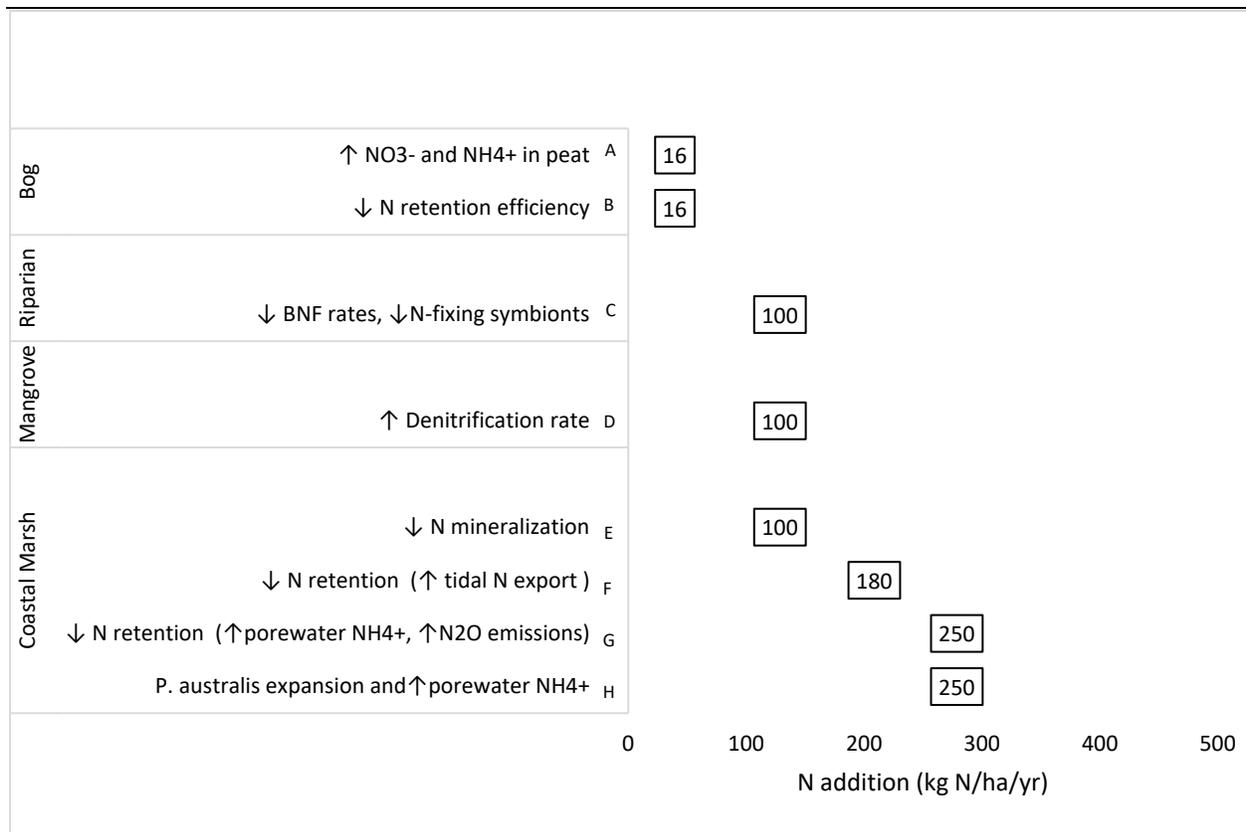

---

### 11.10.1 Causality across Wetland Types

New studies published between 2008–2015 support and extend the findings of the 2008 ISA. As in the 2008 ISA, **the body of evidence is sufficient to infer a causal relationship between N deposition and the alteration of biogeochemical cycling in wetlands.** N deposition changes N and C cycling in wetlands. There is new evidence of N deposition changes to plant physiology, which was not included in the 2008 ISA as an endpoint due to lack of evidence. This evidence expands our understanding of the causal relationship between N deposition and species diversity. **The body of evidence is sufficient to infer a causal relationship between N deposition and the alteration of growth and productivity, species physiology, species richness, community composition, and biodiversity in wetlands.**

N deposition contributes to total N loading in wetlands, with the relative contribution of deposition to total loading variable among wetland types. Chemical indicators of N deposition in wetlands include  $\text{NO}_3^-$  and  $\text{NH}_4^+$  leaching, DON leaching, N mineralization, denitrification rates, and  $\text{N}_2\text{O}$  emissions. A wetland can serve as a source, sink, or transformer of atmospherically deposited N ([Devito et al., 1989](#)). Source/sink N dynamics in wetlands vary with season, hydrological conditions, vegetation type, climate, and surface geology ([Mitchell et al., 1996](#); [Arheimer and Wittgren, 1994](#); [Koerselman et al., 1993](#); [Devito et al., 1989](#)).

Several new studies provide evidence of N deposition alterations to biogeochemical cycling of N within a wetland ecosystem ([Appendix 11.3](#)). A synthesis study of multiple wetland types across the globe shows wetland N removal is proportional to N load ( $\log[\text{N removal}] = 0.943 \times \log[\text{N load}] - 0.033 \text{ N}$ ) and removal efficiency is 26% higher in nontidal than tidal wetlands ([Jordan et al., 2011](#)). Meta-analysis of 19 N addition observations (N addition 15.4 to 300 kg N/ha/yr) found that N enrichment increased wetland  $\text{N}_2\text{O}$  emissions by 207% ([Liu and Greaver, 2009](#)). The emission factor for the amount of N added to a wetland that is converted to  $\text{N}_2\text{O}$  ranges between 0.007–0.07 ([Liu and Greaver, 2009](#)). There are also new studies that evaluate the effects of N loading/N addition on other endpoints related to N cycling in peat bog, riparian, mangrove, and salt marsh wetlands. The endpoints evaluated include ecosystem N retention, wetland export of N to surface waters, N fixation, N mineralization, denitrification, emission of  $\text{N}_2\text{O}$ ; and bacterial abundance, activity, and composition in wetland soils. The results of North American studies are summarized in [Figure 11-2](#). Across studies, N loading decreases the ability of wetlands to retain and store nitrogen, which may diminish the wetland ecosystem service of improving water quality.

BNF =biological nitrogen fixation; ha = hectare; kg = kilogram; N = nitrogen.

<sup>h</sup>[Mozdzer et al. \(2016\)](#).

**Figure 11-2 Summary of the levels of nitrogen addition where a change to nitrogen cycling is observed.**

There is new information on how N deposition alters biogeochemical cycling of C in wetlands. In the 2008 ISA, evidence from Canadian and European peatlands showed that N deposition had negative effects on *Sphagnum* bulk density and mixed effects on *Sphagnum* productivity depending on the history of deposition. In Canadian ombrotrophic peatlands experiencing deposition of 2.7–8.1 kg N/ha/yr, peat accumulation increased with N deposition, but accumulation rates had slowed by 2004, indicating a degree of N saturation ([Moore et al., 2004b](#)). N addition alters belowground and aboveground pools of carbon and also increases wetland methane emissions, as

summarized by meta-analysis in the 2008 ISA and published in [Liu and Greaver \(2009\)](#). In a study of 90 wetlands around the Gulf Coast from Florida to Texas, [Nestlerode et al. \(2014\)](#) found that higher N in the soil correlated with lower bulk density ( $\ln[\text{soil \%N}] = -1.9233 \times [\text{g/cc}] + 0.4165$ ) which indicates that the marsh is less resilient to physical stresses from tidal or storm flooding, and the marsh platform is more likely to shear off or wash away. New evidence shows that N loading increases methane production from wetland soils. In N addition experiments replicated in three California marshes ([Vivanco et al., 2015](#); [Irvine et al., 2012](#)), field-measured methane flux from soils increased linearly with increasing N load (0, 100, 200, 400, 800, 1,600, 3,200 kg N/ha/yr), such that CH<sub>4</sub> flux from soils increased by 1.23 μg CH<sub>4</sub>/m<sup>2</sup>/day for each 10 kg N/ha/yr added, ([Vivanco et al., 2015](#); [Irvine et al., 2012](#)). Methane flux increased from low or nearly negative to net positive values above ~100 kg N/ha/yr, indicating a shift from net methanotrophy to methanogenesis in the microbial community in response to N loading consistent with other studies ([Liu and Greaver, 2009](#)).

Additional literature evaluates the effects of N deposition, N loading, or experimental N addition on C cycling in salt marshes, mangroves, freshwater tidal marshes, riparian or intermittent marshes, bogs, and fens. Significant effects of N loading upon biogeochemical cycling of C in North American wetlands (in which the N addition was 500 kg N/ha/yr or lower) are summarized in [Figure 11-3](#). Ecological endpoints evaluated to assess N loading effects on C cycling include (1) measures of C pools—plant aboveground biomass and productivity, plant belowground biomass of roots and rhizomes, soil organic matter, and total soil C or peat C; (2) measures of C fluxes—microbial mineralization, decomposition rates, CO<sub>2</sub> emissions, and CH<sub>4</sub> emissions; and (3) measures of physical marsh stability as a proxy for long-term C storage—peat chemical composition, temperature, bulk density, physical resistance, and soil water content. In general across wetlands, nitrogen loading increases aboveground C pools, decreases or does not change belowground C pools, and does not change or increases C fluxes. This shift from belowground to aboveground C storage may diminish the wetland ecosystem services of long-term carbon storage and flood protection, as well as reduce the stability and persistence of wetlands on the landscape. N loading effects upon C cycling are uneven across species, which may affect wetland biodiversity and the wetland ecosystem service of provisioning.

**Figure 11-3 Summary of new literature of nitrogen load effects on belowground and aboveground carbon cycling.**

N addition effects on plant stoichiometry and plant architecture were not addressed in the 2008 ISA. Plant stoichiometry theory considers the balance of multiple chemical elements in living tissues, and plant architecture is defined as the three-dimensional organization of the plant body. The stoichiometry of plant tissue is often connected to the tissue's physiological function. Most new studies on physiology and stoichiometry have been conducted in bogs and fens, where N addition typically caused an increase in plant N content, a decrease in N use efficiency and resorption, and an increase in plant production, particularly of vascular plants. At high N loads or cumulative exposure to years of lower N loads plants may experience leaf N saturation and micronutrient limitation (e.g., P, K, and Ca, indicated by altered leaf tissue concentrations or altered reabsorption efficiencies; see [Figure 11-4](#)), which in turn cause leaf damage ([Bubier et al., 2011](#); [Xing et al., 2011](#)) or decreasing plant abundance of sensitive species (see biodiversity section). N loading can disrupt nutrient acquisition of carnivorous plants via their adaptation of capturing and digesting insects; for example, along a narrow N deposition gradient (3.4–5.0 kg N/ha/yr) across bogs in the Adirondack Mountains, purple pitcher plant (*S. purpurea*) experienced negative effects upon growth and insectivory at deposition of 4.4–4.9 kg N/ha/yr ([Crumley et al., 2016](#)). A new European study also found negative effects of N deposition upon insectivory of the wetland plant *Drosera rotundifolia* at 3.81–11.30 kg N/ha/yr ([Millett et al., 2012](#)). Historically low N loads to bogs and fens have made these wetlands and their endemic plant species particularly sensitive to N deposition. New studies of physiology and plant architecture in North American riparian wetlands, freshwater tidal marshes, mangroves, and salt marshes showed that N addition in these systems increased plant tissue N with a cascading effect that increased plant primary production and changed plant architecture. N loading increased plant height in salt and freshwater marshes, which [Deegan et al. \(2012\)](#) showed made salt marshes top-heavy and resulted in a loss of marsh platform stability, with and shredding and loss of marsh surface. In general effects of N loading upon physiology and architecture vary by species across North American wetlands. Even species tolerant of N loading may experience negative effects if N loading causes physiological limitation by other nutrients, including Ca, P, and K. Plant physiology and architecture altered by N loading may affect wetland biodiversity and resiliency to other disturbances.

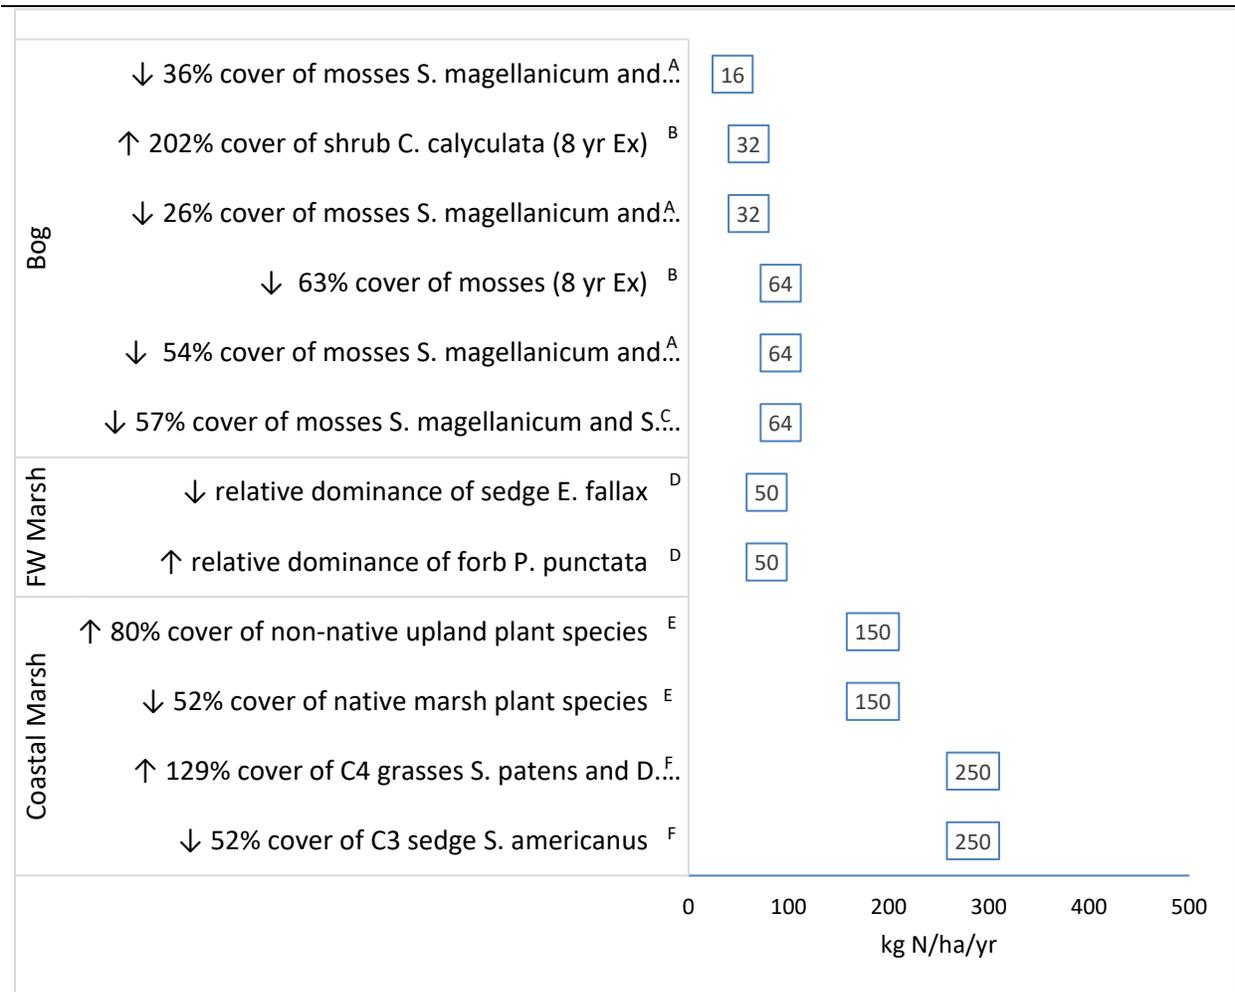

**Figure 11-4 Summary of the level of nitrogen load that caused a change in the response variables of plant stoichiometry and physiology in wetlands.**

The 2008 ISA found that the evidence was sufficient to infer a causal relationship between N deposition and the alteration of species richness, species composition, and biodiversity in wetland ecosystems. Wetlands provide habitat to a disproportionately high number of rare plants given their relative area; for example, fens occupy 0.01% of the land area of northeast Iowa yet contain 17% of the endangered, threatened, or listed species of concern in the area. The 2008 ISA noted that there were 4,200 native plant

species in U.S. wetlands, 121 of which are federally endangered. Wetland species have evolved under N limited conditions, including endangered species in the *Isoetes* (3 endangered species) and *Sphagnum* (15 endangered species) genera, as well as the endangered insectivorous plants *Sarracenia oreophila* and *Drosera rotundifolia*. Plant demography was not specifically addressed in the 2008 ISA, although demography is an important aspect in maintaining species richness and biodiversity. Plant demography is the change in plant population size and structure through time. In bogs and fens, N addition experiments suggest positive population growth rates for *Sarracenia purpurea* at 0 or 1.4 kg N/ha/yr, but population losses at 14 kg N/ha/yr (Gotelli and Ellison, 2006). Demographic modelling of *S. purpurea* found that populations remained stable for 100 years at deposition rates of 4.5–6.8 kg N/ha/yr, but extinction risk for populations increased above 6.8 kg N/ha/yr (Gotelli and Ellison, 2002). Field N addition studies suggest that N addition to bogs and fens will also affect community composition (Figure 11-5). In Mer Bleue Bog, Ontario, N addition decreased the dominance of *Sphagnum* mosses in the northern ombrotrophic peat bog, while increasing dominance of woody shrub species (Larmola et al., 2013; Juutinen et al., 2010). This result is consistent with the earlier European literature summarized in the 2008 ISA, which showed that N deposition decreased moss dominance and increased the dominance of vascular plants in European bogs and fens.

Across freshwater wetlands, N load is correlated with an increase in the abundance of invasive plant species and a decrease in the number of native plant species (see Figure 11-1 and Appendix 11.8.1), as well as an increase in larvae of mosquito species that are vectors for zoonotic diseases (Appendix 11.8.2). In a freshwater tidal marsh on the Tchefuncte River, LA, N addition shifted the relative dominance of the perennial wetland-obligate monocots dominant at the site (Graham and Mendelssohn, 2010). In salt marshes, N addition caused negative reproductive effects in invasive *Spartina foliosa* and *Spartina* hybrids (Tyler et al., 2007), and a positive effect on reproduction in *Salicornia bigelovii* (Boyer and Zedler, 1999). N loading in salt marshes is correlated with species richness. A study on the Patuxent River found marsh soil  $\text{NO}_3^-$ -N and pore water salinity best explained variation in plant species richness out of all factors considered ( $R^2 = 0.67$ ), with  $\text{NO}_3^-$ -N accounting for 26% of the variation in total species richness. In the same system, the best model for rare species richness contained only soil  $\text{NO}_3^-$ -N as an explanatory variable, with a positive relationship between  $\text{NO}_3^-$ -N and species richness [ $R^2 = 0.71$  (Sharpe and Baldwin, 2013)]. In salt marshes in Maryland and California, N addition was shown to alter the relative abundance of plant species [Langley and Megonigal (2010); Goldman Martone and Wasson (2008); Figure 11-5]. N deposition effects can cascade beyond plants up trophic levels to consumers. Meta-analysis showed that N loading increased invertebrate abundance and herbivory, and a field experiment found increased herbivory by the invasive mammal nutria in freshwater tidal and salt

marshes ([Appendix 11.8.2](#)). In New England, N loading decreased salt marsh condition, evaluated by a multidimensional metric that included abundance and richness of plants and invertebrates as well as soil conditions ([Appendix 11.8.2](#)). In general, N loading across North American wetlands decreases richness or abundance of sensitive species while promoting invasive species, with negative effects on biodiversity.

## 11.10.2 Coastal versus Freshwater Wetlands

Coastal and freshwater wetlands tend to have different sensitivity to N deposition/loading. The effect of N deposition on wetland ecosystems depends on the fraction of rainfall in the total water budget, and the sensitivity to N deposition has been suggested as: bogs (70–100% rainfall) > fens (55–83% rainfall) > coastal wetlands [10–20% rainfall ([Morris, 1991](#))].

[Greaver et al. \(2011\)](#) suggested a critical load to protect biodiversity and biogeochemistry of coastal wetlands based on salt marsh community composition, microbial activity, and biogeochemistry (63–400 kg N/ha/yr as total N load). A comparison of those critical loads with data on N addition levels (15–500 kg N/ha/yr) and associated effects, published since the last ISA, is given in [Figure 11-6](#).

In freshwater systems, [Greaver et al. \(2011\)](#) determined a critical load for wetland C cycling as quantified by altered peat accumulation and NPP, between 2.7 and 13 kg N/ha/yr. [Greaver et al. \(2011\)](#) also set a critical load to protect biodiversity based on morphology and population dynamics of the purple pitcher plant (*Sarracenia purpurea*) between 6.8–14 kg N/ha/yr. A more recent study across an N deposition gradient suggests that purple pitcher plant populations experience negative effects of N deposition at 4.4 kg N/ha/yr ([Crumley et al., 2016](#)). A comparison of freshwater wetland CLs to data from N addition levels (16–500 kg N/ha/yr) and associated effects, published since the CLs for wetlands were set, is given in [Figure 11-7](#). There is information on the relationship between N addition and numerous endpoints. At the lowest experimental addition level (16 kg N/ha/yr), there are observations of altered C and N cycling and altered biodiversity. The endpoints affected include decreases in moss cover, increased peat biomass, decreased N retention efficiency, and altered/damaged leaf stoichiometry in vascular plants.

AG = aboveground; BG = belowground; CH<sub>4</sub> = methane; GTR = general technical report; N = nitrogen.

## APPENDIX 12 NONACIDIFYING SULFUR ENRICHMENT EFFECTS

[Appendix 12](#) summarizes research on the nonacidifying impacts of S deposition on ecosystems, synthesizing literature published since the *2008 ISA for Oxides of Nitrogen and Sulfur-Ecological Criteria* (hereafter referred to as the 2008 ISA) with earlier key studies. The causal statements are presented in the Introduction ([Appendix 12.1](#)).

[Appendix 12.2](#) discusses the effects of sulfur (S) deposition on S storage and cycling in ecosystems, sulfide phytotoxicity in wetlands, internal eutrophication in freshwater aquatic systems, methane emissions from wetlands and lakes, and the microbial communities responsible for methanogenesis.

Increasing bioavailability of mercury (Hg) due to S addition is a major focus, and Hg sources, pools, and fluxes in terrestrial and aquatic ecosystems are briefly described in [Appendix 12.3.1](#) and [Appendix 12.8](#). [Appendix 12.3.2](#) includes a discussion of the current understanding about the distribution of Hg methylation potential across the prokaryotic domains and the key role of sulfur-reducing prokaryotes (SRPs). Mercury methylation occurs in lakes in shallow sediments or below the oxycline; in peat wetlands, at the interface with upland areas and generally near the water surface in peat; in periphyton; in saturated decomposing litter or algal biomass; in saturated forest soils; and in estuarine and marine sediments. In freshwater systems, methylation is strongly seasonal, with methylmercury (MeHg) concentrations peaking in summer or fall. Methylation rates and MeHg concentrations are determined by the biological niche and environmental requirements of microbial methylators; the current state of our understanding of those environmental requirements is briefly summarized in [Appendix 12.3.3](#).

In [Appendix 12.3.4](#), multiple lines of evidence are presented establishing the relationship between SO<sub>x</sub> deposition and increases in bioavailable Hg in the environment, including experimental S addition experiments and case studies from well-studied wetlands where S inputs are primarily agricultural. [Appendix 12.3.5](#) considers observational evidence of the correlations between SO<sub>x</sub> deposition and Hg burdens in fish. [Appendix 12.3.5](#) also presents the results of observational studies in prairie pothole wetlands, peat bogs, freshwater marshes, streams, and rivers that show correlations between ambient sulfate and MeHg concentrations in water and sediment samples. [Appendix 12.4](#) summarizes studies that find higher Hg burdens in mosquitos and fish from ecosystems with increased experimental or anthropogenic S loading. Ecosystems especially sensitive to the effects of S deposition are described in [Appendix 12.5](#).

[Appendix 12.6](#) describes critical loads for Hg from European systems; at this time, there are no established critical loads for nonacid S effects in North American ecosystems. [Appendix 12.7](#) is a summary including causal determinations based on the synthesis of new information and previous evidence.

---

## 12.1 Introduction

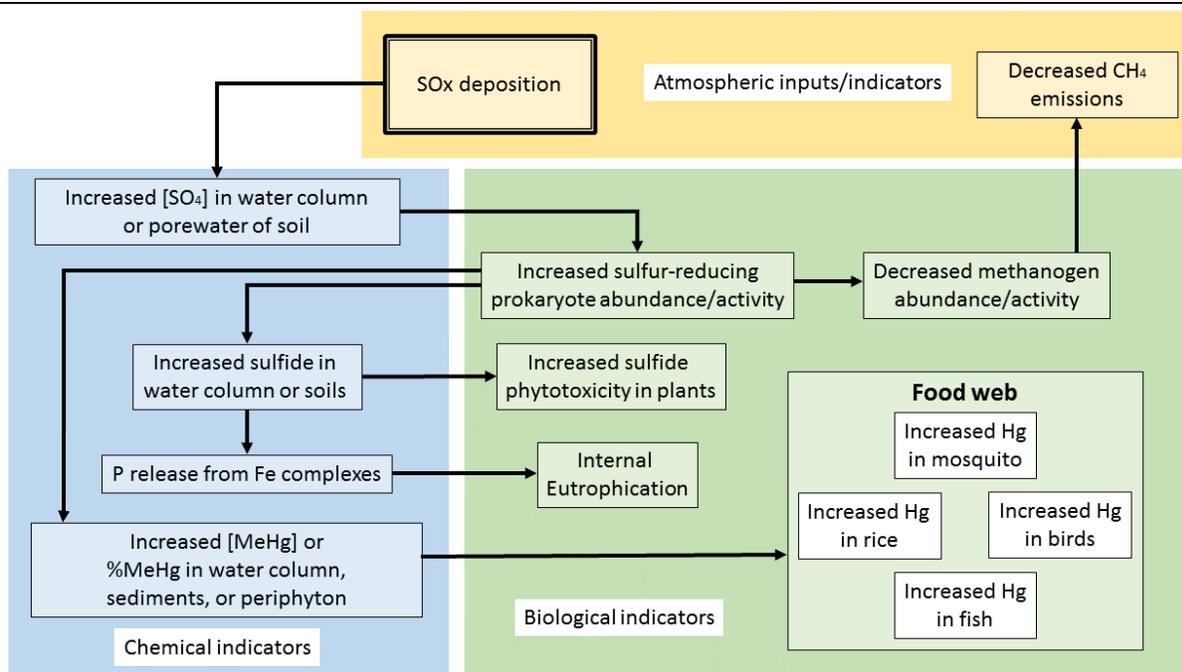

In the 2008 ISA, the evidence was sufficient to infer a causal relationship between S deposition and increased methylation of Hg in aquatic environments where the value of other factors was within adequate range for methylation. Direct atmospheric deposition of S to wetland and aquatic systems, as well as sulfate leaching from terrestrial systems with current or historical S deposition, alters biology and chemistry of these systems. Nonacidifying effects of S deposition in these nonterrestrial systems include toxicity to wetland plants, increased phosphorus (P) availability leading to internal eutrophication, altered methane emissions, and increased Hg methylation and Hg concentration in biota. Consistent with the causal statement in the 2008 ISA, **the body of evidence is sufficient to infer a causal relationship between S deposition and the alteration of Hg methylation in surface water, sediment, and soils in wetland and freshwater ecosystems.** The 2008 ISA described sulfide phytotoxicity in European systems, but there is more recent research demonstrating sulfide phytotoxicity under current conditions in North American wetlands. **The body of evidence is sufficient to infer a causal relationship between S deposition and changes in biota due to sulfide phytotoxicity including alteration of growth and productivity, species physiology, species richness, community composition, and biodiversity in wetland and freshwater ecosystems.**

S deposition contributes to Hg accumulation by stimulating the activity of anoxic-sediment-dwelling sulfur-reducing bacteria (SRB), which convert inorganic Hg to MeHg in the course of metabolism. The 2008 ISA described the activity of SRB, but more recent research indicates that S reducing archaea are also active in wetland sediments, which is why this document will use the broader term sulfur-reducing prokaryotes (SRPs) to denote both bacteria and archaea involved in S reduction. Laboratory and mesocosm-scale experiments reviewed in the 2008 ISA established that only trace amounts of MeHg could be produced in the absence of sulfate. These results were confirmed with larger scale observational studies. MeHg enters the food chain and bioaccumulates in higher trophic levels, and research summarized in the 2008 ISA suggested that numerous wild populations of fish, birds, and mammals experienced MeHg exposures high enough to cause substantial reproductive, behavioral, or health impairment.

At the time of the 2008 ISA, dose-response relationships between S deposition and Hg-methylation rates had not been established, in part because oxygen content, temperature, pH, and labile carbon supply also control the rates of the activity of SRB in aquatic environments. Evidence of commensurate increases in methylation with increased S continued to accumulate, but because of wide variability in those interacting factors, the exact dose-response relationships that have been derived from studies may not be directly applicable to bodies of water under uncontrolled deposition.

Watersheds with conditions known to be conducive to Hg methylation were identified in the northeastern U.S. and southeastern Canada, although significant biotic Hg accumulation had been observed in other regions that had not been studied as extensively. The U.S. EPA set the fish tissue criterion in 2001 for MeHg at 300 ng/g fish tissue (reported as 0.3 mg/kg) for the protection of human health, which resulted in 2,436 fish consumption advisories for Hg in 2004, 2,682 in 2005, and 3,080 in 2006. Forty-eight states, one territory, and two tribes had issued Hg fish-consumption advisories at the time of the 2008 ISA.

[Appendix 12](#) summarizes research on the nonacidifying impacts of S deposition on ecosystems, synthesizing literature published since the 2008 ISA with earlier, key studies ([Figure 12-1](#)).

CH<sub>4</sub> = methane; Fe = iron; Hg = mercury; MeHg = methylmercury; P = phosphorus; SO<sub>4</sub><sup>2-</sup> = sulfate; SO<sub>x</sub> = sulfur oxides.

**Figure 12-1** Effects of sulfur oxide deposition on chemical (blue boxes), biological (green boxes), and atmospheric (yellow boxes) indicators of ecosystem change, as documented by the previous Integrated Science Assessment and more recent research.

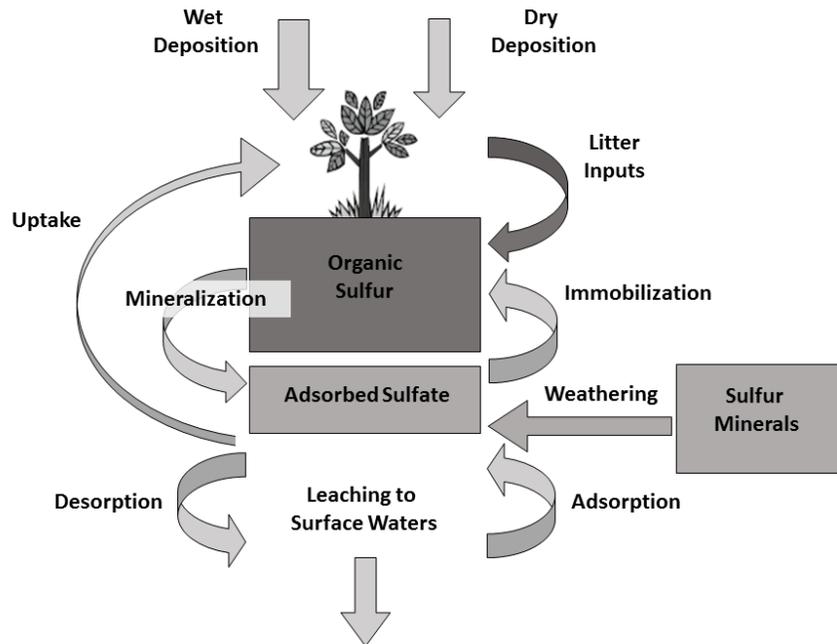

## 12.2 Ecosystem Effects of Altered Sulfur Cycling

This section provides background on the sulfur cycle in terrestrial and aquatic ecosystems ([Appendix 12.2.1](#)). It describes effects of S enrichment (SO<sub>x</sub> deposition or experimental S amendments) upon aquatic S cycling ([Appendix 12.2.2](#)), sulfide toxicity on wetland plants ([Appendix 12.2.3](#)), S enrichment on phosphate cycling in aquatic ecosystems and on uptake of toxic elements by aquatic plants ([Appendix 12.2.4](#)), and S enrichment in altering microbial competition and methanogenesis ([Appendix 12.2.5](#)).

### 12.2.1 The Sulfur Cycle

S cycling in terrestrial ecosystems is relatively well characterized compared to S cycling in aquatic systems. Sulfate is the dominant S source in supplying plant nutrient S

demand. Sulfate in the soil solution, whether its source is weathering of sulfur-containing minerals, mineralization of internal ecosystem S, or atmospheric deposition of  $\text{SO}_x$ , has several possible routes through the S cycle (Figure 12-2).

Source: Adapted from [Mitchell et al. \(2011\)](#).

**Figure 12-2 Sulfur cycle in terrestrial, forested ecosystems.**

Sulfate can be immobilized by incorporation into living cells (microbes, fungi, plants), which ultimately end up in the organic soil S pool. In most North American terrestrial ecosystems, total S pools in soil greatly exceed S stored in living biota (Figure 12-2), with soil S in organic or inorganic molecules. The largest pool of S in soil is organic, typically comprising more than 95% of total soil S in temperate ecosystem soils (Wang et al., 2006; Solomon et al., 2001), although in drained wetland soils of the Florida Everglades Agricultural Area (EAA), the organic fraction was quantified as 87% of total S (Ye et al., 2010). Organic S pools in grassland soils are negatively correlated with mean annual temperature in the North American Great Plains, indicating that climate is a strong control on S cycling (Wang et al., 2006). Organic soil S is found in ester-bound forms (produced via microbial activity) or bound directly to carbon (C) in organic compounds of varying sizes [whose ultimate sources were found to be plant roots or

litter, ([Edwards, 1998](#))]. Organic soil S cannot be taken up by plants directly, but organic S compounds are mineralized back to sulfate by soil microbes under favorable moisture, temperature, and oxic conditions ([Wang et al., 2006](#)). Organic S pools can be indirectly enhanced by SO<sub>x</sub> deposition via microbial and plant incorporation, as indicated by measures of soil [S] and S isotopes. Sulfate in the soil solution can remain in the soil S pool in its inorganic form as it adsorbs to hydrated soil particles. Soil adsorption of sulfate generally results in a smaller S pool than soil organic matter, but this pool can be directly enhanced by SO<sub>x</sub> deposition and associated acidification. Acidification may increase the storage capacity of soils for sulfate. In the case of nonspecific adsorption, increasing acidity and more H<sup>+</sup> held in colloidal suspension create more sulfate binding capacity in soil, while ecosystem recovery towards a more neutral pH may cause desorption of sulfate and higher sulfate concentrations in the soil solution. In the case of specific adsorption, sulfate binds with metal atoms in mineral particles; sulfate specific adsorption to soil also increases with lower pH. However, the rate at which sulfate bound to soil particles is released from adsorption in the soil solution as the ecosystem recovers (see [Appendix 4](#)) towards a more neutral pH will heavily depend upon soil factors such as clay mineralogy, soil age and weathering, calcium availability, content of amorphous iron and aluminum oxides, and glaciation history. Inorganic S storage within terrestrial soils can be directly affected by SO<sub>x</sub> deposition, as indicated by measures of sulfate concentrations in soil fractions and soil solution.

Sulfate in the soil solution may be transported out of the terrestrial ecosystem if it leaches to surface water and into downstream wetland and aquatic ecosystems. Sulfate concentrations in surface water are often measured as an indicator of S fluxes from small terrestrial watersheds. In watersheds that have received historically high S deposition, dissolved organic sulfur (DOS) may also comprise a substantial portion of the S-leaching from terrestrial to aquatic watersheds. In Archer Creek in the Adirondacks, NY, DOS averaged 21% of total dissolved sulfur in the creek ([Kang et al., 2014](#)). Freshwater aquatic S cycling is not as well described in the scientific literature as is terrestrial soil S cycling. The preponderance of evidence is concerned with the locations of redox S reactions within these aquatic systems. Sulfate leached from terrestrial ecosystems, as well as sulfate from direct deposition to surface water, is transformed in aquatic systems under particular conditions. High oxygen levels in the water column or inundated sediments of a wetland, lake, or stream favor S in oxidized form as sulfate. Sulfate in anoxic (very low O<sub>2</sub>) waters or sediments is transformed into more reduced forms such as sulfide or elemental S, which are less soluble and may precipitate into sediments. Sulfur-reducing prokaryotes (SRPs) couple their metabolism to the transformation of sulfate into these reduced forms. SRPs are obligate anaerobes but require sulfate for metabolism, and as a result, they are often present and active at oxic-anoxic boundaries in aquatic environments. In shallow lakes, this boundary (and the majority of sulfate

reduction) occurs at the water-sediment interface, in the top 1–2 cm of sediment ([Rudd et al., 1986](#); [Kelly and Rudd, 1984](#)). In deeper lakes that experience seasonal stratification, the water column may account for up to 15% of sulfate reduction ([Ingvorsen and Brock, 1982](#)), and the anoxic boundary may occur in the flocculant layer (suspended sediment); for example, the boundary occurs 10 cm above the top of the sediment in Little Rock Lake, WI ([Sherman et al., 1994](#)). In wetlands, particularly in peat bogs that depend entirely upon precipitation as their water supply, the anoxic-oxic boundary often coincides with the water table and can be much more dynamic. Finally, recent research suggests that periphyton occupying high-oxygen waters can create anoxic microenvironments that promote the growth and activity of SRPs (see [Appendix 12.3.3](#)). The location and activity of SRPs are important environmentally because some SRPs couple sulfate reduction with Hg methylation (see [Appendix 12.3.2](#)). The transformation of S between reduced and oxidized forms in aquatic and wetland ecosystems occurs in particular locations within these ecosystems but can have broader impacts on chemistry and biota.

Pools of S in freshwater systems (lakes, rivers, streams, and wetlands) and residence times of S in ecosystem pools are addressed in only a few ecological studies. S cycling in lakes removes sulfate from the water column and stores reduced S in sediments. Sulfate in the water column diffuses into sediments where it binds to particulate matter or is incorporated by microbes. Water column sulfate is reduced (by chemical or biological processes) and released into the sediments as sulfide, which can bind to iron and precipitate, or as elemental S, which can precipitate directly. An early study by [Rudd et al. \(1986\)](#) developed a budget for reduction-oxidation cycling of S based on Adirondack lakes, and estimated that 47% of water column sulfate was reduced and stored in sediments. A broader study that included lakes in the Adirondacks, Ontario, the Experimental Lakes Area, Northern Wisconsin, and Southern Norway estimated that 39–80% of annual sulfur load was retained in sediments based on mass balance, or 11–65% based on measured sulfate reduction rates, across all lakes ([Kelly et al., 1987](#)). On average across lakes, one-third to one-half of annual lake sulfate load was transferred to sediments, and variation around this mean correlated with water residence times of lakes. Longer hydraulic residence times correlated with more sulfate removal. The release of reduced S into the water column is responsible for some of the other nonacidifying effects of S deposition, including internal eutrophication and protective effects against certain heavy metals (see [Appendix 12.2.4](#)). The rest of the S originally taken up by microbes as sulfate is incorporated into organic compounds. The growth and activity of SRPs are responsible for Hg methylation in many sediments (see [Appendix 12.3](#)). About one-third of the reduced inorganic S and 57% of the organic S are buried in lake sediments annually, or about 47% of the total sulfate input. The remaining reduced sulfur, 53% of the original sulfate input, is oxidized by chemical reaction with

water molecules ([Bates et al., 2002](#)) and returns to the S cycle ([Rudd et al., 1986](#)). These studies suggest that changes in S inputs to lakes—for example, reductions in SO<sub>x</sub> deposition—could rapidly reduce sulfate concentrations in the water column, assuming other environmental factors remain steady (see below for climatic influences on S cycling).

Wetland S budgets resemble lake budgets in S reduction and burial of reduced S in sediments, but also may include plant uptake and S export if hydrology allows. In a study of depressional freshwater wetlands in two lakes in Germany, the sulfate reduction rate was 2.5 to 7.9 times higher annually in the high sulfate lake (22.7 mg sulfate/L) than in the low sulfate lake [9.0 mg/L; [Kleeberg et al. \(2016\)](#)]. Sulfur budgets have also been determined for the peat soils and freshwater marshes of the Florida Everglades. The EAA has large impacts on S cycling in freshwater marshes in the surrounding designated Water Conservation Areas (WCA), which serve as a water quality buffer around Everglades National Park, a Class I area. In the EAA, the addition of elemental S as an agricultural soil amendment increased sulfate in the soil from 13 to 19% of total soil S, although at the end of the growing season sulfate was 1% of total S due to uptake by growing sugarcane ([Ye et al., 2010](#)) and runoff into surrounding canals and wetlands ([Bates et al., 2002](#)). In an early study quantifying S budgets in the Everglades WCA, ([Bates et al., 2002](#)) determined that most of the sulfate in the system has its source in S agricultural amendments applied in the EAA. In these wetland systems, the pool of S in organic matter is high, and additional sulfate could be rapidly incorporated into organic matter or exported in surface water, in addition to the reduction or burial, which occurs in other aquatic systems.

Weather and climatic factors can disrupt S storage in more stable pools within aquatic and wetland systems. In smaller stratified lakes, sulfate transfer from the epilimnion into lower layers occurs slowly by diffusion between the stable water layers, while in larger lakes, the layers are more prone to perturbation by wind and allow larger transfers of sulfate to zones where SRPs are active ([Ingvorsen and Brock, 1982](#)). Sulfur cycling, like most microbially driven processes, is seasonal; sulfate fluxes to the sediment are 10 times higher in the summer than in winter ([Sherman et al., 1994](#)), and the growing season coincides with peak sulfate reduction in many freshwater systems (see [Appendix 12.3.3.3](#)). In the Experimental Lakes Area (ELA) in Ontario, 10–39% of reduced S ended the summer as sulfide dissolved in the hypolimnion, and this S was reoxidized to sulfate when circulation occurred in the fall ([Kelly et al., 1982](#)). In winter, O<sub>2</sub> can penetrate deeper into sediments or peat, reoxidizing the sulfide ([Sherman et al., 1994](#)). This reoxidation can also occur in water bodies where water levels are controlled by humans, for example in reservoirs ([Eckley et al., 2015](#)). Extreme events like droughts

can also result in reoxidation of reduced S ([Wasik et al., 2015](#)) and can contribute to Hg methylation hotspots upon rewetting and restoration of anaerobic aquatic conditions.

---

## 12.2.2 Deposition and Sulfur Stores

In terrestrial ecosystems, atmospheric deposition of S at levels below amounts that trigger acidification may still induce biochemical effects. These effects were described in the 2008 ISA and include nutrient enrichment of plants, increased S storage in soils, and elevated sulfate concentrations in water leaching from soils. New information regarding the effects of S deposition on terrestrial biogeochemical cycling is sparse, but can be found in [Appendix 4](#). Terrestrial plant productivity is commonly limited by N, so SO<sub>x</sub> deposition at levels low enough to provide S enrichment without associated acidification effects is unlikely to have significant effects upon terrestrial plant productivity. Instead, the nonacidifying effects of SO<sub>x</sub> deposition are strongest in freshwater systems such as wetlands and lakes, where hydrology controls storage and release of S.

Changes in water availability and water levels in aquatic systems alter the S cycle and may release additional S to the aquatic environment from storage in sediment. During a drought at Little Rock Lake in Wisconsin, lake sulfate concentrations increased 0.18 mg/L/yr, from 1.5 mg/L in 1998 to 2.9 mg/L in 2006 ([Watras and Morrison, 2008](#)). During this time period, lake water volume decreased only 30%, which would not account for the 93% increase in water sulfate concentration, suggesting that drought released additional S stored in lake sediment or biomass into the water column. [Watras and Morrison \(2008\)](#) calculated that an additional load of 5 kg S/ha/yr from internal ecosystem sources of S would account for the increase of S in Little Rock Lake. In the S addition experiment at the S6 bog in Marcell Experimental Forest, MN (see [Appendix 12.3.4.1](#)), rewetting of the bog after a drought released a pulse of sulfate into surface water in both control and experimental S addition plots. In plots to which 32 kg S/ha/yr had been added, concentrations of sulfate in peat pore water after the drought were 438% higher than in control plots ([Wasik et al., 2012](#)), indicating that S addition decreases the retention of S in drought-stressed wetlands ([Table 12-1](#)). This is particularly important because intensification of drought frequency and severity is one of the possible effects of climate change and suggests that climate change and SO<sub>x</sub> deposition may synergistically contribute to increased sulfate concentrations in surface water and associated water quality impairment.

**Table 12-1 New study on sulfur (S) deposition effects on sulfur (S) cycling.**

### 12.2.3 Sulfide Toxicity

Wetland ecosystems are characterized by occasional or total soil inundation and typically include water and sediment zones with low oxygen levels. Under low-oxygen conditions, sulfate can be used as an electron acceptor by a number of microorganisms and is quickly converted to sulfide during decomposition of organic C. Sulfide inhibits plant root nutrient uptake at high levels [ $>34.1$  mg/L or  $>1$  mM; ([Koch et al., 1990](#))], and sulfide toxicity due to increased sulfate loads was documented by the 2008 ISA and references therein for wetland plants, including *Carex* spp., *Juncus acutiflorus* (not native to or documented in North America), *Galium palustre* (endangered in Ohio, special concern in Tennessee), other species within *Gramineae* (the grass family), as well as the aquatic macrophytes *Stratiotes aloides* (listed as an Class C noxious weed in Alabama, Class 1 prohibited aquatic plant in Florida) and *Elodea nuttallii* (threatened in Kentucky, special concern in Tennessee). As reviewed in the 2008 ISA, [Smolders et al. \(2003\)](#) set a threshold value of  $<48$  mg SO<sub>4</sub><sup>2-</sup>/L in surface water to protect the sensitive aquatic species *Stratiotes aloides* and *Potamogeton acutifolius* (not native to CONUS), as well as to protect *Potamogeton zosteriformis* and *Utricularia vulgaris*, which are both native and widely distributed in CONUS. This threshold would protect against sulfide phytotoxicity and internal eutrophication and was based on correlations between surface water concentrations and plant presence/absence in Dutch fens ([Smolders et al., 2003](#)). A recent survey of water quality and plant presence/absence data from four water management districts in the Netherlands confirmed that the probability of encountering the S-sensitive plants *S. aloides* and six S-sensitive *Potamogeton* (pondweed) species declined significantly at sulfate concentrations greater than 50 mg/L ([Vermaat et al., 2016](#)).

More recent research confirms sulfide toxicity in wetland habitats and suggests that sulfide toxicity can determine plant community composition in freshwater wetlands. A review of the sulfide toxicity literature by [Lamers et al. \(2013\)](#) found sulfide toxicity occurred between 0.3–29.5 mg S<sup>2-</sup>/L (originally reported as 10–920 μmol L<sup>-1</sup>) in freshwater wetland emergent plants and aquatic submerged macrophytes native to North America (see [Table 12-2](#) for species-specific phytotoxicity levels). A recent study sampled pore water chemistry and plant community composition in Junius Pond Fen, Seneca County, NY, and found that sulfide concentrations (range: not detectable to 5.73 mg/L or 168 μM H<sub>2</sub>S) had negative effects on the plant community. Sulfide concentration was negatively correlated with total plant cover and had strong effects on the cover of the dominant plants in the fen ([Simkin et al., 2013](#)). In models, high sulfide concentrations decreased cover of the moss species *Campyllum stellatum*, decreased cover of the monocot and USDA-classified ([USDA, 2015b](#)) wetland obligate *Eleocharis rostellata* (endangered in Florida and Pennsylvania; threatened in Illinois, Minnesota, and Wisconsin; sensitive or special concern in Rhode Island and Washington), and decreased cover of obligate monocot *Cladium mariscoides* (endangered in Pennsylvania). Sulfide concentrations also correlated negatively with dicot diversity ([Simkin et al., 2013](#)). This study shows that sulfide toxicity effects on sensitive plant species can cascade to affect plant community composition in fens. There are also sensitive species in other freshwater wetlands. A greenhouse experiment with *Taxodium distichum* (baldcypress) seedlings collected from a North Carolina riparian field showed negative effects of sulfate addition (sulfate concentrations: 48 mg/L in drought treatment, 129 mg/L in flooded treatment) on seedling height, which the researchers attributed to sulfide toxicity ([Powell et al., 2016](#)). Baldcypress is a foundation species in southeastern freshwater swamps, which if located in estuaries, may also experience elevated sulfate, sulfide, and salinity as a result of saltwater intrusion. SO<sub>x</sub> deposition may exacerbate sulfide toxicity in baldcypress swamps already stressed by sea level rise.

Source: all columns except "Listing" are from [Lamers et al. \(2013\)](#).

Sulfide toxicity has been proposed as an important causal factor in the expansion of *Typha domingensis* (southern cattail) in the Florida Everglades. Southern cattail is displacing the historically dominant sawgrass, *Cladium jamaicense*, which is the keystone species in the Everglades sawgrass prairies and which has minor agricultural importance as a food source for small mammals and water birds [reported in [Everitt et al. \(1999\)](#)]. In a hydroponic greenhouse study of both species, cattails had a higher tolerance for sulfide in all plant metrics measured. Sulfide concentrations in growth media were 0, 7.5, 15.7, 23.5, 31.4 mg/L sulfide (reported as 0, 0.22, 0.46, 0.69, or 0.92 mM). At 7.5 mg/L sulfide, sawgrass leaf elongation rates decreased 49%; at 15.7 mg/L sulfide, net photosynthetic rate decreased 34%; and at 23.5 mg/L, sawgrass biomass in different compartments decreased 29–41% ([Li et al., 2009](#)). Cattails experienced sulfide toxicity effects on leaf elongation rates at 23.5 mg/L sulfide (38% decrease) and on photosynthesis at 31.4 mg/L sulfide (22% decrease), with no effects of sulfide upon biomass at any concentration ([Li et al., 2009](#)). Together, these results suggest that sulfide toxicity is shifting the competitive balance between these species away from the dominant species in the Everglades. However, studies that assessed cattail and sawgrass growth in mesocosms placed across the naturally occurring sulfate-sulfide gradient in the Everglades ([DeBusk et al., 2015](#)) or in mesocosms with added sulfate ([Li et al., 2009](#)) have not found effects of sulfide toxicity upon sawgrass. Under controlled conditions, sulfide toxicity favors cattails over keystone Everglades species sawgrass, but evidence from field studies in the Everglades ecosystem suggests that geological or ecological factors not reproduced in the greenhouse may mitigate sulfide toxicity.

Recent work by the Minnesota Pollution Control Agency (MNPCA) proposes to incorporate geological and biological factors into water quality regulation in order to prevent sulfide toxicity to an economically important species. Wild rice (*Zizania*

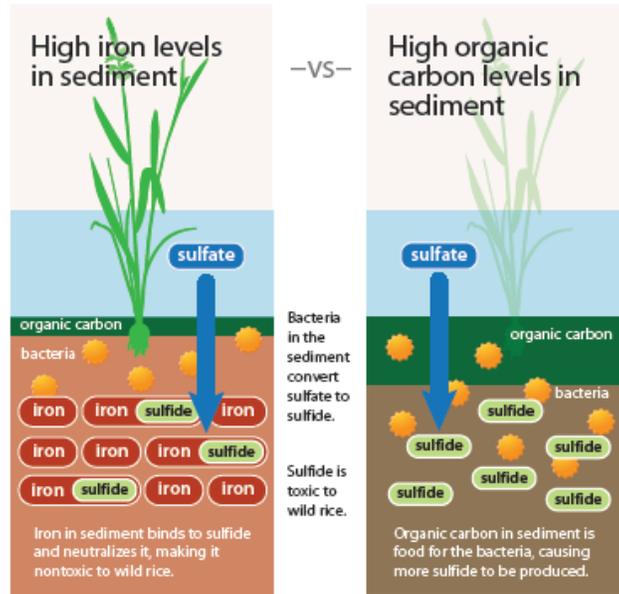

*palustris*) has been protected by the state of Minnesota as ecologically important food for waterfowl and an economically important foraged crop (MPCA, 2015a), and the Ojibwe, Menominee, and Dakota peoples value the plant as a cultural and economic resource (Pastor et al., 2017). The state first set a standard to protect wild rice in 1973, when the water quality standard was set at 10 mg sulfate/L. In 2011, the state began collecting field samples, conducting experiments in hydroponics and mesocosms, and modeling environmental and experimental data in order to revise the standard. The previous standard of 10 mg sulfate/L would only protect 58% of current wild rice sites from sulfide toxicity (MPCA, 2015a). In March 2015, the Minnesota Pollution Control Agency (MPCA) released its recommendations (MPCA, 2015a). Based on the new analyses, the MPCA set a sulfide concentration threshold of 0.165 mg sulfide/L in sediment pore water to protect wild rice, based on 2011–2013 monitoring of 112 Minnesota water bodies in which this level of sulfide corresponded to a 10% decrease in the probability of the species being present (MPCA, 2015b). Sulfide is the end product of microbial sulfate reduction, which is heavily dependent upon other environmental factors, particularly DOC, and sulfide phytotoxicity depends upon its residence time as a free ion in water, which depends upon iron concentrations (see Figure 12-3). As a result, the MPCA did not set a single value of sulfate as a standard to protect wild rice.

Instead, MPCA established a formula that would allow protective sulfate thresholds to be calculated for all wild rice-producing water bodies based on sediment organic carbon and sediment iron concentrations in each water body [Source: (MPCA, 2015b)]:

$$\text{Sulfate} = 0.0000136 \times \text{Organic Carbon} - 1.410 \times \text{Iron} + 1.956$$

**Equation 12-1**

The range in sulfate values that protect wild rice from sulfide toxicity in Minnesota water bodies is from 0.4 to >200 mg SO<sub>4</sub><sup>2-</sup>/L. This proposed standard will require large-scale sediment sampling to determine sediment pore water DOC and Fe concentrations in Minnesota water bodies and is still under review. These regulatory efforts determine protective surface water sulfate concentrations on the basis of a sulfide phytotoxicity threshold protective of wild rice. In hydroponic experiments with *Z. palustris*, sulfate and sulfide exposures did not affect seed germination, but sulfide concentrations of 0.32 mg/L or higher reduced growth rates 88% compared with controls (Pastor et al., 2017). The same research group also conducted growth trials in outdoor tank mesocosms in which surface water sulfate concentrations, and thus sediment sulfide concentrations, could be manipulated. In the mesocosms, 50 mg SO<sub>4</sub><sup>2-</sup>/L did not affect seedlings, but elevated sulfate and sulfide at 100 mg SO<sub>4</sub><sup>2-</sup>/L or higher decreased seed mass, seed viability, seedling emergence rates, and seedling survival rates (Pastor et al., 2017).

Source: [MPCA \(2015b\)](#).

**Figure 12-3 Schematic from Minnesota Pollution Control Agency that illustrates the mitigating effect of iron on the toxicity of sulfide and the stimulatory effect that organic carbon has on sulfide production.**

Sulfide phytotoxicity as a result of  $\text{SO}_x$  deposition alters freshwater wetlands and lakes, but it is unlikely to affect coastal wetlands. Seawater contains high concentrations of sulfate [1 ppt seawater contains 750  $\mu\text{M}$  or 72 mg/L sulfate according to ([Hackney and Avery, 2015](#))], and as a recent study in the Cape Fear Estuary, North Carolina, demonstrates, seawater intrusion and sulfate-reducing conditions structure the distribution of tidal marsh and tidal swamp zones in the estuary. Specifically, tidal marsh plants are salt and sulfide tolerant, and occur in the estuary in areas where sulfate reduction dominates microbial mineralization ([Hackney and Avery, 2015](#)). Tidal swamp plants (such as baldcypress, see above) have been shown to be sensitive to and negatively affected by saltwater intrusion over the decade-long course of the study. This study suggests a biologically plausible link between sulfide increases caused by  $\text{SO}_x$  deposition and tidal marsh intrusion upon tidal swamp zones. However, the authors did not consider sulfate as originating from any source other than seawater, so the effect of salinity could not be separated from the effect of sulfate reduction and resultant sulfide phytotoxicity. There is no evidence of  $\text{SO}_x$  deposition contributing to sulfide phytotoxicity in wetland and aquatic ecosystems with significant seawater contributions.

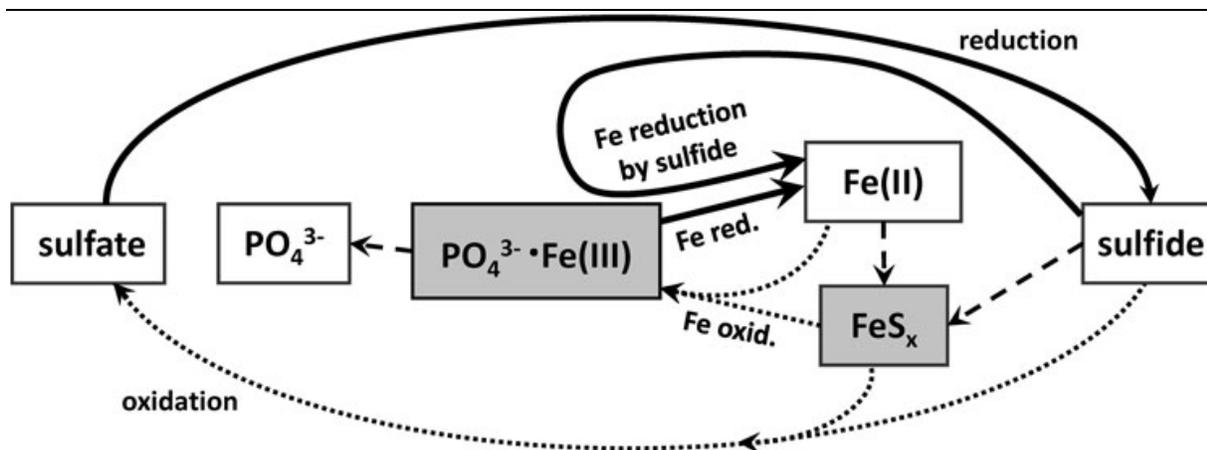

Sulfide toxicity has not been documented for freshwater animal species, since the reducing conditions that produce sulfide also cause hypoxia. However, animal species do vary in their tolerance of sulfate concentrations in water. [Carlisle et al. \(2007\)](#) and [Meador and Carlisle \(2007\)](#) used data from the U.S. Geological Survey's 1993–2003 National Water-Quality Assessment (NAWQA) to generate indicator values for widely distributed North American macroinvertebrates and fish. Each indicator value is the average value for a water quality parameter at which a taxon is detected in NAWQA samples. A follow-up analysis of macroinvertebrates and stream quality in the eastern and midwestern U.S. designated streams with more than 20% loss of expected taxa for the region as degraded habitat ([Carlisle and Meador, 2007](#)). This dataset has identified animals sensitive and tolerant to sulfate and other water quality parameters and allows the evaluation of sulfate impacts on animal species at concentrations lower than those that cause acidification.

---

#### 12.2.4 Internal Eutrophication

Internal eutrophication occurs in saturated soils in freshwater wetlands and lakes when sulfate addition results in the release of bioavailable phosphate from soil forms that are not bioavailable. Additional sulfate in surface waters can increase P mobility and cause internal eutrophication of the recipient ecosystem; farmers growing sugarcane in the oxidized peatland soils of the Florida EAA use S as a soil amendment for this reason ([Ye et al., 2010](#)).

Wetland and aquatic systems often retain phosphate as  $\text{FePO}_4$ . When sulfate is reduced, the resultant sulfide binds with iron to create  $\text{FeS}$ , which precipitates out of solution, releasing P into surface waters ([Figure 12-4](#)). This internal eutrophication can alter plant community composition ([U.S. EPA, 2008a](#)), or can speed the accretion of organic matter and infilling of the wetland, reducing wetland habitat ([Kleeberg et al., 2016](#)). In mesocosms resembling shallow lakes planted with wild rice, experimentally elevated surface water sulfate concentrations raised phosphate concentrations in the water column ([Pastor et al., 2017](#)). Water and sediment mesocosms of samples collected from Lake Moshui in China showed that sodium sulfate addition to raise sulfate concentrations to 500 mg/L also raised peak [P] by 180% in the water column, and by 210% in the sediment pore water, above unamended control mesocosms, and the peak [P] with sulfate addition occurred a week later than in control mesocosms ([Yu et al., 2015](#)). Limitation of microbial sulfate reduction achieved through experimental  $\text{NO}_3^-$  enrichment of the hypolimnion in Onondaga Lake, NY, decreased soluble reactive phosphorus in the hypolimnion by 95% ([Matthews et al., 2013](#)). Sulfate addition can alter P dynamics and cause eutrophication in freshwater systems.

Fe(II) = iron (II); Fe(III) = iron (III);  $\text{FeS}_x$  = iron-sulfide complexes;  $\text{PO}_4^{3-}$  = phosphate.

Open boxes indicate pore water components, and shaded boxes indicate solid-phase chemistry. Reduction reactions are indicated by solid arrows, oxidation reactions are indicated by dotted lines, and phase changes (precipitation or dissolution) are indicated by dashed lines.

Source: [Simkin et al. \(2013\)](#).

**Figure 12-4 Mechanisms of linked sulfur, iron, and phosphorus cycling in wetland waters and soils.**

Surface water sulfate may decrease heavy metal bioaccumulation in plants, but the implications of this process for impacts of  $\text{SO}_x$  deposition may be limited. Sulfate addition can decrease the accumulation of toxic elements in aquatic plants. In soil, S addition decreased dissolved arsenic (As) concentrations in soil solution, but increased As(III):As(V), although the researchers suggested that the formation of As-Fe-sulfide minerals prevented plant As uptake ([Jia et al., 2015](#)). In microbially spiked soil mesocosms, the addition of SRB had a stronger stimulatory effect on As(III):As(V) than did S addition. In rice mesocosms, S addition decreased As concentrations in rice roots and in the iron plaques on roots ([Jia et al., 2015](#)). In laboratory mesocosms, accumulation of selenium (Se) in aquatic plants was a function of both sulfate and Se concentrations in water, but increasing sulfate concentrations decreased Se concentrations in both *Lemna minor* (aquatic macrophyte) and *Pseudokrichneriella subcapitata* [unicellular green alga ([Lo et al., 2015](#))]. Sulfate in surface waters may slow bioaccumulation of heavy metals in biota by forming relatively insoluble S-metal complexes and preventing metal uptake by aquatic plants. However, these findings may have limited applicability to  $\text{SO}_x$  deposition. If there is a common source of both  $\text{SO}_x$  and heavy metal deposition to an aquatic environment, it is unlikely that deposition will correlate with decreasing metal bioavailability. Also, mercury is a focus of research into heavy metal environmental transformations and bioavailability, and  $\text{SO}_x$  deposition is linked instead to increased

bioaccumulation of Hg (see [Appendix 12.3](#) to [Appendix 12.6](#)). There is no research on how SO<sub>x</sub> deposition affects Se or As accumulation in plants growing under field conditions.

---

### 12.2.5 Sulfur Effects on Methane Emissions

The 2008 ISA documented the suppression of methane emissions from aquatic and wetland ecosystems in response to increases in sulfate concentrations. When sulfate is added to freshwater systems, SRPs outcompete methanogens, and methane emissions are suppressed. The activity and environmental preferences of SRPs are key to understanding the effects of SO<sub>x</sub> deposition upon methane and MeHg production. Under anaerobic conditions, SRPs and methanogens compete for organic C as a metabolic substrate, and the reactions of sulfate reduction coupled with organic C oxidation are thermodynamically favored over the reactions of methanogenesis ([Paulo et al., 2015](#)). In many anaerobic environments, sulfate is in short supply, and methanogens are more active than SRPs in mineralizing organic C. Sulfate addition may swing the competitive balance back towards SRPs, decreasing methane production in saturated soils and surface waters. However, studies summarized in other parts of this appendix show that SRPs and methanogens can form syntrophies (see [Appendix 12.3.2](#)) or coexist and rapidly shift dominance within a single wetland (see [Appendix 12.3.2](#) and [Appendix 12.3.3.1](#)).

The relative primacy of methanogens versus SRB in oxidizing carbon is one of the factors which distinguishes freshwater from coastal wetlands and water bodies. Older literature suggests that when SO<sub>x</sub> deposition is not a factor, methanogens dominate anaerobic decomposition in freshwater systems (including wetlands), with methanogenesis responsible for 72–82% of organic C mineralization at the ELA, Ontario ([Kelly and Rudd, 1984](#)), and methanogenesis responsible for 4 times the electron flow and organic C mineralization of sulfate reduction in Lake Mendota, WI ([Ingvorsen and Brock, 1982](#)). In estuarine and marine ecosystems, on the other hand, SRPs are the dominant anaerobic decomposers. In the saltwater marshes at Kirkpatrick Marsh, MD, methanogenesis is <10% of C mineralization, and sulfate reduction is responsible for 45–85% of total C mineralization in the summer, and 5–25% of C mineralization in the fall ([Mitchell and Gilmour, 2008](#)). Older research suggests that in pristine ecosystems, methanogens dominate anaerobic C mineralization in freshwater systems.

New research on microbial communities in saturated sediments contributes to the biological plausibility of the reduction in methanogenesis caused by SO<sub>x</sub> deposition established by the 2008 ISA. Adding sulfate to freshwater systems can depress methanogenesis because anaerobic C mineralization by SRPs is energetically favored

when sulfate and acetate are available at the sediment surface ([Urban et al., 1994](#)). Newer work also supports this finding (see [Table 12-3](#)). Twitchell Island is a restored wetland in the San Joaquin delta, CA, where researchers sampled sediments and water along a gradient of decreasing riverine S load (14–8 mg sulfate/L in February) from the wetland inlet to a transitional site, and to an interior marsh site. In summer, sulfate was 60% lower and methane emissions were 110% higher at the interior site than at the inlet, and 16S rRNA sequencing confirmed that relative SRP abundance was negatively correlated with methanogen abundance ([He et al., 2015](#)). In the Everglades WCA, FL, similar gradients of S loading occur from agricultural runoff in the freshwater marsh. Sampling at sites F4 (7.1 mg/L or 74  $\mu$ M sulfate in pore water), U3 (3.7 mg/L or 39  $\mu$ M sulfate), and W3 ( $\leq 0.4$  mg/L or  $\leq 4$   $\mu$ M sulfate) found effects of sulfate upon SRB (sulfur-reducing archaea were not sampled) and methanogens ([Bae et al., 2015](#)). SRB abundance increased with increasing sulfate pore water concentrations across the three sites and was 6.9 times higher at U3 and 16.8 times higher at F4 than at W3. Sulfate also affected the competitive interaction between SRB and methanogens, which had equal abundances at the most pristine W3 site. At the sites with higher S loads, SRB were 60–80% more abundant than methanogens. The relative abundance of methanogens was determined by copy number of the *mcrA* gene in environmental samples, which correlated positively with methane production rates and mRNA ([Bae et al., 2015](#)), so sulfate loading alterations to the microbial community in the Everglades WCA may also be lowering methane emissions. Sampling from natural microbial communities confirms that sulfate favors SRB over methanogens.

A laboratory study with controlled redox conditions and microbial communities suggests that even when SRB and methanogens are not in direct competition for anaerobic C, methanogen activity will increase when sulfate concentrations decrease. In an incubation of water and sediment collected from oligotrophic Lake Stechlin, Germany, researchers were able to create fluctuating redox conditions while continuously sampling the water column. When the system was reduced, expression of the *dsrB* gene (present in SRB) increased, and sulfide concentrations increased, indicating that SRB abundance and activity increased in response to anoxic conditions in the water column ([Frindte et al., 2015](#)). Methane also increased in the water column, indicating no competition between SRB and methanogens in this system. Over time, *dsrB* diversity decreased, and expression of *pmoA* (present in methanogens) increased ([Frindte et al., 2015](#)), indicating that although there was no competition between SRB and methanogens, methanogens were able to persist after SRB had exhausted the available sulfate and diminished in abundance. Active methanogenesis occurs when SRB activity is constrained by low sulfate availability. Reductions in SO<sub>x</sub> deposition could increase methanogen activity typical of wetland and aquatic sediments.

**Table 12-3 New studies on nonacidifying sulfur effects on methane emissions.**

Type of Ecosystem	Additions or Load (kg S/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Restored peatland island in river	River water is the source of the S load, more interior sites have lower S load, as reflected by February sediment surface measurements: Inlet [SO <sub>4</sub> <sup>2-</sup> ] 14 mg/L; Transitional [SO <sub>4</sub> <sup>2-</sup> ] 11.5 mg/L; Interior [SO <sub>4</sub> <sup>2-</sup> ] 8 mg/L	SRP abundance decreases with increasing methanogen abundance ( $r = -0.67$ ). Denitrifier abundance decreases with increasing methanogen abundance ( $r = -0.64$ ). In August, sulfate decreases 60% from inlet to interior, and methane emissions increases 110%. SRP relative abundance increases with sulfate concentration ( $r = 0.96$ ).	Twitchell Island, San Joaquin delta, CA	Island covered with <i>Typhus</i> spp. and <i>Schoenoplectus acutus</i> , sampled at inlet, transitional, and interior marsh sites. Microbial community quantified by 16S rRNA sequencing of peat sample.	<a href="#">He et al. (2015)</a>
Freshwater marsh	W3 pore water [SO <sub>4</sub> <sup>2-</sup> ] ≤4 μM U3 pore water [SO <sub>4</sub> <sup>2-</sup> ] is 39 μM F4 pore water [SO <sub>4</sub> <sup>2-</sup> ] is 74 μM Deposition = not measured	SRB abundance is 6.9x higher in U3 than W3 and 16.8x higher in F4. In W3, abundance of SRB and methanogens are not significantly different. In U3, SRB abundance is 80% higher than methanogen abundance. In F4, SRB abundance is 60% higher than methanogens. <i>mcrA</i> copy number correlates positively with mRNA and methane production rates. Acetotrophic methanogens are dominant at W3, while at high S U3 and F4 sites, hydrogenotrophic methanogens are dominant.	F4, U3, and W3 sites in Water Conservation Area, Everglades, FL	Methanogens as quantified by <i>mcrA</i> copies. Sulfur-reducing bacteria as quantified by <i>dsrB</i> copies.	<a href="#">Bae et al. (2015)</a>

16S rRNA = 16S ribosomal ribonucleic acid;  $\text{Fe}^{3+}$  = iron; g = gram; ha = hectare; kg = kilogram; L = liter;  $\mu\text{M}$  = micromolar; mg = milligram;  $\text{NO}_3^-$  = nitrate; S = sulfur;  $\text{SO}_4^{2-}$  = sulfate; SRPs = sulfur-reducing prokaryotes; yr = year.

As with sulfide phytotoxicity, impacts of  $\text{SO}_x$  deposition upon methanogenesis may be present in freshwater but not marine ecosystems, as the high endogenous concentration of sulfate in seawater is likely to overwhelm the impact of anthropogenic S. In marine sediments, sulfate reduction accounts for 50–100% of anaerobic carbon mineralization ([Urban et al., 1994](#)); methanogenesis often persists at depths in organic sediments below the depth to which sulfate can diffuse. In estuarine wetlands in the Cape Fear River system in North Carolina, [Hackney and Avery \(2015\)](#) stated that in vertical soil profiles, a concentration of 28 mg/L (300  $\mu\text{M}$ ) sulfate was the threshold where S reduction switched to methanogenesis as the dominant form of C mineralization. This study also determined that in estuaries, the transition from methanogenic to S-reducing conditions occurs when more than 25% of tidal flooding carries more than 1 ppt of seawater ([Hackney and Avery, 2015](#)). In a study of the Min River Estuary in China, there was no relationship between methane emissions and pore water sulfate, but dominant plant species did affect microbial communities, with lower relative abundance of both methanogens (84% decrease) and SRPs (73% decrease) in *Spartina alterniflora* sediments than in *Phragmites australis*-associated sediments ([Tong et al., 2015](#)). Both of these species are dominant plants in North American eastern coastal marshes, and this result suggests plant community may be more important than sulfate deposition in determining methane emissions in coastal marshes.  $\text{SO}_x$  deposition is unlikely to affect methane emissions from coastal marshes and water bodies. Sulfate addition may also

result in lower methane emissions by stimulating microbial methane oxidation. In marine sediments, this occurs in syntrophic associations (associations among heterotrophs dependent on the metabolic byproducts of other microbes) between anaerobic methanotrophic archaea and SRB, which pair anaerobic oxidation of methane with sulfate reduction, or in a clade (monophyletic group) of anaerobic methanotrophs capable of both sulfate reduction and methanotrophy (Joye, 2012). However, these processes have been observed only in marine deep-sea sediments, and it is not yet clear how widely distributed or important they are in other systems. In peat bog mesocosms, by contrast, S addition of 96 mg/L decreased microbial biomass 23–57% and decreased methane oxidation to almost zero (Lozanovska et al., 2016).

---

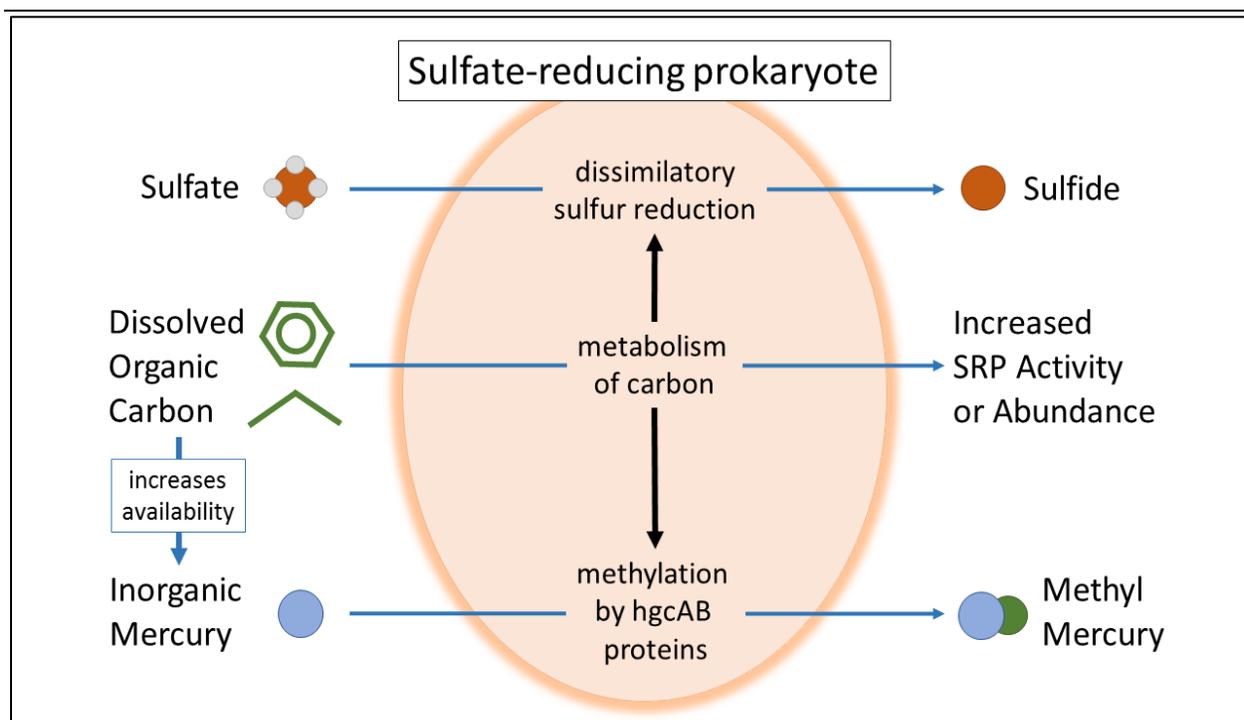

## 12.3 Interactions between Sulfur Deposition and Mercury

The 2008 ISA found the evidence was sufficient to infer a causal relationship between S deposition and increased methylation of Hg, in aquatic environments where the value of other factors was within adequate range for methylation. Recent research, as well as key early papers on the microbial methylation of mercury, is summarized in this section. New evidence is consistent with the 2008 ISA in identifying sulfur-reducing bacteria as a biotic link between increased SO<sub>x</sub> deposition and increased MeHg concentrations in the environment and in biota. New developments since 2008 include identification of both the microbial genes linked to mercury methylation and the methylation capability in certain archaeal strains (Appendix 12.3.1 and Appendix 12.3.2).

Ecosystem areas with high MeHg fractions (as a fraction of total Hg) are considered to indicate active microbial methylation, as well as places where primary producers and animals are at an elevated risk of MeHg accumulation. An active area of research is in identifying areas or zones of ecosystems where %MeHg is elevated. Background information on deposition and biogeochemical cycling of Hg, with particular emphasis on identifying hotspots of mercury methylation, is presented in Appendix 12.8.

Mercury methylation is a microbial process carried out by a subset of prokaryotes that are active under reducing environmental conditions (anoxic water or sediments) while requiring oxidized sulfur and organic C as substrates (see Figure 12-5). As a result, Hg methylation rates are heterogeneous across time and the landscape. Transformation by bacteria and archaea of inorganic Hg to organic MeHg occurs in wetland soils, in Sphagnum mats of wetlands, and at the oxic-anoxic boundary in lakes, estuaries, and the Arctic water column. Hg methylation by SRB embedded in periphyton is a new topic that was not covered in the 2008 ISA (Appendix 12.3.2). Evidence of MeHg production in periphyton has important implications for aquatic MeHg concentrations, because

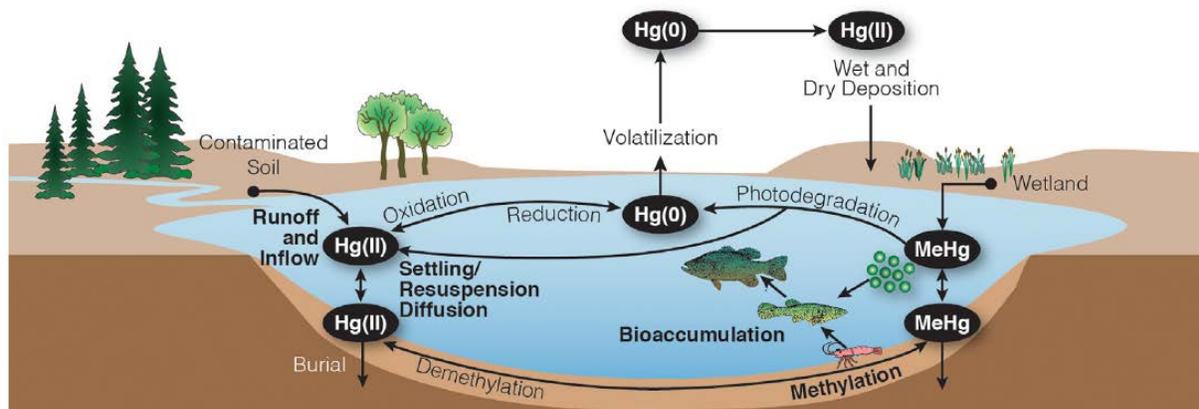

periphyton may extend throughout water columns and are more connected to aquatic and terrestrial food chains than are Hg methylation hotspots in sediment or peat. Regardless of their location within the ecosystem, microbial Hg methylators have specific environmental requirements which affect their rates of Hg methylation ([Appendix 12.3.3](#)). There is new evidence from sulfur addition studies ([Appendix 12.3.4](#)) and from studies of ambient conditions in North American ecosystems ([Appendix 12.3.5](#)) to show that S deposition and ambient sulfate concentrations increase mercury methylation under certain conditions. New evidence is consistent and coherent with the conclusions of the 2008 ISA and **the body of evidence is sufficient to infer a causal relationship between S deposition and the alteration of Hg methylation in surface water, sediment, and soils in wetland and freshwater ecosystems.**

**Figure 12-5. Sulfate, dissolved organic carbon, and inorganic mercury are all important determinants of the rate and amount of methyl mercury produced by sulfate-reducing prokaryotes.**

### 12.3.1 Mercury Cycle and the Importance of Methylation

Mercury is present in ecosystems as elemental  $\text{Hg}^0$ , as  $\text{Hg}^{2+}$  complexed to metals or organic compounds, or as MeHg. Since the Industrial Revolution, Hg emissions have increased Hg concentrations in water and soils above preindustrial levels. Although in recent decades U.S. emissions have declined [79% decrease in Hg emission between 1990 and 2011 as reported by the NEI ([U.S. EPA, 2016a](#))], Hg concentrations remain elevated in air, water, soil, and biota above inferred preindustrial values. Environmental mercury sources and transformations are illustrated in [Figure 12-6](#); important mercury sources to ecosystems that this appendix will consider include geological formations, wet and dry deposition of Hg, and legacy Hg stored in soils from historical deposition or historical (i.e., no longer active) industrial use. Hg released from active industrial sources, active mines, or historical mine sites to soil or water are not considered.

Source: [Bigham et al. \(2017\)](#).

**Figure 12-6** Cycling of mercury (Hg) and methylmercury (MeHg) in ecosystems.

Hg deposition is generally more bioavailable and readily methylated than is Hg already stored in sediments or organic matter within the ecosystem, and sulfate stimulation of methylation favors Hg newly added to the system over Hg already in the ecosystem ([Bigham et al., 2017](#)).

In terrestrial soils, Hg forms complexes with organic matter ([Poulin et al., 2016](#)). New research suggests that disturbances that accelerate carbon fluxes in terrestrial systems also accelerate Hg release from soils and sometimes stimulate methylation. In a study of

*Picea abies* (Norway spruce) stands in Sweden, clear-cutting raised the soil water table and created conditions favorable for Hg methylation. Clear-cutting did not alter Hg concentrations in the organic soil (O) layer, but it did significantly increase MeHg concentrations and %MeHg in the O layer 5–7 times over control conditions ([Kronberg et al., 2016](#)). In a similar study of clear-cutting plantations planted on drained peat soils in Finland, harvesting increased DOC and Hg in drainage waters ([Ukonmaanaho et al., 2016](#)). Peat SRB abundance correlated with MeHg concentrations and varied by geology, with higher MeHg concentrations in watersheds with underlying schist formations (high Hg content). In Oak Ridge, TN, riparian forest soils along East Fork Poplar Creek are contaminated by historical industrial mercury releases and contain 2–3 times the Hg in uncontaminated soils. Soil microcosms showed that flooding of these soils moved mercury bound to soil organic matter into the soil solution, as aqueous Hg<sup>0</sup> or as HgS precipitates, the latter produced by microbial sulfate reduction within the soils ([Poulin et al., 2016](#)). Both Hg<sup>0</sup> and nanoparticulate HgS are bioavailable to microbial methylators, and flooding resulted in a pulse of both aromatic DOC and MeHg in the riparian soil pore waters ([Poulin et al., 2016](#)).

Recent studies using stable isotopes of mercury reviewed by [Paranjape and Hall \(2017\)](#) reported a range of 0.1–15% MeHg in North American and Swedish wetlands, and 0.4–4.6% MeHg in lake sediments. There is new evidence that MeHg concentration in Adirondack surface waters is positively correlated with Hg<sup>0</sup> deposition rate ([Gerson and Driscoll, 2016](#)). Specifically, Hg in terrestrial leaf litter from Arbutus Lake watershed was measured 6 times over 2004–2014 and declined 40% in concert with a 25% decline in Hg<sup>0</sup> atmospheric concentrations. Over the same time period, MeHg concentrations in Arbutus Lake declined ( $p < 0.03$ ), although there was no quantification of the trend reported. [Gerson and Driscoll \(2016\)](#) suggested that these results show that decreases in Hg<sup>0</sup> concentrations will limit the supply of bioavailable Hg to mercury methylators and decrease MeHg in aquatic ecosystems.

Wetlands tend to have higher MeHg fractions than other water bodies at similar locations and order within watersheds. In the Adirondack Mountains, NY, sampling of soils and substrates (upland, riparian, open water, peat bog) at different points in the Sunday Lake watershed found that the highest MeHg fraction was in *Sphagnum* mats ([Yu et al., 2010](#)). In the Archer Creek watershed, also in the Adirondacks, MeHg concentrations in wetland-draining streams were elevated compared to MeHg in upland streams ([Selvendiran et al., 2008a](#)). At a larger scale survey of 44 Adirondack lakes sampled 2003–2004, land cover did not correlate with MeHg in lake water or biota, possibly because variation in wetland cover was low across watersheds ([Yu et al., 2011](#)). In a survey that included 21 freshwater, brackish, and marine wetlands and lakes in the Mississippi River delta near Lake Pontchartrain, LA, MeHg levels in wetlands were

higher than in nearby rivers or lakes with similar salinity levels. In brackish and freshwater wetlands, total MeHg concentrations (ng/L) and MeHg fraction (MeHg/total Hg) were 2 or 3 times as much as in brackish or freshwater rivers ([Hall et al., 2008](#)).

The relationship between Hg and MeHg concentrations may depend heavily on the type and salinity of water body. A recent report on Hg concentrations in streams across the U.S. found no relationship between Hg and MeHg across sites ([Wentz et al., 2014](#)). This is in contrast to an earlier review of Hg methylation and demethylation dynamics found that across studies, there is a positive correlation between Hg and MeHg in estuaries ( $R^2 = 0.78$ ), and weaker positive correlations in rivers ( $R^2 = 0.68$ ) and lakes ( $R^2 = 0.64$ ), but no correlation in wetlands ([Benoit et al., 2003](#)). In a recent study of eight highly Hg-contaminated (up to 226,000 ng Hg/g sediment, reported as 226  $\mu\text{g}$  Hg/g sediment) lakes and water bodies in Sweden, more than 55% of the variation in sediment MeHg was explained by total sediment Hg in three estuary sites, but there was no correlation in the remaining freshwater sites ([Drott et al., 2008](#)). In the freshwater sites, MeHg was instead strongly correlated with potential methylation rates [ $r^2 \geq 0.85$  ([Drott et al., 2008](#))].

---

### 12.3.2 Biology of Sulfate-Reducing Prokaryotes

The 2008 ISA attributed Hg methylation to sulfur-reducing bacteria, and there is new evidence of the link between microbial sulfate reduction and Hg methylation. New (and key older) studies include experimental inhibition of different microbial groups in order to demonstrate microbial mechanisms, molecular sequencing techniques to identify potential microbial Hg methylating strains, and sequencing of environmental or experimental samples to determine microbial dynamics of Hg methylation. These studies were conducted with samples from rivers, lakes, wetlands, and laboratory mesocosms ([Table 12-4](#)). Current knowledge suggests mercury is methylated in the environment by certain strains of sulfur-reducing and iron-reducing bacteria in Deltaproteobacteria (*Desulfovibrio*, *Desulfotomaculum*, *Desulfobulbus*, and *Geobacter* genera) as well as methanogens in Archaea, while the genetic potential for methylation has been identified in the bacterial Firmicutes ([Paranjape and Hall, 2017](#)).

Increasing  $\text{SO}_x$  in the microbial environment increases the metabolic activity and growth of sulfate reducers, and one of the metabolic activities that can be stimulated is the methylation of Hg. Peat samples from the Bog Lake fen in the Macell Experimental Forest showed that experimental increases of wet S deposition to historical levels (32 kg S/ha/yr) changed entire bacterial community composition. Experimental S addition also significantly changed the composition of deltaproteobacterial communities, which contain the SRB and IRB, and this community change correlated with bog %MeHg

([Strickman et al., 2016](#)). In recovery sections of the same wetland (S treatment of 32 kg S/ha/yr had ceased 3 years before sampling), entire bacterial community and deltaproteobacterial community compositions were not significantly different from control wetland communities ([Strickman et al., 2016](#)), suggesting a rapid response time of microbial communities to changes in SO<sub>x</sub> deposition.

**Table 12-4 New studies on the biology of sulfate-reducing prokaryotes.**

Type of Ecosystem	Additions or Load (kg S/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Peatland	Treatment: 32 kg SO <sub>4</sub> <sup>2-</sup> /ha/yr addition, control/ambient: 4.6 SO <sub>4</sub> <sup>2-</sup> kg/ha/yr	Bacterial communities in areas with increased sulfur deposition had significantly different compositions compared to control and recovery areas. Bacterial species diversity was significantly higher in the control than sulfate treated or recovery groups.  Deltaprotobacteria were significantly related to %MeHg in bogs and close to significant in lagg areas ( $p = 0.057$ ).	Marcell Experimental Forest, MN	Pore water, bacterial communities	<a href="#">Strickman et al. (2016)</a>
River	Deposition not reported	Sulfate reduction rates were positively correlated with potential Hg methylation rates ( $r^2 = 0.98$ ).  Methane production in sediment slurries correlated positively with demethylation rates ( $r^2 = 0.61$ ).  Direct inhibition of methanogens decreased demethylation by 83%.	Mesocosms of sediments from St. Lawrence River		<a href="#">Avramescu et al. (2011)</a>
Floating bog	2.0 mM (190 mg/L) sulfate added to slurried samples	Addition of MoO <sub>4</sub> <sup>2-</sup> decreased MeHg production by 44%.  Potential Hg methylation rates (%MeHg/day) were 2.1× higher with SO <sub>4</sub> amendment.	Sunday Lake, Adirondack Mountains, NY	Sphagnum spp.	<a href="#">Yu et al. (2010)</a>

**Table 12-4 (Continued): New studies on the biology of sulfate-reducing prokaryotes.**

Type of Ecosystem	Additions or Load (kg S/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Lakes	Deposition not reported	Addition of $\text{MoO}_4^{2-}$ decreased methylation by 60–90% in settling particles, and by 80% in sediments.	Lake Geneva, Switzerland	Samples of particles from water column and from lake bottom sediments	<a href="#">Gascón Díez et al. (2016)</a>
Lakes	Deposition not reported	Addition of $\text{MoO}_4^{2-}$ decreased MeHg production by 30% for <i>E. crassipes</i> and by 60% for <i>P. glabra</i> .  qPCR of bacterial genes indicated that 3.34% of the total bacterial community in the periphyton belonged to the SRB families <i>desulfovibrionaceae</i> and <i>desulfobacteraceae</i> .  MeHg fraction was positively correlated with relative abundance of <i>desulfobacteraceae</i> in <i>P. glabra</i> periphyton.	Amazon Oxbow Lakes, Bolivia	<i>Eichhornia crassipes</i> and <i>polygonum densiflorum</i> (currently named <i>persicaria glabra</i> )	<a href="#">Achá et al. (2011)</a>
Freshwater marsh	W3 pore water $[\text{SO}_4^{2-}] \leq 4 \mu\text{M}$ U3 pore water $[\text{SO}_4^-]$ is 39 $\mu\text{M}$ F4 pore water $[\text{SO}_4^{2-}]$ is 74 $\mu\text{M}$ Deposition = not measured	SRB abundance is 6.9x higher in U3 than W3 and 16.8x higher in F4. In W3, abundance of SRB and methanogens are not significantly different. In U3, SRB abundance is 80% higher than methanogen abundance. In F4, SRB abundance is 60% higher than methanogens.  <i>mcrA</i> copy number correlates positively with mRNA and methane production rates.  Acetotrophic methanogens are dominant at W3, while at high S U3 and F4 sites, hydrogenotrophic methanogens are dominant. Type of Ecosystem	Additions or Load (kg S/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Marine	Laboratory cultures with different C sources (pyruvate, fumarate, lactate, ethanol, or malate), control and additional sulfate (30 mM)	Methylation increases with increasing bacterial biomass ( $r = 0.83$ ). During exponential growth phase, S addition increases net MeHg production by 50%. hgcAB expression levels do not correlate with methylation capacities.	Laboratory cultures Sediments from Berre Lagoon, France	<i>Desulfovibrio dechloracetivorans</i> , strain BerOC1 from sediments	<a href="#">Goñi-Urriza et al. (2015)</a>

C = carbon; ha = hectare; kg = kilogram; MeHg = methylmercury; mM = millimolar;  $\mu\text{M}$  = micromolar; S = sulfur;  $\text{SO}_4^{2-}$  = sulfate; SRB = sulfur-reducing bacteria; yr = year.

Sulfate-reducing bacteria (SRB) and iron-reducing bacteria (IRB) are primarily responsible for Hg methylation in natural ecosystems. On a broad scale, these bacteria metabolize organic C by pairing its oxidation with the reduction of sulfate and/or  $\text{Fe}^{3+}$ . The sulfide produced by the reduction of  $\text{SO}_x$  can act as a negative feedback on SRP activity and Hg methylation. Methanogens, SRB, and IRB are facultative anaerobes, ([Paranjape and Hall, 2017](#)), and their presence and activity within wetland and freshwater ecosystems is limited to zones with low oxygen availability. Experimental inoculations suggest that microbial methylators are capable of forming syntrophies, in which microbes link their metabolisms by the exchange of metabolic substrates and products. This suggests that sulfate stimulation of methylation may involve more types of organisms than just the sulfate-reducing bacteria and has led to the classification of the group of interest as sulfate reducing-prokaryotes.

Specific inhibition of SRPs using molybdate ( $\text{MoO}_4^{2-}$ ) is a common tool in studies that determine the contribution of SRPs to Hg methylation. An older study of acidic Dickie Lake in Ontario used different microbial inhibitors to determine whether SRPs or methanogens within the sediments were responsible for Hg methylation. Molybdate inhibited sulfate reduction and decreased %MeHg by 75% of production in controls, while 2-bromo-ethanesulfonate (BESA), an inhibitor of methanogens, did not significantly decrease MeHg production ([Kerry et al., 1991](#)). Researchers inferred that SRPs, not methanogens, were responsible for methylation in the lake, and sulfate reduction rates increased 0.35 mg sulfate reduced/L/day with a 1 mg/L increase in sulfate addition. However, additions of sulfate to concentrations of 5–25 mg sulfate/L in sediment slurries did not affect %MeHg, which was 0.20–0.25% MeHg/g sediment ([Kerry et al., 1991](#)). A similar relationship between MeHg and sulfate reduction was

demonstrated using molybdate inhibition in coastal Georgia marsh soils, where Mo addition decreased sulfate reduction by 90% and decreased MeHg production by 85% ([King et al., 1999](#)), indicating that SRPs were involved in both processes.

An early laboratory study cultivated strains of a SRB, a methanogen, or an acetogen with an Hg spike. The SRBs were the only microbes that methylated added Hg, and they did so at a rate that resembled the rate in aquatic sediments, while molybdate inhibited MeHg production and demethylation of added MeHg ([Pak and Bartha, 1998](#)). In a more recent study, incubations of St. Lawrence River sediments with different inhibitors showed that molybdate inhibited sulfate reduction completely, but did not affect methane production ([Avramescu et al., 2011](#)), indicating that methanogens did not play an important role in reducing S. Moreover, sulfate reduction rates were strongly positively correlated with potential Hg methylation rates ( $r^2 = 0.98$ ). However, when methanogens were inhibited, methylation of Hg increased 16% ([Avramescu et al., 2011](#)), indicating that methanogens compete with SRPs and can depress Hg methylation. In Everglades, FL sediment incubations, molybdate decreased MeHg production by 90% ([Gilmour et al., 1998](#)). In incubations of *Sphagnum* sampled from Sunday Lake, NY, molybdate decreased MeHg production by 44% ([Yu et al., 2010](#)). In core incubations from lakes in Wisconsin, including both basins of Little Rock Lake, molybdate reduced MeHg production by 50% ([Gilmour et al., 1998](#)).

In wetlands within the Allequash Creek watershed, WI, sediment incubations with added  $^{14}\text{C}$ -labelled substrate and sodium molybdate suggested a diverse variable microbial methylation community ([Creswell et al., 2017](#)). In some incubations, addition of molybdate increased  $^{14}\text{CO}_2$  produced from the substrate, suggesting that iron-reducing methylators were dominant; in some incubations molybdate decreased  $^{14}\text{CO}_2$ , suggesting that sulfate-reducing methylators were dominant. Incubations from the lower part of the wetland produced  $^{14}\text{CH}_4$  as their dominant product, suggesting that methanogens dominated the microbial methylation at this location ([Creswell et al., 2017](#)). Dominant microbial methylators varied seasonally and spatially, including by sediment depth.

In Lake Geneva, Switzerland, mercury methylation rates were an order of magnitude higher in settling particles than in sediments, and molybdate inhibition suggested that sulfate-reducing methylators were responsible for 60–90% of methylation in settling particles, and 80% of methylation in sediments ([Gascón Díez et al., 2016](#)). [Gascón Díez et al. \(2016\)](#) suggest that this study may be relevant to the Great Lakes, which like Lake Geneva, are large, deep, and experience algal blooms due to nutrient inputs.

New research suggests that SRPs are important methylators of mercury in disturbed terrestrial soils as well. In a Swedish study of the effects of forest harvesting on mercury dynamics, clear-cutting induced changes in mercury methylators as inferred from soil

incubations ([Kronberg et al., 2016](#)). Additions of sulfate and iron enhanced potential methylation rates in clear-cut but not reference forest soils, indicating that SRPs and iron-reducing bacteria were both active methylators in disturbed soils with high water tables (see [Appendix 12.3.2](#)). The role of SRPs was confirmed by inhibition of methylation by molybdate in soils from clear-cut stands, and a role of methanogens in methylating mercury was shown by BES inhibition of methylation ([Kronberg et al., 2016](#)).

The 2008 ISA did not address the role that periphyton play in hosting SRPs and boosting Hg methylation rates within the oxic water column of aquatic and wetland ecosystems. This section summarizes new (and key older) papers that demonstrate that SRB in periphyton methylate Hg in South American lakes as well as North American lakes and wetlands. Periphyton are ecologically important as they form the base of the aquatic food chain for many invertebrates and vertebrates. Periphyton mats are biofilms of algae, bacteria, fungi, microinvertebrates, organic detritus, and inorganic particles, embedded in a polysaccharide matrix, typically attached to a substrate of sediments or submerged macrophytes. The microbial communities embedded within the periphyton can be quite complex and diverse, including autotrophs and heterotrophs, SRB and S oxidizing bacteria, and methanogens; periphyton microbial composition and microbial activity depend on site conditions ([Correia et al., 2012](#)). The polysaccharide matrix slows exchange with the water column while intense aerobic metabolism at the matrix surface quickly consumes oxygen diffusing into the periphyton, creating anoxic, reducing microenvironments in the interior of periphyton where anaerobes including SRPs thrive. In the case of periphyton attached to macrophytes, plant exudates are an important source of carbon for periphyton microbes, boosting activity above rates of activity of similar microbes residing in sediments.

SRPs embedded in periphyton are more efficient in methylating Hg than are SRPs in sediments. Much of the research demonstrating Hg methylation by periphyton has occurred in South America, in tropical lakes where the genus *Eichhornia* (water hyacinth) is native, and where ambient temperatures can support high levels of bacterially mediated Hg methylation ([Guimarães et al., 2006](#)). *Eichhornia crassipes* is a wetland plant present in 24 states and listed as a noxious or invasive weed by 7 states ([USDA, 2015b](#)). Closely related *Eichhornia azurea* is currently present only in Florida; it is listed by the Animal and Plant Health Inspection Service of the U.S. Department of Agriculture (USDA-APHIS) as a noxious weed ([USDA, 2015b](#)). In incubations of chopped *Eichhornia crassipes* roots spiked with  $^{203}\text{HgCl}_2$ , net MeHg production was high, 1.6–30.2% of total Hg ([Guimarães et al., 2006](#)). Other studies have shown a similarly wide range of methylation by periphyton, with high rates exceeding sediment methylation rates. Intact *E. crassipes* periphyton incubations had potential methylation of 12.1–25.2%

of added Hg, and periphyton isolated from *Polygonum densiflorum* [hereafter called by its current accepted scientific name *Persicaria glabra*; a wetland obligate plant also native to the U.S., classified as endangered in Maryland and New Jersey, ([USDA, 2015b](#))] had potential methylation rates of 0.2–36.1%; by comparison, sediment from the same tropical lakes produced 6.4–12.5% MeHg in incubations ([Correia et al., 2012](#)).

Mo inhibition of sulfate reduction also inhibits MeHg production in periphyton, confirming that SRPs are responsible for a significant portion of Hg methylation within these complex microbial communities. Recently, [Achá et al. \(2011\)](#) and [Correia et al. \(2012\)](#) collected macrophyte samples from oxbow lakes in the Bolivian Amazon for inhibition experiments. Incubations with an array of guild-specific inhibitors show the relative contribution of different microbes to Hg methylation. One set of incubations of periphyton associated with the roots of *E. crassipes* or *P. glabra* suggested that SRB were the most important component of the periphyton in producing MeHg. Molybdate, an inhibitor of sulfate reduction, decreased MeHg production by 30% for *E. crassipes* and by 60% for *P. glabra* ([Achá et al., 2011](#)), indicating that in intact periphyton, SRB alone are responsible for 30–60% of Hg methylation. Quantitative PCR of bacterial genes indicated that 3.34% of the total bacterial community in the periphyton belonged to the SRB families Desulfovibrionaceae and Desulfobacteraceae, and MeHg fraction was positively correlated with relative abundance of Desulfobacteraceae in *P. glabra* periphyton ([Achá et al., 2011](#)). A second set of incubations of six tropical macrophyte species-associated periphyton confirmed that inhibition of sulfate reduction and SRB using molybdate decreased MeHg production, but showed that inhibiting both SRB and methanogens resulted in a 90% reduction of MeHg production across sediments and periphyton ([Correia et al., 2012](#)). Algaecide or fungicide additions significantly inhibited MeHg formation in some but not all incubations, indicating that the microbial composition or activity varied across periphyton samples, even when they were collected from the same site or from the same host plant species grown at different sites ([Correia et al., 2012](#)). Together, these studies show that SRB are important in producing MeHg within periphyton, but that other microbes residing in the periphyton contribute through poorly understood mechanisms to total MeHg production.

Mercury methylation by periphyton has also been documented within North American ecosystems. In an older study in Dickie Lake in Ontario, measured Hg concentrations in periphyton were 56.5 ng/g, 22 times higher than Hg concentrations in sediments ([Kerry et al., 1991](#)). A more recent study of periphyton growing in the epilimnion of boreal Lake Croche in Quebec demonstrated that Hg methylation rates are faster in periphyton, reaching steady-state in 12 hours, than the 4–8 days to steady state of MeHg production in sediments ([Desrosiers et al., 2006](#)). MeHg production by periphyton in the boreal lake was dependent on SRB as well as on photosynthesizers, as demonstrated by inhibition

experiments. Despite the lower temperatures of incubations to reflect the lower temperatures of the boreal lake, potential MeHg production was 16.6–18.5% ([Desrosiers et al., 2006](#)), similar to MeHg production in tropical periphyton.

In the Florida Everglades, periphyton are the base of the aquatic food chain. In an older study, incubation of periphyton collected from different sites along the eutrophic gradient between the EAA to the north and Everglades National Park to the south found MeHg production in periphyton from all sites, although rates varied widely ([Cleckner et al., 1999](#)). MeHg potential production rates were highest in periphyton collected at the northern, eutrophic site, and MeHg production correlated positively with both S reduction and S oxidation by photosynthesizing purple S bacteria ([Cleckner et al., 1999](#)). Periphyton may be an important direct source of MeHg to the food chain in the Florida Everglades.

The gene pair conferring the ability to methylate Hg has been identified only recently, after the 2008 ISA. No ecological or evolutionary advantage of the ability to methylate Hg has been established ([Kerin et al., 2006](#); [Benoit et al., 2003](#)), and it appears to be an inadvertent transformation by a corrinoid-dependent protein produced by prokaryotes for a different metabolic pathway ([Gilmour et al., 2013](#)). Recent phylogenetics work indicates that the gene pair *hgcAB* confers the ability to methylate Hg, and that the gene pair and Hg methylation are present in some but not all species within the SRB, iron-reducing bacteria, syntrophic sulfur reducers in the Syntrophobacterales, methanogens in the Archaea, and bacteria in the Clostridia ([Gilmour et al., 2013](#)). The confirmed and predicted Hg methylators from this study occur across alkaline, neutral, or acidic environments, and are mostly heterotrophs that use sulfate, iron, and CO<sub>2</sub> as terminal electron acceptors.

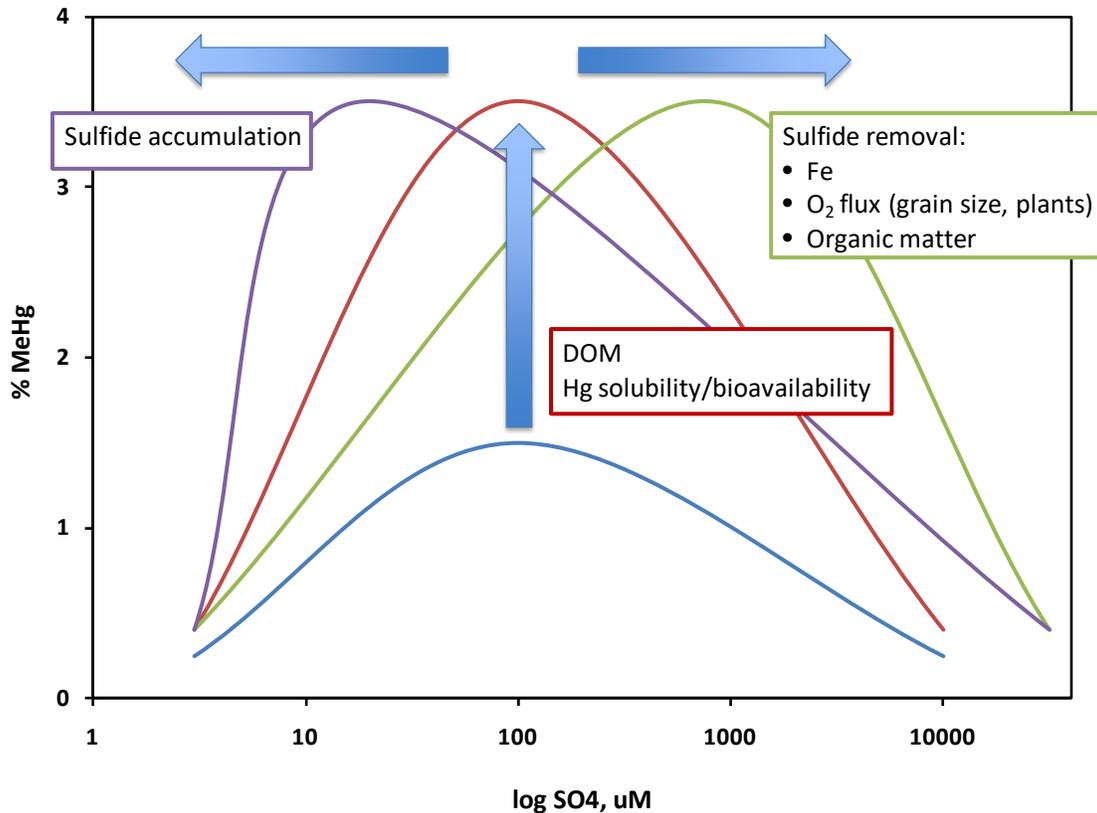

MeHg production rates vary among species, and even among strains within species ([Shao et al., 2012](#)). A recent study of *hgcAB* in the freshwater marshes of the Florida Everglades showed that syntrophs dominated the microbial methylators (49–65% of sequences) and also were the dominant sulfate reducers, as shown by *dsrB* mRNA quantification (75–89%) of sediments sampled within the water conservation areas ([Bae et al., 2014](#)). In a recent study of methylation using a strain of *Desulfovibrio dechloracetivorans*, expression of the *hgcAB* gene did not correlate with methylation capacities of pure cultures, which supports the supposition that Hg methylation is not the main purpose of the proteins encoded by *hgcAB*. However, during the exponential growth phase of the cultures, addition of 2,900 mg/L (30 mM) sulfate increased net MeHg production by 50% ([Goñi-Urriza et al., 2015](#)).

Demethylation is also an important microbial Hg transformation to consider in natural ecosystems. The capacity to transform MeHg to inorganic Hg (elemental Hg or Hg<sup>2+</sup>) is

widely distributed and occurs by different mechanisms in different microbial groups. Microbial demethylation by aerobic and facultative Hg-resistant microbes possessing the *mer* operon break MeHg into methane and Hg<sup>0</sup> via reductive degradation, whereas methanogens, SRPs, and other prokaryotes break MeHg into carbon dioxide, methane, and Hg<sup>2+</sup> via oxidative demethylation. A recent study of St. Lawrence River, Ontario, Canada sediments showed that methane production in sediment slurries correlated positively with demethylation rates ( $r^2 = 0.61$ ), and direct inhibition of methanogens decreased demethylation by 83% ([Avramescu et al., 2011](#)). An earlier study tested a pure culture of the archaeon *Methanococcus maripaludis* and found that it demethylated added MeHg despite no observed methylation potential ([Pak and Bartha, 1998](#)).

Microbial demethylation also occurs in the same prokaryotes that methylate Hg; a laboratory incubation of pure cultures demonstrated that *Desulfovibrio desulfuricans* (an SRB that methylates Hg) demethylated added MeHg at rates similar to those of incubated aquatic sediments ([Pak and Bartha, 1998](#)). In the same study of sediments of the St. Lawrence River, Ontario, inhibition of both SRPs and methanogens decreased demethylation of Hg by 96% ([Avramescu et al., 2011](#)), indicating that while methanogens are responsible for the bulk of demethylation in these sediments, SRPs are involved in demethylation.

New evidence of the genetic basis of Hg methylation and the activity of microbial methylators in the environment and in the laboratory is consistent with the 2008 ISA's link between sulfate reduction and Hg methylation. Mercury methylation by SRP is determined by the same suite of environmental factors that enhance SRP activity or abundance: sulfate, organic matter, and anoxic-oxic conditions ([Figure 12-7](#)). Mercury methylation occurs in wetlands, lakes, reservoirs, streams, and rivers. Algal blooms, periphyton, stratification of the water column, and fluctuating water levels all create favorable conditions for sulfate stimulation of mercury methylation.

Source: [Glimour \(2011\)](#).

**Figure 12-7** The effect of different environmental factors on the relationship between sulfate and mercury methylation. Methylmercury (MeHg) accumulation is minimal at low and high sulfate concentrations, with an optimum near 100  $\mu\text{M}$  sulfate (blue line). High dissolved organic matter (DOM) will increase the magnitude of MeHg production across the range of sulfate concentrations (red line). Sulfide produced by methylators will inhibit further methylation if it accumulates in the aqueous environment where methylation occurs, shifting the MeHg optimum left (purple line). However if ecosystem chemistry (iron [Fe], reoxidation of sulfide, organic matter [OM]) allows for rapid sequestration of sulfide to large particles and sediments, the relaxation of the negative feedback of sulfide to sulfur-reducing prokaryotes (SRPs) will shift the MeHg optimum right (green line).

### 12.3.3 Environmental Drivers of Mercury Methylation Potential

The 2008 causality statement linked S to increased Hg methylation when other conditions are favorable, with a particular emphasis on dissolved organic carbon (DOC) as a control on Hg methylation ([U.S. EPA, 2008a](#)). This section is an overview of factors that control Hg methylation. In a review, [Bigham et al. \(2017\)](#) summarized drivers of mercury methylation in terms of their effect on mercury availability to methylators and on microbial activity associated with Hg methylation ([Table 12-5](#)).

**Table 12-5 Environmental factors that affect mercury (Hg) methylation.**

Geochemical or Physical Parameter Affects	Bioavailability of Hg to Methylators	Microbial Methylator Activity	Notes
Sulfur	Increase or decrease	Increase	Bioavailability of inorganic Hg will increase or decrease depending on Hg-S bonds and chemical species formed.  Increased sulfate can stimulate activity of sulfate-reducing prokaryotes, some which may be capable of Hg methylation.
Organic carbon	Increase or decrease	Increase	Availability of inorganic Hg can decrease if Hg binds to organic carbon molecules of a size or structure that makes the molecules resistant to microbial degradation.  Availability of inorganic Hg can increase if Hg binds to organic molecules that are mobile in water and accessible to microbial degradation.  Increased organic carbon can stimulate microbial activity by increasing electron donors to metabolism.
Iron	Decrease	Increase or decrease	Bioavailability of inorganic Hg can decrease as Fe reduces and binds to Hg.  Fe can increase microbial methylation by binding to sulfide and preventing the negative feedback of this product of sulfate reduction upon its production, which coincides with Hg methylation in some SRP. Also, Fe can stimulate the action of iron-reducing microbial methylators.  Fe can decrease microbial methylation by shifting microbial communities towards nonmethylating organisms.
pH	Increase or decrease	Increase or decrease	Bioavailability of inorganic Hg is reduced at high pH. pH between 4.5 and 9 is optimal for microbial activity.

**Table 12-5 (Continued): Environmental factors that affect mercury (Hg) methylation.**

Geochemical or Physical Parameter Affects	Bioavailability of Hg to Methylators	Microbial Methylator Activity	Notes
Temperature	Increase or decrease	Increase or decrease	Bioavailability of inorganic Hg can increase if weathering of Hg-containing rocks or sediments, or decomposition of older organic matter, increases with higher temperatures. Bioavailability of Hg can decrease if Hg volatilization to the atmosphere increases. Microbial methylators have optimal temperatures for growth.
Oxygen availability	Increase	Decrease	Bioavailability of Hg in reduced chemical species is low. Microbial methylators are anaerobes, methylating Hg under reducing conditions.
Drying and wetting cycles (drought, seasonal variation in water levels, etc.)	Increase	Increase	Fluctuating water levels can increase the release of Hg from particles in sediment. Fluctuating water levels can increase the reoxidation and release of S from sediments as sulfate.

Adapted from [Bigham et al. \(2017\)](#).

Seasonal patterns of Hg methylation and transport of Hg in many systems can affect MeHg accumulation. Also, a number of chemical constituents can stimulate or inhibit Hg methylation. Given our understanding of the microbial mechanisms of Hg transport and methylation, and the complexity and diversity of aquatic environments, chemical controls on MeHg processes are not fully established. This section is meant to lend context to the description of how S deposition affects methylation, but it is not a complete review of the chemical controls on biological Hg methylation in natural environments.

### 12.3.3.1 Sulfur and Methylation Potential

Sulfate in soil pore water, surface water, or in sediment pore waters can stimulate mercury methylation. Sulfate is utilized as a terminal electron acceptor in heterotrophic metabolism by some classes of bacteria, and in the course of this dissimilatory sulfur reduction, these bacteria transform sulfate to sulfide and expel the reduced sulfur into the environment as a waste product. Sulfate-reducing bacteria can also form syntrophies, symbiotic exchanges of metabolic substrates and products, with methanogens and other archaea, so that sulfate stimulates metabolism even in organisms that do not utilize it directly as an electron acceptor. The current scientific understanding is that MeHg is produced as an accidental byproduct in both sulfate-reducing bacteria and syntrophic archaea. Conditions optimal for these organisms and which favor their activity over

competing anaerobic heterotrophs probably occur in short time frames and in shifting locations in many ecosystems. Sulfate stimulation of mercury methylation will probably occur at an annual time scale at very low or undetectable background levels, with occasional peaks of microbial methylation (hotspots) when other controls (temperature, organic matter, anoxic microsites, or hypoxic zones) on microbial metabolism reach their optima. At temporal and spatial hotspots of mercury methylation, sulfate concentrations may drop as sulfate is converted to sulfide, particularly in shallow water bodies with longer water residence times. As a result, concentrations of sulfate in surface water may not correlate with sulfate inputs to the ecosystem or with MeHg produced by sulfate reduction, particularly in aquatic or wetland ecosystems where there are active SRPs.

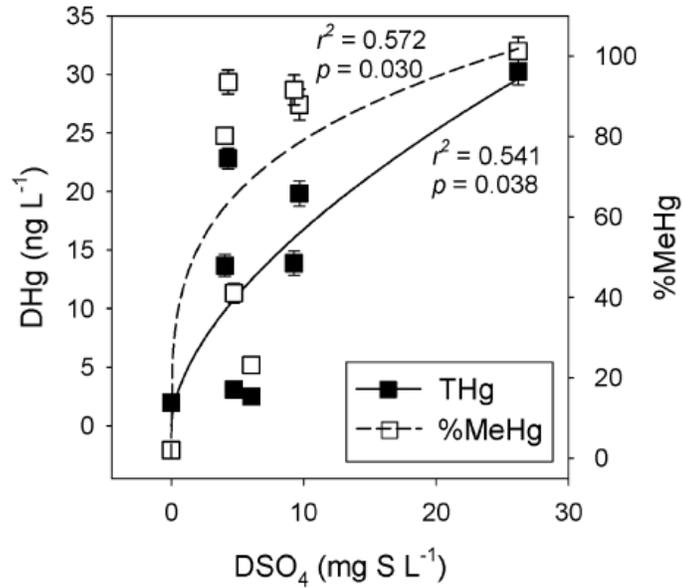

The byproduct of microbial sulfate reduction, sulfide, is also an important regulator of mercury methylation. Sulfide dissolved in surface water or pore water inhibits microbial methylation, and interferes with plant nutrient uptake (see [Appendix 12.2.3](#)). Sulfide can also produce a negative feedback on mercury methylation by binding with inorganic mercury in the water column and precipitating into cinnabar in the sediment, lowering the bioavailability of Hg to microbial methylators. However, in water bodies with a high fraction of mineral sediments or dissolved minerals, particularly iron, iron will bind to sulfide and precipitate out of solution, preventing the formation of a negative feedback to sulfur reduction and mercury methylation. In water bodies with longer residence times, sulfide concentrations in sediments may correlate with microbial sulfate reduction, and if SRPs are the primary methylators in the system, with MeHg concentrations.

Laboratory studies support field research in demonstrating that under controlled conditions, sulfate additions increased Hg methylation in environmental samples. The 2008 ISA reported evidence of Hg methylation in lake water and sediment samples in response to experimental sulfate addition. In slurries of sediment collected from Quabbin Reservoir, MA, adding 4.8 mg/L (reported as 50  $\mu\text{M}$ ) sulfate to the slurry (ambient lake water sulfate = 5.8–7.7 mg/L or 60–80  $\mu\text{M}$ ) increased potential MeHg production 150%, adding 9.6 mg/L sulfate (100  $\mu\text{M}$ ) increased MeHg production 160%, and adding 19.2 mg/L sulfate (200  $\mu\text{M}$ ) sulfate increased MeHg 410% above ambient lake water MeHg ([Gilmour et al., 1992](#)). Slurries can overestimate the potential rates of MeHg production, so this study also incubated intact sediment cores with sulfate concentrations from 0.3–110 mg/L (reported as 3–1,140  $\mu\text{M}$ ). Peak potential MeHg production was at 11 mg/L sulfate (110  $\mu\text{M}$ ), where MeHg was 8.6 ng MeHg/g, a 200% increase from MeHg production at 0.3 mg/L sulfate [3  $\mu\text{M}$  ([Gilmour et al., 1992](#))]. In longer incubations of sediment cores from two lakes in Wisconsin, including Little Rock Lake, adding 5.8–23 mg/L sulfate (60–240  $\mu\text{M}$ ) changed sediments from net demethylating (–100 ng MeHg/m<sup>2</sup>/day or –0.1  $\mu\text{g}$  MeHg/m<sup>2</sup>/day) to net methylating

(5,500 ng MeHg/m<sup>2</sup>/day or 5.5 µg MeHg/m<sup>2</sup>/day) environments ([Gilmour and Riedel, 1995](#)).

Since the 2008 ISA, several new studies have provided experimental evidence of sulfate stimulation of Hg methylation in a broader range of aquatic freshwater environments ([Table 12-6](#)). Laboratory experiments using samples from wetlands at Sunday Lake in the Adirondack Mountains of New York were conducted to determine potential Hg methylation rates. When slurried peat-and-water samples from a floating fen (bog mat composed of *Sphagnum* spp. and ericaceous shrubs) received an addition of sulfate to raise the concentration of sulfate by 190 mg/L (initial sulfate concentration not given), Hg methylation rates (%MeHg/day) were 2.1 times higher than unamended samples ([Yu et al., 2010](#)). This result is consistent with evidence from observational ([Appendix 12.3.5](#)) and S addition studies ([Appendix 12.3.4](#)) in peat bogs that sulfate stimulates Hg methylation in these wetland systems.

There are three new studies that demonstrate sulfate stimulation of water and sediment Hg methylation in samples taken from rivers. Slurried sediments collected in 2010 from the South River, VA, were spiked with sulfate to raise sulfate levels from average ambient levels of 19.2 mg/L to 38.2 or 96.1 mg sulfate/L. Sulfate addition significantly increased the potential methylation rate of Hg (%/day), with methylation rates 1.6–2.6 times higher in sulfate-spiked sediments than in sediments with ambient sulfate concentrations ([Yu et al., 2012](#)). There was a significant difference in methylation rates between the low and high S addition treatments in only one of three sampled river sediments; this sample showed methylation was higher in the sediment when sulfate levels were 96.1 mg/L ([Yu et al., 2012](#)). In microcosm slurries composed of water and sediment samples from the Wupper River in Germany, higher MeHg in water correlated weakly ( $R^2 = 0.28$ , both variables natural log-transformed) with higher sulfate concentrations, with mean pore water sulfate of 32.2 mg/L and range of 2–223 mg/L ([Frohne et al., 2012](#)). Higher total Hg concentrations in water correlated weakly ( $R^2 = 0.20$ ) with higher sulfate, although DOC was a stronger predictor of total Hg [ $R^2 = 0.53$  ([Frohne et al., 2012](#))]. [Tsui et al. \(2008\)](#) constructed mesocosms to mimic leaf decomposition in the hyporheic zone of Minnesota streams and rivers, where conditions are hypothesized to be favorable for the SRB that methylate inorganic Hg. Water samples were collected from seven streams or rivers in Minnesota, with sulfate levels at collection of 4.0–26.2 mg sulfate-S/L (with an ultrapure water sample as a control, 0.0 mg S/L), and incubated with *Acer* sp. (maple) leaves. After 66 days of decomposition, the total Hg released from the decomposing litter into solution as dissolved Hg increased with initial sulfate concentration ( $R^2 = 0.541$ ,  $p = 0.038$ ), and the fraction of total Hg that had been transformed to MeHg increased in a power law dependence upon initial sulfate concentration [ $R^2 = 0.572$ ,  $p = 0.030$ , see [Figure 12-8, \(Tsui et al., 2008\)](#)].

**Figure 12-8 The relationship between surface water sulfate and total mercury or methylmercury fraction in river/leaf litter mesocosms.**

This evidence of sulfate stimulation of Hg methylation in river ecosystems is consistent with observational studies of positive correlations between sulfate and Hg methylation in rivers and streams.

**Table 12-6 New mesocosm or incubation studies on sulfur addition effects on methylmercury.**

Type of Ecosystem	Additions or Load (kg S/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
River	S deposition not reported Soil: 2.0–2.6 mg S/g soil [SO <sub>4</sub> <sup>2-</sup> ] pore water in microcosm: 2.2–223 mg/L, mean 32.0 mg/L	Total Hg and MeHg were positively correlated with sulfate concentrations: ln(THg) = 2.956 + 0.697 × ln(SO <sub>4</sub> <sup>2-</sup> ), ln(MeHg) = 4.962 + 0.473 × ln(SO <sub>4</sub> <sup>2-</sup> ). ---

### 12.3.3.2 Total Mercury Concentration and Methylation Potential

The 2008 ISA did not present information on how total Hg concentration affects rates of MeHg production, in part because there is no consensus across studies as to whether there is a linear relationship between total Hg and MeHg in water or soil. In part this is because most reported MeHg rates are potential rates determined by experimental incubations with added Hg, and methylation rates have been shown to be dependent on initial concentrations of Hg ([King et al., 1999](#); [Gilmour et al., 1992](#)). Additionally, different chemical forms of inorganic Hg vary in bioavailability and affect methylation rates ([Kucharzyk et al., 2015](#); [Graham et al., 2012](#)).

Two studies that sampled MeHg fractions at different locations within the U.S. provide information at the landscape level about factors that increase probability of detrimental effects upon wildlife due to Hg availability. There is a large variability across systems in MeHg fraction. In a study of five forested watersheds distributed across the U.S. (in Vermont, Wisconsin, Colorado, Georgia, and Puerto Rico), total Hg flux out of the watershed in the streams was highest at Rio Icacos, Puerto Rico (54,400 ng Hg/m<sup>2</sup>/yr, reported as 54.4 µg Hg/m<sup>2</sup>/yr) and lowest at Allequash Creek, WI [250 ng Hg/m<sup>2</sup>/yr or 0.25 µg Hg/m<sup>2</sup>/yr ([Shanley et al., 2008](#))]. MeHg fraction was highest at Allequash Creek (14.8% of total Hg) and lowest at Rio Icacos (0.7%), indicating that watershed flux of total Hg does not directly indicate risk to organisms ([Shanley et al., 2008](#)). In a study of eight streams in Oregon, Wisconsin, and Florida, MeHg fractions and concentrations (range: <0.01–17.8 ng/g sediment) in streambed sediments were higher in nonurban than in urban streams ([Marvin-Dipasquale et al., 2009](#)).

---

### 12.3.3.3 Temperature and Methylation Potential

The 2008 ISA did not describe temperature or seasonal effects on Hg methylation. This section presents information from key older papers and recent research on temperature effects in lakes, wetlands, and watersheds. Seasonal patterns of microbial methylation are directly controlled by temperature effects on microbial metabolism, as well as by indirect temperature effects, such as oxygen depletion and stratification and mixing of water bodies.

As a microbial process, Hg methylation is temperature dependent. In Lake Clara, WI, incubation at in situ temperatures of seasonally sampled sediment cores from a lake depth of 10.5 m showed that Hg methylation increased slowly from near 0% in April to peaks of 1% methylation in August and September, with temperature accounting for 30% of methylation rate variation ([Korthals and Winfrey, 1987](#)). Demethylation was also

measured in incubations and displayed slightly different seasonal variation; it increased sharply from 1% in May to 4% in early July, then fell sharply to 1% in late July, staying low for the rest of the sampling year. As a result, the methylation:demethylation ratio (a predictor of MeHg concentrations in water) rose above 1 in late July through August, and then again in late September ([Korthals and Winfrey, 1987](#)). Timing of methylation and demethylation peaks were similar in sediments sampled from a lake depth of 1.0 m, although gross methylation and demethylation rates were slightly higher ([Korthals and Winfrey, 1987](#)). Sampling across the ELA in Ontario suggests that seasonal patterns of methylation in lakes are due to seasonal shifts in oxygen availability, as locations and depths within the lake where methylation was documented in the summer had no methylation potential when resampled in the fall following turnover ([Eckley and Hintelmann, 2006](#)).

Fall mixing of stratified lakes can have significant effects on total MeHg in lake food chains. In all years of sampling at Onondaga Lake, NY, there was a significant peak in MeHg concentrations and in MeHg:total Hg ratios in the epilimnion in the fall following turnover ([Todorova et al., 2014](#)). In Little Rock Lake, WI, researchers inferred that considerable demethylation occurred in the fall following mixing because high MeHg in the summer water column did not accumulate in sediments and was not reflected in low spring MeHg water column concentrations ([Watras et al., 2006](#)). Short weather events can also affect Hg exchange. During the fall of 2006, regular weekly sampling in Onondaga Lake, NY, captured the effects of strong winds and heavy rains mixing the stratified layers of the lake upon MeHg dynamics. Dissolved oxygen values dropped in the sampled surface waters, and MeHg concentrations rose 23% to 0.236 ng/L in surface waters, even as MeHg concentrations dropped in the hypolimnion ([Todorova et al., 2014](#)).

There are seasonal patterns of Hg methylation in wetlands as well. In peatlands of Allequash Creek Watershed, WI, MeHg concentrations and MeHg fraction (percentage of total Hg) peak in early fall ([Creswell et al., 2008](#)). In the Adirondack Mountains, NY, sampling at the inlet stream of Arbutus Lake showed a pulse of MeHg entering the lake in summer months from the upstream wetlands ([Gerson and Driscoll, 2016](#)). Sampling of the streams in the lake watershed showed no seasonal patterns of MeHg in streams draining forest; but in streams draining wetlands, MeHg increased 300% during the growing season compared to winter MeHg concentrations ([Selvendiran et al., 2008a](#)). In freshwater marshes in the Yolo Bypass, CA, seasonal wetland export of MeHg occurs during the winter as well as the summer. In the summer, newly methylated MeHg is drawn into the root zone of the sediment by plant transpiration, and in winter, diffusion releases MeHg from the sediment into the water column ([Bachand et al., 2014](#)). Seasonal changes have also been documented in the salt and freshwater marshes at Kirkpatrick

Marsh on the Chesapeake Bay, MD, with higher MeHg concentrations and higher methylation rates in summer than in fall ([Mitchell and Gilmour, 2008](#)), and temperature effects have been experimentally demonstrated in Georgia coastal marshes, where the methylation rate was 2 times higher at 25°C than at 4°C, and was 30 times higher at 35°C than at 4°C ([King et al., 1999](#)). Seasonal patterns are even observed in the Florida Everglades, where December potential methylation rates were lower than March or July rates, although water temperatures at midday in December were 18°C ([Gilmour et al., 1998](#)).

In addition to affecting Hg methylation rates, seasonal changes in hydrology can alter fluxes of Hg in watersheds. In the Marcell Experimental Forest, MN, water flow during snowmelt over 2 weeks in spring is 30 or 41% of total annual discharge from two wetland catchments ([Mitchell et al., 2008c](#)), and 26 or 39% of total annual Hg export from the catchment occurred during that time. The majority of MeHg within the catchments (79 or 95% of total catchment MeHg) was in the wetlands and exported in high amounts during snowmelt, about 22–23% of annual MeHg export from the catchments ([Mitchell et al., 2008c](#)). In the Adirondacks, there were increases in stream MeHg concentrations and %MeHg in summer months, when stream discharge was low and water residence time was long in the wetlands where methylators were active ([Gerson and Driscoll, 2016](#); [Selvendiran et al., 2008a](#)). High flow events can be important for transporting MeHg through ecosystems but do not necessarily cause methylation of mercury in aquatic ecosystems.

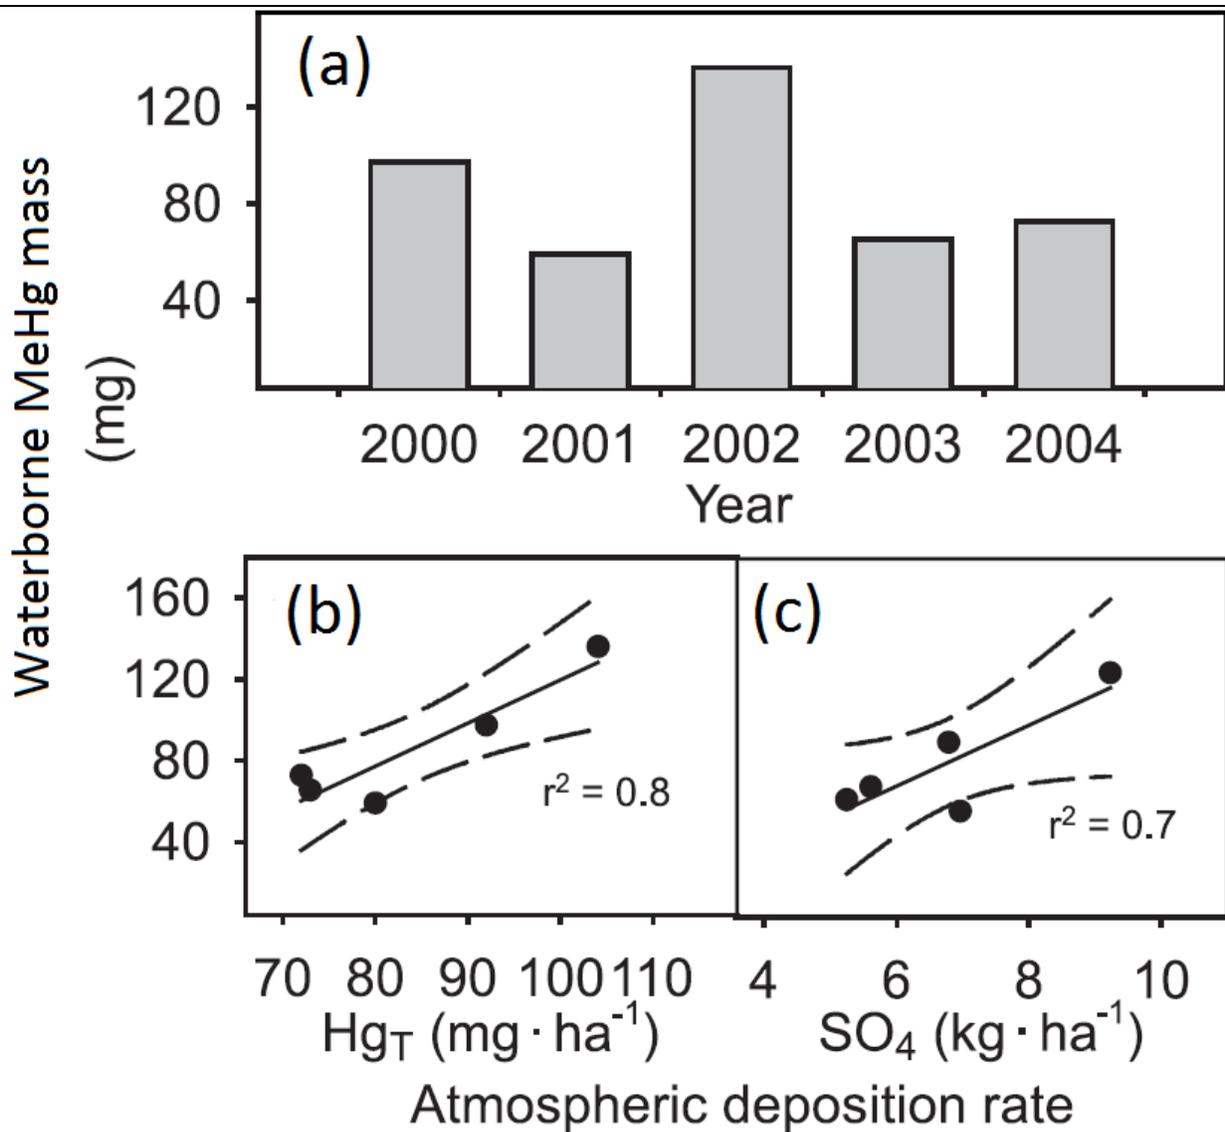

#### **12.3.3.3.1 Climate Modification of S Effects on Ecosystems**

Climate factors that will modify ecosystem response to S include changes in temperature and intensification of hydrologic cycling ([Paranjape and Hall, 2017](#)). Recent evidence from experiments in lakes and bogs allows evaluation of how climate change will affect the relationship between SO<sub>x</sub> deposition and MeHg production. Climate change will affect aquatic and wetland ecosystems via warming temperatures and increasing fluctuations in water tables due to changes in the timing and magnitude of precipitation ([IPCC, 2013](#)). Generally, microbial activity increases with temperature. It is biologically plausible that warming could increase MeHg via stimulation of both the decomposer guilds of microbes producing DOC and of SRPs actively methylating Hg; however, it is also plausible that warming will increase the activity of microbes that demethylate MeHg. [IPCC \(2013\)](#) projected that heavy precipitation events will increase in number and strength due to climate change, which can lead to rapid changes in water table level in wetlands and lakes. These changes in water level can move pulses of labile carbon and sulfate into the anoxic zones of the water, sediment, and periphyton where SRPs are

active, and flooding or rewetting of previously dry zones can create new environments favorable for SRPs. The following studies suggest that drought and warming increase S cycling and Hg cycling. Drought, but not warming, increases MeHg production in lakes and wetlands.

As reviewed in the 2008 ISA, recovery in Little Rock Lake, WI, has been monitored because the lake was experimentally acidified for 5 years (1984–1989). Drought affected sulfate and MeHg concentrations in the lake, which is rain-fed. During the drought years of 1998–2006, MeHg increased 0.004 ng/L/yr, although high variation among samples made this trend marginally significant [ $p = 0.06$  ([Watras and Morrison, 2008](#))]. MeHg increased from 0.04 ng/L in 1997 to 0.07 ng/L in 2006, a 75% increase, which is more than can be attributed to evapoconcentration from the lake's 30% decrease in volume ([Watras and Morrison, 2008](#)). During this time period, there were no significant changes in total Hg deposition; although between 1988 and 2006, the total Hg concentration in Little Rock Lake has declined 0.04 ng/L/yr ([Watras and Morrison, 2008](#)). During the drought, between 2000 and 2004, total MeHg mass in the north basin of the lake was positively correlated with higher Hg and S deposition in precipitation ([Figure 12-9](#)).

Wetlands are characterized by fluctuating water tables, and microbial communities in wetlands are adapted to respond rapidly to changes in substrate and oxygen availability. This is particularly true for SRPs, which methylate Hg in geographic and temporal pulses, resulting in hotspots of high MeHg concentrations within wetlands where Hg is actively methylated ([Appendix 12.8](#)). Fluctuations in water tables caused by periods of drought and periods of flooding can create pulses of SRP activity and hotspots of Hg methylation, raising MeHg concentrations in the environment. The following studies present evidence that climate change (through drought and warming) will interact with S addition to change MeHg and Hg dynamics in wetlands.

ha = hectare;  $Hg_T$  = total mercury deposition  $kg =$  kilogram; MeHg = methylmercury; mg = milligram;  $SO_4^{2-}$  = sulfate.  
 Source: adapted from [Watras and Morrison \(2008\)](#).

**Figure 12-9** Total methylmercury mass in water at Little Rock Lake, WI, annually (a), and in relationship to annual mercury (b) or sulfur (c) deposition.

Drought and rewetting increased MeHg in Bog Lake Fen, and S addition treatments enhanced this effect. A 9-month drought from the summer of 2006 to the spring of 2007 resulted in a pulse of reduced S when the water levels rose again, and the sulfate concentrations were 147% higher in the S addition treatment, and 78% higher in the recovery treatment, than in the control wetland ([Wasik et al., 2015](#)). Sulfate pulses

resulted in proportional increases in Hg methylation, with peak MeHg fraction 150% higher in the S addition and 60% higher in the recovery treatment ([Wasik et al., 2015](#)). The peat experienced drought conditions in summer 2007 as well, and pulses of sulfate in the experimental treatments that fall (165% higher in S addition, 14% higher in recovery wetland than in control wetlands) resulted in higher peak MeHg fractions in fall and the following spring in both the S addition and recovery treatments. Experimental manipulation of water levels in the different wetland treatments showed that higher water levels raised sulfate, total Hg, and MeHg in S addition wetlands, but did not affect these parameters in control and recovery wetlands ([Wasik et al., 2015](#)). In the recovery treatment, S and MeHg pulses were higher than in control plots, indicating persistent effects of S addition several years after addition ceased. However, because experimentally raising water levels did not alter S or Hg chemistry in control or recovery wetlands, the recovery wetland was returning to S and Hg processes more similar to the control plots.

Warming may ameliorate the effect of S upon MeHg production in wetlands, but experimental evidence suggests that it will also increase sulfate and MeHg export from peatlands into downstream aquatic ecosystems. Degerö Stormyr in Sweden is the site of a wetland experiment that addresses the effects of S and N deposition as well as warming due to climate change. Warming altered the S and Hg dynamics under S deposition at Degerö Stormyr. Total Hg (per mass of peat) was 19% lower in 20 kg S/ha/yr + warming plots than in S only plots, indicating increased mobilization or volatilization of Hg from the peat. The Hg methylation constant in S + warming was similar to the rate in unamended control plots, much lower than the rate in S only plots ([Akerblom et al., 2013](#)). MeHg concentrations in the S and warming treatment were lower than in any other treatment, 73% lower in the 20 kg S/ha/yr + warming treatment than in the 20 kg S/ha/yr treatment, and 54% lower than in the control treatment ([Akerblom et al., 2013](#)). This last result suggests that the combination of warming and S addition increases MeHg mobility beyond current ambient rates. Given the decreases in both total Hg and MeHg, it appears that all forms of Hg were mobilized and either exported or volatilized by the warming + S addition treatment, despite decreases in Hg methylation rate.

---

#### **12.3.3.4 pH and Methylation Potential**

The 2008 ISA described the state of knowledge current at the time that lower pH waters had higher MeHg production. This relationship was assumed to be causal. However, the laboratory body of evidence suggests that if all other factors are held equal, methylation is highest at near neutral pH and drops with increasing acidity. The apparent discrepancy

is due to the fact that SO<sub>x</sub> deposition causes both elevated sulfate concentrations and acidification in aquatic ecosystems.

Studies from the early 1980s assumed that acidification, not sulfate concentration, was the causal factor in observed increases of MeHg in water and increased Hg burdens in fish in response to SO<sub>x</sub> deposition. For example, samples from circumneutral lakes at the ELA in Ontario that were experimentally acidified with H<sub>2</sub>SO<sub>4</sub> had increased methylation and decreased demethylation, so that methylation:demethylation rates were 2.9 to 4 times higher at pH 5.1 than at pH 7.1 ([Xun et al., 1987](#); [Ramial et al., 1985](#)).

Recent research on the role of S reducing bacteria in methylating Hg ([Appendix 12.3.2](#)) suggests reinterpretation of an acid pH-MeHg relationship. Controlled laboratory experiments showed that it was the added sulfate, not pH, that increased Hg methylation rates in these lakes. Slurries with sediments from Lake Clara, WI, were made with added H<sub>2</sub>SO<sub>4</sub> or a molar equivalent amount of sulfate as Na<sub>2</sub>SO<sub>4</sub>. Acidification from neutral slurries to pH 4.5 with H<sub>2</sub>SO<sub>4</sub> decreased methylation by 65%, while an equivalent addition of Na<sub>2</sub>SO<sub>4</sub> did not alter methylation rates; acidification to pH 3.0 almost entirely inhibited methylation ([Steffan et al., 1988](#)). This study also measured demethylation over a range of pH 2.0–8.0. The results showed that demethylation was higher than 2% from pH 4.4–8, while methylation rose above 2% from pH 6.0–8.0, and both processes slowed with decreasing pH ([Steffan et al., 1988](#)). The 2008 ISA correctly identified the correlation between acidic surface water and high rates of MeHg, but the two factors share a common cause, which is increased surface water sulfate concentrations, rather than a direct causal relationship. In the Adirondacks, which have historically experienced high S deposition (see [Appendix 16.2](#)), surface water total Hg, MeHg, and %MeHg were unrelated to pH when all variables were measured across 44 lakes in 2003–2004 ([Yu et al., 2011](#)). However, there were effects of pH on Hg in biota (see [Appendix 12.4](#)). In regions like the Adirondacks, which historically received high S deposition and have not fully recovered from this historical acidification, pH remains an important predictor of Hg in biota.

---

### 12.3.3.5 Organic Matter and Methylation Potential

Organic matter is the metabolic substrate of all the microbial methylators, including both the group of organisms responsive to sulfate and the microbial methylators that depend on other metabolic pathways. Organic matter in environments where carbon affects mercury cycling may be quantified as soil organic matter (SOM; as percentage of soil or in g OM/g sediment); total organic carbon (TOC, g carbon/mL pore or surface water) or its components; particulate organic carbon (POC, g C/mL water); and dissolved organic

carbon (DOC, g C/mL water). The 2008 ISA described some of the complex qualitative relationships (stimulatory and/or inhibitory) between DOC and rates of Hg methylation. Organic matter influences the mercury cycle in a number of important ways. Organic matter affects MeHg production through effects on inorganic Hg ion chemistry and availability to microbes, and by serving as a metabolic substrate for SRPs. New studies from lakes, rivers, wetlands, and estuaries have found positive relationships between a range of lower DOC concentrations and MeHg production or concentrations. However, the chemical form of DOC or the salinity of the water body can alter DOC and MeHg relationships.

Certain forms of DOC may serve as a metabolic substrate that increases SRP activity, and by extension, Hg methylation. In wetlands in the Arbutus Lake Watershed, NY, there were strong correlations ( $r^2 = 0.58$  or  $0.60$ ) between Hg and total carbon in the upper 30 cm of peat ([Selvendiran et al., 2008b](#)). In northern Wisconsin lakes, the quantity of DOC derived from wetlands is the strongest (>80% variance) predictor of MeHg ([Watras et al., 2006](#)). In Canadian boreal lakes, there was a positive relationship between methylation rates and DOC ( $r^2 = 0.62$ ). In Little Rock Lake, WI, DOC and S reduction had a complex relationship: in the range of 3.6–7.6 mg C/L (reported as 300–600  $\mu\text{mol/L}$ ), sulfide (a proxy for S reduction) increased linearly with DOC concentration, while S reduction did not occur at DOC less than 3.6 mg C/L, and S reduction did not increase at DOC concentrations above 7.6 mg C/L ([Watras et al., 2006](#)).

In Lake Geneva, Switzerland, mercury methylation rates were an order of magnitude higher in settling particles than in sediments, and analysis of the particles suggested that they were derived from algal biomass ([Gascón Díez et al., 2016](#)).

Sediment organic matter may also increase microbial Hg methylation. At another watershed in the Adirondacks, Sunday Lake, NY, the highest MeHg concentrations were in samples that were more than 20% organic material ([Yu et al., 2010](#)). In prairie potholes in Saskatchewan, surface water [MeHg] increased in a linear relationship with the sediment percentage of organic matter (OM), with a 2.65 ng/L increase in MeHg for every 10% increase in the percentage of OM ([Hoggarth et al., 2015](#)).

In wetlands, rivers, and lakes of the Mississippi River Delta, LA, total Hg dissolved in surface water was positively correlated with DOC concentrations, but negatively correlated with sulfate concentrations. However, this correlation is confounded by ecosystem salinity, because mean sulfate concentrations in surface water were 16 mg/L in freshwater wetlands, 63 mg/L in brackish wetlands, and 909 mg/L in marine wetlands ([Hall et al., 2008](#)). Also, dissolved MeHg in surface water increased linearly with the hydrophobic organic acid fraction of DOC, with dissolved MeHg increasing 1 ng/L (0.000001 mg/L) for each increase of 0.048 mg organic acid/L ([Hall et al., 2008](#)). The

hydrophobic organic acid fraction represents a recalcitrant source of aromatic carbon such as that found in peat, which would account for the high amounts of MeHg in these wetlands. The hydrophobic organic acid fraction of terrestrially derived C also controls Hg export (see paragraph below). Another recent study used controlled incubations of an SRP strain, varying concentrations of Hg, and two well-characterized forms of DOC to quantify the effects of DOC on methylation. DOC typical of terrestrial sources (high aromatic fraction, high molecular weights) increased MeHg production 10–40 times above unamended controls, while aquatic DOC (high aliphatic fraction, low molecular weights) doubled MeHg production ([Graham et al., 2012](#)). The authors hypothesize that DOC increases MeHg production by slowing the growth of Hg-S particles, increasing Hg-S residence time in the water, and enhancing Hg bioavailability ([Graham et al., 2012](#)). The stronger effects of terrestrial DOC on MeHg may explain why MeHg production is particularly high in wetlands, recently flooded reservoirs, and periodically flooded river plains ([Benoit et al., 2003](#)). In estuarine and marine sediments of the Chesapeake Bay, MD, organic C in the sediments had a strong positive correlation ( $r = 0.96$ ) with sediment MeHg concentrations ([Hollweg et al., 2010](#)). In coastal marshes of the Chesapeake such as Kirkpatrick Marsh, MD, there was also a statistically significant positive relationship ( $r^2 = 0.478$ ) between Hg methylation rate and mineralization of organic C, a metric of cellular metabolism within the sediment ([Mitchell and Gilmour, 2008](#)).

Organic matter in surface water can increase the amount of Hg transported throughout a watershed, as well as MeHg production at the watershed scale. DOC can form complexes with Hg ions that facilitate their transport. In lakes and rivers of the St. Louis River, DOC and dissolved Hg were correlated ( $r^2=0.69$ ), as were aromatic DOC and dissolved Hg ( $r^2 = 0.70$ ), indicating that aromatic DOC transports Hg through aquatic ecosystems in this watershed ([Jeremiason et al., 2016](#)). In riparian forest soils in Oak Ridge, TN, flooding resulted in a pulse of both aromatic DOC and MeHg in the soil solution ([Poulin et al., 2016](#)). In the Arbutus Lake watershed in the Adirondack Mountains, NY, the fluxes of Hg and DOC in streams were correlated ( $r^2 = 0.80$ ) across seasons, and the highest fluxes were in June and July ([Selvendiran et al., 2008a](#)). In a study of five watersheds across the U.S., MeHg concentrations in catchment outflows correlated positively with particulate organic matter (POC) in Sleepers River, VT ( $r^2 = 0.93$ ), and in Rio Icacos, Puerto Rico [ $r^2 = 0.83$  ([Shanley et al., 2008](#))]. In three Northeast watersheds, stream export of dissolved Hg correlated positively with DOC, with 0.34 ng Hg/L increase for each 1 mg C/L increase ( $r^2 = 0.87$ ), and hydrophobic organic acid fraction of DOC explained 91% of variation in dissolved Hg ([Dittman et al., 2010](#)). Storm events, which increased water flow through surface soil layers and stream discharger, also increased the export of organic matter and associated Hg ([Dittman et al., 2010](#)). Thus, the evidence

indicates that the amount and form of organic matter will affect Hg transport in watersheds.

DOC affects the partitioning of inorganic Hg between sediment and water, and hence the bioavailability of inorganic Hg to methylating organisms ([Hsu-Kim et al., 2013](#); [Marvin-Dipasquale et al., 2009](#); [Benoit et al., 2003](#)). In Kirkpatrick Marsh on the Chesapeake Bay, MD, linear relationships between methylation rates and absorbance values indicated that Hg methylation rates were higher when the DOC was composed of high molecular weight, aromatic organic compounds ([Mitchell and Gilmour, 2008](#)). There were no correlations between DOC characterization and measures of microbial activity, so the authors suggested that the form of DOC (size and aromaticity of compounds) controls Hg bioavailability rather than serving as a metabolic substrate powering MeHg production ([Mitchell and Gilmour, 2008](#)). However, the relationship between DOC and Hg partitioning is complex [reviewed in [Hsu-Kim et al. \(2013\)](#)], and in an extensive survey of the Alabama River basin around Mobile, AL, there was no relationship across 52 sampling sites between DOC and Hg fractions [total, aqueous, particulate ([Warner et al., 2005](#))].

---

### 12.3.3.6 Iron and Methylation Potential

The 2008 ISA briefly identified iron (Fe) as a surface water component that can alter the relationship between SO<sub>x</sub> deposition and MeHg production (as it also interacts with sulfide phytotoxicity and internal eutrophication, see [Appendix 12.2.3](#) and [Appendix 12.2.4](#)). Iron can alter the rates of Hg methylation via abiotic and biotic mechanisms. Iron binds with sulfide produced by SRPs during methylation to precipitate out of solution ([Hellal et al., 2015](#)), preventing the negative feedback of sulfide on sulfate reduction. Iron oxides form surface complexes with inorganic Hg that decrease Hg bioavailability. However, sulfide released by SRPs can react with Fe-Hg complexes to release Hg into the water column ([Hellal et al., 2015](#)). Iron can increase methylation rates directly, by stimulating the activity of iron-reducing bacteria capable of Hg methylation, including *Geobacter* spp. In laboratory incubations mimicking freshwater sediments, iron reduction and sulfate reduction co-occurred in time but at different zones in the sediment ([Hellal et al., 2015](#)). Iron and S reduction also co-occurred in wetlands of the Yolo Bypass, CA (see [Appendix 12.3.4.3](#)).

In Kirkpatrick Marsh on the Chesapeake Bay, MD, there was a positive relationship ( $r^2 = 0.478$ ) between Hg methylation rate and mineralization of organic C and an equally strong positive relationship between Hg methylation rate and the pool of Fe<sup>2+</sup> [ $r^2 = 0.478$  ([Mitchell and Gilmour, 2008](#))]. Although Fe precipitation with Hg-S has been posited as

one of the mechanisms by which Hg is buried in sediments, there was no relationship between iron concentration and partitioning of Hg between water and soil.

---

### 12.3.3.7 Nitrate and Methylation Potential

The 2008 ISA did not address the effect of nitrate upon MeHg production. Nitrate ions are energetically favored over sulfate in redox reactions, so N addition can depress Hg methylation by shifting the energetic advantage from SRPs to denitrifiers ([Dev et al., 2015](#)). In Florida Everglades sediment incubations, addition of 1.4 mg N/L as  $\text{NO}_3^-$  to incubations decreased MeHg production by 70% ([Gilmour et al., 1998](#)). In Onondaga Lake, NY, the Syracuse water treatment plant incorporated year-round nitrification in 2004, doubling the nitrate concentrations measured annually in May before the lake stratified ([Todorova et al., 2009](#)). MeHg concentrations decreased exponentially with increasing  $\text{NO}_3^-$  concentrations (estimated pseudo- $r^2 = 0.61$ ) in the 2–3 years following the change in water treatment. This change in N load reduced MeHg accumulation in the hypolimnion by 50% in 2006, and by 93% in 2007 compared to MeHg measured earlier, in 1982, 1992, and 2002 ([Todorova et al., 2009](#)). In summer 2011, a calcium nitrate solution was pumped directly into the hypolimnion of Onondaga Lake thrice weekly, adding 84 MT of N over the course of the season ([Matthews et al., 2013](#)). As a result, hypolimnion N- $\text{NO}_3^-$  remained above 1.0 mg/L during summer stratification, and hypolimnion maximum MeHg concentration decreased 94% compared to 2009. ([Matthews et al., 2013](#)) attributed this to two effects of N: a shift in competitive advantage from SRP to denitrifying bacteria, and increased sorption of MeHg to lake sediments.

---

### 12.3.3.8 Salinity and Methylation Potential

Mercury methylation occurs in estuarine and marine ecosystems ([Lehnherr et al., 2011](#); [Benoit et al., 1998](#)), but sulfate concentrations in saline water are generally so high that direct deposition of  $\text{SO}_x$  is unlikely to alter existing MeHg dynamics. An early study on coastal marshes in Georgia showed that both sulfate reduction and MeHg production were at their highest rates in the top 4 cm of the marsh soil ([King et al., 1999](#)). An older study of Hg dynamics in the Patuxent River Estuary, MD, where sulfate concentrations range from 150 to 1,200 mg/L, found no correlation between sediment pore water sulfate concentrations and MeHg fraction in sediments ([Benoit et al., 1998](#)). There was a peak in surface water MeHg fraction of 25% at the mouth of the river, which authors speculated was due to mixing by wind of stratified anoxic water from the Chesapeake Bay with the river water ([Benoit et al., 1998](#)). MeHg sediment fraction across the Patuxent River, MD,

was negatively correlated with sulfide sediment concentrations, presumably because Hg bound to sulfide is unavailable to methylating bacteria ([Benoit et al., 1998](#)).

---

## 12.3.4 Mercury Methylation in Sulfur Addition Field Studies

There are a number of ecosystems in which sulfate is elevated by anthropogenic activities. Scientists have added sulfate to ecosystems in order to study S and Hg cycling (see [Appendix 12.3.4.1](#)). S is used as an agricultural amendment in peat soils, and so Hg cycling has been extensively studied in the Everglades Water Conservation Area (see [Appendix 12.3.4.2](#)) and the San Joaquin Delta (see [Appendix 12.3.4.3](#)).

---

### 12.3.4.1 Ecosystem Scale and Field Mesocosm Studies

The 2008 ISA found that experimental S addition to aquatic and wetland ecosystems increased MeHg concentrations in surface water (and Hg concentrations in biota, see [Appendix 12.4](#)). Key studies supporting this finding focused on the long-term S acidification (1984–1989) and recovery (1990–present) experiment at Little Rock Lake, WI and the relatively recent (initiated in 2001) experimental S addition experiment at Bog Lake Fen in the Marcell Experimental Forest, MN. This section integrates older published reports and recent papers from S addition experiments that presented quantitative relationships between S addition and Hg mobilization, methylation, and MeHg concentrations in surface water. There is new evidence from the S addition experiment at Bog Lake Fen and from an S addition by warming experiment in a Swedish bog that confirms the relationship reported in the 2008 ISA between increased S loading and environmental increases in MeHg. There is also new evidence that decreases in S addition allow recovery of MeHg toward control conditions, as well as new evidence that climate change (drought, warming) will increase S cycling and increase MeHg concentrations ([Table 12-7](#)).

As reported in the 2008 ISA, experimental S addition increases MeHg production in lake ecosystems, and cessation of S addition results in reductions in MeHg production in lakes. Little Rock Lake, WI was an S addition experiment that ran from 1985–1991. In this experiment, the north and south basins of the lake were artificially isolated by a plastic barrier, and then annual S additions were used to acidify the northern basin, while the unamended south basin served as a control. In 1993, after S addition had ceased but sulfate concentrations in the north treatment basin (4.8 mg/L or 50  $\mu$ M) were still twice that of the reference basin (2.4 mg/L or 25  $\mu$ M), the potential methylation rate was 220% higher in the treatment basin ([Gilmour and Riedel, 1995](#)). In June 1993, when MeHg

fractions were at their highest, the MeHg fraction of total Hg was 30% higher in the treatment basin ([Gilmour and Riedel, 1995](#)). Mercury and S cycling were monitored in the lake through 2003, and elevated sulfate concentrations and acidification persisted in the lake through 1996; the lake was considered recovered from 1998–2003. During acidified years, 25% more of annual Hg<sup>2+</sup> inputs were transformed into water column MeHg than in recovery years ([Watras et al., 2006](#)). Net methylation during the summer was 70% higher in acidified than in recovery years, and summertime MeHg accumulation was 75% higher in the whole lake in acidified years ([Watras et al., 2006](#)). There was a strong positive correlation between summer MeHg accumulation (1990–2003) and the interaction of epilimnion sulfate concentration and epilimnion Hg<sup>2+</sup> concentration. The hypolimnion or the anoxic-oxic boundary were likely the sites of Hg methylation, because the hypolimnion, which was less than 5% of the lake volume, accumulated more than 70% of the total MeHg mass of the lake in acidified years ([Watras et al., 2006](#)). Hypolimnion MeHg was associated with hypolimnion S reduction, as there was a 10.8 ng MeHg/L (0.0000108 mg MeHg/L) increase for each 1 mg/L increase in hydrogen sulfide (H<sub>2</sub>S; reported as 1.71 pmol/L increase in MeHg for each 1 μmol/L increase in H<sub>2</sub>S;  $r^2 = 0.65$ ). Total MeHg in Little Rock Lake, WI increased 14.4 mg for every 1 kg/ha increase in sulfate deposition ([Watras and Morrison, 2008](#)).

**Table 12-7 New studies on mercury methylation in sulfur-amended ecosystems.**

Type of Ecosystem	Additions or Load (kg S/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Peat fen	Ambient S deposition: 3 kg S/ha/yr S addition: low S (7 kg S/ha/yr added for total load of 10 kg S/ha/yr) or high S (17 kg S/ha/yr added for total load of 20 kg S/ha/yr) as Na <sub>2</sub> SO <sub>4</sub> , with 0 or 30 kg N/ha/yr as NH <sub>4</sub> NO <sub>3</sub>	At 30-cm depth, total Hg (per peat mass) in warming + high S was 19% lower than in high S plots. <hr/> Low S decreased total Hg in peat methylation hotspots by 25 or 31% on a per-mass or per-volume basis. <hr/> The Hg methylation rate constant increased by 71% in low S and by 400% in high S. <hr/> Peat MeHg concentrations decreased by 22% in low S and increased by 74% in high S. **Table 12-7 (Continued): New studies on mercury methylation in sulfur-amended ecosystems.**

Type of Ecosystem	Additions or Load (kg S/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Lakes: rain-fed LRL, DL drains stream fed by wetland	LRL: [SO <sub>4</sub> <sup>2-</sup> ] = 2.5 mg/L, DL: [SO <sub>4</sub> <sup>2-</sup> ] = 2.8 mg/L, stream feeding DL [SO <sub>4</sub> <sup>2-</sup> ] = 1.6 mg/L S deposition not reported	In LRL during drought years, lake SO <sub>4</sub> <sup>2-</sup> concentrations increased 0.18 mg/L/yr, as MeHg concentrations increased 0.004 ng/L/yr. In stratified basin of LRL, total MeHg increased with increasing S deposition: mg MeHg = 14.368 × (kg S/ha) – 18.494. In stream draining wetland, SO <sub>4</sub> <sup>2-</sup> decreased 80% as MeHg increased 69% over the course of spring and summer.	Little Rock Lake (LRL) and Devils Lake (DL), WI	Lake water	<a href="#">Watras and Morrison (2008)</a>

C = carbon; cm = centimeter; DL = Devils Lake; Ha = hectare; Hg = mercury; kg = kilogram; L = liter; LRL = Little Rock Lake; MeHg = methylmercury; mg = milligram; Na<sub>2</sub>SO<sub>4</sub> = sodium sulfate; NADP = National Atmospheric Deposition Program; ng = nanogram; NH<sub>4</sub>NO<sub>3</sub> = ammonium nitrate; S = sulfur; SO<sub>4</sub><sup>2-</sup> = sulfate; yr = year.

DL = Devils Lake; ha = hectare; kg = kilogram; L = liter; LRL = Little Rock Lake; LTER = Long Term Ecological Research; MeHg = methylmercury; mg = milligram; ng = nanogram; S = sulfur; SO<sub>4</sub><sup>2-</sup> = sulfate; yr = year.

Experimental S addition substantially increases MeHg in wetlands. The ELA in Ontario has been the subject of considerable research in Hg cycling (see [Appendix 12.8](#)). An early experiment added pulses of sulfate to peat inside collars installed in a poor fen and monitored changes in MeHg concentrations over 4 days. In one experiment, addition of 14 kg sulfate/ha increased MeHg pore water concentrations (ng/L) at the water table surface 30% above the highest measured MeHg concentrations in the control plot, with a 100% increase in MeHg above control plot concentrations at a 10-cm depth in the water table ([Branfireun et al., 1999](#)). Following a second 14 kg sulfate/ha addition, MeHg at 5-cm depth in the peat water table increased to 130% above maximum MeHg in the control plot. Four days after the first S addition, MeHg at the 5-cm depth remained elevated at 250% above maximum measured MeHg in control plots ([Branfireun et al., 1999](#)). In an experiment the following year, one sulfate addition equivalent to 2.8 kg sulfate/ha was added. After 24 hours, this S addition had increased MeHg pore water concentrations at the water table surface 100% above maximum measured MeHg in the control plot, and at the 10-cm depth below the water table, MeHg increased 20%. This MeHg increase did not persist to 48 hours after addition ([Branfireun et al., 1999](#)).

There is new evidence that addition of labile DOC typical of leachate from a forested watershed enhanced the stimulatory effect of S addition upon MeHg concentrations in wetlands. At the Marcell Experimental Forest, MN, field mesocosms were initiated in Bog Lake Fen to test the effects of S and carbon addition on Hg cycling in an ombrotrophic peat bog. Mesocosms received experimentally added loads of 8.3 kg S/ha/yr or 20.7 kg S/ha/yr, alone or in combination with additions of organic

carbon in different forms ([Mitchell et al., 2008a](#)). S addition increased peat pore water concentrations of MeHg 219–246% above MeHg levels in unamended control plots, with no significant difference between net methylation under 8.3 versus 20.7 kg S/ha addition ([Mitchell et al., 2008a](#)). Adding 20.7 kg S/ha/yr to mesocosms increased the fraction of the total Hg pool that took the form of MeHg, with MeHg 117% higher than in control plots ([Mitchell et al., 2008a](#)). The combined addition of sulfate and organic carbon (as glucose, acetate, or leachate from coniferous leaf litter) increased methylation rates (reported in pg MeHg/L/day) by 163% and increased the fraction of MeHg (%MeHg) by 152% over rates measured in mesocosms that received only S addition ([Mitchell et al., 2008a](#)). This study showed that S addition will increase MeHg in surface water in bogs, particularly when combined with labile C inputs. These results coincide with findings presented elsewhere in the ISA that DOC concentrations are increasing in surface waters ([Appendix 7](#)) as terrestrial ecosystems recover from acidification.

A decade of research at Bog Lake Fen in Minnesota shows that additional S increases MeHg production in this wetland, with consequences for water quality and also for resident organisms (see [Appendix 12.4](#)). Bog Lake Fen is the site of a long-term S addition experiment in which entire sections of the *Sphagnum* peat wetland have received additional S loading in simulated wet deposition. As reported in the 2008 ISA, S addition began in 2001 at a rate of 32 kg S/ha/yr, and increased the levels of MeHg in the bog by 40–190% in the first summer and increased the MeHg export from the bog by 144% in 2002 ([Jeremiason et al., 2006](#)). More recent sampling has confirmed the relationship between S addition and elevated MeHg production and concentrations in the wetland. In peat pore water sampled 5 cm below the water table for 2 weeks after S addition events, S addition increased MeHg concentrations by 880–1,790% in 2006 (0.2–0.3 ng MeHg/L in control, 2.9–4.2 ng/L in S addition plots), and increased MeHg concentrations 340–1,170% in 2008 ([Wasik et al., 2012](#)). Pore water MeHg fraction (percentage of total Hg in MeHg form) increased 610–1,340% over control levels in 2006 and 390–1,160% over control levels in 2008 ([Wasik et al., 2012](#)). Researchers also sampled surface peat and found that S addition altered MeHg concentrations in peat. MeHg concentrations (ng/L) and MeHg fraction (percentage of total Hg as MeHg) were 4–9 times higher in S addition plots than in control plots, although there was no effect of S addition on total Hg in plots ([Wasik et al., 2012](#)). The elevated MeHg in water and peat had consequences for the food chain (see [Appendix 12.4](#)).

There is also evidence of a link between S addition and MeHg production from a European wetland experiment. Degerö Stormyr in Sweden is the site of an experiment that addresses the effects of S and N deposition as well as warming due to climate change. Plots received S loads of 10 kg S/ha/yr or 20 kg S/ha/yr, and a subset of plots was enclosed by greenhouses to raise air temperature by about 4°C and peat temperature

(at the 20-cm depth) by about 2°C. Four years after the 1995 initiation of the experiment, [Bergman et al. \(2012\)](#) measured MeHg production in the control and 20-kg-S/ha/yr plots. S addition increased mean growing season peat pore water MeHg concentrations 117% over MeHg concentrations in control plots ([Bergman et al., 2012](#)). There was higher variation in MeHg in S addition plots (20 kg S/ha/yr), as the range of measured concentrations was 4.3 times the range of measured MeHg in control plots ([Bergman et al., 2012](#)). The experiment was resampled 12 years after initiation, and the Hg methylation constant was 71% higher in methylation hotspots (a hotspot was experimentally defined as the point in each sampled peat profile with the highest Hg methylation rate constant) under addition of 10 kg S/ha/yr compared to control plots, while MeHg concentrations were 22% lower than in control hotspots ([Akerblom et al., 2013](#)). These seemingly contradictory results (higher production, lower concentration) may indicate increased mobilization of MeHg from methylation hotspots (see below) or increased microbial demethylation rates, which were not tested. Under higher S addition of 20 kg S/ha/yr, the Hg methylation rate constant was 400% higher than in the control plots, while the MeHg concentrations were 74% higher than in control plots ([Akerblom et al., 2013](#)). Together, these results indicate that in wetlands an S addition of 10 or 20 kg/ha/yr increases microbial MeHg production and that an S addition of 20 kg/ha/yr increases MeHg concentrations.

S addition also increases the mobilization and transport of Hg and MeHg from peat methylation hotspots into the water column, increasing bioavailability. After 4 years of S addition at Degerö Stormyr in Sweden, plots that received 20 kg S/ha/yr had 133% higher total Hg levels in the top 5 cm of peat than control plots ([Bergman et al., 2012](#)). After 12 years, sampling of Hg methylation hotspots in plots with 10-kg-S/ha/yr addition found total Hg was 25% lower per peat mass or 31% per peat volume than in control plots ([Akerblom et al., 2013](#)). These results indicate that S addition mobilizes Hg stored in deeper parts of the peat profile, resulting in Hg transport to more accessible parts of the peat profile.

Recent work from the experiment at Bog Lake Fen also provides evidence that reduction of experimental S addition to wetlands results in reductions of MeHg concentrations in wetlands. In 2006, after 5 years of elevated S levels, a recovery treatment was initiated in the S6 bog experiment, where S addition was halted in recovery plots. Following the cessation of S addition, pore water MeHg (ng/L) declined by 32% between 2006 and 2008, and peat MeHg concentration and peat MeHg fraction declined by 62 and 76%, respectively ([Wasik et al., 2012](#)).

### 12.3.4.2 Agricultural Systems: The Everglades Water Conservation Area, Florida

There are multiple new studies that relate Hg concentrations in water, periphyton, soil, or fish to sulfate concentrations in the Everglades Water Conservation Area (see [Table 12-8](#)). In the Water Conservation Areas outside Everglades National Park, FL (Class I area), sulfate concentrations were as high as 48 mg/L near the EAA, whereas in pristine areas distant from the EAA, sulfate concentrations were less than 0.5 mg/L. Previous studies noted that Hg methylation was highest in areas of the wetland where sulfate concentrations ranged from 0.7 to 1.9 mg sulfate/L ([Bates et al., 2002](#); [Gilmour et al., 1998](#)). More recently, a study by [Corrales et al. \(2011\)](#), quantified the S budget and determined that atmospheric deposition of S is 15 kg S/ha/yr, 4% of the total S load in the WCAs. MeHg concentrations in surface water in the Florida Everglades increase when sulfate concentrations are above 1 mg/L, which [Corrales et al. \(2011\)](#) recommended as a target level for sulfate reduction efforts ([Figure 12-10](#)).

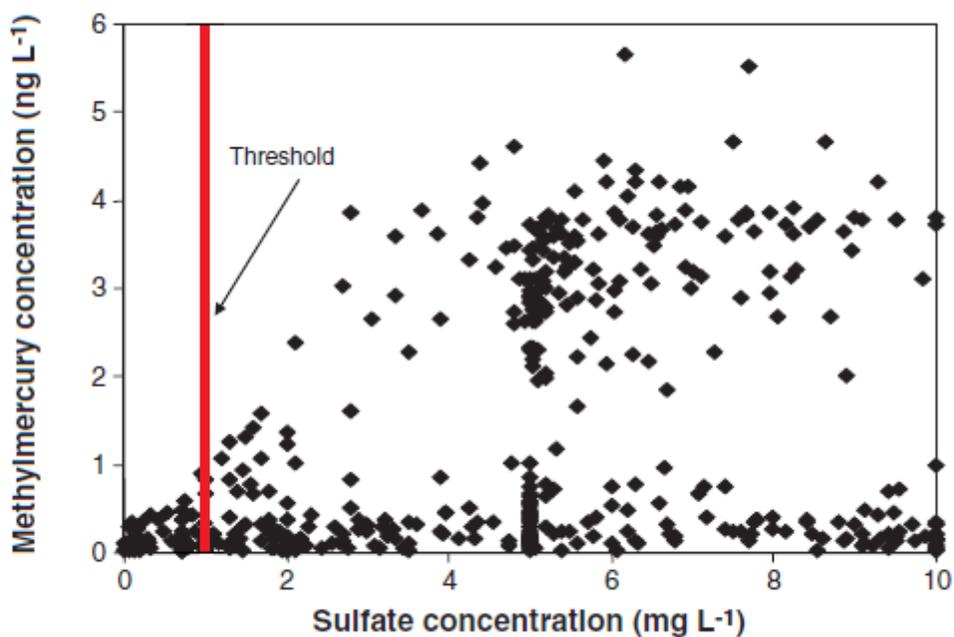

**Table 12-8 New studies on mercury (Hg) and sulfur (S) cycling in the Everglades Water Conservation Areas (WCA).**

Type of Ecosystem	Additions or Load (kg S/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Freshwater marsh	W3 pore water [SO <sub>4</sub> <sup>2-</sup> ] ≤4 μM U3 pore water [SO <sub>4</sub> <sup>2-</sup> ] is 39 μM F4 pore water [SO <sub>4</sub> <sup>2-</sup> ] is 74 μM Deposition = not measured	SRB abundance was 6.9x higher in U3 than W3, 16.8x higher in F4. In W3, abundance of SRB and methanogens are not significantly different. In U3, SRB abundance is 80% higher than methanogen abundance. In F4, SRB abundance is 60% higher than methanogens. mcrA copy number correlates positively with mRNA and methane production rates. Acetotrophic methanogens are dominant at W3, while at high S U3 and F4 sites, hydrogenotrophic methanogens are dominant. Source: adapted from [Corrales et al. \(2011\)](#).

**Figure 12-10 The relationship between surface water sulfate and methylmercury concentrations in the Florida Everglades.**

[Orem et al. \(2011\)](#) suggested that at high surface water sulfate (>20 mg/L) concentrations in the Florida Everglades, sulfide accumulates and inhibits methylation. In treatment wetlands that collect stormwater runoff from the EAA, the concentrations of sulfate are so high that sulfide inhibition of MeHg may occur at the higher end of the sulfate range. [Zheng et al. \(2013\)](#) reported on the water quality parameters, total Hg, and MeHg in the inflow and outflow waters of a constructed treatment wetland in the Everglades WCAs. The wetland was a net source of MeHg to surface water between 2000 and 2004, and during this time, total Hg and MeHg concentrations in water exiting the wetland were negatively correlated with sulfate concentrations of water flowing into the wetland ([Zheng et al., 2013](#)). The range of sulfate concentrations of inflow was 39–110 mg/L sulfate, with mean sulfate of 59.5 mg/L. [Zheng et al. \(2013\)](#) also constructed multivariate models for total Hg and MeHg, and even with other factors such as DOC, pH, and chloride in the model, inflow sulfate remained a strong and negative correlate of outflow

Hg concentrations. The positive relationship between sulfate and MeHg in the Florida Everglades is significant only at low sulfate concentrations (in this study, 39 mg SO<sub>4</sub><sup>2-</sup>/L).

A gradient of nutrient eutrophication (N, P, and S) from agricultural runoff runs from northeast to southwest across the WCA, with sulfate concentrations around 4.8 mg/L (reported as 50 µM) in southern, less disturbed sites ([Gilmour et al., 1998](#)). Sediment Hg increased from north to south by a factor of 3–4, and MeHg sediment concentrations increased across the same gradient by a factor of 25 ([Gilmour et al., 1998](#)). A more recent study in the Everglades suggested that mercury hotspots (elevated Hg in mosquitofish) were correlated with relatively oligotrophic conditions (low soil total phosphorus, TP) and native sawgrass sloughs, while fish Hg was lower in sites with higher soil TP with invasive cattail stands ([Julian et al., 2016a](#)). Surface water sulfate concentrations measured at the same sites ranged from 0.2–35 mg SO<sub>4</sub><sup>2-</sup>/L in the Hg hotspots and 6.5–70 mg SO<sub>4</sub><sup>2-</sup>/L at the nonhotspots ([Julian et al., 2016b](#)). Surface water sulfate and pore water sulfate were correlated, and the ratio of pore water sulfide:pore water sulfate correlated with pore water DOC ([Julian et al., 2016b](#)), suggesting that dissimilatory sulfate reduction (and by extension, a portion of mercury methylation) is controlled by DOC as well as sulfate in these marshes. In addition to the studies described in this section, studies in the Everglades WCA have focused on the microbial mechanisms of mercury methylation (see [Appendix 12.3.2](#)) and Hg loads in wildlife (see [Appendix 12.4](#)).

---

#### 12.3.4.3 Agricultural Systems: Rice in the San Joaquin Delta, California

There is evidence from the California Central Valley that microbial Hg methylation occurs in managed agricultural wetlands that produce rice, which suggests a route of MeHg exposure to humans and wildlife. California (particularly the Central Valley where these studies were conducted) is the second largest producer of rice in the U.S., as well as an important stop along a major bird migratory route. The USGS coordinated an intensive research effort on Hg cycling and methylation of Hg in wetlands of the Central Valley of California, focusing on the Yolo Bypass Wildlife Area, located in the northwestern region of the San Francisco Bay delta where there are permanent wetlands dominated by *Typha* spp. (cattails) and *Scirpus* spp. (tule) and also agricultural wetlands in which *Oryza sativa* (white rice) and *Zizania palustris* (wild rice) are cultivated. Rice fields go through annual drying and rewetting cycles. They are flooded in the summer, drained for fall harvesting, and flooded in the winter to speed decomposition of rice straw and organic residue.

In the Yolo Bypass, CA, permanent and agricultural wetlands were sampled over the course of a growing season, June 2007–April 2008. About 10% of the 105 water samples taken over that time period exceeded the U.S. EPA Hg water quality criterion of 50 ng total Hg/L, and total Hg was higher in the center and outflow of agricultural wetlands than in permanent wetlands ([Alpers et al., 2014](#)).

Across the wetlands, all of the water samples taken for MeHg determination exceeded the San Joaquin Delta regulatory total maximum daily load (TMDL) limit of 0.06 ng MeHg/L. In fact, MeHg concentrations in all water samples exceeded 1 ng/L, with maximum measured water MeHg of 37 ng/L at the outlet of wild rice fields during harvest. Water MeHg concentrations were significantly higher, about twice as high, in the agricultural fields as in the permanent wetlands ([Alpers et al., 2014](#)), and sediment MeHg concentrations were also higher in the agricultural wetlands ([Marvin-Dipasquale et al., 2014](#)). The water MeHg fraction ranged from 1–80%, with a median value of 6.4%, and there were seasonal variations in agricultural but not permanent wetlands. In agricultural wetlands, the MeHg fraction increased 20 times between June and August in fields where white or wild rice was grown, and the MeHg fraction increased 5 times in fallow fields over the same time period ([Alpers et al., 2014](#)).

Hg methylation in the permanent and agricultural wetlands of the Yolo Bypass, CA correlated with S, Fe, and manganese (Mn) reduction. The strongest correlations of MeHg fraction in the wetlands were with metrics of Mn reduction, not reduction of Fe or S ([Alpers et al., 2014](#)). Sulfate was not a limiting factor of Hg methylation in the wetlands, although  $\delta^{34}\text{S}$  and sulfate:Cl in outlet waters indicated that sulfate reduction occurred in the wetlands, with at least 20% of the sulfate in the water column reduced ([Alpers et al., 2014](#)). In agricultural wetland sediments, mineralization of C by iron reduction was 2.4 times the mineralization of C by sulfate reduction, indicating that Fe reduction was more important than S reduction in terms of anaerobic decomposition ([Marvin-Dipasquale et al., 2014](#)). Furthermore, addition of sulfate fertilizer in rice fields did not raise measured sulfate reduction rates to the higher levels observed in fallow, unfertilized fields, indicating that sulfate was not a limiting factor on anaerobic microbial activity in the agricultural wetlands ([Alpers et al., 2014](#); [Marvin-Dipasquale et al., 2014](#)).

In the Yolo Bypass, CA, seasonal wetland export of MeHg occurs during the winter as well as the summer. In the summer, newly methylated MeHg is drawn into the root zone of the sediment by plant transpiration, and in winter, diffusion releases MeHg from the sediment into the water column ([Bachand et al., 2014](#)). The short-term storage of MeHg in wetland soils decreases MeHg exports from the wetland, but increases exposure of wetland fish to MeHg ([Windham-Myers et al., 2014b](#)). Also, MeHg in rice seeds were correlated with root MeHg ( $r = 0.90$ ), suggesting that MeHg from the root zone may be

transported through the plant to tissues that are consumed by migrating waterfowl ([Windham-Myers et al., 2014a](#)). Research in other systems has shown that MeHg produced in sediments is transported to rice grains ([Paranjape and Hall, 2017](#)). In a study of rice paddies surrounding industrial emitters of SO<sub>x</sub> and Hg in Hunan Province, China ([Xu et al., 2017a](#)), MeHg and %MeHg in rice grains were positively correlated with soil S, soil MeHg, and atmospheric concentrations of gaseous elemental Hg. MeHg in rice fields and in rice grains may be an important pathway to human and wildlife Hg exposure via rice consumption.

Evidence from fish Hg levels in different wetland types suggests that fluctuating water levels in the agricultural fields, as well as high levels of organic carbon from winter decomposition of rice straw, raise Hg methylation rates in the rice fields above rates in the permanent wetlands. Mercury concentrations of penned *Gambusia affinis* (mosquitofish) rose 12 times over initial concentration in white rice fields, 5.8 times in wild rice fields, and 2.9 over initial fish Hg concentration in the permanent wetlands ([Ackerman and Eagles-Smith, 2010](#)), and these trends were similar to Hg concentration trends in wild mosquitofish and *Menidia audens* (Mississippi silversides) caught in the wetlands. However, trends of Hg concentrations in macroinvertebrates did not follow trends in fish. There was no difference by wetland type (permanent, white rice, wild rice) in Hg concentrations of collected water boatmen, *Corisella* spp., which feed on plant and algal biomass. Hg concentrations in collected backswimmers, *Notonecta* spp., which are predatory, were higher in collections from permanent wetlands than in collections from cultivated rice wetlands ([Ackerman et al., 2010](#)).

---

### 12.3.5 Drivers of Mercury Methylation under Ambient Conditions

The 2008 ISA presented evidence that elevated sulfate concentrations increased MeHg concentrations in aquatic and wetland ecosystems. At the time, most studies documenting this relationship were conducted in lakes and wetlands, and sulfate was often added experimentally to test the mechanisms of the relationship. Since then, a number of new studies have shown that increases in ambient sulfate concentrations can produce increased MeHg concentrations in surface water and sediments in lakes and wetlands (as well as increased Hg in wildlife, see [Appendix 12.4](#)). In addition, there is new evidence that increased sulfate in rivers, streams, and watersheds increase Hg methylation. Not all studies include information about the form or relative contribution of S sources in these ecosystems, but the studies provide evidence that current concentrations of surface water sulfate contribute to Hg methylation in a broad range of American aquatic and wetland ecosystems.

The 2008 ISA described watersheds with low pH waters and high wetland cover as sensitive to Hg methylation but did not describe MeHg fraction in the environment as an indicator of Hg methylation. MeHg is bioavailable and bioaccumulates within organisms due to the strong complexes it forms with thiosulfate and sulfhydryl groups in organic molecules. The fraction of total Hg that is in the form of MeHg (or %MeHg) is used as an indicator of bioavailable Hg within an ecosystem. New studies (as well as key older studies) of MeHg fractions in watersheds, streams, lakes, and wetlands show the link between S deposition and MeHg fraction in water and sediments, and confirm the importance of wetlands and nonurban watersheds as sources of MeHg to aquatic ecosystems.

---

### 12.3.5.1 Sulfur in Ambient Conditions

Aquatic and wetland ecosystems which have received high loads of S generally have higher MeHg fractions. In sampling of Little Rock Lake and four nearby lakes in Wisconsin, MeHg fractions in lake water ranged from 6–25% MeHg, with no relationship to pH ([Bloom et al., 1991](#)). In the Adirondacks, which have historically experienced high S deposition (see case study), surface water total Hg, MeHg, and %MeHg were unrelated to pH when all variables were measured across 44 lakes in 2003–2004. Surface water MeHg ranged from 0–48% MeHg, with a mean of 6% ([Yu et al., 2011](#)).

At the time of the 2008 ISA, only one paper had considered the links between measures of SO<sub>x</sub> deposition and MeHg concentrations in ecosystems. Since then, two additional papers have been published documenting the effects of SO<sub>x</sub> deposition on Hg levels in water or fish ([Table 12-9](#)). The large scale and scope of these studies include confounding and interacting environmental factors, such as correlated Hg deposition and variations in wetland cover, the full effects of which researchers are unable to fully quantify. Despite this limitation, each of these papers show evidence of temporal or spatial correlations between SO<sub>x</sub> deposition and MeHg concentrations in fish or water.

**Table 12-9 New studies on correlations between sulfur (S) and methylmercury (MeHg) in ecosystems.**

Type of Ecosystem	Additions or Load (kg S/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
River and reservoir	S addition or deposition not reported [SO <sub>4</sub> <sup>2-</sup> ] in Rio Grande: pore water: (means) 74–230 mg/L; deep water: (range) 152–342 mg/L [SO <sub>4</sub> <sup>2-</sup> ] in Devils River: pore water: (means) 74–230 mg/L; deep water: (range) 15–168 mg/L	Sediment MeHg (ng/g) correlated negatively with pore water sulfate concentrations. RG had 40% higher THg than DR. DR sediment MeHg was 65% higher than in RG sediment, and DR sediment %MeHg was 65% than in RG sediment. A study of fish and SO<sub>x</sub> deposition sediment records at Isle Royale in Lake Superior indicated a temporal relationship in this remote location between S deposition and Hg loads in fish. Isle Royale is a Class I area and contains several lakes impacted by S and Hg deposition. Between 1981 and 2006, S deposition in the region fell 40–60% (from about 10 kg S/ha/yr in 1981 to about 6 kg S/ha/yr in 2006 at NADP site MN18 in mainland Minnesota), while Hg deposition remained stable. S deposition on the island between 1985 and 2006 was in the range of 2.3 to 7 kg S/ha/yr with a trend (*p* = 0.09) toward a decline in deposition over that time period ([Drevnick et al., 2007](#)). Fish collections were conducted in eight Isle Royale lakes in 1995–1996 and again in 2004–2006. In six lakes, 1995 collections of northern pike (*Esox lucius*) exceeded the U.S. EPA fish tissue Hg limit (0.3 µg Hg/g wet weight). When these lakes were resampled in 2004–2006, northern pike mean Hg levels were below the U.S. EPA limit,

which the authors attributed to a decline in SO<sub>x</sub> deposition despite steady Hg deposition. This study also used museum collections of fish from Isle Royale (collected in 1905, 1929, 1966) and an analysis of lake sediment cores to test the relationship between historical S loads and fish Hg burdens. The chromium-reducible sulfur (CRS) fraction in sediment cores was determined to closely track known patterns of S deposition since monitoring began in 1985, allowing the inference of S loads to island lakes since the Industrial Revolution in the late nineteenth century. The historical S load data were compared to Hg loads in both the historical and recent fish collections from Isle Royale lakes. The CRS fraction explained 79% of the variation in Hg concentration of northern pike fish fillets. There were similar correlations between sediment reduced S and Hg burden in other fish species, but sample sizes for those species were low and correlations were not statistically significant ([Drevnick et al., 2007](#)). DOC and pH were not directly tested for their relationship with Hg levels in fish, but the authors note that there are no significant trends in DOC or pH in these lakes from 1980–2006. This study showed that Hg fish burdens increased in Isle Royale lakes with increasing SO<sub>x</sub> deposition in the twentieth century, and that Hg fish burdens declined in response to reductions in SO<sub>x</sub> deposition since the 1990s.

The other two studies that find effects of SO<sub>x</sub> deposition are summarized in the following sections. A 12-year study of MeHg and fish Hg in Voyageurs National Park found that declines in SO<sub>x</sub> deposition have resulted in MeHg declines only in lakes where DOC has remained stable (see [Appendix 12.3.5.3](#)). A study that compiled data from reservoir fish sampling in Texas found correlations between geographic variations in SO<sub>x</sub> and Hg deposition and average fish Hg burden over 25 years (see [Appendix 12.3.5.2](#)).

Sampling at small scales within peatlands has shown positive relationships between sulfate concentrations and MeHg concentrations ([Table 12-9](#)). In two peatlands at the Marcell Experimental Forest, MN, researchers monitored water quality at the upland-peatland interface, hypothesized to be an important zone for methylation due to labile carbon inputs in runoff from terrestrial communities to the peatland microbial community. Sulfate peat pore water concentrations ranged from 0–20 mg sulfate/L, and MeHg concentrations increased 0.037 ng/L for each 1 mg/L increase in sulfate ([Mitchell et al., 2009](#)). The relationship between sulfate and MeHg is also significant at a larger spatial scale in the same region. Across four peatlands at the temperate-boreal boundary in Minnesota and Ontario, MeHg was positively correlated with sulfate in peat pore water (Spearman's  $R = 0.237$ ) as well as with pH during the 2005 growing season ([Mitchell et al., 2008b](#)). The range of median sulfate levels in these peat bogs during the course of the study was 0.01–3 mg/L, while the range of MeHg concentrations was 0.35–0.62 ng MeHg/L ([Mitchell et al., 2008b](#)).

The South River in Waynesboro, VA, was contaminated by historical (1929–1950) textile industrial use and release of Hg. In 2008, sediments were collected within the channel at 10 study sites at increasing distances downstream of the historic Hg source. MeHg concentrations in the sediment increased linearly with increasing sediment pore water sulfate concentrations, with a 0.06 ng increase in MeHg per gram of sediment for every 1 mg/L increase in sulfate pore water concentration, with mean pore water sulfate concentrations ranging from 2–16 mg/L ([Yu et al., 2012](#)).

Chemical constituents measured at watershed outflows represent the cumulative microbial and abiotic chemical transformations within the watershed. A watershed in which SRPs are present will therefore have higher MeHg and lower sulfate concentrations in its outflow than an adjacent watershed without active SRPs that experiences the same S and Hg deposition loads. Many of the following studies document inverse relationships between sulfate concentrations and MeHg concentrations in outflows of trunk streams (those that drain an entire watershed) where sulfate and Hg concentrations reflect upstream sulfate stimulation of SRPs and Hg methylation. In a tributary stream draining a wetland in Wisconsin, there were seasonal trends in sulfate and MeHg concentrations indicative of wetland Hg methylation. Sulfate in the stream declined 80% between April and June 2003, indicating S immobilization or reduction in the wetland during the early summer, and MeHg increased 69% over the same time period ([Watras and Morrison, 2008](#)). This increase in MeHg and simultaneous decrease in sulfate in stream water concentrations suggests upstream activity of SRB in Hg methylation.

In streams draining wetlands in the Archer Creek watershed in the Adirondack Mountains, NY, water sulfate concentrations were lower than in streams upstream of the wetlands ([Selvendiran et al., 2008a](#)). Wetland microbial communities reduced sulfate while methylating Hg, which would account for the elevated MeHg concentrations in wetland-draining streams compared to upland streams. There was a negative correlation between sulfate concentrations and MeHg concentrations in streams draining the wetlands where Hg methylation occurred, with a 0.11 ng/L increase in MeHg concentrations in the stream for each mg/L sulfate removed from surface water ([Selvendiran et al., 2008a](#)). [Selvendiran et al. \(2009\)](#) measured and calculated Hg budgets for the adjacent watersheds of Arbutus Lake and Sunday Lake in the Adirondacks, NY, measuring inlet and outlet streams at both water bodies as well as lake surface water at Arbutus. Across both watersheds, MeHg concentrations were inversely correlated with sulfate concentrations. This pattern was driven by the concentrations measured in the streams in Sunday Lake, which drains a watershed that is approximately 20% wetlands ([Selvendiran et al., 2009](#)), indicating that SRB in upstream wetlands may have been reducing sulfate and methylating Hg to impact the measured stream surface water.

Arbutus Lake drains a watershed of which wetlands comprise only 4% of surface area, which may explain the relatively higher sulfate concentrations and the lower mean and variability of MeHg (Selvendiran et al., 2009). In watersheds where S and Hg deposition rates do not differ spatially, negative correlations between sulfate concentrations and MeHg show the link between sulfate reduction and Hg methylation.

Highly elevated sulfate concentrations, as can result from agricultural runoff, can depress SRP activity and Hg methylation, as sulfide produced by SRPs accumulates and downregulates SRP activity. In a sampling study of the Amistad International Reservoir on the Texas-Mexico border, Hg pools in sediment, water, and largemouth bass (for more on this endpoint, see [Appendix 12.4](#)) were quantified and compared between the Rio Grande and Devils River branches of the reservoir. The Rio Grande branch had sulfate concentrations an order of magnitude higher (site with highest sulfate concentration: 230 mg/L sediment pore water), as well as 40% higher total Hg pools in sediments, than did the Devils River branch [site with highest sulfate concentrations: 23 mg/L ([Becker et al., 2011](#))]. However, total Hg and sulfate were negatively correlated with MeHg, and SRB (researchers used techniques to detect bacterial sulfur reducers) were present at all sites. Hg methylation in this system was not limited by Hg supply or biota and was not stimulated by the Rio Grande's high sulfate levels, originating from agricultural land use in the watershed. The Devils River branch had 65% higher MeHg concentrations in sediments, and a 230% higher proportion of total sediment Hg in the form of MeHg ([Becker et al., 2011](#)). [Becker et al. \(2011\)](#) posited that the higher MeHg in Devils River sediments was due to higher DOC in this area of the reservoir and to sulfate concentrations (in sediment pore water, 2.5–23 mg/L) being optimal for the metabolism of SRB.

Two wetlands in the St Louis River Watershed, MN, were the subject of a study of Hg and S because one wetland regularly receives high-sulfate mine effluent ([Johnson et al., 2016b](#)). Peat %MeHg increased with S reduction (quantified as pore water sulfide or soil acid volatile sulfide) in the wetland that did not receive mine effluent, and in which surface water sulfate concentrations averaged less than 5 mg/L. In wetlands that received sulfate mine effluent of >500 mg  $\text{SO}_4^{2-}$ /L, peat %MeHg decreased with increasing S reduction. Together, these results support the model of methylation first proposed for the Everglades [see [Figure 12-7](#), and [Glimour \(2011\)](#)], in which there is a net methylation optimum at low moderate sulfate concentrations (1–10s of mg  $\text{SO}_4^{2-}$ /L) and a suppression of net methylation at high sulfate (100s of mg  $\text{SO}_4^{2-}$ /L) and sulfide (0.6–0.7 mg S/L in pore water) concentrations ([Johnson et al., 2016b](#)).

In contrast, in the St. Denis National Wildlife Area in Saskatchewan, Canada, prairie potholes vary in sulfate concentrations in relation to geology and position in the

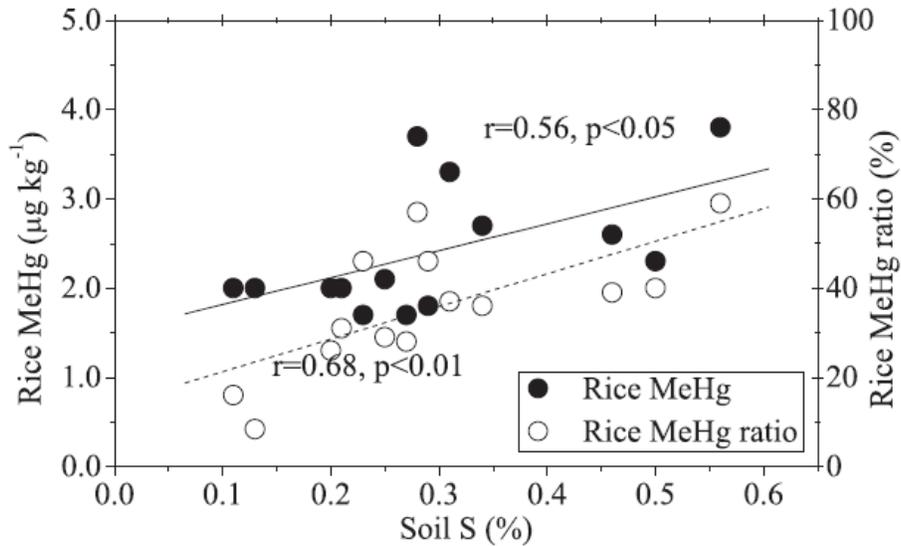

landscape. In a study of water MeHg, five upland ponds had average sulfate concentrations of 1,490 mg/L (S sources are geologic), and four lowland ponds had average sulfate concentrations of 14 mg/L ([Hoggarth et al., 2015](#)). MeHg fraction was 185% higher in surface water and 205% higher in sediments in the upland ponds than in the lowland ponds, which had lower sulfate concentrations ([Hoggarth et al., 2015](#)).

---

### 12.3.5.2 Mercury and Sulfur Interactions in Ambient Conditions

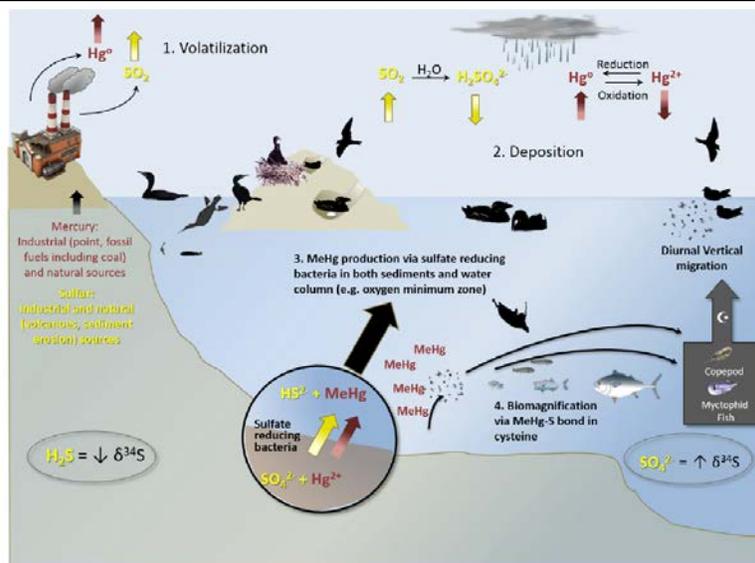

It can be difficult to tease apart the effects of Hg and SO<sub>x</sub> deposition upon mercury methylation rates or concentrations of MeHg in biota, because at some scales, Hg and SO<sub>x</sub> emissions are correlated ([Figure 12-11](#), [Figure 12-12](#), and [Table 12-10](#)). In a small-scale (15 km, single sampling event) gradient study of Hg, MeHg, and S downwind of a coal plant and other industrial sources in China ([Xu et al., 2017a](#)), soil S and gaseous elemental Hg (GEM) were positively correlated, with effects upon cultivated rice. In surrounding rice paddies, MeHg and %MeHg in rice grains were positively correlated with soil S, soil MeHg, and atmospheric concentrations of gaseous elemental Hg ([Figure 12-11](#)).

Regionally, Hg and S depositions were correlated in Texas ([Drenner et al., 2011](#)) and atmospheric reactive Hg and SO<sub>2</sub> were correlated in the Ohio River valley ([Yatavelli et al., 2006](#)). At a national or international spatial scale, different factors govern long-range transport and deposition of SO<sub>x</sub>, PM, and Hg, so S deposition and Hg deposition may not be spatially correlated. However, at a longer temporal scale, Hg and S deposition have declined in concert over the past decades in the U.S. [U.S. emissions of Hg declined 79% and SO<sub>2</sub> emissions declined 73% between 1990 and 2011 ([U.S. EPA, 2017a](#))]. Temporal and spatial correlations between Hg and S emissions and deposition make it difficult to distinguish between Hg and SO<sub>4</sub><sup>2-</sup> as the limiting factor in ecosystems receiving high deposition.

CT = Cross Timber; ECTP = East Central Texas Plains; ha = hectare; kg = kilogram; MeHg = methylmercury; NADP = National Atmospheric Deposition Program; S = sulfur; SCTP = South Central Texas Plains; SO<sub>4</sub><sup>2-</sup> = sulfate; SO<sub>x</sub> = sulfur oxides; TBP = Texas Blackland Prairie; yr = year.

A study that compiled data from reservoir fish sampling in Texas found correlations between geographic variations in SO<sub>x</sub> deposition and average fish Hg burden over 25 years. Largemouth bass (*Micropterus salmoides*) were collected between 1985 and 2009 with heavy sampling between 2004 and 2008 (45% of the samples) from 145 reservoirs in eastern Texas. The samples were grouped and analyzed by Level 3 ecoregions which received varying amounts of Hg and S deposition, increasing from the westernmost Cross Timber region where S deposition was 7.7 kg/ha to the easternmost South Central Plains region where S deposition was 11.9 kg/ha ([Drenner et al., 2011](#)). The South Central Plains region received high deposition of SO<sub>x</sub> and Hg, and also had the highest percentage of land area as wetlands (12%) and the lowest percentage of land area in agriculture of the four regions, all of which are conducive to high methylation rates in aquatic ecosystems. Mean Hg levels in sampled largemouth bass were 61–89% higher in the South Central Plains than in other eastern Texas regions ([Drenner et al., 2011](#)). These results have regional implications because the South Central Plains ecoregion extends into Arkansas, Louisiana, and Oklahoma. This study showed that within Texas, the geographic region with the most wetlands and the highest SO<sub>x</sub> deposition also had fish with the highest Hg burden.

In the Adirondacks, a temporal study of water MeHg, water sulfate concentrations, and mercury deposition reported no correlation between stream sulfate and MeHg (as concentration or as %MeHg) in the summer when SRB are active, in lake data collected in 2004–2005 ([Gerson and Driscoll, 2016](#)). Over the decade in which these data were collected, Hg<sup>0</sup> atmospheric concentration and deposition in the watershed, litter Hg concentration, and sulfate concentrations in streams all declined in this system; [Gerson and Driscoll \(2016\)](#) suggested that decreases in surface water MeHg in the watershed were attributable to decreased Hg deposition, and that surface water sulfate concentration over the entire decade was so high in the lake that it did not control Hg methylation.

---

### **12.3.5.3 Organic Matter and Sulfur Interactions in Ambient Conditions**

There is evidence from recent research of interactions between organic matter and sulfur in controlling mercury methylation ([Table 12-11](#)). A 12-year study of MeHg and fish Hg in Voyageurs National Park found that declines in SO<sub>x</sub> deposition have resulted in MeHg declines only in lakes where DOC has remained stable. In lakes in Voyageurs National Park, MN, a Class I area, researchers measured MeHg in the epilimnion of four lakes between 2000 and 2012 and compared trends in lake water Hg concentrations with trends of measured Hg and S deposition ([Brigham et al., 2014](#)). S deposition to the region decreased 48% between 1998 and 2012 based on regression analysis of data measured at

National Atmospheric Deposition Program (NADP) stations MN16 and MN18, and Hg deposition decreased 32%. In two lakes, MeHg surface water concentrations decreased over 12 years of measurement, 50% in Peary Lake and 43% in Ryan Lake ([Brigham et al., 2014](#)), and fish Hg concentrations followed suit (see [Appendix 12.4](#)). In contrast, Brown Lake MeHg concentrations increased 85% over the same time period, which the authors ascribed to increasing inputs from upstream methylating aquatic environments. An alternative explanation may be in the differences between lakes in dissolved organic carbon (DOC) concentrations; in Peary and Ryan Lakes, DOC concentrations remained flat over the decade in which MeHg concentrations decreased, while in Brown Lake, DOC concentrations increased 30% ([Brigham et al., 2014](#)). *Perca flavescens* (yellow perch) were collected between 2000 and 2012 to determine fish Hg levels in comparison with Hg lake water trends and S deposition. Between 2000 and 2012, *P. flavescens* Hg concentrations decreased 37% in Peary Lake and 32% in Ryan Lake, just as S deposition and lake MeHg declined ([Brigham et al., 2014](#)). In Brown Lake, where DOC increased 30% over the same time period, *P. flavescens* Hg increased 80% ([Brigham et al., 2014](#)). In Voyageurs National Park, lakes with stable DOC responded to decreased S deposition with decreasing MeHg in water and Hg concentrations in fish.

There is evidence from recent research that higher sulfate concentrations correspond to higher MeHg concentrations and sulfate reduction rates in prairie potholes. Prairie potholes are shallow wetlands and lakes in depressions created by glaciation, which depend upon snowmelt and precipitation for their water supply and tend to be hydrologically isolated. A survey of prairie pothole wetlands and lakes in Saskatchewan measured Hg levels in water. Surface water MeHg correlated positively with sulfate concentrations and negatively with conductivity and specific ultraviolet absorbance (SUVA; an indicator of aromatic fraction of DOM), such that surface water MeHg increased 0.03 ng/L for each mg/L increase in sulfate concentrations, when all other factors remained constant ([Hall et al., 2009a](#)).

In wetlands in the Allequash Watershed, WI, potential methylation rates in streambed sediments were positively correlated with microbial sulfate reduction (quantified as sediment acid volatile sulfide,  $r^2 = 0.258$ ), DOC, and reduced iron ([Creswell et al., 2017](#)). These correlations reflect the activity of methylating SRB, IRB, and methanogens, which shift in dominance spatially and seasonally across the wetland streams (see [Appendix 12.3.2](#)). Hg concentrations did not correlate with mercury methylation in this system ([Creswell et al., 2017](#)). The total dissolved S and sulfide fraction did not correlate with methylation rate, suggesting that sulfate was not a limiting factor, and that DOC was probably the main driver of methylation in this system.

**Table 12-11 New studies of Interactions between organic matter and sulfur (S) in Controlling methylmercury (MeHg).**

Type of Ecosystem	Additions or Load (kg S/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Lakes	6.44 kg S/ha in 1998, 3.35 kg S/ha in 2012 as quantified by NADP sites MN16 and MN18	As SO <sub>x</sub> deposition decreased 48% in 1998–2012, water MeHg decreased 50% in Peary Lake and 43% in Ryan Lake. In Brown Lake, water MeHg increased 85% in 1998–2012.  Between 2000 and 2012, Hg concentration in <i>P. flavescens</i> decreased 37% in Peary Lake and 32% in Ryan Lake, and increased 80% in Brown Lake. Lakes and wetlands	Not reported	Surface water MeHg was positively correlated with sulfate concentrations: ng MeHg/L = $-2.94 - 0.44$ (conductivity) + $0.303(\text{SO}_4^{2-}) - 0.268$ (aromatic fraction of DOM).	49 lakes and wetlands, prairie pothole region, Saskatchewan, Canada	Lake water	<a href="#">Hall et al. (2009a)</a>
Artificial reservoir	Concentrations ranged from 3–12 mg/ L SO <sub>4</sub> <sup>2-</sup>	Strong correlation noted between sulfate and chlorophyll a ( $r = 0.73$ ), DOC ( $r = 0.92$ ), and conductivity ( $r = 0.83$ )	Reservoirs in South Korea	Surface water	<a href="#">Noh et al. (2016)</a>

Reservoirs have been identified as sources of MeHg. Cottage Grove Reservoir, OR, was built for flood control and experiences large, seasonal fluctuations in water levels. Hg and MeHg dynamics differ between permanently flooded portions of the reservoir and areas that are inundated during summer months ([Eckley et al., 2017](#)). When the reservoir was flooded in the spring, sulfate, inorganic Hg, and DOC were released in high concentrations from previously exposed sediments, creating zones of high mercury methylation in seasonally inundated sediments. Across nine reservoirs in South Korea, algal blooms stimulated methylation of mercury. Algal blooms released large pulses of labile C, as demonstrated by a positive correlation of Chl *a* and DOC [ $r = 0.73$ ; [Noh et al. \(2016\)](#)]. Sulfate concentrations ranged from 3 to 12 mg/L, and also correlated with DOC ( $r = 0.92$ ). Concentrations of MeHg and %MeHg were positively correlated with Chl *a*, DOC, and sulfate across reservoirs.

---

#### 12.3.5.4 pH and Sulfur Interactions in Ambient Conditions

Sulfate deposition is not the primary driver of MeHg concentrations in every ecosystem with elevated Hg concentrations in its biota. In Wallowa-Whitman National Forest, OR and ID, fish Hg sampled in high-elevation lakes in 2011 correlated positively with basal area of conifers in the lake catchment and correlated negatively with lake area, surface water  $\text{SO}_4^{2-}$ , and DOC ([Eagles-Smith et al., 2016](#)). This study did not test microbial methylation rates or community composition, but lakes with low  $\text{SO}_4^{2-}$  and low DOC were acidified, as quantified by pH measurements. [Eagles-Smith et al. \(2016\)](#) interpreted model results to show that acidification of lakes had negative effects upon fish condition and resulted in high Hg bioaccumulation, with conifer-forested catchments most at risk. In Kejimikujik National Park, Nova Scotia, regressions and model selection of Hg in biota against  $\delta^{34}\text{S}$ ,  $\delta^{13}\text{C}$ , and  $\delta^{15}\text{N}$  suggested that lake productivity was a stronger driver of Hg in biota than sulfur reduction (indicated by enrichment of  $\delta^{34}\text{S}$ ), which was negatively correlated with Hg in lake biota ([Clayden et al., 2017](#)). The lakes in this study are unstratified, shallow and acidic, with S deposition enriched in  $\delta^{34}\text{S}$  from nearby marine waters, all conditions unfavorable to sulfate-reducing bacteria. [Clayden et al. \(2017\)](#) suggested that microbial methylators not utilizing sulfate are responsible for producing MeHg in these lakes, and that trophic interactions are responsible for variations in Hg in biota across lakes.

---

#### 12.3.5.5 Nutrient Enrichment Effects on Methylmercury (MeHg)

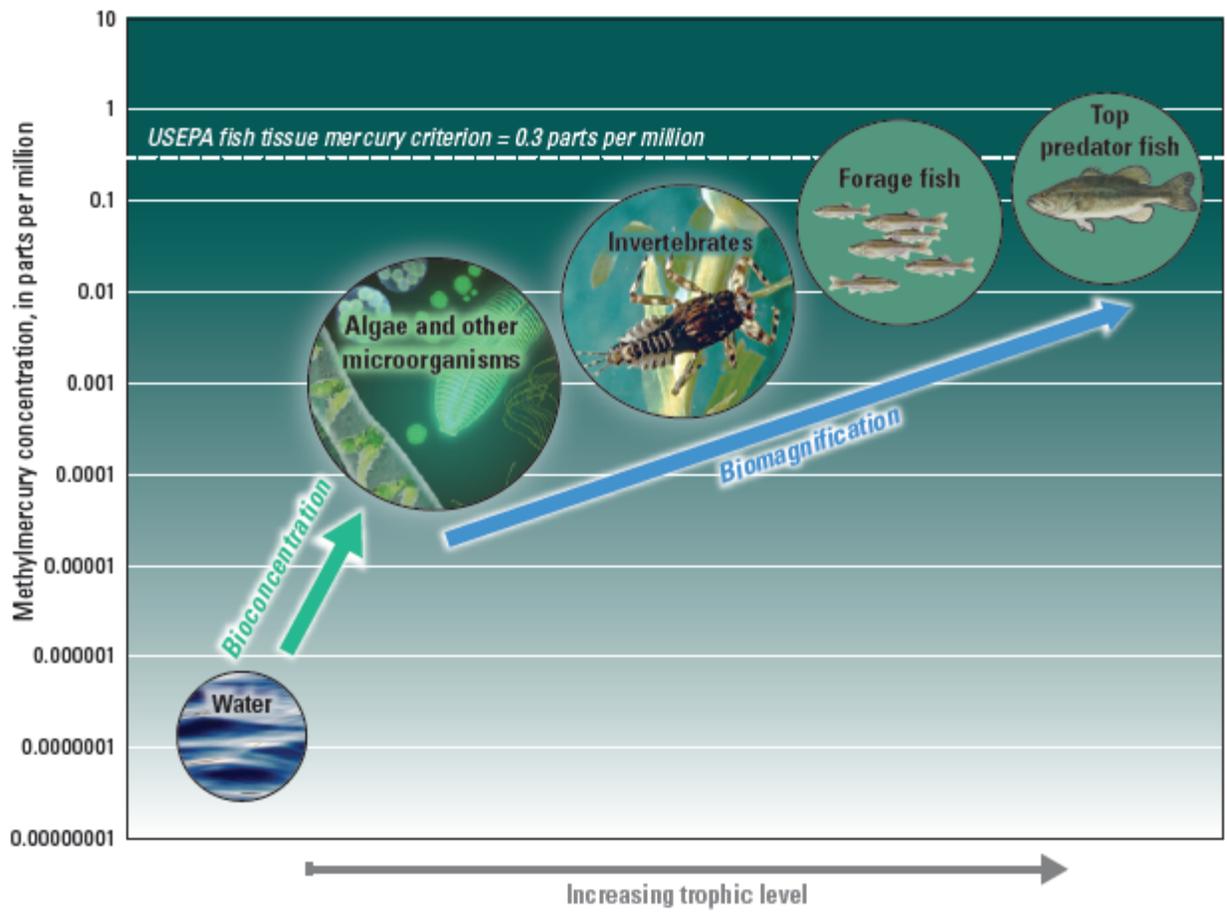

Nutrient availability—the relative availability of nitrogen (N) and P as well as of S—can impact MeHg fraction, with low or intermediate levels of nutrients most conducive to

higher MeHg across two very different nutrient gradients. In seven wetlands across a nutrient gradient in Sweden, total Hg was 113–287 ng/g in soils, MeHg was 3.5–21 ng/g in soils, and the highest MeHg fraction was 16%. Potential methylation rate constants and MeHg fractions were highest in wetlands with an intermediate nutrient status ([Tjerngren et al., 2012](#)). N and P concentrations have also been implicated as contributing to variation in Hg methylation rate in the Everglades (see [Appendix 12.3.4.3](#)).

---

## 12.4 Sulfur Impacts on Mercury in Wildlife

Mercury has no known beneficial property in living cells. MeHg is bioconcentrated by living cells, in which it forms strong bonds with thiosulfate and sulfhydryl groups in organic compounds. It is common for MeHg to be present at progressively higher concentrations up the trophic level of food chains, as MeHg consumed is remarkably persistent ([Figure 12-13](#)). A recent report by the USGS reviews the known effects of Hg on wildlife. Fish and birds experience negative physiological and reproductive effects at Hg levels below the 0.3 ppm tissue level set by the U.S. EPA to protect human health ([Wentz et al., 2014](#)). There are a number of new studies on the effects of sulfur upon Hg in wildlife ([Figure 12-12](#)).

Note logarithmic scale of y-axis. The top and bottom of each circle represent the range of measured methylmercury concentrations from streams in Oregon, Wisconsin, and Florida sampled during 2002–2006, and in New York and South Carolina sampled during 2007–2009.

Bog	Ambient S deposition: 5.5 kg/ha/yr (mid 2000s) as quantified by NADP Station MN16 S addition: 32 kg S/ha/yr dissolved in pond water and delivered by sprinklers (mimics 4x the 1990s deposition rate)	Hg levels in <i>Culex</i> spp. increased 126%. <i>Culex</i> spp. Hg was 41% lower in recovery treatment than under SO <sub>4</sub> <sup>2-</sup> treatment, but still 34% higher than control.	S6 peatland, bog section, Marcell Experimental Forest, MN	Pore water, peat, and <i>Culex</i> spp. (mosquito) larvae	<a href="#">Wasik et al. (2012)</a>

DR = Devils River; ha = hectare; Hg = mercury; kg = kilogram; L = liter; mg = milligram; NADP = National Atmospheric Deposition Program; RG = Rio Grande; S = sulfur; SO<sub>4</sub><sup>2-</sup> = sulfate; yr = year.

S deposition affects the production and net amount of MeHg in water bodies, increasing accumulation of Hg up the food chain ([Table 12-12](#)) but not affecting the rates at which Hg is transferred between trophic levels. Early work by [Bloom et al. \(1991\)](#) in seepage lakes of varying pH in the Northern Highland Lake District, WI, considered whether varying deposition would affect the rates at which MeHg accumulates in biota. The authors sampled five lakes with common geology but a range of pH (5.1–7.2, including the experimentally acidified north basin of Little Rock Lake), which the authors ascribed to varying acidic deposition loads. The fraction of Hg was higher in *Perca flavescens*, yellow perch, than in seston, reflecting bioaccumulation of MeHg at higher trophic levels, but there was no detected effect of pH (and by extension, S deposition load) on relative bioaccumulation across lakes ([Bloom et al., 1991](#)). In Dickie Lake, Ontario, early studies documented the biomagnification of Hg in higher trophic levels of the lake. MeHg concentrations were 0.2 ng/g in sediments; Hg concentrations were 56.5 ng/g in periphyton, 143 ng/g in *P. flavescens*, and 703 ng/g in *Micropterus* spp. [largemouth and smallmouth bass, ([Kerry et al., 1991](#))]. Sulfate effects on biomagnification were not documented in these studies, although sulfate was measured at 6–8 mg/L in lake water, and microbial sulfate reduction and Hg methylation within the lake sediments were demonstrated with sediment slurry incubations ([Kerry et al., 1991](#)). There is evidence from 44 Adirondack lakes sampled in 2003–2004 that the legacy of acidic deposition, low surface water pH, low ANC, and high aluminum concentrations, all correlated with increasing Hg concentrations in zooplankton and Hg body burdens in fish and loons ([Yu et al., 2011](#)). Because these factors did not affect Hg or MeHg concentrations in water, [Yu et al. \(2011\)](#) concluded that acidic lake conditions enhanced bioaccumulation of MeHg.

Experimental S addition studies demonstrate that S addition increases Hg burdens in different trophic levels. Little Rock Lake, WI was the site of a multiyear (1985–1990), progressively acidic S addition study, in which the basins of this lake were separated by a plastic barrier, allowing the northern half to be experimentally acidified while the southern half served as a control. Abiotic compartments and biota of the lake were intensively sampled during the course of the experiment. Aqueous MeHg concentrations were 2 times higher in the treatment basin, while zooplankton MeHg concentrations (ng/g) were 1.8 times higher and microseston MeHg concentrations were 2.75 times higher in the treatment than the control basin ([Frost et al., 1999](#); [Watras and Bloom, 1992](#)). S amendment also affected MeHg in *Perca flavescens* (yellow perch); MeHg concentrations were 12–100% higher in 1-year-old yellow perch from the treatment basin, and the annual mean burden ( $\mu\text{g MeHg/fish}$ ) was 16–214% higher in the treatment basin over 5 of the 6 years of the experiment ([Frost et al., 1999](#); [Wiener et al., 1990](#)).

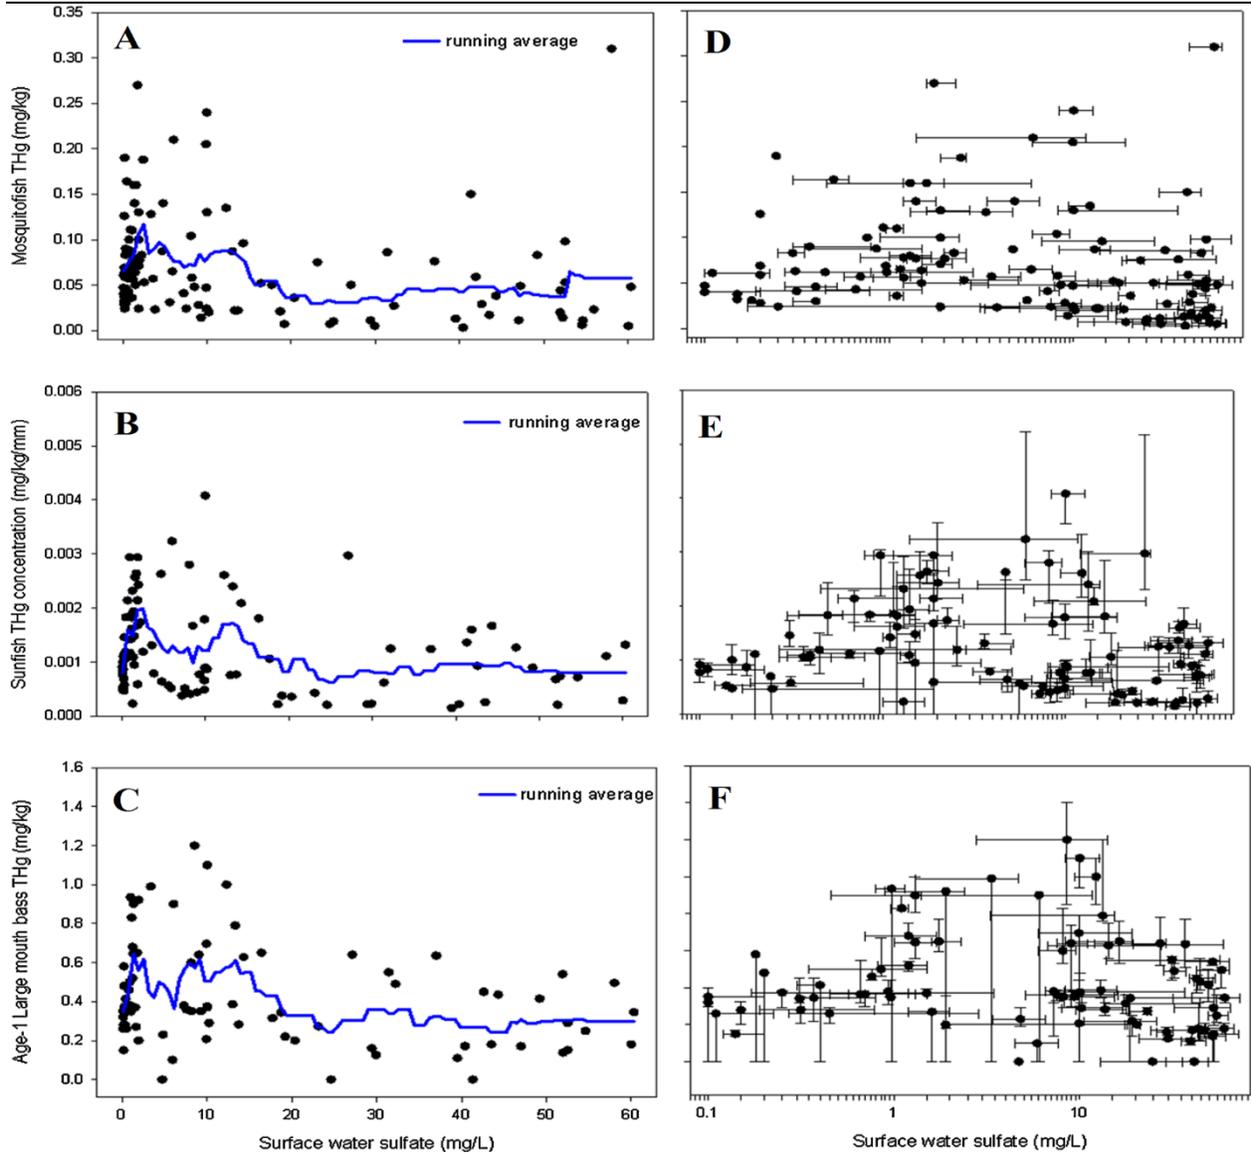

Decreasing S loads result in decreased Hg burdens in biota. The S addition experiment at the Marcell peat bog also shows the effects of S addition on Hg burdens in an animal on a lower trophic level. In the S addition and S recovery experiments at the S6 peat bog, Marcell Experimental Forest, MN, elevated S increased Hg levels in sampled *Culex* spp. (mosquito) larvae. Mosquito larvae are important to consider as a food source because they are widely consumed by invertebrate predators, fish, amphibians, and birds. In spring 2009, mosquito larvae Hg was 126% higher in plots that had received 32 kg S/ha/yr addition for 9 years than in mosquito larvae from the control plots ([Wasik et al., 2012](#)). The recovery plots received 32 kg S/ha/yr from 2001–2006 and no S addition after 2006, and when these plots were sampled in 2009, *Culex* spp. (mosquito) larvae had Hg levels 34% higher in recovery plots than in control plot mosquitoes, indicating legacy effects of past S addition. However, recovery plot mosquito Hg concentrations were 41% lower than in mosquitoes from plots still receiving S additions, indicating that decreases in S addition will decrease biotic Hg concentrations ([Wasik et al., 2012](#)).

In stormwater treatment wetlands draining the EAA in Florida, sulfate concentrations have been elevated by agricultural runoff, and concentrations ranged from 39–110 mg/L between 2000 and 2007. Under these very high sulfate surface water concentrations, Hg levels (mg Hg/kg fish) in bioindicator fish species *Gambusia holbrooki* (mosquitofish) were negatively correlated with inflow water sulfate concentrations ([Feng et al., 2014](#)) because the higher end of the sulfate concentration range reached levels inhibitory to SRPs. In the Everglades Protection Area, where water sulfate concentrations were lower and ranged from 0–60 mg/L in surface water, relationships between sulfate and fish Hg levels were more complicated. *Gambusia* spp. (mosquitofish), *Lepomis* spp. (sunfish), and largemouth bass were sampled annually between 1998 and 2009 ([Gabriel et al.,](#)

2014). In all three fishes, Hg tissue concentrations increased between 0–1 mg sulfate/L in the water, and reached their highest tissue levels between 1 and 12 mg sulfate/L (see [Figure 12-14](#)). Based on these relationships, [Gabriel et al. \(2014\)](#) recommended a sulfate water standard of 1 mg/L. Two papers challenged this analysis and interpretation of the sulfate and fish Hg data. In a commentary, [Julian et al. \(2015\)](#) suggested that the variability in fish Hg levels was too high to correlate with sulfate concentrations, and in analyses of largemouth bass collected between 2005–2011, Hg concentrations in fish correlated with alkalinity, pH, and specific conductance as well as sulfate ([Julian and Gu, 2015](#)). [Gabriel et al. \(2015\)](#) responded to Julian’s commentary by highlighting the similarity of fish Hg patterns to documented MeHg water column concentrations in the Florida Everglades and suggested that sulfate reductions are the most efficient way to reduce Hg loads in fish because about 60% of the Everglades area has sulfate concentrations exceeding 1 mg/L ([Orem et al., 2011](#)). Using structural equation modeling, [Pollman \(2014\)](#) showed that sulfate was second only to periphyton MeHg concentrations in predicting Hg burdens in mosquitofish in the Everglades, although the relationships among predictive factors were complex and involved both direct and indirect effects.

A number of studies document Hg burdens in fish without also quantifying contributions of S to methylation, but other relationships between S and MeHg documented in the 2008 ISA suggest that the findings of these studies may be relevant ([U.S. EPA, 2008a](#)). In the Alabama River basin around Mobile, AL, there was no relationship across 52 sites in the watershed between Hg burdens in largemouth bass and MeHg fractions in sediments or water ([Warner et al., 2005](#)). However, a subset of seven of the sites were downstream of wetlands, and in these sites the bass Hg burden was positively correlated with watershed area ( $r^2 = 0.71$ ), indicating that wetlands may contribute to higher Hg burdens in fish as well as to higher MeHg concentrations in water ([Warner et al., 2005](#)). In a study of Hg burdens in South Dakota, [Stone et al. \(2011\)](#) analyzed water quality and fish samples from one impoundment and five natural lakes, and found a positive correlation ( $R^2 = 0.928$ ) between water sulfate measurements and Hg in piscivorous *Sander vitreus* (walleye). However, sulfate concentrations were not reported, and sulfate measurements and fish samples were not collected simultaneously, with a gap of up to 3 years between collection of fish and water samples. In the Amistad International Reservoir, Texas, elevated MeHg in sediments of one branch of the reservoir correlated with Hg accumulation in young (age: 0–3 years) largemouth bass. The Devils River area had elevated sediment MeHg compared to the Rio Grande area of the reservoir (see [Appendix 12.3.5.1](#)), and the length-standardized mean of muscle Hg was 38% higher in Devils River than in Rio Grande bass ([Becker et al., 2011](#)). Of 138 largemouth bass (age >3 years) line-caught at the reservoir in April 2007, 77% exceeded the U.S. EPA recommended human consumption value of 0.3 mg Hg/kg (or 0.3 ppm), and mean fish

Hg was 0.51 mg/kg fish, although fishing site data for these samples were unavailable, preventing assessment of connections between sediment MeHg and Hg levels in these large fish (Becker et al., 2011).

L = liter; kg = kilogram; mg = milligram; mm = millimeter; THg = total mercury.

Panels A–C show the running average of mercury concentrations in (A) *Gambusia* spp. (n = 484), (B) *Lepomis* spp. (n = 2,559), and (C) *Micropterus salmoides* (n = 679). Panels D–F show the same data with sulfate transformed to a log scale to better illustrate the peak in fish Hg concentrations that approximately corresponds to sulfate concentrations of 1–10 mg/L. Samples were collected from 12 fish and 12 sulfate stations within the Everglades, between 1998–2009.

## 12.5 Extent and Distribution of Sensitive Ecosystems

Reservoirs in which water levels fluctuate enough to expose sediments may be particularly susceptible to S deposition effects on MeHg production because mud flats are directly exposed to the atmosphere and then flooded to create conditions favorable to Hg methylation by SRPs. Older work in the ELA, Ontario, showed that reservoir creation leads to a pulse of MeHg production. A small watershed was flooded in 1993, and Hg and MeHg fluxes were measured over the next decade ([St.Louis et al., 2004](#)). Before flooding, 90% of the annual total Hg input and 130% of the annual MeHg was retained by the wetland. In the first 3 years following flooding, 100–170% of the annual total Hg input was exported annually; and in years 5–9, 69–79% of the annual total Hg input was exported annually. MeHg levels were high following flooding, 60–80% in water, and 300–860% of the annual MeHg input was exported annually from the reservoir ([St.Louis et al., 2004](#)). The reservoir creation also affected Hg in the food web: the level of MeHg in zooplankton was 7 to 10 times higher in the first 3 years of flooding, and 14 to 30 times higher years 4–9, than MeHg in pre-flood zooplankton ([St.Louis et al., 2004](#)). Researchers stocked finescale dace (current scientific name, *Chrosomus neogaeus*) annually and found that the Hg body burden of the fish increased 306% following a year in the reservoir ([St.Louis et al., 2004](#)). More recently, at the Cottage Grove Reservoir, OR, elevated MeHg concentrations in the fall outflow (4–13% MeHg fraction compared to 0.5–7% MeHg in the river flowing into the reservoir) were linked to seasonal water fluctuations ([Eckley et al., 2015](#)). The reservoir water level is lowered from September to February to allow the dam to catch and regulate spring flooding, so 50% of the reservoir area is exposed mud flats in the winter. Sulfate was below detection limits (0.005 mg sulfate/g sediment, reported as 5 µg/g) in permanently inundated reservoir sediments, but was 0.0011 mg sulfate/g sediment (11 µg/g) in mudflat sediment. MeHg concentrations were higher at sediment surfaces than in the sediment profile at seasonally inundated sites, indicating that MeHg production was occurring there; in contrast, [MeHg] was constant across sediment depths in the permanently inundated sites, indicating that settling of MeHg into sediments was the only process occurring there ([Eckley et al., 2015](#)).

*The National-Scale Assessment of Mercury Risk to Populations with High Consumption of Self-Caught Freshwater Fish of 2011* ([U.S. EPA, 2011b](#)) compiled fish Hg load data on a national scale, which can be considered a county-wide sampling of ecosystems where Hg loads in fish are high. The assessment did not directly quantify or analyze sulfate effects, but it considered patterns of Hg deposition and Hg concentrations in freshwater fish caught between 2005–2009 by state regulatory agencies, and modeled the

extent to which reductions in Hg deposition would affect subsistence-level human consumers of fish from U.S. water bodies. Fish collections showed that there were elevated fish Hg levels in water bodies across the country, although high fish Hg concentrations were more common in the eastern U.S. [see [Figure 12-15 \(U.S. EPA, 2011b\)](#)]. In this study, 5% of total Hg deposition was attributed to coal and oil-fired electric utility steam generating units (EGUs), but EGUs contributed 9% to fish tissue levels of Hg.

The 2014 USGS's report on mercury in streams ([Wentz et al., 2014](#)) suggests that eastern water bodies, watersheds with high wetland cover, and watersheds with low population densities are linked to higher MeHg concentrations in streams and in stream biota.

## 12.6 Critical Loads

There are currently no critical loads for SO<sub>x</sub> deposition related to the nonacidifying effects described in this appendix. There are European critical loads for Hg deposition and Hg effects upon human health and ecosystems. A critical load of 1 µg Hg/L in soil drainage water was set to protect drinking water ([Hettelingh et al., 2015](#)). A critical load of 0.3 mg Hg/kg fresh weight fish tissue was set to protect human health. A critical load to protect soil invertebrates and soil microbial process of 0.5 mg Hg/kg organic material was set for the humus layer of forest soils ([Hettelingh et al., 2015](#)). This source did not report critical loads in terms of areal deposition rates, but did map exceedances based on soil, water, and fish tissue samples, and found that about 59% of European natural areas received Hg deposition in exceedance of these critical loads ([Hettelingh et al., 2015](#)).

---

## 12.7 Summary of Nonacidifying Sulfur Effects

Sulfate deposition has a number of effects beyond acidification in ecosystems. In the 2008 ISA, the evidence was sufficient to infer a causal relationship between S deposition and increased methylation of Hg in aquatic environments where the value of other factors was within adequate range for methylation. The 2008 ISA surveyed literature from approximately 1980 to 2008 and described the qualitative relationships between sulfate deposition and a number of ecological endpoints, including altered S cycling, sulfide phytotoxicity, internal eutrophication of aquatic systems, altered methane emissions, increased Hg methylation, and increased Hg loading in animals, particularly fish. New evidence from wetland and freshwater aquatic ecosystems strengthens and extends the causal findings of the 2008 ISA regarding nonacidifying sulfur effects and provides the basis for a new causal determination. [Table 12-13](#) summarizes recent thresholds and quantitative relationships describing effects of sulfate deposition. This new information strengthens the weight of evidence presented in the 2008 ISA, and consistent with the 2008 causal statement, **the body of evidence is sufficient to infer a causal relationship between S deposition and the alteration of Hg methylation in surface water, sediment, and soils in wetland and freshwater ecosystems.** In addition, recent research demonstrates sulfide phytotoxicity under current conditions in North American wetlands, consistent with the 2008 ISA's summary of sulfide phytotoxicity in European wetland and freshwater ecosystems. **The body of evidence is sufficient to infer a causal relationship between S deposition and changes in biota due to sulfide phytotoxicity including alteration of growth and productivity, species physiology, species richness, community composition, and biodiversity in wetland and freshwater ecosystems.**

C = carbon; DOC = dissolved organic carbon;  $\text{H}_2\text{S}$  = hydrogen sulfide; ha = hectare; Hg = mercury; kg = kilogram; L = liter; MeHg = methylmercury; mg = milligram; ng = nanogram; S = sulfur; yr = year.

### 12.7.1 Terrestrial Sulfur Cycling

The 2008 ISA noted that S is an essential plant nutrient and that S deposition can affect plant protein synthesis by affecting S availability for S-containing amino acids as well by affecting N uptake. Sulfate can be taken up directly by plant roots as well as by soil microbes, or it can adsorb to soil particles. The 2008 ISA reported that watersheds in the Southeast, which retained more S than was deposited during high S loading in the 1980s, received decreasing S deposition over the 1990s but continued to export historically deposited sulfate in streams. In the Northeast, budgets of sites from the 1980s indicated that high S deposition caused high sulfate export in streams. On a national level, S deposition resulted in increased S content in organic matter in soils, and studies suggested that mineralization of this stored S may contribute to elevated sulfate leaching for decades after reductions in S deposition. More recent research confirms that watersheds

in the Northeast continue to leach more S than they currently receive from S deposition, as much as 24–45% more S than the S deposition load ([Mitchell et al., 2011](#)).

---

### 12.7.2 Aquatic Sulfur Cycling

The 2008 ISA reported that nonacidifying effects of S in freshwater systems will be affected by water residence times, with larger lakes and beaver ponds providing ample opportunity for SRPs to reduce sulfate and generate acid-neutralizing capacity (ANC). Early work showed that a 1 mg/L increase in sulfate concentration in Dickie Lake, Ontario, increased S reduction rates 0.35 mg S/L/day ([Kerry et al., 1991](#)).

The 2008 ISA reported the role of wetlands in removing sulfate from surface water and storing it in sediments or biomass, but it also highlighted the way drought reverses this capacity to make wetlands sources of S to downstream waters. Specifically, studies reviewed in the 2008 ISA demonstrated that under drought conditions, sulfide in previously saturated moss or sediments is exposed to atmospheric oxygen and reoxidized to sulfate. This resulted in high sulfate concentrations in surface water when the water table rose to its former level, and MAGIC modeling showed that variable water levels due to climate change-induced droughts would delay ANC recovery in the Plastic Lake Watershed, NY ([Aherne et al., 2004](#)). In Little Rock Lake, WI, water level fluctuation due to drought added an additional 5 kg S/ha/yr from internal ecosystem S stores to the lake ([Watras and Morrison, 2008](#)). Recent work confirmed that periods of drought result in elevated water sulfate concentrations during the recovery period following the drought ([Wasik et al., 2012](#)).

---

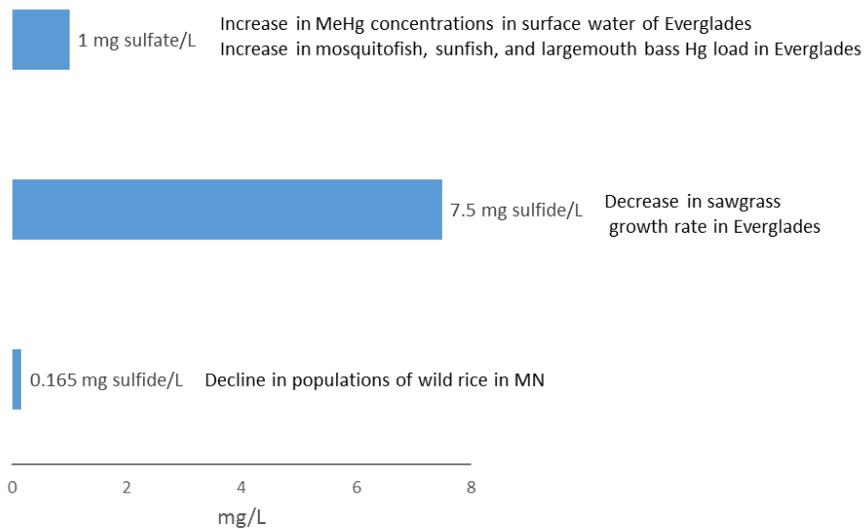

### 12.7.3 Sulfide Toxicity

In aquatic systems or in saturated soils, SRPs convert sulfate into sulfide, which inhibits nutrient uptake in freshwater aquatic and wetland plant species. The 2008 ISA showed that sulfide toxicity reduced biomass of wetland plants and aquatic macrophytes in mesocosms under aquatic S concentrations higher than those that occur in U.S. regions with high S deposition. Recent research has shown sulfide phytotoxicity occurs at ambient aquatic S concentrations within multiple ecosystems in the U.S. ([Figure 12-16](#)). Sulfide decreases total plant cover and cover of dominant species in a New York fen ([Simkin et al., 2013](#)) and decreases the growth rate of Everglades, FL, keystone species *Cladium jamaicense* (sawgrass) at surface water concentrations of 7.5 mg sulfide/L ([Li et al., 2009](#)). The state of Minnesota is also working on a sulfide standard to protect the economically and culturally important *Zizania palustris* (wild rice) and has proposed a

water standard of 0.165 mg sulfide/L to protect the species ([MPCA, 2015a](#)). Additionally, a review by [Lamers et al. \(2013\)](#) reported experimentally-determined sulfide toxicity values between 0.3–29.5 mg S<sup>2-</sup>/L for 16 North American species (see [Table 12-2](#)), and there are sulfate tolerance values for North American fish and macroinvertebrates based on USGS’s NAWQA. This new information shows that sulfide toxicity occurs in North American wetlands under current deposition conditions, and **the body of evidence is sufficient to infer a causal relationship between S deposition and changes in biota due to sulfide phytotoxicity including alteration of growth and productivity, species physiology, species richness, community composition, and biodiversity in wetland and freshwater ecosystems.**

---

### Water quality thresholds for non-acidifying S effects

L = liter; Hg = mercury; MeHg = methylmercury; mg = milligram; S = sulfide.

**Figure 12-16** Thresholds of sulfate or sulfide concentrations in water, which cause biological and chemical effects in ecosystems.

---

#### 12.7.4 Internal Eutrophication

The 2008 ISA described the contribution of S deposition to internal eutrophication in aquatic systems. In wetland and lake waters, sulfate is reduced to sulfide, which reacts with Fe to form insoluble iron sulfide complexes. In many ecosystems, the iron in this reaction is provided by  $\text{FePO}_4$ , which releases phosphorus as it forms  $\text{FeS}_x$  thus contributing to downstream eutrophication. More recently, internal eutrophication caused by sulfate addition was observed in mesocosms of samples collected from Lake Moshui, China ([Yu et al., 2015](#)).

---

#### 12.7.5 Effects on Methane Production

Sulfate deposition can shift microbial community interactions, resulting in lower methane emissions. The 2008 ISA documented the suppression of methane emissions in wetland soils by sulfate addition in several studies and noted that 15 kg S/ha/yr (the lowest S load in experimental treatments) suppressed methane emissions to the same extent as higher S loads ([Gauci et al., 2004](#)). There is no recent research that relates  $\text{SO}_x$  deposition to wetland methane emissions, but recent research has confirmed the underlying microbial mechanisms of this process. Sulfate deposition increases the abundance or metabolic activity of SRPs. In many freshwater water bodies, including wetlands, low primary productivity limits microbially available, labile C during the growing season when higher temperatures favor microbial activity. Recent research documents competition among microbial guilds for labile C, and when SRPs are favored, competing methanogens decline, resulting in suppressed methane emissions ([Bae et al., 2015](#); [He et al., 2015](#); [Paulo et al., 2015](#)). However, there is also evidence of methanogens forming syntrophic associations with SRPs ([Paranjape and Hall, 2017](#)), suggesting that these groups may not always directly compete in all ecosystems.

---

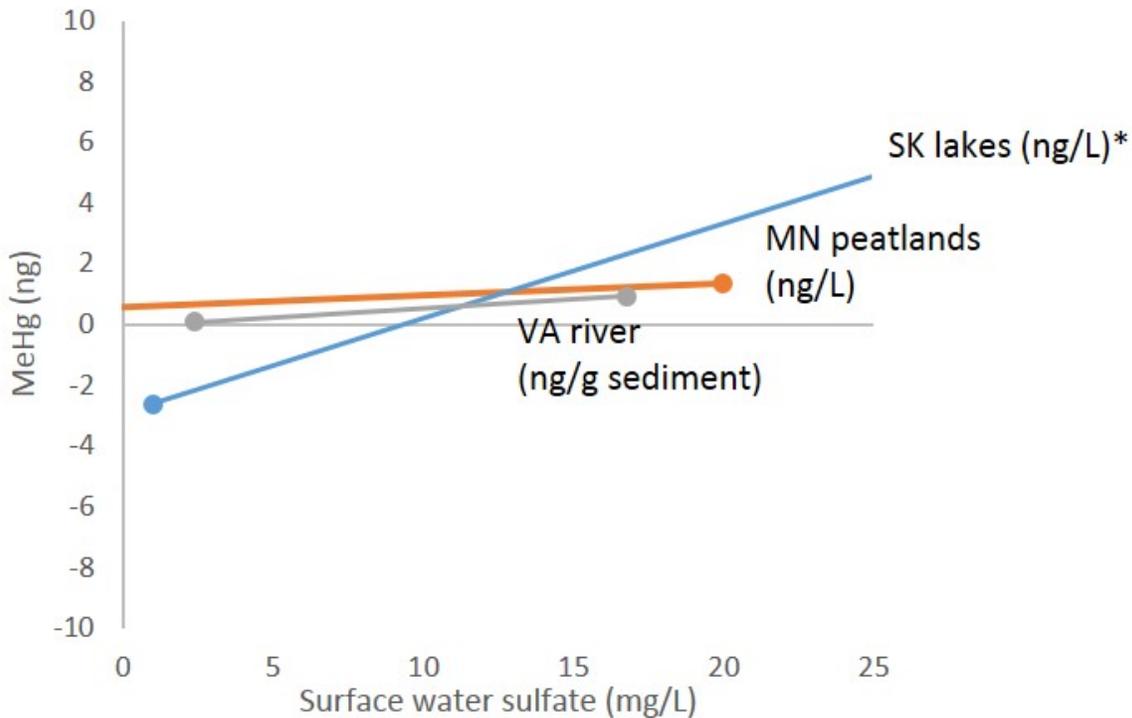

#### 12.7.6 The Role of Microbes in Mercury Methylation

The 2008 ISA identified sulfur-reducing bacteria as responsible for Hg methylation, and identified anoxic wetland and lake bottom sediments as their location within watersheds. More recent research confirms that SRB in these locations methylate Hg, but also shows that the ability to methylate Hg is more broadly distributed in the prokaryotic taxa and across the environment.

Recent research suggests that the *hgcAB* gene pair confers the ability to methylate inorganic Hg. *HgcAB* has been sequenced in lineages within bacteria and archaea, which

is why this document refers to mercury methylators as SRPs rather than the SRB described in the previous ISA ([Gilmour et al., 2013](#)). Experimental work has shown that MeHg production rates vary among prokaryotic strains ([Shao et al., 2012](#)), but also has confirmed that sulfate addition causes Hg methylation in the Everglades ([Goñi-Urriza et al., 2015](#)), as abundant syntrophs (heterotrophs dependent on the metabolic byproducts of other microbes) were responsible for both Hg methylation and sulfate reduction ([Bae et al., 2014](#)).

Recent research shows that the microbial communities responsible for Hg methylation are more widely distributed than in the freshwater lake or wetland bottom sediments described in the 2008 ISA ([Figure 12-17](#)). There is evidence from Sweden, Finland, and the U.S. that disturbances in terrestrial forests stimulate mercury methylation in soils and MeHg export to surface waters ([Kronberg et al., 2016](#); [Poulin et al., 2016](#); [Ukonmaanaho et al., 2016](#)). The *Sphagnum* (moss) mat of wetlands was the most efficient retention site of deposited Hg in a forested watershed in the Adirondacks ([Selvendiran et al., 2008b](#)), as well as an important location of mercury methylation within peat wetlands in New York and Wisconsin ([Yu et al., 2010](#); [Creswell et al., 2008](#); [Selvendiran et al., 2008b](#)). Experiments using samples from rivers or streams in Virginia, Minnesota, or Germany showed that higher sulfate concentrations increased methylation rates or [MeHg] ([Frohne et al., 2012](#); [Yu et al., 2012](#); [Tsui et al., 2008](#)), with a 0.06 ng/L increase in MeHg per gram of sediment for every 1 mg/L increase in sulfate pore water concentration in South River, VA ([Yu et al., 2012](#)). New research shows that SRPs actively methylate Hg within periphyton, the aquatic biofilms attached to substrate or macrophytes in oxic freshwater environments ([Correia et al., 2012](#); [Achá et al., 2011](#)). MeHg production has also been documented in estuarine and marine sediments of the Chesapeake Bay ([Hollweg et al., 2009](#)) and in the marine water columns sampled at 20 to 327 m depths in the Canadian Arctic Archipelago ([Lehnherr et al., 2011](#)).

C = carbon; cm = centimeter; DOM = dissolved organic matter; g = gram; L = liter; MeHg = methylmercury; mg = milligram; mS = millisiemens; ng = nanogram; SK = Saskatchewan;  $\text{SO}_4^{2-}$  = sulfate.

Note: A study of prairie lakes and wetlands in Saskatchewan found that conductivity, aromatic DOM, and sulfate concentrations correlate with water MeHg ( $\text{ng MeHg/L} = -2.94 - 0.44 (\text{conductivity, mS/cm}) + 0.303 (\text{mg SO}_4^{2-}/\text{L}) - 0.268 (\text{aromatic fraction of DOM, L/mg C/cm})$ ). Simple linear regressions relate MeHg to water sulfate concentrations in Minnesota peatlands ( $\text{water ng MeHg/L} = 0.58 + 0.037 \text{ mg SO}_4^{2-}/\text{L}$ ) and in South River, VA ( $\text{riverbed ng MeHg/g sediment} = -0.08 + 0.059 \text{ mg SO}_4^{2-}/\text{L}$ ).

**Figure 12-17 Linear relationships between sulfate and methylmercury concentrations in published studies.**

As a microbial process, Hg methylation is determined not just by sulfate and Hg concentrations, but by other environmental and nutritional requirements of SRPs: pH, temperature, and water quality parameters, and carbon supply. The 2008 ISA identified pH and dissolved organic carbon (DOC) to be major controls on Hg production, with low pH and moderately high DOC correlating with high fish MeHg levels in lakes. The 2008 ISA also identified wetland area or density as an important determinant of MeHg bioaccumulation and export in watersheds. Recent research presented in [Appendix 12.3.3](#) evaluates temperature, total Hg concentration, pH, organic matter in water and sediments, iron, and nitrate for their influence on Hg methylation rates.

The 2008 ISA identified organic C as an important control on microbial sulfate reduction and Hg methylation, and recent research has quantified this relationship. In Little Rock Lake, WI, DOC concentrations had to be at least 3.6 mg C/L to allow microbial sulfate

reduction, and microbial sulfate reduction increased linearly with an increase of C only when DOC was in the range of 3.6–7.6 mg C/L (Watras et al., 2006). Across prairie potholes in Saskatchewan, surface water [MeHg] increased 2.65 ng/L for every 10% increase in percentage organic matter in underlying sediment (Hoggarth et al., 2015). In wetlands, rivers, and lakes of the Mississippi River delta, LA, there was a 1 ng MeHg/L increase in surface water for each additional 0.048 mg hydrophobic organic acid fraction (aromatic carbon typical of peat) of DOC/L (Hall et al., 2008).

---

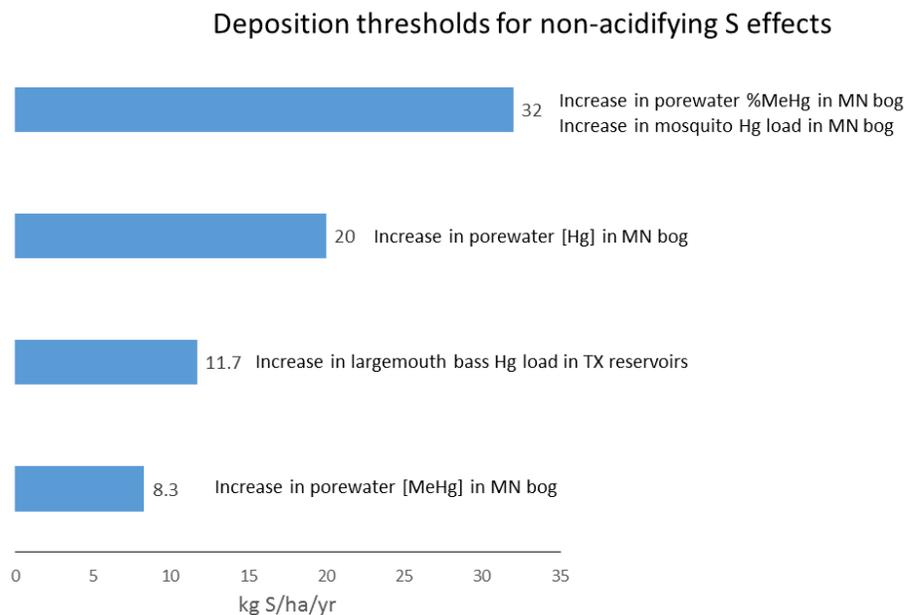

### 12.7.7 Impacts of Sulfur upon Mercury Cycling

Based on experimental evidence, the 2008 ISA identified maximum MeHg production occurring at sulfate concentrations of 200–400  $\mu\text{eq sulfate/L}$  (9.6–19.2 mg  $\text{SO}_4^{2-}/\text{L}$ ) and noted that waters under S deposition in the U.S. have sulfate concentrations in the range of 60–200  $\mu\text{eq sulfate/L}$  (2.9–9.6 mg  $\text{SO}_4^{2-}/\text{L}$ ). More recent research shows that detectable mercury methylation and bioaccumulation occurs at water sulfate concentrations  $>1$  mg/L in the Everglades (Gabriel et al., 2014; Corrales et al., 2011) and at ambient S deposition and water sulfate concentrations within the U.S. There was a positive relationship between sulfate reduction and concentrations of MeHg in the hypolimnion of Little Rock Lake, WI, with a 10.8 ng MeHg/L increase for each mg S/L reduced (Watras et al., 2006). There was also a positive relationship at this site between total lake MeHg and annual  $\text{SO}_x$  deposition, with a 14.4 mg MeHg/lake increase for every 1 kg S/ha/yr increase in  $\text{SO}_x$  deposition (Watras and Morrison, 2008).

There are multiple lines of evidence of a positive relationship between sulfate surface water concentrations and MeHg concentration or production in multiple freshwater systems. Both experimental manipulations and observational studies show that higher sulfate concentrations in peat wetlands increase MeHg concentrations (Figure 12-18). Experimental addition of sulfate to Bog Lake Fen in Minnesota showed that 8.3 kg S/ha increased pore water [MeHg] (Mitchell et al., 2008a), and 32 kg S/ha/yr increased pore water [MeHg] as well as MeHg fraction of total Hg, or %MeHg (Jeremiason et al., 2006). In other bogs sampled in the same region of Minnesota and Ontario, [MeHg] in water increased 0.037 ng/L for each 1 mg sulfate/L increase (Mitchell et al., 2009). These results were confirmed in a peatland S addition experiment in Sweden, which found that 20 kg S/ha/yr addition to the peat increased [MeHg] (Akerblom et al., 2013; Bergman et al., 2012).

Recent work also established positive relationships between sulfate and MeHg in ecosystems other than peat wetlands. In prairie potholes in the West (Hoggarth et al., 2015), with surface water MeHg increasing 0.3 ng/L for each additional mg sulfate/L

where conductivity and aromatic DOC remain constant (Hall et al., 2009a). In a freshwater marsh in the Everglades, water [MeHg] concentrations increased when sulfate concentrations exceeded 1 mg sulfate/L (Corrales et al., 2011), which is also an important threshold value for fish in the Everglades (see below). There are also recent ecosystem-scale studies that show that sulfate reduction and MeHg can be correlated at the landscape level. At the watershed level in the Adirondacks, [MeHg] in stream outflows was negatively correlated with sulfate concentration (Selvendiran et al., 2009), with a 0.11 ng/L increase in stream [MeHg] for each mg sulfate/L removed from surface water (Selvendiran et al., 2008a).

ha = hectare; Hg = mercury; kg = kilogram; MeHg = methylmercury; S = sulfur; yr = year.

**Figure 12-18** Thresholds of sulfate addition or deposition from published studies which affect chemical or biological changes in ecosystems.

---

## 12.7.8 Sensitive Ecosystems

The 2008 ISA identified ecosystems in the Northeast as particularly sensitive to Hg methylation in response to S deposition, because many watersheds there have abundant wetlands and freshwater water bodies with high DOC and low pH. Recent analyses confirm that ecosystems east of the Mississippi tend to have higher Hg concentrations in fish ([Wentz et al., 2014](#); [U.S. EPA, 2011b](#)). Recent papers suggest that reservoirs with high water-level fluctuation or high algal productivity also have high methylmercury production or bioaccumulation within fishes ([Eckley et al., 2017](#); [Noh et al., 2016](#); [Eckley et al., 2015](#); [Becker et al., 2011](#)), and that at the ecoregion level, reservoir fish Hg concentrations correlate with both Hg and S deposition ([Drenner et al., 2011](#)).

Recent research in the Yolo Bypass Wildlife Area, CA, indicates that Hg methylation occurs in both permanent and agricultural wetlands and was higher in the agricultural wetlands where rice is grown ([Alpers et al., 2014](#); [Marvin-Dipasquale et al., 2014](#)). Hg methylation in this system was associated with Mn reduction, and then to a lesser extent with Fe reduction, and was only marginally associated with S reduction; sulfate addition did not affect Hg methylation ([Alpers et al., 2014](#); [Marvin-Dipasquale et al., 2014](#)). However, MeHg produced in the sediments where rice grew was highly correlated with MeHg concentrations in rice seeds ([Windham-Myers et al., 2014a](#)), suggesting a route to human exposure, and there were higher MeHg burdens in several animal species collected from agricultural wetlands than from permanent marshes (see below).

---

## 12.7.9 Mercury Effects on Animal Species

Mercury is a developmental, neurological, endocrine, and reproductive toxin across animal species. It is transformed by SRPs from inorganic Hg into methylmercury (MeHg), which forms strong complexes with thiosulfate and sulfhydryl groups of organic molecules. This bound MeHg accumulates in biota in successively higher concentrations at ascending trophic levels. The 2008 ISA documented Hg accumulation in four turtle species, songbirds, insectivorous passerines, and the common loon (*Gavia immer*). A recent report by the USGS notes that Hg accumulation has also been documented in insectivorous songbirds and bats ([Wentz et al., 2014](#)). In recent research conducted in the Yolo Bypass, CA, higher water [MeHg] in agricultural rice-producing wetlands than in permanent marshes led to higher MeHg concentrations in mosquitofish (*Gambusia affinis*) and Mississippi silversides (*Menidia audens*) from the agricultural wetland than from the permanent marshes ([Ackerman and Eagles-Smith, 2010](#)).

The 2008 ISA reported that 23 states had issued fish advisories by 2007 in response to the U.S. EPA's fish tissue criterion set to protect human health of 0.3 µg MeHg/g fish, or 0.3 ppm. The 2008 ISA reported on the negative impacts of Hg on development, morphology, survival, or reproduction in the following fish species: walleye (*Stizostedion vitreum*), grayling (*Thymallus thymallus*), mummichog (*Fundulus heteroclitus*), rainbow trout (*Oncorhynchus mykiss*), fathead minnows (*Pimephales promelas*), and zebrafish (*Danio rerio*). However, a recent report on Hg in streams of the U.S. by the USGS summarizes current research that birds, fish, and fish-eating wildlife experience negative effects of Hg at lower concentrations than the 0.3 ppm criteria ([Wentz et al., 2014](#)).

The 2008 ISA reviewed two studies that considered the link between S deposition and Hg levels in fish ([Drevnick et al., 2007](#); [Hrabik and Watras, 2002](#)); both studies showed that decreases in S deposition resulted in decreases in fish MeHg levels. Recent research supports this finding in Voyageurs National Park (a Class I area) in Ryan Lake between 1998–2012 ([Brigham et al., 2014](#)), when decreasing S deposition correlated with decreasing fish Hg. In addition, a survey of fish caught in Texas reservoirs found that fish in the highest deposition region (11.7 kg S/ha/yr) had significantly higher mean Hg levels than fish from other regions ([Drenner et al., 2011](#)). Experimental S addition to the Marcell peat bog in Minnesota demonstrated that 32 kg S/ha/yr increased the Hg concentrations in larval *Culex* spp. (mosquitoes), which are an important food source for both aquatic and terrestrial species ([Wasik et al., 2012](#)).

In addition to the studies that consider S deposition, there are recent studies that consider sulfate concentrations in water in relation to fish Hg concentrations. A study of fish from six lakes in South Dakota found a positive correlation between sulfate water concentrations and walleye Hg concentrations ([Stone et al., 2011](#)). The marshes of the Everglades receive high S loading as agricultural runoff, and recent analysis of Hg loads in mosquitofish, sunfish (*Lepomis* spp.), and largemouth bass (*Micropterus salmoides*) collected from 1998–2009 showed that Hg levels in fish were highest when sulfate concentrations were between 1 and 12 mg sulfate/L; the researchers proposed 1 mg sulfate/L as a water standard ([Gabriel et al., 2014](#)).

---

## 12.8 Supplemental Materials: Mercury Cycling

This appendix describes the deposition and cycling of mercury within North American ecosystems. Connections to sulfur cycling are emphasized where such information is available. This appendix provides background information and context for the discussion of nonacidifying sulfur stimulation of mercury methylation in wetland and aquatic ecosystems ([Appendix 12](#)).

---

### 12.8.1 Transfer of Mercury from the Atmosphere to Terrestrial Ecosystems

Mercury enters most natural terrestrial and aquatic ecosystems in the U.S. via atmospheric deposition, although both active and historic mining and industrial sites have contaminated soil and water in many ecosystems. Sources and atmospheric processes governing Hg deposition are covered more exhaustively elsewhere ([Wentz et al., 2014](#); [Pirrone et al., 2010](#)). For the purposes of this section, we will focus on the deposition of reactive Hg, which is deposited into ecosystems in the form of free Hg(II), particulate-bound Hg, or as MeHg. In a jack pine/birch forest in the ELA sampled in 1998–1999, wet deposition was 71,000,000 ng/ha/yr (reported as 71 mg total Hg/ha/yr), with dry deposition estimated at 9,000,000 ng/ha/yr [reported as 9 mg/ha/yr in ([St Louis et al., 2001](#))].

Foliage is an important Hg pool in both forested and wetland ecosystems because it can directly absorb Hg deposition as well as store Hg taken up by plant roots. In the Arbutus Lake watershed in the Adirondack Mountains, Hg in the *Alnus* and *Betula* overstory was 3,080 ng Hg/m<sup>2</sup> (3.08 µg Hg/m<sup>2</sup>), and was 9,480 ng/m<sup>2</sup> (9.48 µg/m<sup>2</sup>) in the *Sphagnum* mat of the wetlands ([Selvendiran et al., 2008b](#)). In a 3-year-long Hg tracer isotope annual addition experiment at ELA, upland canopy and ground vegetation retained 40% of added Hg. In a wetland ecosystem, vegetation retained 80% of added Hg ([Harris et al., 2007](#)). Although the wetland ecosystems exported Hg and MeHg to an adjacent lake in the watershed during the course of the study, the Hg was from sources existing before the start of the experiment, indicating that Hg storage in wetland vegetation may have a residence time greater than 1 year ([Harris et al., 2007](#)).

Foliage also represents an important flux of Hg; following senescence, leaf litter becomes the substrate for microbial decomposition, and Hg moves out of plant biomass and into microbial biomass, soil, or water. Flux of total Hg from litter in the ELA, Ontario, was twice that of wet deposition in litter from upland trees and was of a similar magnitude to deposition in litter from wetland shrubs and trees [72,000,000 ng/ha/yr or 72 mg

Hg/ha/yr, and 88,000,000 ng/ha/yr or 88 mg/ha/yr; ([St Louis et al., 2001](#))]. The organic horizon of the soil, where litter and microbial communities are concentrated, was a major sink of Hg within the forested and wetland ecosystems for the 20 years preceding this study, with annual Hg accumulation rates of 130,000,000 ng Hg/ha/yr (reported as 130 mg Hg/ha/yr) for ridgetop soils (160% of total annual deposition), 200,000,000 ng/ha/yr (200 mg/ha/yr) for upland forest (250% of deposition), and 590,000,000 ng/ha/yr (590 mg/ha/yr) in wet soils supporting *Sphagnum* mosses [7.4 times annual deposition; ([St Louis et al., 2001](#))]. In forest catchments, much of the Hg deposition is retained in soil ([St Louis et al., 2001](#); [St. Louis et al., 1996](#)), as confirmed by the Hg tracer isotope addition experiment in ELA, which found that after 3 years of Hg addition, 58% of the added Hg was retained in soil in the upland forest catchment ([Harris et al., 2007](#)). The length of residence within the soil for Hg likely depends on the same factors that control the storage of organic matter, such as soil structure, temperature, precipitation, and timing of disturbances, particularly of wildfire.

---

## 12.8.2 Transfer of Mercury from Terrestrial to Aquatic Ecosystems

When Hg is released from plant tissue, detritus, or soil particles into surface water or the soil solution, it becomes available for transport into aquatic systems. In five boreal forest catchments in the ELA, Ontario, measured during the period 1990–1993, the flux of total Hg from the forest into water bodies was estimated to be 14,000,000–21,000,000 ng/ha/yr (reported as 14–21 mg/ha/yr 28–42% of annual Hg input), in response to approximately 47,000,000 ng/ha/yr (47 mg/ha/yr) wet + dry deposition of Hg, and estimated contributions from weathering of granite of as much as 3,000,000 ng/ha/yr [reported as 3 mg/ha/yr in [St. Louis et al. \(1996\)](#)]. On Isle Royale, a large island in Lake Superior and a Class I Area, researchers estimated that lakes received one-third of their annual Hg load directly from atmospheric deposition, and the remaining two-thirds of annual Hg load was mobilized from soils in the watersheds ([Drevnick et al., 2007](#)). In aquatic environments, specialized microbes (SRPs; as well as iron-reducing bacteria) in anoxic zones can methylate inorganic Hg, transforming it into the toxic, persistent MeHg.

---

### 12.8.3 Transfer of Mercury from Atmosphere to Aquatic Ecosystems

Total Hg deposited directly to lakes is rapidly incorporated into Hg cycling in abiotic and biotic pools. In a Hg isotope addition experiment at the ELA, Ontario, a spike of isotope  $^{202}\text{Hg}$  was added directly to the lake annually over the course of 3 years. The  $^{202}\text{Hg}$  was detected in the anoxic hypolimnion within days of addition, and in bottom sediments of the lake within 4 weeks ([Harris et al., 2007](#)), and methylated  $^{202}\text{Hg}$  was detected in zooplankton, benthic amphipod *Hyallolella Azteca*, and fish species within 2 months of addition ([Harris et al., 2007](#)), indicating that Hg methylation and movement of MeHg within the food web can occur within a single season in aquatic ecosystems. Estimated residence time of atmospherically deposited  $\text{Hg}^{2+}$  in the water column of Little Rock Lake, WI, was 150 days ([Watras et al., 2006](#)).

---

### 12.8.4 Methylmercury Cycling

Methylmercury (MeHg) is produced by sulfur-reducing prokaryotes (SRPs) in the course of sulfate reduction. It is toxic to humans and vertebrate animals, particularly because it biomagnifies up the food chain and bioaccumulates within organisms. The following sections describe transfer of MeHg between ecosystem compartments, as well as characteristics of zones of high MeHg production within the landscape.

---

### 12.8.5 Transfer of Methylmercury from Terrestrial to Aquatic Ecosystems

MeHg is a very small component (1%) of Hg atmospheric deposition to ecosystems ([Wentz et al., 2014](#)); most MeHg in ecosystems is microbially produced from inorganic Hg. Much of our knowledge about Hg cycling in natural ecosystems comes from the Experimental Lakes Area (ELA) in northwestern Ontario, Canada, which receives low Hg deposition [47,000,000 ng/ha/yr or 47 mg/ha/yr in 1990–1993; 80,000,000 ng/ha/yr or 80 mg/ha/yr in 1998–1999 ([St Louis et al., 2001](#); [St. Louis et al., 1996](#))]. A small portion of total Hg deposition in the ELA is in the form of MeHg, 900,000 ng/ha/yr (reported as 0.9 mg/ha/yr, or <1.5% of total Hg deposition). MeHg cycles through the terrestrial ecosystem as total Hg does. Leaf litter represents a significant flux of MeHg from the living canopy in upland forest to the detrital food web of 800,000 ng MeHg/ha/yr (reported as 0.8 mg MeHg/ha/yr), a flux of a similar magnitude to atmospheric deposition ([St Louis et al., 2001](#)). In the 20 years preceding the study, 600,000 ng MeHg/ha/yr (reported as 0.6 mg/ha/yr of MeHg) were annually stored in the organic soil pool, and on average 100,000 ng MeHg/ha/yr (reported as 0.1 mg MeHg/ha/yr) was exported from the catchment in stream flow ([St Louis et al., 2001](#)).

In five boreal forest catchments at the ELA, [St. Louis et al. \(1996\)](#) assumed a background MeHg deposition rate of <500,000 ng MeHg/ha/yr (reported as <0.5 mg MeHg/ha/yr). A catchment consisting only of upland forests exported 18% of estimated annual MeHg deposition, indicating that terrestrial ecosystems retain MeHg ([St. Louis et al., 1996](#)), and that aquatic MeHg is produced endogenously.

---

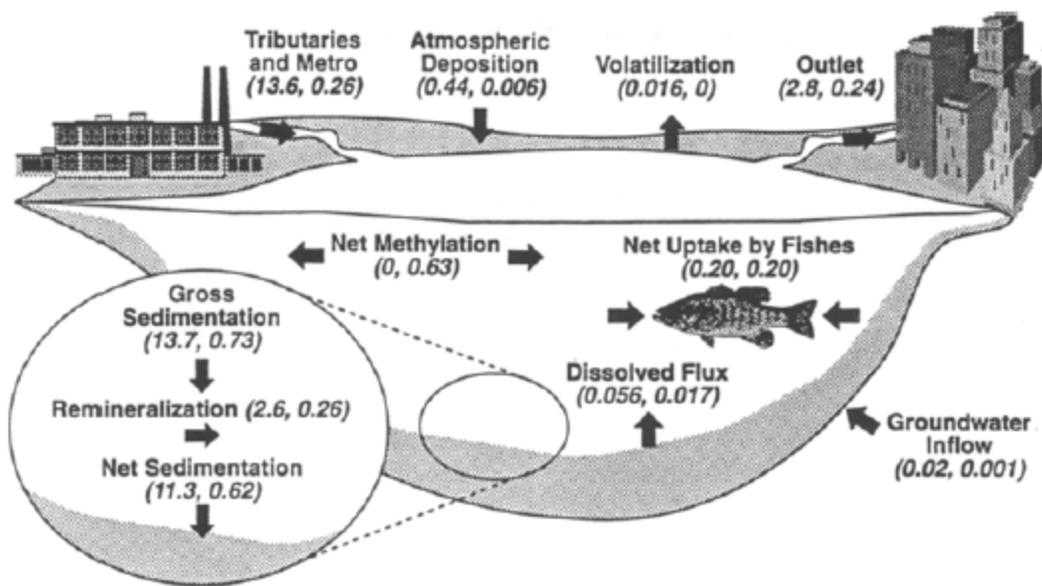

## 12.8.6 Transfer of Methylmercury from Wetlands to Aquatic Ecosystems

At the landscape level, MeHg export from wetlands in streams and rivers is correlated with wetland cover in watersheds. In the ELA in Ontario, a catchment with valley bottom wetlands exported 73% of deposited MeHg in a dry year, but 158–200% of deposited MeHg in a wet year, indicating that the wetlands produced MeHg in wet years. MeHg export was high in catchments with other types of wetlands as well. A catchment with riverine wetland (peatland fed by surface water flow) exported 120–130% of annually deposited MeHg in dry and wet years, and a catchment containing a basin wetland exported 213% MeHg in a dry year and 500–719% annually deposited MeHg in wet years, indicating a strong source of MeHg within the watershed, presumably in the wetlands ([St. Louis et al., 1996](#)). More recent work in the watershed of Arbutus Lake, NY measured Hg and MeHg in streams draining upland and wetland areas; MeHg was 1.7–3.0% of total Hg in upland streams and 7.8% of total Hg in a similarly low-order stream that drained a wetland. In downstream peatlands, MeHg was 5.4–9.5% of total Hg ([Selvendiran et al., 2008a](#)), and the beaver meadow peatland exported 623% of total MeHg input annually, while the riparian wetland exported 8% of total MeHg input ([Selvendiran et al., 2008b](#)). Wetlands with high dissolved organic carbon and fluctuating water levels and anoxic zones are areas of high MeHg production within watersheds, and such wetlands will affect MeHg concentrations in water and biota downstream.

---

## 12.8.7 Methylmercury Cycling in Aquatic Ecosystems—Lake Onondaga, NY

Lake Onondaga, NY was the subject of a Hg budget project in 1992 because the eutrophic lake received high Hg loads through the late 1970s from industry [[Figure 12-19](#); ([Henry et al., 1995](#))].

Hg = mercury; kg = kilogram; MeHg = methylmercury; yr = year.  
 Source: [Henry et al. \(1995\)](#).

**Figure 12-19** Mercury and methylmercury mass balance cycle in Lake Onondaga in 1992. The quantities of mercury in each flux are indicated in parentheses by (kg total Hg/yr, kg MeHg/yr).

In 1992, 14.1 kg of total Hg entered the lake, 96% of which was carried into the lake by tributaries, including one that drained a former chlor-alkali plant. The largest sink for Hg within the lake was through sedimentation, which accounted for 11.1 kg of total Hg. In that same year, 2.8 kg of total Hg flowed out of the lake downstream and 0.20 kg Hg (0.1% of total annual Hg load) was incorporated into fish biomass ([Henry et al., 1995](#)).

A budget for Hg methylation was also constructed for the lake, and differs from that of total Hg in several important points ([Figure 12-4](#)). First, only 29% of the annual lake MeHg load of 0.88 kg entered the lake via tributaries (compared to nearly the entire total Hg load). The water column, particularly deep, anoxic water, contributed 0.60 kg or 68% of the annual MeHg load of the lake ([Henry et al., 1995](#)). More than half (about 0.47 kg) of the annual MeHg load was incorporated into sediments, and while sedimentation rates were high, about one- to two-thirds of MeHg in sediments was released back into the water column. Because most of the total Hg in fish is in the form of MeHg, the model calculated that the MeHg in fish biomass was the same amount as total Hg in fish biomass, 0.20 kg, although this value constituted a much higher portion of the annual

MeHg load [23% of annual MeHg; ([Henry et al., 1995](#))]. This early study showed that the majority of MeHg in Lake Onondaga was produced within the lake itself, specifically in the anoxic zone, and that MeHg cycled between the sediments and water column, with a significant amount stored in fish tissue.

Lake Onondaga was resampled in 2006, 2007, and 2009, following industrial remediation projects and incorporation of nitrification treatment in the municipal wastewater plant discharging into the lake ([Todorova et al., 2014](#)). In the 2006–2009 sampling, MeHg concentrations in the epilimnion were significantly lower than in 1992, and total Hg in the epilimnion was half of the total Hg concentrations measured in 1992 ([Todorova et al., 2014](#)). However, in all years there was a significant peak in MeHg concentrations and in MeHg:tHG ratios in the epilimnion in the fall following turnover ([Todorova et al., 2014](#)), indicating that this seasonal event will have significant effects on total MeHg in the food chain of the lake.

---

### 12.8.8 Methylmercury in Sediments and Water Column—Lakes

The sediments under shallow, oxygenated lake waters are an important site of Hg methylation. Early literature showed that Hg methylation rates are higher in shallow organic sediments than in deep clay-rich sediments in Southern Indian Lake in Manitoba, Canada, and that the ratio of methylation:demethylation was also higher in organic sediments ([Ramlal et al., 1986](#)). In the Quabbin Reservoir, MA, MeHg fractions in sediments were 3.1–16.3% at 1-m depth, and decreased with increasing lake depth to 0.1–0.2% at a 22 to 23-m depth ([Gilmour et al., 1992](#)). At Lake Clara, WI, Hg methylation rates were sampled in the water column, flocculant surface sediments, and deeper sediments at water depths of 1–10.5 m ([Korthals and Winfrey, 1987](#)). At all sampling depths, methylation and demethylation were detectable in the water column and in the surface sediments. Gross Hg methylation rates were highest in surficial sediments sampled at depths of 5–7.5 m, but the methylation:demethylation ratio was highest (5.5–5.8) in surficial sediments at depths of 1–2 m ([Korthals and Winfrey, 1987](#)).

Larger, deeper lakes stratify during the summer; waters near the surface (epilimnion) of the lake are high in oxygen and primary productivity, while deeper waters (hypolimnion) have low oxygen, lower primary productivity, and high rates of S reduction and MeHg production. In the experimentally acidified Little Rock Lake, WI, MeHg was low (less than 0.1 ng/L) in surface waters during the summer months, but increased at anoxic depths below 4–6 m to 1 ng/L in June, 3 ng/L in July, and 3.5 ng/L in August ([Bloom et al., 1991](#)). In stratified Lake Onondaga, NY, the water column, particularly deep, anoxic water, contributed 0.60 kg or 68% of the annual MeHg load of the lake ([Henry et al.,](#)

[1995](#)). Sampling in Palette Lake, WI, showed that the oxic-anoxic boundary was at 12 m depth in this stratified lake, which was also the location of the sulfate-sulfide transition ([Watras et al., 1995](#)). There were peaks in both sulfate reduction and Hg methylation from 12–13 m depth, right at the top of the hypolimnion, which was enriched in MeHg (20–30%) compared to the epilimnion (5–10% MeHg). There was no sulfate reduction detected in the profundal sediments or deep layers of the hypolimnion. MeHg was transported from the oxic-anoxic boundary and hypolimnion where it was produced to the epilimnion, and the flux of MeHg from the hypolimnion (3,400,000–6,800,000 ng/day, reported as 3.4–6.8 mg/day) was much larger than the flux of MeHg into the epilimnion from the atmosphere [10,500 ng MeHg/day, or 0.0105 mg MeHg/day; ([Watras et al., 1995](#))]. [Eckley and Hintelmann \(2006\)](#) showed that in boreal Canadian lakes, potential methylation is highest approximately 1 m below the oxycline, and this methylation zone moves up the water column as the oxycline rises due to oxygen depletion at depth in the summer ([Eckley and Hintelmann, 2006](#)).

---

### 12.8.9 Methylmercury in Sediments and Water Column—Wetlands

In wetlands at Bog Lake Fen in the Marcell Experimental Forest, MN, the highest levels of MeHg production occurred at the upland-peatland interface. When mesocosms installed in the bog interior received additions of labile C and sulfate, MeHg concentrations were similar to MeHg concentrations from the upland-peatland interface, indicating that upland inputs of C may contribute to high methylation rates in the peatland ([Mitchell et al., 2008a](#)). A larger study that sampled peatlands within the Marcell Experimental Forest, MN, as well as at the ELA in Ontario found that %MeHg was highest within 5–10 m of the upland-peatland interface across wetlands, and that sulfate and pH were higher at the interface, and DOC was lower at the interface, than in the interior of the peatlands ([Mitchell et al., 2008a](#)). In peatlands in the Arbutus Lake watershed in the Adirondack Mountains, NY, MeHg and total Hg were higher in pore water near the top of the peat profile, at 20 to 40-cm depth, than at 80 to 100-cm depth ([Selvendiran et al., 2008a](#)), and the total Hg and MeHg were highest in both peat and pore water in the top 15 cm of the peat ([Selvendiran et al., 2008a](#)). The Hg in the top 15 cm of peat was estimated to be about 27% of the total Hg, and MeHg in the top 15 cm was 30% of the total MeHg in a riparian peatland and 50% of the total MeHg in a beaver meadow ([Selvendiran et al., 2008a](#)). In freshwater *Sphagnum* peatlands of the Allequash Creek watershed in the Northern Highland Lake District of Wisconsin, reducing conditions exist below 2-cm depth in the peat, and MeHg concentrations peak at 7-cm depth in the peat ([Creswell et al., 2008](#)).

In wetlands not dominated by *Sphagnum*, Hg methylation occurs in sediments and in periphyton (see [Appendix 12.3](#)). In the freshwater marshes of the Florida Everglades, where periphyton and flocculation often extend the sediment-water interface, methylation rates were highest in the top 6 cm of sediments ([Gilmour et al., 1998](#)). In coastal marsh sediments, such as at Kirkpatrick Marsh on the Chesapeake Bay, MeHg was highest in the top 6 cm of sediment, although total Hg was highest at a depth of 12–15 cm in the sediments ([Mitchell and Gilmour, 2008](#)), and in coastal Georgia marshes, sediment core incubations showed that MeHg production was highest in the top 4 cm of the marsh sediments ([King et al., 1999](#)).

---

### 12.8.10 Methylmercury in Sediments and Water Column—Estuarine and Marine Ecosystems

Research shows that Hg methylation occurs in estuaries and in marine sediments. Incubations of samples collected in the Patuxent River and Estuary, MD, showed that net MeHg production in sediments was four times the rate of MeHg accumulation in sediments, suggesting that MeHg in estuary surface waters comes from estuarine sediment sources as well as sources upstream in the watershed ([Benoit et al., 1998](#)). MeHg comprised 5% of surface water particulate Hg (unclassified compounds large enough to be removed by filtration) and 2% of total Hg in surface water, and 0.3% of Hg in estuarine sediments ([Benoit et al., 1998](#)). More recently, surface sediments were sampled from the Chesapeake Bay, from four locations in the main channel, two locations on the continental shelf, and one location on the slope of the continental shelf. Total Hg in the upper bay ranged from 50 to 171 ng Hg/g sediment (reported as 250–850 pmol/g), in the lower bay and continental shelf ranged from 2.0 to 20 ng Hg/g sediment (10–100 pmol/g), and at the single continental slope site was 50–70 ng Hg/g sediment (250–350 pmol Hg/g); ([Hollweg et al., 2009](#)). MeHg was 0.2–1.5% in the top 0–12 cm of sediments across sites, and bottom water salinity was strongly correlated with %MeHg [ $r = 0.814$ ; ([Hollweg et al., 2009](#))], suggesting that MeHg was produced in marine sediments.

An incubation study of water samples collected at depths of 20–327 m in the ocean around the Canadian Arctic Archipelago found measurable rates of Hg methylation at all depths from all five sites sampled. Methylation of inorganic Hg accounted for 47% of the MeHg present in the water column at these locations, and demethylation was also widely observed, indicating that marine MeHg represents marine production of MeHg, not merely transport of MeHg from other systems ([Lehnherr et al., 2011](#)).

---

## APPENDIX 13 CLIMATE MODIFICATION OF ECOSYSTEM RESPONSE TO NITROGEN AND SULFUR

The scope of this appendix is to identify key papers describing how climate alters ecosystem response to nitrogen (N) and sulfur (S) addition. N and S loading occurs in many ecosystems concurrently experiencing multiple stressors, including human-driven climate change. Climate change effects on U.S. ecosystems were recently summarized in the U.S. National Climate Assessment ([Galloway et al., 2014](#); [Groffman et al., 2014](#)). Each appendix of the ISA evaluating the effects of N enrichment or acidification includes a section on how climate modifies the ecosystem response to N or N + S deposition. Additionally, in this appendix, we have excerpted text from [Greaver et al. \(2016\)](#), to serve as a foundation for the discussion. This paper, which focuses on empirical observations, provides a current review of how climate (e.g., temperature and precipitation) modifies ecosystem response to N.

Anthropogenic emissions of greenhouse gases are likely to cause a global average temperature increase of 1.5 to 4.0°C and a significant shift in the amount and distribution of precipitation by the end of the 21st century ([Collins et al., 2013](#)). Recent work has focused on the effects of anthropogenic N on the Earth's radiative forcing ([Pinder et al., 2012](#)) and how temperature and precipitation alter ecological responses to N exposure ([Greaver et al., 2016](#)). Most work is conducted on the effects of climate and N or acidifying deposition (N + S). There are only a couple of studies on how climate modifies ecosystem response to S.

Climate effects on ecosystems is a rapidly expanding field. For some processes we are beginning to understand how temperature and precipitation may interact; however, for many biogeochemical pools and processes, data are insufficient to quantify either the direction or magnitude of how climate may alter ecosystem response to N with certainty. Some global-scale earth systems models now incorporate interactions between N and carbon (C) in ecosystems. They are summarized in [Appendix 6. Greaver et al. \(2016\)](#) includes information on terrestrial and surface water ecosystems. A brief summary of climate modification of estuary response to N is also included in [Appendix 13.2](#).

---

## 13.1 Climate Modification of Soil Acidification and Nitrogen Enrichment

Climate-driven changes in N cycling may alter the N supply in terms of quantity and timing of N available for uptake by biota. Alteration of N availability relative to a given organism's life cycle or physiological thresholds may alter overall ecosystem function. These effects may be further modified when temperature and precipitation cause direct stress to biota. In the following sections we describe how climate alters the cycling of N and how temperature and precipitation interact with two important mechanisms affected by N availability to taxa: (1) nitrogen-driven eutrophication, which will stimulate the growth of opportunistic plant and animal species, and (2) acidification, which may decrease growth and cause mortality among sensitive species. We describe how these changes in growth will alter C cycling and biodiversity.

---

### 13.1.1 Nitrogen Transport and Transformation

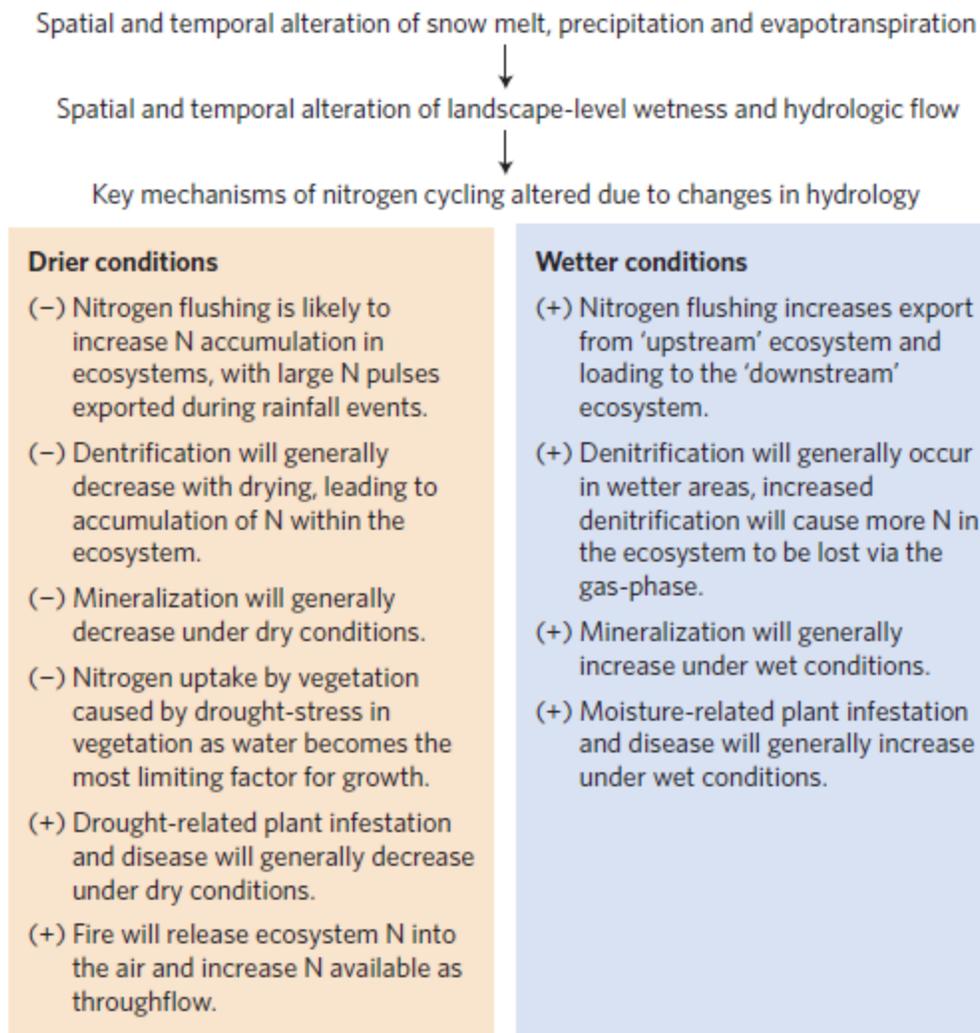

---

#### 13.1.1.1 Excerpt from [Greaver et al. \(2016\)](#)

“Although global N cycling is complex, the movement of N through the biosphere can largely be explained by describing a few key transformations ([Figure 13-1](#)). Atmospheric N<sub>2</sub> is converted into reactive N by lightning or by specialized bacteria capable of biological N fixation, in addition to the human activities that create reactive N.

Organisms use reactive N to produce proteins and other essential compounds. Dead organic matter is decomposed by microbial enzymes, producing smaller N containing organic molecules such as amino acids. This organic N is largely converted to mineral forms that are readily assimilated by plants and microorganisms. Where reactive N is present under aerobic conditions, some microorganisms convert ammonium (NH<sub>4</sub><sup>+</sup>) to nitrate (NO<sub>3</sub><sup>-</sup>), a process termed nitrification. Nitrate is mobile in soils and often leaches into aquatic systems and groundwater. In anaerobic conditions, microorganisms can convert NO<sub>3</sub><sup>-</sup> to gaseous N via denitrification, emitting N back to the atmosphere.

“In nonagricultural terrestrial ecosystems, atmospheric deposition is the dominant source of anthropogenic N. Through changes in precipitation, shifts in atmospheric circulation, and temperature-related effects on the stability of N compounds, climate change is expected to alter the relative contribution of wet and dry forms of N deposition and shift the spatial distribution of N deposition ([Engardt and Langner, 2013](#); [Tagaris et al., 2008](#)). Local N deposition rates are generally predicted to change by 0–20% ([Engardt and Langner, 2013](#); [Tagaris et al., 2008](#)).

N = nitrogen.

Source: [Greaver et al. \(2016\)](#).

**Figure 13-1 Summary of key interactions between nitrogen, anthropogenic-driven climate change, and hydrology.**

“The influence of N addition on reactive N availability within terrestrial and aquatic ecosystems is mediated by microbial transformations and transport within and between ecosystems. Climate change is expected to strongly affect these processes through increasing temperature and through temporal and spatial shifts in temperature and precipitation ([Baron et al., 2012](#)). Warming directly increases the metabolic biokinetics of enzyme activity necessary for microbial N transformation until a temperature [optimum] is reached. Climate change is also expected to cause numerous modifications of the

hydrologic cycle, and moisture availability regulates the biokinetic temperature response ([Borken and Matzner, 2009](#); [Rustad et al., 2001](#)) because water is needed to transport enzymes and substrates and water influences oxygen availability. Warming is predicted to intensify the hydrologic cycle, with heavy rainfall events expected to become more frequent and intense, along with the potential for deepening and lengthening of dry periods, as well as altered snow accumulation and melt and changes in evapotranspiration ([Jiménez Cisneros et al., 2014](#); [Collins et al., 2013](#)). These changes may cause soil conditions for microbial activity to shift between optimal and inhibitory ([Morse et al., 2015b](#)), modifying the link between climate warming and the rate of microbial N transformations such as decomposition, mineralization, nitrification, denitrification, and biological N fixation. Of these transformations, the rates of N fixation may be the most uncertain part of the N cycle ([Vitousek et al., 2013](#)), altering N supply and influencing the C cycle ([Welter et al., 2015](#)).

“Climate-driven changes to the hydrologic cycle will also alter the quantity of N transported through a system via waterborne transport and soil water content-mediated N cycling ([Billen et al., 2013](#)). Alteration of N retention in the soil due to changes in moisture and flushing may be significant enough to determine whether an ecosystem is an N source versus [an] N sink ([Boulton, 2007](#); [Band et al., 2001](#)). Greater precipitation generally increases water flow, which may (1) increase leaching/export of N through terrestrial landscapes, (2) increase terrestrial N inputs to streams and rivers, and (3) increase N transport rates through streams and rivers ([Whitehead et al., 2009](#)), although adaptation by microbes and plants may increase their ability to retain N as flushing increases, thereby potentially limiting some of the overall impact of increased precipitation and flow.

“Under dry conditions, landscapes can become more hydrologically disconnected and N retentive, which can increase N concentrations in subsequent flushing events ([Goodridge and Melack, 2012](#); [Kaushal et al., 2008](#)). Drought can inhibit nitrification and cause N to accumulate in the soil; once precipitation occurs it often results in a pulse of nitrification that produces nitrate and subsequent nitrate leaching ([Lamersdorf et al., 1998](#)). For example, the 2012 droughts in the midwestern U.S. were followed during the spring 2013 by extremely high river nitrate concentrations ([Beeman, 2013](#)). Likewise, longer periods between wet cycles lead to accumulation of nitrate and other acidifying solutes in the soil, causing less frequent, yet more extreme acidification events ([Bayley et al., 1992](#)). Beyond simply the total volume, precipitation intensity influences the rate of N flow through ecosystems. Increased precipitation intensity of cold season frontal storm systems and warm season convective storms would likely increase the frequency of high N loading events to aquatic systems. Due to the limited capacity for in-stream removal of

N during high flow pulse events, most N is transported downstream ([Kaushal et al., 2014](#)).

“Such hydrologic cycle changes are also expected to affect the timing of N transport. Changes in the seasonality of precipitation, and in particular snowmelt, will tend to alter the timing of N flushing through the ecosystem. There has already been widespread earlier snowmelt and increased winter thaws associated with warming over the last few decades ([Collins et al., 2013](#)), but implications for the timing of N export have been assessed in only a few sites ([Casson et al., 2012](#)). Timing changes ultimately can alter the magnitude of N export to downstream water bodies, particularly if the timing of flushing changes relative to the timing of biologically mediated uptake in either terrestrial or aquatic ecosystems ([Baron et al., 2009](#)). Thus, it is possible to have a modification in sink/source behavior in regions where annual or seasonal patterns of water-filled pore space shift with climate change.

“The rate at which denitrification returns reactive N to the atmosphere varies across space and time, with landscape- to micro-scale denitrification hot spots or moments that depend on interactions with hydrologic flow paths, the persistence and variability of low oxygen conditions, and the residence time of water and N, all of which are likely to respond to climate-driven changes in the hydrologic cycle ([Anderson et al., 2015](#); [Weier et al., 1993](#)). Generally, warmer and wetter conditions under climate change would facilitate greater rates of denitrification, whereas warmer and drier areas might experience decreased denitrification or concentrate ‘hot spots’ into smaller areas with higher soil moisture, substrate concentrations, and fluxes ([Duncan et al., 2013](#)). Alternating wet and dry states may promote coupled nitrification/denitrification processes or build-up and flushing of mobile N depending on the ratio of transport to reaction rates. These are general trends associated with moisture availability and transport. Carbon substrate availability and other controls on microbial processes, however, will also be influenced by climate change (discussed below) and can mediate these hydrologic effects.”

---

### 13.1.1.2 Additional Considerations

There are considerations to note in addition to the excerpt from [Greaver et al. \(2016\)](#). Additional papers on climate interactions with N and S soil biogeochemistry discussed in [Appendix 4](#) are summarized in [Table 13-1](#). Featured most notably are the effects of precipitation on S cycling, snow on soil N cycling, N addition effects on biogenic GHG flux, and the results of integrating climate parameters into N and S biogeochemistry modeling.

**Table 13-1 Summary on climate modification sulfur and nitrogen cycling in [Appendix 4](#) and [Appendix 6](#) in addition to those in [Appendix 13](#).**

Indicator/Process	T	P	Snow	Reference
<b>Biogeochemical effects (<a href="#">Appendix 4</a>)</b>				
S mineralization	X	X		<b>Empirical:</b> Watershed mass balances of sulfur are increasingly regulated by watershed moisture because high-moisture soil conditions stimulate the net mineralization of soil sulfur pools. <a href="#">Mitchell et al. (2011)</a>
S retention		X		<b>Model:</b> Watersheds with higher runoff ratio tend to convert sooner from net retention to net release of SO <sub>4</sub> <sup>2-</sup> . <a href="#">Rice et al. (2014)</a>
Soil N variables			X	<b>Meta-analysis:</b> Meta-analysis data is from 41 publications based on snow depth manipulation experiments. The general responses of 12 variables related to terrestrial nitrogen (N) pools and dynamics to altered snowpack depth are evaluated. <a href="#">Li et al. (2016c)</a>
N mineralization	X		X	<b>Empirical:</b> More freeze/thaw cycles anticipated with climate warming; supported lower rates of N mineralization. <a href="#">Duran et al. (2016)</a>
N mineralization	X		X	<b>Empirical:</b> Snow-manipulation experiment at Hubbard Brook to evaluate soil freezing later in the season due to prolonged warm season. Freezing likely increases soil NO <sub>3</sub> <sup>-</sup> levels by physical disruption (increased fine root mortality) causing reduced N uptake by plants and reduced competition for inorganic N, allowing soil NO <sub>3</sub> <sup>-</sup> levels to increase even with no increase in net mineralization or nitrification. <a href="#">Groffman et al. (2001)</a>
N mineralization			X	<b>Empirical:</b> N mineralization rates were more strongly related to soil volumetric water content than to root biomass, snow or soil frost, or winter soil temperature. <a href="#">Sorensen et al. (2016)</a>
N effects CO <sub>2</sub> , CH <sub>4</sub> , and N <sub>2</sub> O				<b>Meta-analysis:</b> 313 observations across 109 studies evaluated the effect of N addition on the flux of three major GHGs: CO <sub>2</sub> , CH <sub>4</sub> , and N <sub>2</sub> O. <a href="#">Liu and Greaver (2009)</a>
Soil acidification and N enrichment	X	X		<b>Model:</b> 2009–2100—six climate change simulations of temperature, precipitation, and photosynthesis active radiation (PAR). Without CO <sub>2</sub> fertilization effects, net soil mineralization and nitrification increased, soil and stream acidified, and the percentage of base saturation in soils declined due to increased NO <sub>3</sub> <sup>-</sup> . With CO <sub>2</sub> fertilization effects, the N loss to streams was suppressed due to increased plant uptake. <a href="#">Pourmokhtarian et al. (2012)</a>

**Table 13-1 (Continued): Summary on climate modification of nitrogen (N) effects on nitrogen cycling in Appendix 4 and Appendix 6 in addition to those in Appendix 13.**

Indicator/Process	T	P	Snow	Reference
Soil acidification, N enrichment, and plant community	X	X		<b>Model:</b> The ForSAFE-VEG model simulations show that climate and atmospheric deposition have comparably important effects on N mobilization in the soil, as climate triggers the release of organically bound nitrogen stored in the soil during the elevated deposition period. Climate has the most important effect on plant community composition; thus, climate change cannot be ignored in future simulations of vegetation dynamics. <a href="#">Belyazid et al. (2011a)</a>
Soil acidification and N enrichment	X	X		<b>Model:</b> PnET-BGC modeling found climate change played a larger role in ANC than base cation deposition changes. Temperature had a larger effect than precipitation on decomposition. Net mineralization and nitrification increased faster with climate change than plant NO <sub>3</sub> <sup>-</sup> uptake. <a href="#">Wu and Driscoll (2010)</a>

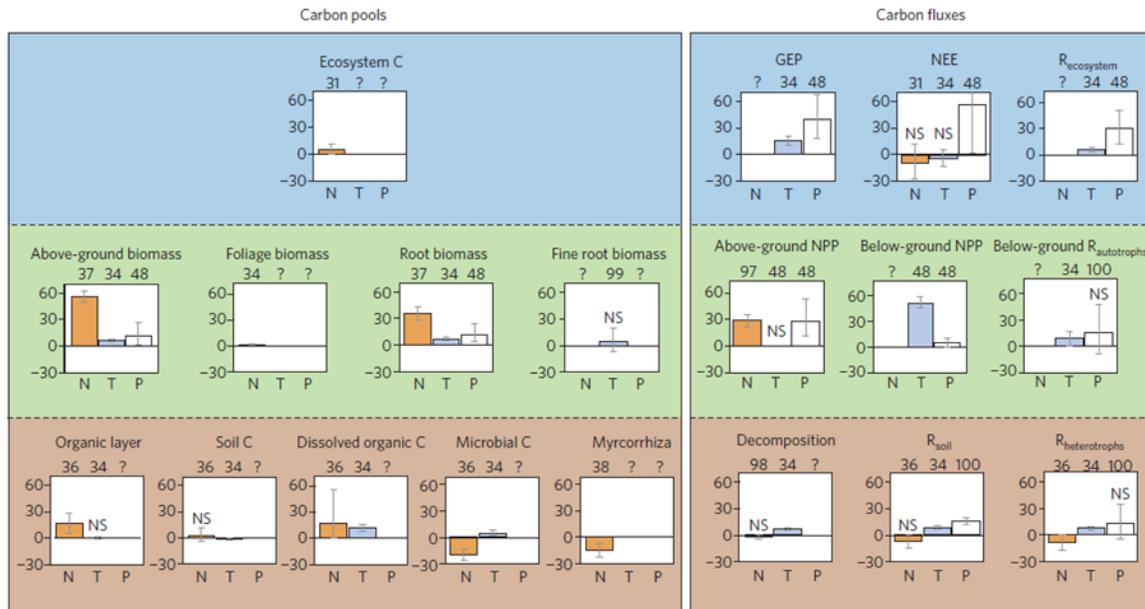

## 13.1.2 Nitrogen, Climate, and Carbon Cycling

### 13.1.2.1 Excerpt from [Greaver et al. \(2016\)](#)

“Changes in N supply alter plant growth and C cycling. The addition of N to terrestrial and aquatic ecosystems can cause eutrophication, a state of high nutrient availability that alters ecosystem function. Autotrophs (plant/algae) capture CO<sub>2</sub> through photosynthesis, storing C in biomass until it is oxidized through respiration or combustion and released back to the atmosphere. In terrestrial systems, N addition usually stimulates autotrophic growth until biotic N demand has been satisfied, although high rates of N addition may increase the concentration of acid anions, which often decreases plant growth (see acidification discussion below). At certain sites, N additions have uneven effects, stimulating growth of some tree species, while impairing the health and growth of others ([Thomas et al., 2010](#)). When considering the net effects on multiple tree species, growth in most forests is stimulated. This additional growth increases the overall amount of C stored in plant biomass; one unit of N input may cause an additional 24.5 to 177 units of forest C uptake ([de Vries et al., 2014a](#); [Liu and Greaver, 2009](#)).

“A number of published meta-analyses evaluate the response of C pools and fluxes to single stressors of N, precipitation, or temperature. To gain insight on stressor interactions from single stressor response studies, we have synthesized existing meta-analyses of terrestrial ecosystem response to additions of N, precipitation, and

temperature (e.g., [see [Figure 13-2](#) in this document]). A recent correlation analysis of growth (in terms of net primary production [NPP]) for 1,247 woody plant communities across global climate gradients confirms that NPP increases with higher temperature and precipitation ([Chu et al., 2016](#)). However, ecological changes along broad natural gradients may differ from the response of ecosystems to comparatively rapid environmental change caused by human activities ([Chu et al., 2016](#)). This latter process may be more accurately characterized by addition experiments, such as those summarized by meta-analysis. Our synthesis of existing meta-analyses indicates that aboveground NPP is highly responsive to N addition and enhanced precipitation, while temperature rise does not increase aboveground NPP. This result is consistent with the basic biokinetic effects of warming on enzyme activity, which would have the counteracting effects of stimulating both plant C capture (photosynthesis) and plant C release (autotrophic respiration). Although there are no meta-analyses on warming and whole-ecosystem autotrophic respiration, [Lu et al. \(2013\)](#) observed in a meta-analysis that temperature increased gross ecosystem production, a metric that does not subtract respiration from gross production (photosynthesis). Therefore, temperature may have larger effects on plant C fluxes than on NPP. Note that precipitation-induced changes in NPP may vary depending on whether there is sufficient enhancement of precipitation to offset increased evapotranspiration in a warmer climate ([Bachelet et al., 2001](#)).

C = carbon; CI = confidence interval; GEP = gross ecosystem photosynthesis; N = nitrogen; NEE = net ecosystem C exchange; NPP = net primary production; NS = nonsignificant effects; P = precipitation;  $R_{\text{autotrophs}}$  = plant/autotroph respiration;  $R_{\text{ecosystem}}$  = ecosystem respiration;  $R_{\text{heterotrophs}}$  = heterotroph respiration;  $R_{\text{soil}}$  = soil respiration; T = temperature; ? = an effect that has not been assessed by meta-analytic review.

Note: Bars indicate response ratios (treatment/control  $\times$  100), and error bars represent 95% confidence intervals for the response. Orange bars indicate the magnitude of response to nitrogen enrichment, blue bars show response to temperature increase, white bars show response to precipitation increase. Blue zone indicates ecosystem carbon inputs and outputs, green zone indicates plant responses, and brown zone indicates soil and microbial responses. The upper confidence interval for the precipitation effect on net ecosystem C exchange is 124.6 and beyond the scale of the chart. The response of aboveground net primary production to warming was stated to be nonsignificant (Wu et al., 2011), but no effect size was given.

Source: Greaver et al. (2016). The number above each bar indicates the published source of the effect size as follows: 1. LeBauer and Treseder (2008); 2. Wu et al. (2011); 3. Lu et al. (2013); 4. Liu and Greaver (2009); 5. Liu and Greaver (2010); 6. Xia and Wan (2008); 7. Knorr et al. (2005); 8. Dieleman et al. (2012); 9. Treseder (2004); 10. Lu et al. (2011b); 11. Liu et al. (2016b).

**Figure 13-2 The effects of increased nitrogen, temperature, and precipitation on terrestrial carbon pools (left panel) and fluxes (right panel) from published meta-analyses.**

“Belowground, initial findings are that N addition tends to increase the C stored in the soil organic layer and in root biomass (Liu and Greaver, 2010; Xia and Wan, 2008), while it tends to decrease mycorrhizae/microbial abundance and heterotrophic respiration (Liu and Greaver, 2010; Treseder, 2004). This offset may result in no net change in soil respiration (Liu and Greaver, 2010); however, this is an active area of research. Consistent with the biokinetic effects of warming, long-term data and meta-analyses show that soil respiration, including decomposition and microbial respiration, is stimulated by increasing temperature (Lu et al., 2013; Bond-Lamberty and Thomson, 2010; Rustad et al., 2001). Most empirical studies show rising temperature stimulates N release by mineralization (Churkina et al., 2010), which may be driven more by

temperature effects on moisture ([Emmett et al., 2004](#)). In some dynamic land models, the additional N from mineralization will stimulate C uptake by plants even more than current N deposition ([Burd et al., 2016](#)). At the same time, increased N from mineralization may cause N induced inhibition of decomposition, a feedback mechanism that might decrease the amount of N released that is currently considered by few models ([Gerber et al., 2010](#)). The mechanisms causing N driven reduction in decomposition are not well understood, but are thought to result from changes in microbial community composition and their production of decomposition enzymes, as well as possible changes in the character and degradability of soil organic matter ([Conant et al., 2011](#); [Janssens et al., 2010](#)). Climate change could also affect decomposition rates by altering both available soil moisture and microscale connectivity among microorganisms, water, and nutrients within the soil matrix that in turn may alter microbial processes ([Xiang et al., 2008](#)). Although there is no consensus about how dissolved organic carbon (DOC) in surface water is regulated overall, increasing N and temperature increase DOC concentrations ([Laudon et al., 2012](#)). While few meta-analyses examine precipitation effects on the soil C cycle, precipitation tends to increase the root C pool (e.g., [see [Figure 13-2](#) in this document]).

“Overall ecosystem C balance is assessed by summing measurements of individual pools to quantify ecosystem carbon (EC) content or by measuring C fluxes to quantify the net ecosystem exchange (NEE) of C. The meta-analysis we identified indicated that temperature did not increase NEE [[Lu et al. \(2013\)](#); positive NEE indicates ecosystem C gain], and as previously mentioned this is likely because the biokinetic effects of warming stimulate respiration that offsets the C capture via stimulation of primary production. Increased precipitation tends to increase NEE ([Wu et al., 2011](#)), likely because water availability increases photosynthesis, while not increasing plant respiratory losses. A meta-analysis of N addition studies indicates that adding N to grasslands had no effect on NEE, but that N addition increased forests EC ([Liu and Greaver, 2009](#)). There may be differences between grasslands and forests in terms of the extent that C gain simulated by N is offset by heterotrophic and autotrophic respiration. Increasing temperature may decrease C storage if the warming causes inhibition of photosystems or enhances evaporation and reduces water availability. A better understanding of these and other contributing processes is needed.

“Traditionally, primary production in freshwater systems was thought to be phosphorous (P) limited, but recent data have shown an increase of limitation by N or colimitation by N and P ([Elser et al., 2007](#)). In N limited fresh waters, N addition enhances rapid growth of nitrophilic algae. This is an important food source to consumer species in the trophic cascade; however, it is unclear if this is an important source of long-term C storage. Sediments are estimated to be the largest pool of long-term C storage ([Cole et al., 2007](#)),

and N stimulates the production of terrestrial biomass that may be transported to aquatic sediments. Nitrogen also stimulates primary production of aquatic algae which contribute to C in sediments ([Kastowski et al., 2011](#)), although few studies have examined this effect. [Gudasz et al. \(2010\)](#) found a strong positive relationship between increasing temperature and organic C mineralization. They conclude future organic C burial in boreal lakes could decrease 4–27% under scenarios of warming due to enhanced temperature-dependent microbial activities. We were unable to identify studies examining precipitation effects, or the combined effects of N, temperature, and precipitation effects, on C storage in freshwater ecosystems. A discussion of biodiversity associated with eutrophication of fresh waters is included in the biodiversity section.”

---

### 13.1.2.2 Additional Considerations

There are considerations to note in addition to the excerpt from [Greaver et al. \(2016\)](#). Additional papers on the interacting effects of climate and N on C cycling discussed in [Appendix 4](#) and [Appendix 6](#) are summarized in [Table 13-2](#). Notably there is a new meta-analysis on N and warming interactions and several new papers on the interacting effects of N on plant biomass and precipitation.

---

**Table 13-2 Summary on climate modification of nitrogen (N) effects on carbon (C) cycling in [Appendix 4](#) and [Appendix 6](#) in addition to those in [Appendix 13](#).**

Indicator/Process	T	P	Snow	Reference
<b>Biogeochemical effects (<a href="#">Appendix 4</a>)</b>				
19 different C pools and processes within ecosystems	X	X		<b>Synthesis:</b> A synthesis of meta-analyses for single factor experiments on N, T, or P manipulation for 19 different C pools and processes within ecosystems. <a href="#">Greaver et al. (2016)</a>
Soil C	X	X		<b>Meta-analysis:</b> Results showed that the interaction of warming and N deposition greatly increased the soil C input (+49%) compared with the single factor of either warming (+5%) or N deposition (+20%). Soil C loss was not significantly affected by the interaction of N and warming, likely because increases in decomposition due to warming are offset by the decreases by N addition. <a href="#">Ni et al. (2017)</a>
N effects CO <sub>2</sub> , CH <sub>4</sub> , and N <sub>2</sub> O				<b>Meta-analysis:</b> 313 observations across 109 studies evaluated the effect of N addition on the flux of three major GHGs: CO <sub>2</sub> , CH <sub>4</sub> , and N <sub>2</sub> O. <a href="#">Liu and Greaver (2009)</a>

<b>Biological effects (<a href="#">Appendix 6</a>)</b>				
Biomass		X		<b>Empirical:</b> Using 1,600 observations, the study authors found that biomass responses to N increased linearly with mean annual precipitation (MAP). <a href="#">Xia and Wan (2008)</a>
Biomass		X		<b>Empirical:</b> Using 126 observations, the study authors found no relationship between biomass and mean annual precipitation (MAP). <a href="#">LeBauer and Treseder (2008)</a>
ANPP	X	X		<b>Empirical:</b> Plant growth response to N increased with precipitation until annual precipitation reached 800 mm/yr. The N response efficiency also peaked with moderate annual temperatures (~8°C) and declined under cooler or warmer conditions. <a href="#">Tian et al. (2016a)</a>
ANPP		X		<b>Empirical:</b> In the Sonoran Desert near Phoenix, AZ, 60 kg N/ha/yr caused little or no increase in production among herbaceous annuals in low precipitation years, moderate N responses with average rainfall, and strong increases in biomass with added N during above-normal rainfall seasons. <a href="#">Hall et al. (2011)</a>
Aboveground biomass and litter production		X		<b>Empirical:</b> Added N was positively correlated with precipitation and was only significant in the high rainfall years. <a href="#">Vourlitis (2012)</a>

### 13.1.3 Climate and Acidification

#### 13.1.3.1 Excerpt from [Greaver et al. \(2016\)](#)

“Atmospheric deposition of acidic N and sulfur (S) compounds (e.g., HNO<sub>3</sub>, H<sub>2</sub>SO<sub>4</sub>) has directly caused widespread acidification of terrestrial and freshwater ecosystems in many industrial areas. More broadly, other forms of atmospheric N deposition (e.g., NH<sub>x</sub>) can indirectly cause acidification by increasing inorganic N availability enough to induce nitrification. Freshwater and terrestrial ecosystem acidification is well studied and is characterized by decreased pH and elevated aluminum (Al) concentrations/mobility in soils and surface waters that cause plant physiological changes ([Schaberg et al., 2002](#)), tree mortality ([McNulty et al., 2007](#)), aquatic fauna mortality, and decreased aquatic

biodiversity ([Driscoll et al., 2001b](#)). Acidification driven by N (as opposed to N + S) occurs at higher levels of N addition than for initial changes to the C cycle. Often N saturation of the terrestrial ecosystem and subsequent leaching into adjacent aquatic systems is observed in the process of aquatic acidification ([Aber et al., 1998](#)). The threshold for the onset of acidification changes across the landscape, depending on geochemical sensitivity and historical loading of acidifying deposition. Although recent declines in emissions of SO<sub>x</sub> and NO<sub>x</sub> in eastern North America and throughout Europe ([NAPAP, 2011](#)) have led to many improvements in acid-base balances in acid sensitive ecosystems in recent decades, it is unclear whether sensitive ecosystems will continue to improve as emissions decline or whether secondary processes will promote, arrest, or reverse ecosystem recovery as climate changes.

“Potential future changes in the quantity and temporal distribution of precipitation and temperature (and their interactions) is expected to alter the wet-dry cycles that govern the timing and amount of acidic inputs in precipitation, microbial transformation in the soil, and the flush of acid anions from soils to surface waters. If acid anions build up in soil during periods of drought, the eventual flushing likely causes a more potent acidification event ([Mosley, 2015](#); [Whitehead et al., 2009](#)). If the acidification event occurs during a time when sensitive biota or lifestages of biota are present, acidification may cause more adversity to these populations ([Kowalik et al., 2007](#)). Increases in storm frequency associated with global climate change ([Collins et al., 2013](#)) could increase the frequency and severity of acidification driven by high levels of sea salt deposition in coastal regions ([Wright and Schindler, 1995](#)). Although the mechanisms of interaction are unclear, increases in DOC concentrations in aquatic ecosystems across Europe and the U.S. have been linked to acidification, N cycling, and climate change, with important implications for water quality and ecosystem function ([Evans et al., 2008](#)).

“As previously mentioned, warmer temperatures increase decomposition and nitrification. Nitrification will also increase with increased N supply caused by increased weathering or decomposition ([Booth et al., 2005](#)). The process of nitrification generates protons that increase the rate of nitrate and base cation leaching to drainage waters ([Murdoch et al., 1998](#)). The combined increase of NO<sub>3</sub><sup>-</sup> leaching and loss of base cations has the potential to magnify acidification in forest soils ([Fernandez et al., 2003](#)). Soil weathering is typically the key buffer to acidic deposition ([Li and McNulty, 2007](#)), and while weathering is increased by both soil temperature and soil moisture ([Gwiazda and Broecker, 1994](#)), it is unclear whether any future change in the magnitude of temperature and precipitation will be enough to alter base cation supply or influence the acid-base balance of sensitive ecosystems. Furthermore, it is unclear whether increased supply of N in soils from either deposition, increased decomposition, or increased nitrogen fixation may negate the ameliorative effect of enhanced weathering. Some studies show that

climate change will mitigate acidification through increased weathering ([Belyazid et al., 2011a](#)), whereas others show that climate change will aggravate acidification through increased nitrification outpacing enhanced weathering ([Wu and Driscoll, 2010](#)). In general, increased temperature and precipitation will likely enhance inputs of buffering agents from weathering and deposition, but also increase inputs of acidifying agents from deposition and enhanced N cycling. The relative sensitivity of these opposing processes to a given change in climate remains unresolved.

“Climate change may alter the sensitivity of biota to acidification, creating the need to adapt to a combination of acidity and climate change stresses. For example, the suitable habitat for brook trout in the Catskills and Adirondack mountains of the northeastern U.S. may be constrained as climate change increases downstream water temperatures, reducing downstream range where the trout can survive, while upstream migration is limited in part by acid conditions in the headwaters. In another example, Al is toxic to many fish and known to be mobilized during acidification events. It is known that the mortality rate of Atlantic salmon exposed to Al increases at higher temperatures ([Poleo and Muniz, 1993](#)); it is unclear how many other aquatic species would experience temperature-dependent toxicity, which could make them more vulnerable to acidification in a warming climate. Overall, there is little knowledge of how the biological thresholds to acidity will be affected by climate change.”

---

### **13.1.3.2 Additional Considerations**

There are considerations to note in addition to the excerpt from [Greaver et al. \(2016\)](#). Additional papers on climate interactions with acidification discussed in [Appendix 4](#) and [Appendix 5](#) are summarized in [Table 13-3](#). Most notably, several new studies model the interacting effects of climate and deposition on soil biogeochemistry, plant growth, and plant community composition.

**Table 13-3 Summary on climate modification of acidification in [Appendix 4](#) and [Appendix 5](#) in addition to those in [Appendix 13](#).**

Indicator/Process	T	P	Snow	Reference
<b>Biogeochemical effects (<a href="#">Appendix 4</a>)</b>				
Soil acidification and N enrichment	X	X		<b>Model:</b> 2009–2100—six climate change simulations of temperature, precipitation, and photosynthetically active radiation (PAR). Without CO <sub>2</sub> fertilization effects, net soil mineralization and nitrification increased; soil and stream acidified; and percentage of base saturation in soils declined due to increased NO <sub>3</sub> <sup>-</sup> . With CO <sub>2</sub> fertilization effects, N loss to streams is suppressed due to increased plant uptake. <a href="#">Pourmokhtarian et al. (2012)</a>
Soil acidification, N enrichment, and plant community	X	X		<b>Model:</b> The ForSAFE-VEG model simulations show that climate and atmospheric deposition have comparably important effects on N mobilization in the soil, because climate triggers the release of organically bound nitrogen stored in the soil during the elevated deposition period. Climate has the most important effect on plant community composition, underlining the fact that this cannot be ignored in future simulations of vegetation dynamics. <a href="#">Belyazid et al. (2011a)</a>
Soil acidification and N enrichment	X	X		<b>Model:</b> PnET-BGC modeling found climate change played a larger role in ANC than base cation deposition changes. Temperature had a larger effect than precipitation on decomposition. Net mineralization and nitrification increased faster with climate change than plant NO <sub>3</sub> <sup>-</sup> uptake. <a href="#">Wu and Driscoll (2010)</a>
<b>Biological effects (<a href="#">Appendix 5</a>)</b>				
Growth of red spruce and balsam fir	X	X		<b>Empirical:</b> Tree ring analysis was conducted along an elevation gradient (proxy for climate change). Both species showed increased growth with increased precipitation pH. Red spruce appeared to show increased growth with a warming climate, but balsam fir did not. No changes were noted in the [species?] distribution in the spruce-fir forest, and the authors suggest any such change may be part of a longer term process. <a href="#">Wason et al. (2017)</a>
Growth of red spruce	X	X		<b>Model:</b> The Annual Radial Model used to investigate projected climate change effects and changing air pollution on red spruce growth. High-elevation (<1,700 m) red spruce growth would decline if climate change co-occurred with an increase in air pollution. However, growth would increase under climate change, if air pollution decreased. In contrast, low-elevation red spruce growth would decrease with future climate change regardless of change in air pollution. <a href="#">Koo et al. (2014)</a>

**Table 13-3 (Continued): Summary on climate modification of acidification in Appendix 4 and Appendix 5 in addition to those in Appendix 13.**

Indicator/Process	T	P	Snow	Reference
<b>Biological effects of freshwater acidification (<a href="#">Appendix 8</a>)</b>				
Water DOC	X			<a href="#">Warren et al. (2017)</a> The major stressor affecting native cold-water fish species in the eastern U.S. is shifting from acidification to thermal stress and some lakes recovering from acidification may provide a degree of protection against climate effects. As DOC in the water increases with increasing lake pH in recovering lakes, decreased water clarity may create cooler refuge habitat for fish.

### 13.1.4 Nitrogen, Climate, and Biodiversity

#### 13.1.4.1 Excerpt from [Greaver et al. \(2016\)](#)

“Biodiversity, which contributes to the structure and function of ecosystems, is declining globally ([Rockstrom et al., 2009](#)). Decades of study show that added N reduces autotrophic diversity in terrestrial and aquatic systems, fungal biodiversity in soils, and, although less studied, animal diversity in terrestrial and aquatic systems ([Howarth et al., 2011](#); [Bobbink et al., 2010](#)). As previously mentioned, two mechanisms that contribute to altered biodiversity are eutrophication and acidification. Eutrophication often causes N stimulated growth for opportunistic species, which may cause competitive exclusion of poorer competitors and soil acidification driving cation imbalances and physiological stresses, suppressing seed germination and seedling regeneration ([Sullivan et al., 2013](#); [Roem et al., 2002](#)). In addition, N may alter physiology and/or community properties, increasing the risk to secondary factors such as pests, fire, frost, and drought ([Bobbink et al., 2010](#)). Lastly, direct damage to vegetation from ammonia (NH<sub>3</sub>), nitrogen dioxide (NO<sub>2</sub>), nitrogen monoxide (NO), peroxyacetyl nitrate (PAN), and nitric acid (HNO<sub>3</sub>) exposure is known to occur, but most likely occurs in highly polluted areas and in close proximity to high emission sources ([Greaver et al., 2012](#)). In terrestrial ecosystems, all processes generally reduce local autotroph diversity and homogenize habitats into communities with small numbers of generally fast-growing or acid-tolerant autotrophic species. These changes propagate through the food web, leading to increases of generalist pests, herbivores, and parasitic soil bacteria, and decreases in specialist herbivores and beneficial microbial communities that occur belowground ([de Sassi et al., 2012](#)).

“Biodiversity responses on land may be moderated by the type of climate change occurring and the mechanism of N response. In terrestrial systems that get warmer and wetter, eutrophication may be amplified if endogenous N sources are low or dampened if endogenous sources are high/more liberated to meet community demand. The response of the acidification pathway may depend on whether the change in net fluxes of cations from climate change exceeds the net fluxes of N [i.e., from enhanced deposition of cations and N, decomposition or weathering, and leaching ([Howarth et al., 2011](#); [Roem et al., 2002](#))]. Many of these processes may be dampened in terrestrial systems that are anticipated to get warmer and drier (e.g., southwestern U.S.) due to the drier conditions reducing biological activity ([Bobbink et al., 2010](#)). Colder regions such as montane, alpine, and tundra systems are often strongly N limited and poorly buffered; thus, an extended growing season under climate change will lead to greater opportunities for all operating processes. Climate change may also magnify the effects of secondary stressors in several ways, including increased pest populations under warmer wetter conditions, as well as increasing fire potential and drought vulnerability as more aboveground plant tissue is produced under elevated N ([Dise et al., 2011](#)). Nonetheless, field evidence for interactions between N and climate change under controlled conditions is scarce. The few existing studies find additive effects in Mediterranean California ([Zavaleta et al., 2003](#)), and no interactive effects of precipitation and N addition in Minnesota ([Reich et al., 2014](#); [Reich, 2009](#)). Not all terrestrial ecosystems are anticipated to be equally sensitive to these pressures. In grasslands, many forbs and slow-growing species such as native C4 grasses appear especially vulnerable to added N ([Clark and Tilman, 2008](#); [Zavaleta et al., 2003](#)). In a study of northeastern forests, all three tree species with negative growth responses to N deposition were evergreen conifers (e.g., *Pinus resinosa*, *Picea rubens*, *Thuja occidentalis*), while all five tree species with positive growth responses were broadleaf species with arbuscular mycorrhizal associations [e.g., *Acer rubrum*, *A. saccharum*, *Fraxinus americana*, *Liriodendron tulipifera*, and *Prunus serotina* ([Thomas et al., 2010](#))]. However, contingent factors underly these general patterns, as there were tree species from each group that did follow these generalities.

“In aquatic systems, elevated temperatures and N inputs from increased rain and glacial retreat will likely magnify changes in algal assemblages that can propagate through the food web ([Hobbs et al., 2010](#); [Elser et al., 2009a](#)). In freshwater aquatic biodiversity research, there is a substantial amount of work on lakes investigating the effects of warming via gradient studies (latitude or altitude), warming experiments, time series, and paleoecology ([Jeppesen et al., 2014](#)). Fish community assemblages, size, structure, and dynamics are likely to change with continued global warming, and in some cases the elevated temperatures that have already occurred in the past decades. Fish cannot thermoregulate, but only physically move to areas with appropriate temperatures, if those are accessible. In general, changes in fish composition, particularly in shallow lakes, are

characterized by a decline in abundance of several cold-stenothermal species ([Kangur et al., 2013](#); [Winfield et al., 2010](#)) and in increases in eurythermal species, which exhibit a wide range of thermal tolerance ([Jeppesen et al., 2012](#)). Many fish species are also adapted to specific oxygen concentrations; when temperature increases, oxygen may drop to critical levels as warm water holds less oxygen and the respiration rates increase. Warming effects on the biodiversity of grazing macroinvertebrates and zooplankton is mixed across studies ([Özen et al., 2013](#); [Burgmer et al., 2007](#)). Warming is shown to increase cyanobacteria biomass ([Kosten et al., 2012](#)) and biofilm biomass ([Williamson et al., 2016](#)), while warming effects on phytoplankton show mixed results ([Meerhoff et al., 2012](#); [Feuchtmayr et al., 2009](#)).

“Warming may cause increases in evaporation that will lower water level and increase salinity ([Williams, 2001](#)). Increasing salinity of freshwater systems tends to have a negative effect on phytoplankton, zooplankton, macroinvertebrates, and fish ([Jeppesen et al., 2007](#)). Climate change will alter the transport, availability, and timing of N in ecosystems, and recent data indicates an increase of primary production limitation by N or colimitation by N and P ([Elser et al., 2009a](#)). In N-limited fresh waters, N enrichment enhances rapid growth of nitrophilic algae that outcompete other populations for light and resources such as P and silicon (Si), leading to dominance by a few algal species and a reduction in the nutritional quality of invertebrates as food for fish ([Baron et al., 2012](#); [Hobbs et al., 2010](#); [Elser et al., 2009a](#)). The combination of increasing both N and temperature may be synergistic and sometimes difficult to uncouple ([Kangur et al., 2013](#)), as both may stimulate hypoxic conditions, consequently altering community structure ([Özen et al., 2013](#); [Feuchtmayr et al., 2009](#)) and the frequency, intensity, extent, and duration of harmful algal blooms ([Paerl et al., 2011](#)).

“Presently, there are at least 78 listed or candidate species for threatened or endangered status in North America that have N impacts identified as a primary contributor, and an estimated 15–37% of species may be at risk from climate change ([Hernández et al., 2016](#)). In total, there are numerous pathways whereby these dominant global change factors can interact to impact biodiversity, and it is likely, although not definitive, that N and climate often have additive and potentially amplifying effects on decreasing biodiversity in many systems.”

---

#### **13.1.4.2 Additional Considerations**

There are considerations to note in addition to the excerpt from [Greaver et al. \(2016\)](#). Additional papers on climate interactions with N and biodiversity discussed in [Appendix 6](#) are summarized in [Table 13-4](#). Most notably there are several new studies on

the interacting effects of climate and N deposition on plant species richness, and community composition of plants, soil microbes and soil animals.

**Table 13-4 Summary on climate modification of nitrogen (N) effects on biodiversity in [Appendix 6](#) in addition to those in [Appendix 13](#).**

Indicator/Process	T	P	Snow	Reference
Plant species richness	X			<b>Empirical:</b> No significant interaction between N and temperature on plant species richness for closed-canopy systems (deciduous, evergreen, and mixed forests), but significant interaction in open-canopy systems (grasslands, shrublands, and woodlands). In these open-canopy ecosystems, N had a more negative effect on species richness at lower temperatures. <a href="#">Simkin et al. (2016)</a>
Plant community composition	X	X		<b>Model:</b> In the ForSAFE-VEG model projections of plant community composition in three French forests two N reduction scenarios showed that recovery of these plant communities occurred only if climatic factors are held constant at current levels. <a href="#">Rizzetto et al. (2016)</a>
Plant community composition	X	X		<b>Model:</b> Understory plant community composition in northern hardwood forests at Bear Brook Watershed in Maine and Hubbard Brook in New Hampshire: the simulated plant community composition returned toward preindustrial conditions over the next century only in a scenario in which N deposition rates returned to background and climate was kept stable. <a href="#">Phelan et al. (2016)</a>
Soil microbial community		X		<b>Empirical:</b> N additions and lower precipitation interacted to shift microbial community composition in forests soils in northeastern China. <a href="#">Wang et al. (2014c)</a>
Soil microbial community		X		<b>Empirical:</b> N additions and lower precipitation interacted to shift microbial community composition in grassland soils in Inner Mongolia. <a href="#">Li et al. (2016a)</a>
Ectomycorrhizal species composition		X		<b>Empirical:</b> Both changes in precipitation and nitrogen were associated with shifts in ectomycorrhizal species composition in European Scots pine. <a href="#">Jarvis et al. (2013)</a>
Nematode predators, microarthropod herbivores, and taxa richness of nematodes and microarthropods		X		<b>Empirical:</b> In Minnesota grassland, a decline was observed in several categories of biota within a soil food web (numbers of nematode predators, microarthropod herbivores, and taxa richness of nematodes and microarthropods) under increased N, and a decrease in ciliate protists under high N and drought. <a href="#">Eisenhauer et al. (2012)</a>

**Table 13-4 (Continued): Summary on climate modification of nitrogen (N) effects on biodiversity in Appendix 6 in addition to those in Appendix 13.**

Indicator/Process	T	P	Snow	Reference
Algal species composition	X			<a href="#">Rühland et al. (2015)</a> . In regions with no evidence of increased atmospheric nutrient inputs, warming trends are observed to enhance competitiveness of planktonic diatoms like <i>Asterionella formosa</i> , which are typically associated with elevated N, indicating that climate change has significant direct and indirect effects on algal species composition. Climate change may thus enhance the effects observed in areas with nutrient increases alone.

## 13.2 Estuaries

In addition to terrestrial and freshwater systems described above, climate change modifies key processes in estuarine and near-coastal systems linked to nutrient inputs. Atmospheric deposition may represent more than 40% of N in coastal water bodies ([Appendix 7](#)). N sources to near-coastal ecosystems include direct deposition to the water surface and all other N sources upstream. Coastal eutrophication is a process of increasing nutrient over-enrichment indicated by water quality deterioration, resulting in numerous adverse effects including hypoxic zones (water with dissolved oxygen that is too low to support marine life), species mortality, proliferation of phytoplankton and macroalgae (including harmful algal blooms), and decreased coverage of submerged aquatic vegetation [([Bricker et al., 2007](#)); [Appendix 10](#)].

Indicators of nutrient enrichment may be affected by climate-related changes in estuaries including temperature, precipitation, wind patterns, stronger estuary stratification, increased metabolism and organic production, and sea-level rise [see discussion in [Appendix 10](#); ([Altieri and Gedan, 2015](#); [Statham, 2012](#); [Rabalais et al., 2009](#))]. For example, eutrophic conditions and the extent and duration of hypoxia are predicted to increase with changes in temperature and precipitation ([Altieri and Gedan, 2015](#); [Rabalais et al., 2009](#); [Boesch et al., 2007](#)). [Doney et al. \(2012\)](#) reviewed effects of climate change, including coastal hypoxia, on marine biodiversity and reported population-level shifts. In estuaries affected by nutrient enrichment and climate-associated alterations described above, conditions favor a shift in phytoplankton composition toward greater abundance and distribution of toxic cyanobacteria associated with an increased prevalence of harmful algal blooms ([Paerl et al., 2016a](#)). In a meta-analysis of temperature effects on benthic macrofauna, survival times significantly decreased in hypoxic conditions under warmer temperatures ([Vaquer-Sunyer and Duarte,](#)

[2011](#)). Decreases in estuarine biodiversity associated with N loading can be magnified by hydrologic factors. [Glibert et al. \(2014\)](#) observed a regional change in phytoplankton community composition and decreased coverage of submerged aquatic vegetation following a shift from long-term dry to long-term wet conditions in the early 2000s in shallow coastal lagoons along the coast of Maryland and Virginia. Shifts in phytoplankton community structure are known to occur in estuaries due to N enrichment, but climate changes may at times outweigh the impacts of eutrophication ([Paerl et al., 2010](#)). Thus, physical changes caused by climate change should be considered when modeling phytoplankton community response to N enrichment ([Paerl et al., 2014](#)).

---

### 13.3 Wetlands

Changes in mean annual temperature and frequency and magnitude of precipitation will affect the responses of all wetlands to N loading ([Appendix 11](#)).

Increasing temperatures may strengthen N effects upon wetland ecosystems. Temperature effects on wetlands have been demonstrated in European bog ecosystems, where increased temperatures increased the cover of woody species and decreased *Sphagnum*. N addition and temperature are known to synergistically depress *Sphagnum* production, with a 1°C increase in summer temperature having an impact on the *Sphagnum* equivalent to an additional 40 kg N/ha/yr ([Limpens et al., 2011](#)).

Hydrologic regimes are important controls on wetland cycling and productivity, so changes in the magnitude and frequency of precipitation can have strong effects on ecosystem N retention and C storage. Increased precipitation is shown to increase *Sphagnum* sensitivity to N addition-induced decreases in production ([Limpens et al., 2011](#)). Experimental mesocosms modeling changes in precipitation to salt marshes found that precipitation delivered in infrequent, heavy storm events decreased N retention and plant productivity, even though storm events delivered a higher N deposition load to the marsh ([Hanson et al., 2016](#); [Oczkowski et al., 2016](#)). Shifts in precipitation towards less frequent, more intense rain events may strengthen N deposition-induced decreases in salt marsh N retention while weakening N deposition-induced increases in plant productivity.

---

## APPENDIX 14 ECOSYSTEM SERVICES

This appendix is a review of the state of the science on ecosystem services altered by nitrogen (N) and sulfur (S) deposition. The state of the science in 2008, as presented in the *2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur-Ecological Criteria* (hereafter referred to as the 2008 ISA), is summarized and sets the foundation for the discussion on the new literature (published from 2008–present).

---

### 14.1 Introduction

“Ecosystem services” refers to the concept that ecosystems provide benefits to people, directly or indirectly ([Costanza et al., 2017](#)), and that ecosystems produce socially valuable goods and services deserving of protection, restoration, and enhancement ([Boyd and Banzhaf, 2007](#)). The concept of ecosystem services recognizes that human well-being and survival are not independent of the rest of nature, but rather that humans are an integral and interdependent part of the biosphere ([Costanza et al., 2017](#)). In some cases, and in line with more conventional economic thinking, ecosystem services analysis can result in attaching monetary values to ecosystem outcomes. However, because ecosystem services are often public goods their benefits can be difficult to monetize (see case study boxes for lace lichen on page 14-5 and the Chesapeake Bay on 14-10 as examples). We emphasize that this practical difficulty in no way implies that ecosystem service benefits are small or without value. At a minimum, ecosystem services analysis involves discussion and, ideally, quantification of ecological outcomes understood by households, communities, and businesses. Explicitly linking ecosystem services to social and economic welfare measures has proven difficult because of the broad definition of ecosystem services and the numerous types of services that could be affected. An analysis of ecosystem services specifically altered by NO<sub>x</sub>, SO<sub>x</sub>, and PM would translate the effects of ambient concentrations and deposition into biological, physical, or monetary metrics that give insight to public welfare effects.

The 2008 ISA documented the ecosystem services frameworks that were published at that time and provided several examples of how N and S deposition would alter services based on those frameworks. Since the 2008 ISA, new ecosystem services frameworks have been developed and several new approaches have been applied to conduct ecosystem services analysis specifically evaluating outcomes altered by N and S deposition. The conclusions considering the full body of literature published are that (1) there is evidence that N and S deposition has a range of effects on ecosystem services and their social value; (2) there are some economic studies that demonstrate such effects

in broad terms; however, it remains methodologically difficult to derive economic costs and benefits associated with specific regulatory decisions/standards; and (3) new work has identified a large number of scientifically and economically plausible causal relationships that link N and S air pollution to changes in Final Ecosystem Goods and Services (FEGS), defined as the “components of nature, directly enjoyed, consumed or used to yield human wellbeing” ([Boyd and Banzhaf, 2007](#)). The following sections discuss the relevant ecosystem services frameworks ([Appendix 14.2](#)), the studies in the U.S. on ecosystem services altered by acidification and eutrophication ([Appendix 14.3](#)), the studies of ecosystem services analyses conducted in countries outside of the U.S. ([Appendix 14.4](#) and [Appendix 14.5](#)), and a summary ([Appendix 14.6](#)).

---

## 14.2 Ecosystem Services Frameworks

Ecosystem services frameworks can help identify causal pathways between specific ecosystem changes and potential human beneficiaries. A single classification system may be desirable to promote standardization and communication. However, classification systems do not by themselves solve the core issue of how to empirically quantify causal relationships between N and S and final ecosystem goods and services. Here an overview of key frameworks is presented to give context on conceptual advances in ecosystem services research.

Several ecosystem services frameworks were published in 2008 and described in the 2008 ISA. These frameworks provided qualitative and/or quantitative metrics by which to identify the services that ecosystems provide to benefit human welfare and society ([WRI, 2000](#); [Costanza et al., 1997](#); [Daily, 1997](#); [Pimentel et al., 1997](#)). It was well documented at that time that some goods and services have explicit market value; however, the value of other services is more difficult to assess ([U.S. EPA, 2008a](#); [Goulder and Kennedy, 1997](#)). The most accepted framework for ecosystem services identified by the 2008 ISA was the 2005 Millennium Ecosystem Assessment (MEA) by [Hassan et al. \(2005\)](#). Since the 2008 ISA, several new ecosystem services frameworks and classification systems have been published. These include The Economics of Ecosystems and Biodiversity [TEEB; [Sukhdev et al. \(2014\)](#)], the Common International Classification of Ecosystem Services [CICES; [Haines-Young and Potschin \(2011\)](#)], U.S. EPA Final Ecosystem Goods and Services Classification System [FEGS-CS; [Landers and Nahlik \(2013\)](#)], and The National Ecosystem Services Classification System [NESCS; [U.S. EPA \(2015d\)](#)].

The goal of the TEEB initiative is to demonstrate the economic value of services provided by species and ecosystems and then capture the value of these services through market- or policy-based approaches ([Sukhdev et al., 2014](#)). The TEEB initiative uses four

primary categories of ecosystem services. Three of the four categories are from the MEA (provisioning, regulating, and cultural services). However, TEEB replaces the MEA's "supporting services" with "habitat services," which emphasizes the provisioning of species and genetic diversity.

The CICES framework was developed in part as a reaction to the increasingly diverse ways that ecosystem services were discussed, categorized, and assessed by different organizations around the world. The CICES program has as a primary goal to create a more uniform approach to assessing ecosystem services ([Haines-Young and Potschin, 2011](#)). The classification approach CICES developed recognizes only final outputs from ecosystems, in other words, "products" that are directly consumed or used by people ([Haines-Young and Potschin, 2011](#)). Thus, the concept of "supporting services" identified by the MEA was dropped under the assumption that these functions would be recognized for their role in facilitating the final outputs. CICES developed a hierarchical structure, beginning with the three broad categories (provisioning, regulating, and cultural), which were broken down into 23 "service groups" and then 59 "service types" ([Haines-Young and Potschin, 2011](#)).

The FECS-CS framework uses the concept of Final Ecosystem Goods and Services (FECS), which are defined as a subset of ecological outcomes, specifically the "components of nature, directly enjoyed, consumed or used to yield human well-being" ([Boyd and Banzhaf, 2007](#)). The U.S. EPA FECS-CS approach defines and classifies 338 unique FECS, each uniquely numbered by a combination of environmental class or subclass and a beneficiary category or subcategory ([Landers and Nahlik, 2013](#)). In addition to FECS-CS, the U.S. EPA also developed NESCS to specifically analyze the human welfare impacts of policy-induced changes to ecosystems ([U.S. EPA, 2015d](#)). The goal of NESCS is to support analysis of changes from baseline conditions, such as cost-benefit analysis, and support systematic accounting of changes in ecosystem services. The NESCS structure defines categories and numeric codes that are designed to help identify flows of services from ecosystems to human beings, while distinguishing between the producers (i.e., "supply-side") and users (i.e., "demand-side") of the service.

Lastly, [Bell et al. \(2017\)](#) developed the Stressor—Ecological Production function—final ecosystem Services (STEPS) framework. STEPS produces "chains" comprised of the biological indicator, the ecological production function (EPF, which uses ecological components to link the biological indicator to a final ecosystem service), and the user group who directly uses, appreciates, or values the component. To this end, STEPS is used in conjunction with other frameworks that identify user groups, like FECS-CS. The framework uses a qualitative score (high, medium, low) to describe the strength of science (SOS) for the relationship between each component in the EPF.

---

## 14.3 United States Applications

Among the ecological effects of N and S deposition, the ecosystem services altered by acidification are the most well documented, with several new papers published since 2008 ([Beier et al., 2017](#); [Caputo et al., 2017](#); [Irvine et al., 2017](#); [O'Dea et al., 2017](#); [Banzhaf et al., 2016](#); [Office of Air and Radiation, 2011](#); [Chestnut and Mills, 2005](#); [Banzhaf et al., 2004](#); [U.S. EPA, 1999](#); [NAPAP, 1991](#)). In the 2008 ISA, no publications were identified describing how ecosystem services were altered as a result of N driven eutrophication; however, several new comprehensive studies have been published since 2008 ([Clark et al., 2017](#); [Rhodes et al., 2017a](#); [Compton et al., 2013](#); [Birch et al., 2011](#); [Compton et al., 2011](#)). Also new to the literature since 2008 is a group of publications ([Bell et al., 2017](#); [Clark et al., 2017](#); [Irvine et al., 2017](#); [O'Dea et al., 2017](#); [Rhodes et al., 2017a](#)) evaluating the FECS altered by four modes of ecological response to N and S deposition (aquatic acidification, terrestrial acidification, aquatic eutrophication, and terrestrial eutrophication). In these analyses critical load (CL) exceedances for N related air pollution were used as a model stressor from which a total of 1,104 unique chains linking stressor to beneficiary were identified. These analyses, built using a holistic STEPS approach, represent a great advance for identifying the wide range of ecosystem processes and types of final ecosystem services affected by N and S deposition. However, it also underscores the many information gaps that exist for quantifying the dose-response relationships between N and S air pollution exposures and final ecosystem services and the values associated with changes in these services.

Two recently published studies ([Jaramillo and Muller, 2016](#); [Holland et al., 2015](#)) have used the Air Pollution Emissions Experiments and Policy (APEEP or AP2) to calculate the value of damages from emissions of SO<sub>2</sub>, VOCs, NO<sub>x</sub>, PM<sub>2.5</sub>, PM<sub>10</sub>, and NH<sub>3</sub>. The model connects changes in emissions to concentrations of several criteria air pollutants. A large majority of the damage estimates are associated with human health impacts and ozone-related damages to crops and forests. A very small portion of damages are linked to forest and recreation impacts from a mix of ambient pollutants including NO<sub>x</sub> and SO<sub>x</sub>, but this portion of the model was developed before 2006, has not been updated, and is not well documented (i.e., the model structure is described but not the estimated parameters).

### How do N deposition impacts on lace lichen affect forest ecosystem services?

Native to the Pacific coast of North America, lace lichen (*Ramalina menziesii* [Ramalinaceae]) grows from Alaska to Baja California. It has a unique morphology that adds to the natural beauty of coastal woodlands along the Pacific Coast ([Hastings Reserve, 2015](#)). It is a food source for browsing mammals, including deer, cows, and squirrels, and is also used as a nesting material for hummingbirds and orioles (Hastings Reserve).

*Photos source: 2016 AQE workshop report.*

Unfortunately, lace lichen abundance is threatened by nitrogen and sulfur pollutants' deposition ([Hernández et al., 2016](#)). It is very sensitive to air pollution, including exposure to nitric acid ([Riddell et al., 2008](#)), and it has been found to contribute to the global uptake of sulfur dioxide, an airborne pollutant ([Gries et al., 1997](#)). Lace lichen was formerly found in the San Jacinto Mountains near Los Angeles and on the surrounding coastal plain but now it only grows at elevations above the smog layer ([Hastings Reserve, 2015](#)).

Declines in lace lichen abundance can reduce ecosystem services to humans in several ways. In addition to reducing the aesthetic benefits provided by lichens, declines in lace lichen may be indirectly contributing to declining populations of the spotted owl, which is an endangered, widely recognized, and charismatic species native to Pacific Northwest forests. This indirect impact may be occurring because the northern flying squirrel, which is an almost exclusive food source for the spotted owl, relies exclusively on forage lichens as a winter time food source.

## **14.3.1 Acidification**

Prior to 2008, ecosystem acidification in the U.S. was evaluated with regard to how ecosystems services respond to lowering NO<sub>x</sub> and SO<sub>x</sub> emissions. Initial monetary valuation of the total annual value for improvements in recreational fishing ([NAPAP, 1991](#)) were improved with updated economic studies and new models for estimating the changes in fish stocks and catch rates in the Adirondacks ([U.S. EPA, 1999](#)). A few years later, [Chestnut and Mills \(2005\)](#) derived new estimates and compared them with the 1990

estimates of the benefits of reducing emissions of NO<sub>x</sub> and SO<sub>x</sub> in Title IV of the Clean Air Act Amendments (CAAA). They concluded that the 1990 quantitative assessment was limited by a lack of measurement units to gauge changes in the quality and quantity of ecosystem services and a lack of dose-response relationships to indicate how quality and quantity may change as a function of changes in pollution exposures. A different approach, that did not rely on dose-response relationships, documented that New York households are willing to pay an average of \$45 to \$100 annually to reduce the number of acidified lakes by 40% and improve forest health in the Adirondacks ([Banzhaf et al., 2004](#)).

Several ecosystem services valuations for acidification published (since 2008) are given in [Table 14-1](#). [Rea et al. \(2012\)](#) paired biogeochemical modeling using the Model for Acidification of Groundwater in Catchment (MAGIC) with two different approaches, one benefit transfer and one random utility, to estimate ecosystem services values for remediation scenarios of acidic deposition on lakes in New York's Adirondack Park. [Beier et al. \(2017\)](#) and [Caputo et al. \(2017\)](#) have also calculated new monetary valuations of acidification effects in the Adirondacks ([Table 14-1](#)). New work in the southern Appalachian region used an approach that wedges biogeochemical (e.g., MAGIC) and economic modeling to evaluate the cost of aquatic and terrestrial acidification ([Banzhaf et al., 2016](#)).

Two new studies used FECS-CS to quantify how many FECS are altered by ecosystem acidification and associated critical load (CL) or total load (TL) exceedance ([Irvine et al., 2017](#); [O'Dea et al., 2017](#)). [O'Dea et al. \(2017\)](#) identified human beneficiary groups for each ecological endpoint affected by aquatic acidification, including effects on otter, mink, loon, aquatic vegetation, shellfish, brook trout, and bass. [Irvine et al. \(2017\)](#) documented the effects of terrestrial acidification on two acid-sensitive tree species, balsam fir (*Abies balsamea*) and white ash (*Fraxinus Americana*; [Table 14-1](#)).

Overall, the new literature since the 2008 ISA includes studies that better characterize ecosystem services valuation by pairing biogeochemical modeling and benefit transfer equations informed by WTP surveys, especially for the Adirondacks and Shenandoah regions. Aside from valuation, the estimate of the total number of ecosystem services affected by N and S deposition is better quantified by the new studies that use FECS-CS. However, for many regions and specific services, poorly characterized dose-response relationships between deposition, ecological effect, and services are the greatest challenge to quantification of the economic benefits of emission reductions ([NAPAP, 2011](#)).

**Table 14-1 Ecosystem services research related to ecosystem acidification.**

Mode	Region	Effect	Reference
Aquatic acidification	Adirondacks	In 1990, the estimates of total annual value for improvements due to lowering NO <sub>x</sub> and SO <sub>x</sub> emissions in recreational fishing were \$12 to \$24 million.	<a href="#">NAPAP (1991)</a>
Aquatic acidification	Adirondacks	Reported estimates of annual value of improvements in conditions for recreational fishing in the Adirondacks of about \$65 million for the reductions in acid deposition as a result of the 1990 CAAA, primarily Title IV.	<a href="#">U.S. EPA (1999)</a>
Aquatic acidification		Compare the actual benefits of reducing emissions of NO <sub>x</sub> and SO <sub>x</sub> in Title IV of the Clean Air Act Amendments (CAAA) by the estimate of benefits made in 1990.	<a href="#">Chestnut and Mills (2005)</a>
Aquatic acidification	Adirondacks	New York households are willing to pay an average of \$45 to \$100 annually to reduce the number of acidified lakes by 40% and improve forest health in the Adirondacks.	<a href="#">Banzhaf et al. (2004)</a>
Aquatic acidification	Adirondacks	Linked NO <sub>x</sub> and SO <sub>x</sub> emissions estimates to CMAQ modeling, MAGIC modeling, then a Random Effects Model that was developed to account for fishing site choices made by recreational fishers based on attributes of sites specifically in the Adirondack region. The difference in economic welfare values between the value of fishable (i.e., not impaired) lakes in the with-CAAA scenario and the without-CAAA scenario represented the benefits to recreational fishing in the Adirondack region associated with the CAAA.	<a href="#">Office of Air and Radiation (2011)</a>
Terrestrial Acidification	Adirondacks	The changes in percent base saturation levels in timber harvest areas were mapped in relation to potential changes in the growth and health of tree species present in these areas and the likely effects of altered tree growth and health on timber harvest rates and volumes. Of the forest types of interest, the paper birch forest type experiences the greatest increase in percent base saturation due to the CAAA, followed by the eastern hemlock and the sugar maple/beech/yellow birch forest types.	<a href="#">Office of Air and Radiation (2011)</a>
Aquatic acidification	Adirondacks (44 lakes)	Biogeochemical modeling (e.g., MAGIC) is combined with a benefit transfer approach based on a stated preference study, which captures ecosystem services values as a whole. Total values range from \$547 million to \$1 billion/yr. In contrast, an approach based on a preference study, which only captures recreation fishing values, estimated benefits ranging from \$7 million to \$9 million/yr.	<a href="#">Rea et al. (2012)</a>
Aquatic and terrestrial acidification	Southern Appalachia (169 sites)	Hypothetical scenarios of lower emissions are coupled with biogeochemical modeling (e.g., MAGIC) and a novel stated preference survey to determine individuals' WTP is used to generate aggregate benefits of about \$3.7 billion, or about \$16/yr/household in the region.	<a href="#">Banzhaf et al. (2016)</a>

**Table 14-1 (Continued): Ecosystem services research related to ecosystem acidification.**

Mode	Region	Effect	Reference
Terrestrial acidification	Adirondacks	Blending regression analysis of tree growth and soil condition with a benefit transfer approach, it was estimated that acid-impaired hardwood forests provide roughly half of the potential benefits of forests on moderate to well-buffered soils—an estimated loss of ~\$10,000 ha <sup>-1</sup> in net present value of wood products, maple syrup, carbon sequestration, and visual quality.	<a href="#">Beier et al. (2017)</a>
Aquatic acidification	Adirondacks (52 study lakes)	Acidic deposition has had little effect on lakes water suitable for drinking in the region. However, as pH declines in lakes, the estimated value of recreational fishing decreases significantly due to loss of desirable fish. The expected value of recreational fishing increased with increasing pH, from a minimum of \$4.41 angler/day in unstocked, acid-impaired lakes to a maximum of \$38.40 angler/day in well-buffered lakes that were stocked with trout.	<a href="#">Beier et al. (2017)</a>
Aquatic acidification	Adirondacks	Analysis of benefit transfer using willingness-to-pay (WTP) for recreational fishing and logistic regression of fish populations demonstrated that under low emissions scenarios combined with fish stocking. These are the same results reported in <a href="#">Beier et al. (2017)</a> .	<a href="#">Caputo et al. (2017)</a>
Aquatic acidification	U.S. national-scale	Using FEGS-CS to quantify the total number of causal relationships between aquatic acidification driven by N and S deposition and beneficiaries. Effects were documented on otter, mink, loon, aquatic vegetation, shellfish, brook trout, and bass.	<a href="#">O'Dea et al. (2017)</a>
Terrestrial acidification	Northeastern U.S.	Using FEGS-CS to identify 160 chains with 10 classes of human beneficiaries for balsam fir and white ash combined, the authors concluded there are resources at risk that the public may value. Estimated ~1,200 chains if all vulnerable tree species are evaluated.	<a href="#">Irvine et al. (2017)</a>

### 14.3.2 Eutrophication

Since the 2008 ISA, several comprehensive studies have been published on the ecosystems services related to N pollution in the U.S. ([Table 14-4](#)). These include an evaluation of services effected by multiple N inputs (including N deposition) to the Chesapeake Bay ([Birch et al., 2011](#)) and syntheses by [Compton et al. \(2011\)](#) and [Compton et al. \(2013\)](#) of the cost-benefits on N loading across the nation for services that included coastal fish harvests, recreational uses of inland and coastal waters, lakefront property values, and water treatment costs. Further expanding on this work, [Sobota et al. \(2015\)](#) calculated the amount of N loading from human activity that is leaked into adjacent ecosystems and the associated effects on ecosystem services. In their work, [Sobota et al. \(2015\)](#) specifically identified the costs of the atmospheric portion of total N

loading. [Baron et al. \(2012\)](#) evaluated the interactions between climate and N, identifying some key services in which a changing climate will modify the response to N.

[Birch et al. \(2011\)](#) examined the spatial and temporal movement of reactive N through multiple ecosystems and media in the Chesapeake Bay watershed and estimated damage costs in several categories ([Figure 14-1](#)). Their analysis estimates the contribution of atmospheric N sources to the total annual N loads delivered to the bay estuary. According to the study, roughly 20% of N related ecosystem services impacts in the estuary are attributable to atmospheric N deposition in the watershed.

Building on the work by [Birch et al. \(2011\)](#), a review and synthesis of the published literature by [Compton et al. \(2011\)](#) compared estimates of the average damage costs/unit of N across a range of affected services. Further building on this work, [Sobota et al. \(2015\)](#) estimated how unintentional N input into the environment (via air/deposition, surface freshwater, groundwater, and coastal zones) alters services. They did this by multiplying watershed-level N inputs (8-digit U.S. Geologic Survey hydrologic unit codes; [HUC8s]) with published coefficients describing nutrient uptake efficiency, leaching losses, and gaseous emissions. [Sobota et al. \(2015\)](#) then applied per-unit damage cost values (\$/N) for a wide variety of ecological effects (based on estimates from various sources, [Table 14-2](#)) to the input estimates.

### Why are aquatic grasses on the path between N deposition and ecosystem services in the Chesapeake Bay?

The Chesapeake Bay is the largest estuary (4,480 sq miles) in the U.S. draining from eight major river basins covering 64,000 sq miles of watershed in six states and a population of 18 million watershed residents. The public's use of the bay is significant with more than 700 public access points on the bay and its tributaries. More than 3,600 species of plants and animals are supported by the bay, including over 80 resident and migratory waterfowl species. About 500 million pounds of seafood is produced annually by the bay (<https://www.chesapeakebay.net>).

Unfortunately, this vital natural resource and estuarine ecosystem are under stress, and nitrogen deposition in the Chesapeake Bay watershed is one of the main contributing sources. The Chesapeake Bay Program reports that one-third of the nitrogen loading to the bay comes from atmospheric deposition, often as nitrogen oxides or ammonia ([https://www.chesapeakebay.net/issues/air\\_pollution](https://www.chesapeakebay.net/issues/air_pollution)). Nitrogen air emission sources include automobiles, fossil fuel-fired electric generating units, and intensive animal operations both within and upwind of the bay watershed.

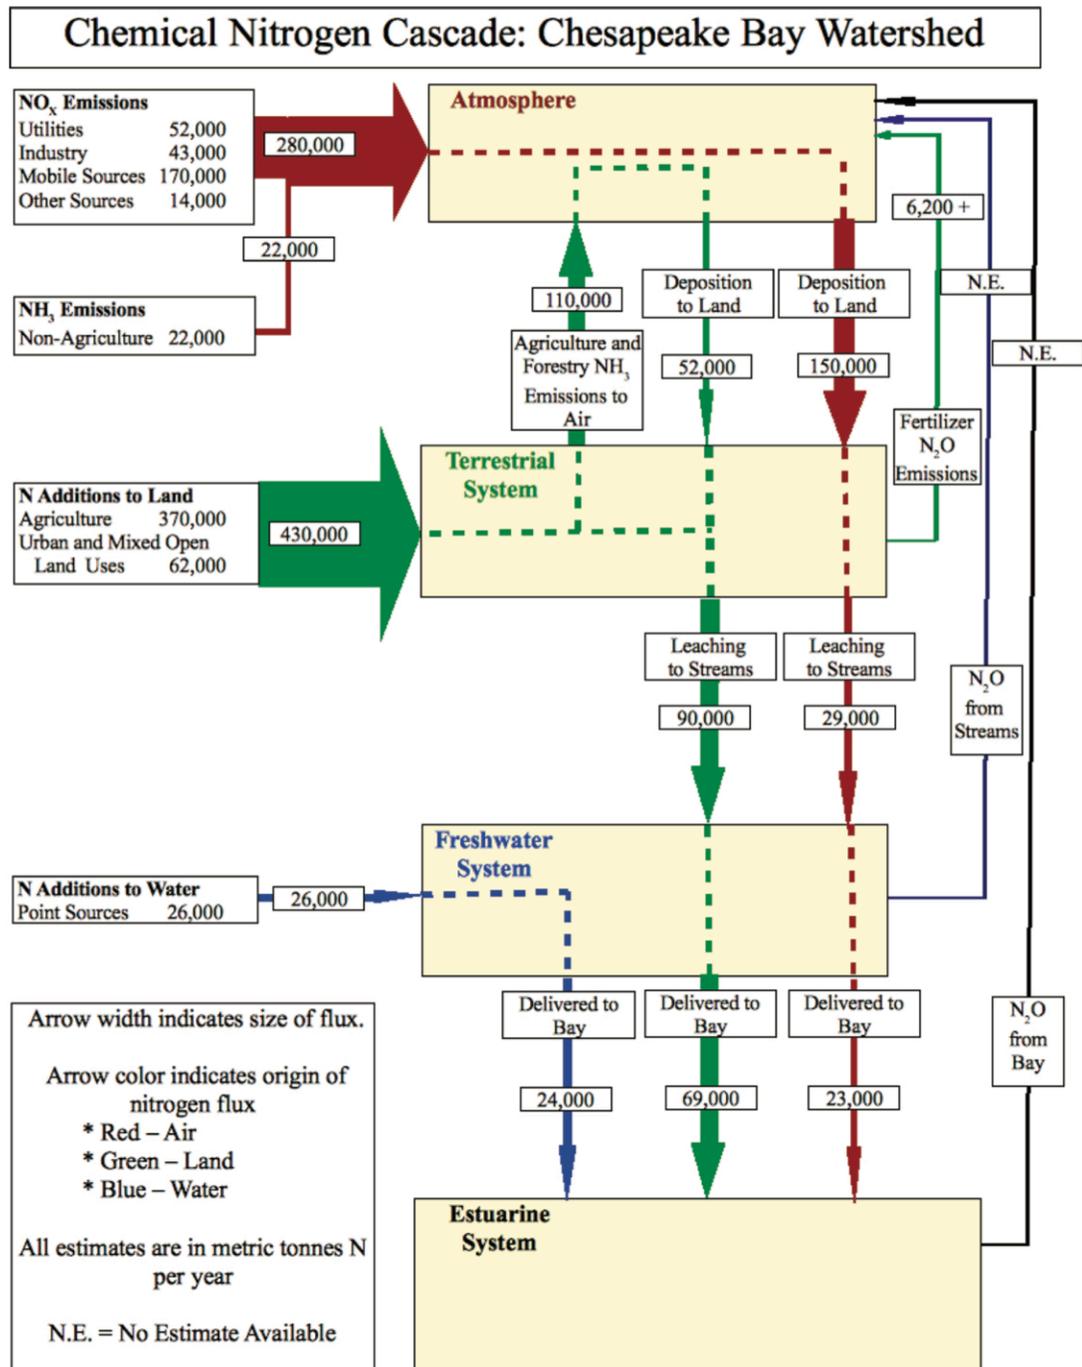

One of the most important indicators of environmental stress to the Chesapeake Bay is the loss of submerged aquatic vegetation (SAV). Nutrient over-enrichment and sediment overloading to the bay has led to SAV loss. Although SAV appears to be recovering as NO<sub>x</sub> emissions have declined in recent decades, the bay still contains only an estimated 53% of the SAV it once supported. The Chesapeake Bay Program's target restoration goal is 185,000 acres ([https://www.chesapeakebay.net/state/underwater\\_grasses](https://www.chesapeakebay.net/state/underwater_grasses)).

Photo courtesy of Chesapeake Bay Program

SAV is a critical indicator of the bay's health in part because of the essential role it plays in supporting a wide range of final ecosystem services to humans. The 80,000 acres of underwater grasses protect and host young and molting blue crabs and juvenile, for example (<https://www.chesapeakebay.net/discover/facts>). SAV supports natural ecosystems in additional ways, including serving as a food source for wildlife, waterfowl, and humans and as habitat (and protection) for wildlife and waterfowl (Barbier et al., 2011; Kemp et al., 2005). In turn, SAV facilitates important recreation, tourism, and commerce, including wildlife and waterfowl watching, fishing, and crabbing. In addition to these valuable indicators of overall WQ and ecosystem health, SAV deters and dissipates wave energy and promotes sedimentation for landowners along the bay, thus, mitigating erosion and protecting and sustaining land value.

The SAV connection is, therefore, one important pathway through which N deposition affects the well-being of human populations in and around the bay.

Still another advance is offered by [Clark et al. \(2017\)](#) and [Rhodes et al. \(2017a\)](#), who synthesized information on N induced terrestrial and aquatic eutrophication, respectively, from the published literature to link the ecological effects of critical load exceedances with human beneficiaries by using STEPS and FECS-CS. [Rhodes et al. \(2017a\)](#) identified that N loading to aquatic ecosystems affects 154 chains that link changes in biological indicators of aquatic eutrophication (a shift in phytoplankton community) to FECS, 13 ecological production functions (EPF) within three different ecosystems (alpine lakes, lakes, and estuaries) and 18 classes of human beneficiaries that potentially will be effected by a change in one of these endpoints. For terrestrial eutrophication, [Clark et al. \(2017\)](#) identified that N critical load exceedances affected beneficiary types through 582 individual chains in the five ecoregions examined (Eastern Temperate Forests, Marine West Coast Forests, Northwestern Forested Mountains, North American Deserts, Mediterranean California) and 66 FECS across a range of final ecosystem services categories (21 categories; e.g., changes in timber production, fire regimes, and native plant and animal communities; [Figure 14-3](#) and [Table 14-3](#)).

Map of (a) Level 1 ecoregions examined and (b) the count of unique chains, biological indicators, Final Ecosystem Goods and Services, and beneficiaries for each ecoregion.

**Figure 14-2 Map of ecosystem services altered by nitrogen critical load exceedance.**

**Table 14-3 Numbers of chains, Final Ecosystem Goods and Services (FEGS), and beneficiaries (bens) associated with each initial biological indicator (Clark et al., 2017).**

Biological Indicator	No. Chains	No. FEGS	No. Bens
Increased grass-to-forb ratio and/or increase in total biomass	192	11	12
Decreased lichen biodiversity	62	7	11
Decreased native mycorrhizal diversity	61	5	10
Decreased abundance of ectomycorrhizal fungi	43	3	12
Increased bark beetle abundance	34	4	12
Decreased survival of bigtooth aspen	32	4	11
Decreased survival of scarlet oak	32	4	11
Decreased survival of trembling aspen	32	4	11
Decreased abundance of arbuscular mycorrhizal fungi	25	3	10
Decreased growth of red pine	25	3	10
Increased cover of understory nitrophilic species	18	2	10
Increased bacteria-to-fungi ratio	17	2	9
Change in herbaceous community composition	7	1	7
Increase in N leaching	2	1	2

FEGS = Final Ecosystem Goods and Services.

**Table 14-4 Ecosystem services research related to nitrogen-driven eutrophication.**

Mode	Region	Effect	Reference HERO ID
Estuarine N driven eutrophication	Chesapeake Bay	Recreation and commercial fishing are the main ecosystem services impacts; however, it is difficult to quantify these impacts due to data limitations. The analysis finds that, although atmospheric releases of N are lower than direct releases to land and water, their total damages are larger yet have associated abatement costs that are relatively low.	<a href="#">Birch et al. (2011)</a>
Includes acidification and eutrophication		Damage to services associated with productivity, biodiversity, recreation, and clean water are less certain and although generally lower, these costs are quite variable (<\$2.2–\$56/kg N). In the current Chesapeake Bay restoration effort, for example, the collection of available damage costs clearly exceeds the projected abatement costs to reduce N loads to the bay.	<a href="#">Compton et al. (2011)</a>
Includes acidification and eutrophication	National scale, calculated for 8-digit HUCs	Annual damage costs associated with anthropogenic N leakage range from \$1.94 to \$2,255/ha/yr. Nationally, the total quantifiable damages were estimated to be between \$81–\$144 billion/yr. Between 14–24% of the potential damage costs were associated with fossil fuel combustion. Areas with the largest damage costs corresponded to areas with the largest N inputs and leakages, such as the upper Midwest and central California.	<a href="#">Sobota et al. (2015)</a>
Terrestrial N driven eutrophication	National scale	N critical load exceedances affected beneficiary types through 582 individual and 66 FEGS across a range of final ecosystem services categories.	<a href="#">Clark et al. (2017)</a>
Aquatic N driven eutrophication	National scale	Using STEPS and FEGS-CS, the authors identify 154 chains that link changes in biological indicators of aquatic eutrophication (a shift in phytoplankton community) to FEGS, and 18 classes of human beneficiaries.	<a href="#">Rhodes et al. (2017a)</a>
Terrestrial N driven eutrophication	Indiana	One calculation of the economic value of removing N from the landscape is \$5.91/kg/yr (mean) or \$10.50/kg/yr (high end). These values are based on the estimated cost to remove a kg of N from a community water system using available nutrient removal technologies, as summarized by the <a href="#">U.S. EPA (2008d)</a> .	<a href="#">Wang et al. (2017e)</a>
Includes acidification and eutrophication	Minnesota	The study authors measured the social cost of nitrogen (SCN) in Minnesota. They noted that each kg of N applied to a field generates four compounds: NO <sub>3</sub> <sup>-</sup> , N <sub>2</sub> O, NH <sub>3</sub> , and NO <sub>x</sub> . The total annual damage done by the four compounds measured in dollars/kg of N applied to a field is \$2.62 (mean), \$0.44 (low), and \$10.79 (high). To convert annual values to a net present value, the authors assumed a 20-year time horizon and a 3% rate of discount. This conversion generates values of \$40.15 (mean), \$6.74 (low), and \$165.34 (high)/kg of N applied. All dollar values are in 2010 dollars.	<a href="#">Keeler et al. (2016)</a>
Wetland N eutrophication	Mississippi Alluvial Valley	The study authors estimated an “annualized” value of N mitigation service (\$/kg N) in the Mississippi Delta Region in 2008 as \$25.27 (mean), \$22.82 (low), and \$106.09 (high) with a value of \$1,248/ha/yr for the region.	<a href="#">Jenkins et al. (2010)</a>

### 14.3.3 Nitrogen and Climate Modification

Some work has discussed the implications of climate change and N loading on ecosystem services such as fish harvests, property values, water treatment, human and wildlife health, ocean acidification, and freshwater diversity ([Baron et al., 2012](#)). The combined effect of N loading and climate change on the economic value of water resources and related products has yet to be evaluated, and even the separate economic effects of N loading or climate change are difficult to determine. However, climate change will modify the effects of N loading on some key ecological services. [Porter et al. \(2013\)](#) and [Compton et al. \(2013\)](#) also identified some effects on the interactions between nitrogen and climate, which include:

- As eutrophication increases with warmer water temperatures, there will be costs associated with upgrades of municipal drinking water treatment facilities, the greater reliance on bottled water, and the health costs of  $\text{NO}_3^-$  in drinking water associated with toxicity and disease ([Compton et al., 2011](#)).
- The U.S. will increasingly rely on groundwater for drinking water under future climate change scenarios ([U.S. Global Change Research Program, 2009](#)), creating a strong potential for increased costs for treating exposure to  $\text{NO}_3^-$ -stimulated disease.
- Increasingly, N enrichment is correlated in waters with pathogen abundance and human and wildlife diseases ([Johnson et al., 2010](#)). Climate warming opens the possibility for more vector-transmitted diseases to migrate to higher latitudes, where N loading may enhance their success ([Johnson et al., 2010](#)).
- Acidification causes direct harm to calcifying shellfish and crustaceans ([Howarth et al., 2012](#)). Changes in climate and the N cycle will intensify ocean acidification, and there are feedbacks from acidification to N cycling ([Doney et al., 2009](#)). [Table 14-5](#) provides a summary of recent studies and findings regarding the economic effects of ocean acidification on U.S. fisheries.

**Table 14-5 Summary of recent literature examining economic impacts of ocean acidification on U.S. fisheries.**

Region	Type of Fish	Key Findings	Reference
Northeast Pacific from northern California to southeast Alaska	Crustaceans (especially shrimp), echinoderms, molluscs, and euphaeids	Ocean acidification alone results in very minor changes in landings relative to the 2060 baseline projections; however, ocean acidification in combination with three other climate change effects (primary productivity, zooplankton community structure, and ocean deoxygenation) reduces landings by about 20%, which suggests that synergies exist.	<a href="#">Ainsworth et al. (2011)</a>
U.S.	Sea scallops	Increased scallop growth rates from warming predicted to outweigh decreasing growth rates from ocean acidification until 2030, at which point the negative influence of ocean acidification will become the dominant effect. After 2030, fewer scallops will attain largest (“U10”) size before they are harvested in current fishing levels are maintained.	<a href="#">Cooley et al. (2015)</a>
U.S.	Various commercial species with a focus on molluscs	Considerable revenue declines, job losses, and indirect economic costs are possible due to ocean acidification broadly damaging marine habitats, altering marine resource availability, and disrupting other ecosystem services. Under a moderate 2% discount rate, U.S. ex-vessel revenue losses are predicted to be \$0.6–\$2.6 billion and broader economic losses are predicted to be \$1.5–\$6.4 billion.	<a href="#">Cooley and Doney (2009)</a>
U.S.	Shellfish	Analysis of sensitivity and adaptive capacity to ocean acidification across 23 regions indicates that the most socially vulnerable communities can be found on the U.S. East Coast and Gulf of Mexico. The East Coast is vulnerable mostly due to economic dependence whereas the Gulf of Mexico is vulnerable because of low adaptive capacity.	<a href="#">Ekstrom et al. (2015)</a>
Washington, Oregon, California	Shellfish	Survey results from a sample of shellfish industry participants (70% owners or managers of hatcheries) indicated that about half had experienced negative impacts from ocean acidification and that more than half the industry felt they would be somewhat or definitely able to adapt to ocean acidification.	<a href="#">Mabardy et al. (2015)</a>
Global, disaggregated by region	Shellfish	The economic cost of mollusc loss estimates for the U.S. are estimated to be roughly \$400 million USD, assuming no change in income but taking into account welfare losses from shellfish price changes.	<a href="#">(Narita et al., 2012)</a>

---

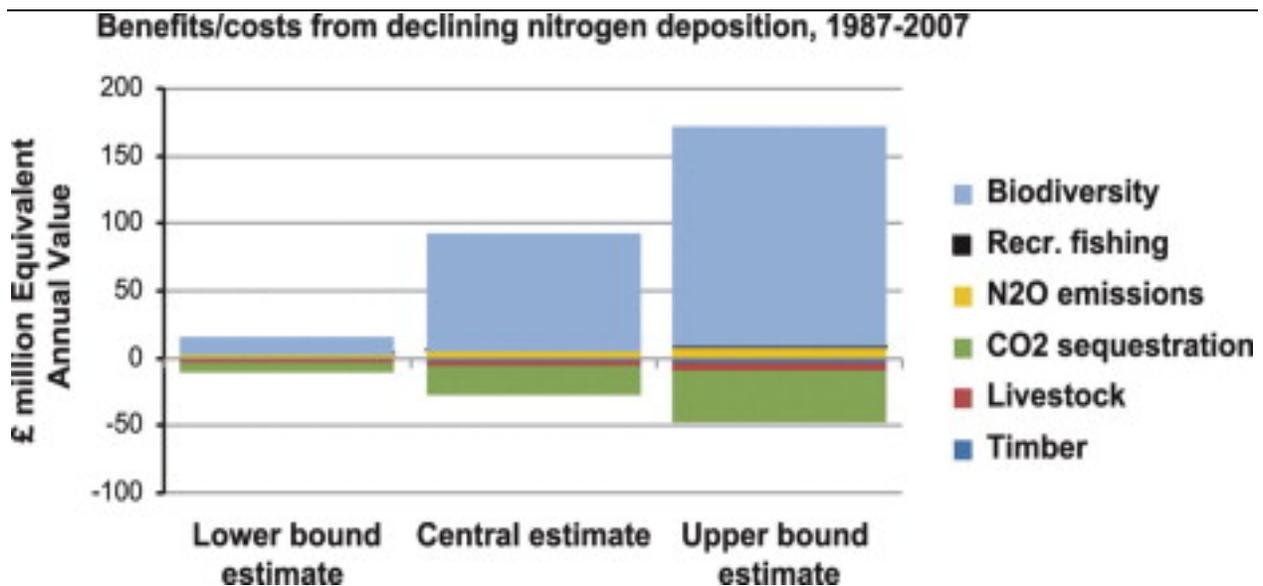

## 14.4 European and Canadian Applications

Since the 2008 ISA, several qualitative and quantitative assessments of either N deposition or the combination of N and S deposition have been conducted in the U.K. ([Jones et al., 2014](#)), across Europe ([de Vries et al., 2014b](#); [de Vries et al., 2014c](#); [Van Grinsven et al., 2013](#)), and Canada ([Aherne and Posch, 2013](#)). Although these assessments have varied considerably in their approaches, all have used simplified methods that intentionally omitted much of the mechanistic and spatial complexity in how deposition affects ecosystem services. Some of the qualitative and conceptual assessments provided descriptions of impacts of N deposition on ecosystems ([de Vries et al., 2014b](#); [de Vries et al., 2014c](#); [Jones et al., 2014](#)).

In Canada, [Aherne and Posch \(2013\)](#) examined critical load exceedances to assess the impacts of N and S deposition on water quality (eutrophication), soil quality (acidification), and plant species diversity. The approach was quantitative but did not assign values for ecosystem services. Instead, the analysis focused on the sources of these emissions and understanding what regions within Canada faced a loss of these services because critical loads had been exceeded.

Studies in Europe found that N deposition has both positive and negative effects on ecosystem services. [de Vries et al. \(2014b\)](#) modeled ecosystem response to N deposition, using the Very Simple Dynamic soil model. The model quantified changes in these services for the 2000–2050 period using three emissions scenarios: 1980 emissions, current legislation, and a scenario where deposition does not exceed critical loads for any ecosystem. The biggest differences among the emission scenarios were that regulations imposed since the 1980s created significant decreases in areas receiving critical N loads for water  $\text{NO}_3^-$  and Al, but also likely decreased  $\text{CO}_2$  uptake by ~20%. A second study by [Van Grinsven et al. \(2013\)](#) conducted economic analysis of the influence of N cycling in Europe and found that most economic impacts were related to atmospheric N emissions. Although there were positive impacts on agricultural production from fertilization, there were large negative impacts of atmospheric N emissions on human health (direct effects on human health are outside the scope of the secondary NAAQS review) and ecosystem function. Overall, the costs of added reactive N (atmospheric and agricultural) in the European Union were between £75 and £485 billion/year. Within the U.K., [Jones et al. \(2014\)](#) conducted a quantitative analysis that focused on six main ecosystem services impact pathways ([Figure 14-3](#)): timber production, livestock production, carbon sequestration, greenhouse gas (GHG) emissions, recreational fishing, and biodiversity appreciation. For the first three pathways, declining N deposition is estimated to result in ecosystem services losses of £27.2 million/year, due to decreased fertilization of woodlands, grasslands, and heathland. For the other three pathways, declining deposition

is estimated to result in ecosystem services gains totaling £93 million/year, due to decreased GHG emissions, improved water quality for recreational fishing, and enhanced nonuse values for biodiversity through habitat protection. The estimated net gains to U.K. society are, therefore, £65.8 million/year, with a 95% confidence interval of £15.1–£123.2 million pounds/year. Because of the large number of assumptions and simplifications, these studies present broad conceptual analyses demonstrating the potential of ecosystem services to quantify the impacts of reactive N in ways that could be valuable for policymakers, rather than as definitive assessments.

CO<sub>2</sub> = carbon dioxide; N<sub>2</sub>O = nitrous oxide; recr = recreational.  
 Source: [Jones et al. \(2014\)](#).

**Figure 14-3 Benefits and costs associated with the 25% decline in nitrogen deposition in the U.K. since 1990.**

## 14.5 Global Perspective

There is one study on ecosystem services with a global perspective published since 2008 and one study published in 2005 not included in the 2008 ISA. [Alcamo et al. \(2005\)](#) modeled global and regional impacts of stressors that included critical load exceedance for acidification and eutrophication on provisions, regulations, support, and cultural ecosystem services. However, these impacts represent the combined effects of eight

drivers (including climate change, land use change, mineral extractions, and N fertilizer use). Consequently, the analysis does not define ecosystem services changes that are specifically attributable to changes in N or S deposition.

[Erisman et al. \(2013\)](#) examined the impact of humans on the global N cycle and how these impacts relate to changes in ecosystem services. They group services into the following categories:

- Drinking water (nitrates),
- Air pollution effects on human health,
- Air pollution effects on crops (due to ozone),
- Freshwater eutrophication [defined as areas where the concentration of nitrate exceeds 1 mg NO<sub>3</sub><sup>-</sup>-N/L; [UNEP \(2007\)](#); [Camargo and Alonso \(2006\)](#); [Vörösmarty et al. \(2005\)](#)],
- Biodiversity loss [they identify the global critical load for biodiversity loss as 5–10 kg/ha/yr; [Bobbink et al. \(2010\)](#)],
- Stratospheric ozone depletion,
- Changes in climate, and
- Coastal dead zones.

It is especially noteworthy that the authors selected thresholds of level of N addition to an ecosystem which begins to cause adverse effects. The paper concludes that better quantitative relationships need to be established between N and the effects on ecosystems at smaller scales, including a better understanding of how N shortages can affect certain populations.

---

## 14.6 Summary

Since 2008, several studies have identified a range of ways in which N and S deposition could affect socially valuable ecosystem services. Several new ecosystem services frameworks and classification systems have been published, including The Economics of Ecosystems and Biodiversity [TEEB; [Sukhdev et al. \(2014\)](#)], the Common International Classification of Ecosystem Services [CICES; [Haines-Young and Potschin \(2011\)](#)], and U.S. EPA Final Ecosystem Goods and Services Classification System [FEGS-CS; [Landers and Nahlik \(2013\)](#)].

For acidification, the literature since the 2008 ISA includes studies that better characterize ecosystem services valuation by pairing biogeochemical modeling and benefit transfer equations informed by WTP surveys, especially for the Adirondacks and Shenandoah regions ([Table 14-1](#)). Aside from valuation efforts, studies using the

FED-CS have improved understanding of the numerous causal pathways by which N and S deposition may affect ecosystem services ([Bell et al., 2017](#); [Clark et al., 2017](#); [Irvine et al., 2017](#); [O'Dea et al., 2017](#); [Rhodes et al., 2017a](#)). The estimate of the total number of ecosystem services affected by N and S deposition is better quantified by the new studies that use FEG-CS. However, for many regions and specific services, poorly characterized dose-response between deposition, ecological effect, and services are the greatest challenge in developing specific data on the economic benefits of emission reductions ([NAPAP, 2011](#)).

In the 2008 ISA there were no publications specifically evaluating the effects of N deposition on ecosystem services associated with N driven eutrophication. Since the 2008 ISA, several comprehensive studies have been published on the ecosystems services related to N pollution in the U.S. ([Table 14-4](#)). These include an evaluation of services effected by multiple N inputs (including N deposition) to the Chesapeake, a syntheses of the cost/-benefits on N loading across the nation, and analysis of the amount of N leaked from its intended use and the effects on ecosystem services (this work specifically identified the costs of the atmospheric portion of total N loading). Aside from valuation, the estimate of the total number of ecosystem services affected by N is more well quantified by the new studies that use FEG-CS ([Bell et al., 2017](#); [Clark et al., 2017](#); [Irvine et al., 2017](#); [O'Dea et al., 2017](#); [Rhodes et al., 2017a](#)). In these analyses critical load exceedances for N related air pollution were used as a model stressor from which a total of 1,104 unique chains linking stressor to beneficiary were identified.

In the time since the 2008 ISA, several qualitative and quantitative assessments of either N deposition or the combination of N and S deposition have been conducted in the U.K., across Europe, Canada, and at the global scale. Although these assessments have varied considerably in their approaches, all were intentionally simplified to neglect much of the mechanistic and spatial complexity on how N deposition affects ecosystem services. At the global scale, an analysis selected general quantitative thresholds of N loading for the onset of ecologically adverse effects. However, the paper concludes that better quantitative relationships need to be established between N and the effects on ecosystems at smaller scales.

The conclusions considering the full body of literature are that (1) there is evidence that N and S emissions/deposition have a range of effects on U.S. ecosystem services and their social value; (2) there are some economic studies that demonstrate such effects in broad terms; however, it remains methodologically difficult to derive economic costs and benefits associated with specific regulatory decisions/standards; and (3) there is an improved understanding of the number of causal pathways by which N and S deposition

may affect ecosystem services, though most of these causal relationships remain to be quantified.

---

## 14.7 Supplemental Materials: Ecosystem Services Profiles of Select Species

Several species profiles have been created to better characterize the ecosystem services provided by species affected by NO<sub>y</sub> and SO<sub>x</sub>. The species included here are identified as threatened and endangered with N identified as a contributing stressor ([Hernández et al., 2016](#)). The species are balsam fir (*Abies balsamea*), eelgrass (*Zostera marina*), green turtle (*Chelonia mydas*), white ash (*Fraxinus americana*), and lace lichen (*Ramalina menziesii*). These profiles identify the geographic distribution within the U.S., ecological function, Class I areas, FEGS, and cultural importance; information on economic valuation is presented when available.

---

### 14.7.1 Balsam Fir

**Scientific Name:** *Abies balsamea*.

- **Family:** Pinaceae (pine).

**Symbolic Role:** NA.

**Federal or State Threatened or Endangered Species Listing Status:** Endangered species in Connecticut.

**Geographic Range/Distribution:**

- **Native and Current Range:** The range of balsam fir is North America, including most of eastern Canada. In the U.S., it extends from Minnesota to Maine and south into central Pennsylvania and the mountains of Virginia and West Virginia. Of the two main varieties—*balsamea* and *phanerolepis*—it is the latter that is found in Virginia and West Virginia.

**Overlap with Class I Areas:**

- <http://www.epa.gov/visibility/maps.html>.
- [http://www.epa.gov/ttn/oarpg/t1/fr\\_notices/classimp.gif](http://www.epa.gov/ttn/oarpg/t1/fr_notices/classimp.gif).

**Habitat:** Grows best in areas characterized by cool temperatures and moist soils. In the U.S., it is most commonly found in mixed stands, where associates include red spruce, black spruce, paper birch, aspen, and red maple ([Uchytil, 1991](#); [USDA, 1990b](#)).

### Primary Threats:

- **Related to N or S Deposition:** None.
- **Other:** Balsam fir are particularly vulnerable to insect damage from spruce budworms ([Uchytil, 1991](#)) and from decay caused by the red heart fungus [*Haematostereum sanguinolentum*; [USDA \(1990b\)](#)].

### Ecosystem Role and Function:

- **Nutrition:** Provides some nutrition for mice, voles, red squirrels, and grouse ([USDA, 1990b](#)).
- **Cover:** Provides winter cover to ungulates, including white-tailed deer and moose, and to grouse and songbirds ([Uchytil, 1991](#)). Also provides cover for small mammals including martens and snowshoe hares ([Darveau et al., 2001](#); [de Bellefeuille et al., 2001](#); [Darveau et al., 1998](#)).
- **Other:** As with other tree species in general, balsam fir trees provide a number of other intermediate ecosystem services that are indirectly valued by humans including nutrient cycling, carbon sequestration, soil stabilization and erosion control, water regulation and filtration, and air pollutant filtration ([Krieger, 2001](#)).

### Final Ecosystem Services:

- **Direct Human Uses:**
  - **Raw material in wood products and other industries:** Used as pulpwood and lumber for a variety of products. Oleoresin from balsam fir bark blisters has various uses including as a medium for mounting microscopic specimens and cement for optical systems ([USDA, 1990b](#)). It is also used in developing fragrances ([Zerbe et al., 2012](#)).
  - **Energy/fuel source:** Wood wastes for producers using balsam fir wood or pulp are sometimes used for energy ([USDA, 1990b](#)).
  - **Cultural and human health:** Balsam fir are commonly grown and used as Christmas trees and as material for wreath-making. In 2009 they accounted for 7% of Christmas tree sales in the U.S. ([USDA, 2010](#)). A large number of ethnobotanical uses of balsam fir by Native Americans has also been documented. The Native American Ethnobotany database maintained by [University of Michigan \(2015\)](#) references documents citing 87 specific uses by 13 different tribes, including a wide variety of medicinal uses (e.g., dermatological and venereal aid; cold and cough remedy) and uses as a material for rugs and bedding, sewing, and canoe waterproofing.

---

## 14.7.2 Eel Grass

**Scientific Name:** *Zostera marina* (Zosteraceae).

**Symbolic, Federal, or State Threatened or Endangered Species Listing Status:** Listed as a conservation species of least concern.

**Geographic Range/Distribution:**

- **Native Range:** Eelgrass is native to coastal regions of both the Pacific and Atlantic Oceans along the coast of North America.
- **Current Range:** Eelgrass is currently found in coastal regions in the Pacific Ocean along the western U.S. and Canada. It is also found along the eastern coast of North America from Canada to the Mid-Atlantic region in the U.S. ([USDA, 2015a](#)). Seagrasses have been disappearing from their native range at an average rate of 110 km<sup>2</sup>/year since 1980 ([Waycott et al., 2009](#)) and are especially sensitive to changes in temperature along the southern limits of their current range in North America ([Kaldy, 2014](#)).

**Overlap with Class I Areas:**

- <http://www.epa.gov/visibility/maps.html>.
- [http://www.epa.gov/ttn/oarpg/t1/fr\\_notices/classimp.gif](http://www.epa.gov/ttn/oarpg/t1/fr_notices/classimp.gif).

**Habitat:** Coastlines in both the Atlantic and Pacific oceans. It can be found in bays, estuaries, lagoons, and beaches.

**Primary Threats:**

- **Related to N or S Deposition:** [Hernández et al. \(2016\)](#).
- **Other:** Threats to eelgrass include dredging for coastal development, overfishing of predator species that lead to losses of herbivores that clean the leaves, and sediment and nutrient loading from coastal development ([Waycott et al., 2009](#); [Orth et al., 2006](#)). More broad changes in climate, such as temperature and sea-level rise also contribute to the loss of seagrasses ([Kaldy, 2014](#); [Douglass et al., 2010](#)).

**Ecosystem Role and Function:** Eelgrass are an important marine species for primary productivity ([Duarte, 2013](#)), and provides a suitable reproductive habitat and nursery grounds for many species of fish and shellfish ([Barbier et al., 2011](#)). Birds, invertebrates, green turtles, and manatees use eelgrass as a food source. Some commercially viable fish species like pacific salmon, pacific herring, and Dungeness crabs rely on eelgrass to provide cover and habitat ([Plummer et al., 2013](#); [Orth et al., 2006](#)). Another function of eelgrass is its ability to improve water quality through nutrient uptake and particle deposition. Eelgrass is an important species for coastal erosion protection because it helps control wave attenuation ([Barbier et al., 2011](#)). Eelgrass also provides indirect human benefits through carbon sequestration because it uses dissolved carbon in seawater to grow, and at the end of its lifecycle, the carbon is buried and stored as detritus ([Barbier et al., 2011](#)).

### Final Ecosystem Services:

- **Direct Human Uses:**
  - **Cultural:** Native Americans used dried eelgrass to bake into cakes and also for smoking deer meat ([Felger and Moser, 1985](#)). Native Americans consume the roots of the plant or use it to flavor other foods ([University of Michigan, 2015](#)).
  - **Raw Material:** Eelgrass is used to pack crabs to keep them moist during transport in the Mid-Atlantic region of the U.S. ([Barbier et al., 2011](#)).

---

### 14.7.3 Green Turtle

**Scientific Name:** *Chelonia mydas* (Cheloniidae).

**Symbolic Role:** Green sea turtles are symbols of guidance and protection in Hawaiian culture.

**Federal or State Threatened or Endangered Species Listing Status:** Listed as an endangered species ([Seminoff, 2004](#)).

#### Geographic Range/Distribution:

- **Native Range:** Green sea turtles have distinct native populations in both the Pacific and Atlantic oceans.
- **Current Range:** In the North American Atlantic, nesting sites are found in coastal regions in Florida, as well as Georgia, South Carolina, and North Carolina ([USFWS, 2015](#)). In the Pacific, green turtles nest along the French Frigate Shoals in the northwestern Hawaiian Islands ([NOAA Fisheries Pacific Islands Regional Office, 2015a](#)).

#### Overlap with Class I Areas:

- <http://www.epa.gov/visibility/maps.html>.
- [http://www.epa.gov/ttn/oarpg/t1/fr\\_notices/classimp.gif](http://www.epa.gov/ttn/oarpg/t1/fr_notices/classimp.gif).

**Habitat:** Mature green sea turtles are found in shallow coastal regions with large seagrass beds such as bays, reefs, and inlets. Green turtles nest on open beaches with minimal disturbance ([USFWS, 2015](#)).

#### Primary Threats:

- **Related to N or S Deposition:** [Hernández et al. \(2016\)](#).
- **Other:** Other major threats to green sea turtles include entanglement in fishing gear, incidental bycatch, and collisions with fishing boats or jet skis. Green turtles also face threats from illegal human harvesting and habitat loss and degradation

due to human development along coastal areas and reefs ([Malama na Honu, 2015](#)).

**Ecosystem Role and Function:** Green sea turtles are herbivores that mostly feed on seagrasses and algae in near-shore marine ecosystems. Green sea turtle eggs are a food source for many coastal species like ghost crabs or marine birds, as well as other scavenging animals. Tiger sharks are the only nonhuman predator for large juvenile and mature turtles ([NOAA Fisheries Pacific Islands Regional Office, 2015b](#)). Green sea turtles are valued for their natural beauty, and several conservation groups are dedicated to increasing sea turtle populations ([Komoroske et al., 2011](#)). Turtles can also be a source of ecotourism ([Campbell, 2002](#)).

**Final Ecosystem Services:**

- **Direct Human Uses:**
  - **Cultural:** Some native Hawaiians consider the green turtle to be a personal or family deity, which should not be harmed. The green turtle is featured in Hawaiian culture through depictions in petroglyphs ([NOAA Fisheries Pacific Islands Regional Office, 2015a](#)).

---

#### 14.7.4 White Ash

**Scientific Name:** *Fraxinus americana*.

- **Family:** Oleaceae (olive).

**Symbolic Role:** NA.

**Federal or State Threatened or Endangered Species Listing Status:** No special status.

**Geographic Range/Distribution:**

- **Native Range:** Most of eastern North America from southern Canada to northern Florida and as far west as Minnesota ([Griffith, 1991](#)).
- **Current Range:** In addition to its native range, white ash is cultivated in other areas, including Hawaii ([Griffith, 1991](#)).

**Overlap with Class I Areas:**

- <http://www.epa.gov/visibility/maps.html>.
- [http://www.epa.gov/ttn/oarpg/t1/fr\\_notices/classimp.gif](http://www.epa.gov/ttn/oarpg/t1/fr_notices/classimp.gif).

**Habitat:** Usually found mixed with other hardwoods (not the dominant species) in various topographic conditions. It can grow in a wide variety of soil types but does best

in soils with high nitrogen and calcium content, as well as moist and well-drained soils ([USDA, 1990a](#)).

#### **Primary Threats:**

- **Related to N or S Deposition:** [Hernández et al. \(2016\)](#).
- **Other:** White ash has experienced extensive dieback and mortality in its native range since the 1920s, due to a variety of factors, including ash yellows (AshY phytoplasma), canker fungi, viruses, drought ([Hibben and Silverborg, 1978](#)), and more recently, invasions of the emerald ash borer [*Agrilus planipennis*; [Poland and McCullough \(2006\)](#)]. White ash has also been found to be sensitive to ground level ozone exposures ([Chappelka et al., 1988](#)).

#### **Ecosystem Role and Function:**

- **Nutrition:** Samaras (seeds) are good forage for wood ducks, northern bobwhites, purple finches, pine grosbeaks, fox squirrels, mice, and many other birds and small mammals. It is browsed by white-tailed deer and cattle, and its bark is occasionally used as food by beavers, porcupines, and rabbits ([Griffith, 1991](#)).
- **Cover:** It provides cover to primary cavity nesters, such as red-headed, red-bellied, and pileated woodpeckers, and to secondary nesters such as wood ducks, owls, nuthatches, and gray squirrels ([Griffith, 1991](#)).
- **Other:** As with other hardwood tree species in general, white ash trees provide a number of other intermediate ecosystem services that are indirectly valued by humans, including nutrient cycling, carbon sequestration, soil stabilization and erosion control, water regulation and filtration, and air pollutant filtration ([Krieger, 2001](#)).

#### **Final Ecosystem Services:**

- **Direct Human Uses (Final Ecosystem Services)**
  - **Raw material in wood products and related industries:** White ash trees provide a dense, shock resistant, and durable wood that is used in a variety of products, including baseball bats, tool handles, furniture, cabinets, canoe paddles, snowshoes, and railroad ties ([USDA NRCS, 2011](#)).
  - **Energy/fuel source:** Used for fuel wood ([USDA NRCS, 2011](#)).
  - **Human health:** Leaves from the white ash have purported beneficial uses, including the relief of swelling and itching from mosquito bites and as a deterrent to snake bites ([Griffith, 1991](#)).
  - **Cultural:** A large number of ethnobotanical uses of white ash by Native Americans has been documented. The Native American Ethnobotany database maintained by [University of Michigan \(2015\)](#) references documents citing 38 specific uses by 9 different tribes, including a wide variety of medicinal uses (e.g., gastrointestinal, dermatological, and gynecological aids) and uses as a material for snow gear, basketry, furniture, canoes, hunting, and fishing.

- **Aesthetic:** Provides attractive and vivid fall foliage, including combinations of orange, yellow, maroon, and purple. For landscaping uses, it is also considered to be a good and relatively quick-growing shade tree ([University of Kentucky, 2015](#)).
- **Nonuse value:** Survey-based economic studies have found evidence of nonuse values among the general population for protecting white ash from air pollution in the Adirondacks region ([Banzhaf et al., 2006](#)).

### 14.7.5 Lace Lichen

**Scientific Name:** *Ramalina menziesii* (Ramalinaceae).

**Federal or State Threatened or Endangered Species Listing Status:** Listed as a conservation species of least concern.

**Geographic Range/Distribution:**

- **Native Range:** Lace lichen is native to the western coast of North America; in the past it was found in the San Jacinto Mountains near Los Angeles and on the surrounding coastal plain but now only grows at elevations above the smog layer ([Hastings Reserve, 2015](#)).
- **Current Range:** Lace lichen grows along the Pacific Coast of North America from Alaska to Baja California. It grows at elevations up to 3,500 feet ([Werth and Sork, 2008](#)).

**Overlap with Class I Areas:**

- <http://www.epa.gov/visibility/maps.html>.
- [http://www.epa.gov/ttn/oarpg/t1/fr\\_notices/classimp.gif](http://www.epa.gov/ttn/oarpg/t1/fr_notices/classimp.gif).

**Habitat:** Grows on tree species in coastal areas with enough moisture from fog and strong winds ([Egan and Holzman, 2003](#)).

**Primary Threats:**

- **Related to N or S Deposition:** [Hernández et al. \(2016\)](#).
- **Other:** Other threats to lace lichen include changes in climate. This species requires a good amount of moisture and a temperate climate to survive; it is absent from drier areas within its range ([Egan and Holzman, 2003](#)).

**Final Ecosystem Services:**

- **Direct Human Uses:**
  - **Aesthetic:** Lace lichen has a unique morphology that adds to the natural beauty of coastal woodlands along the Pacific Coast ([Hastings Reserve, 2015](#)).

---

## APPENDIX 15 OTHER ECOLOGICAL EFFECTS OF PARTICULATE MATTER

Evidence for effects of particulate matter (PM) on ecological receptors include direct effects of airborne PM on radiative flux and both direct and indirect effects of deposited particles. In addition to nitrogen (N) and sulfur (S) and their transformation products (discussed in [Appendix 3–Appendix 12](#)), other PM components such as trace metals and organics are deposited to ecosystems and may subsequently impact biota. Direct effects include alteration of leaf processes from deposition of PM (“dust”) to vegetative surfaces ([Appendix 15.4.1](#)). Indirect effects encompass physiological responses associated with uptake of PM components and alterations to ecosystem structure and function. Exposures can occur directly to surfaces of vegetation (leaves, bark, twigs), by ingestion, or via soil or water through uptake by roots or other biological tissues. Bioaccumulation and biomagnification of PM components can lead to effects at higher trophic levels. Direct and indirect effects of PM on vegetation, fauna, and the soil environment, and evidence for effects at higher levels of biological organization (communities, ecosystems) from PM deposition are evaluated in the context of what was known from previous PM assessments ([U.S. EPA, 2009a, 2004](#)) and newly available studies.

---

### 15.1 Introduction

PM-associated components include N and S and their transformation products, trace metals, organics, base cations, and salts. Base cations (especially  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ , and  $\text{K}^{+}$ ) from atmospheric deposition can help ameliorate the effects of acidic deposition associated with oxides of N and S, although under very high base cation deposition, plant health can be adversely affected ([U.S. EPA, 2009a](#)). Particulate salt may be added to an ecosystem from deicing salt ([U.S. EPA, 2009a](#)). The focus of this appendix is on the PM effects not associated with N and S components that are covered elsewhere in this ISA. The primary non-N and S components covered in this appendix include trace metals ([Appendix 15.3.1](#)) and organics ([Appendix 15.3.2](#)).

Effects of PM on ecological receptors can be both chemical and physical ([U.S. EPA, 2009a, 2004](#)). As described in the *2009 Integrated Science Assessment for Particulate Matter* (2009 PM ISA), particulates that elicit direct and indirect effects on ecological receptors vary in terms of size, origin, and chemical composition. Particle composition is attributed to ecological outcomes to a greater extent than particle size ([Grantz et al., 2003](#)). PM-associated metals and organics are linked to responses in biota; however, the heterogeneous nature of PM composition and distribution coupled with variability

inherent in natural environments confound assessment of the ecological effects of particulates.

Ecological effects evaluated in the 2009 PM ISA included direct effects on metabolic processes of plants, the contribution of PM to total metal loading which alters soil biogeochemistry and microbiology, the effects on plant and animal growth and reproduction, and the contribution to total organics loading resulting in trophic transfer.

Newly available information on the ecological effects of PM published since the 2009 PM ISA is summarized in the following sections along with key studies from previous PM assessments ([U.S. EPA, 2009a](#), [2004](#)). Studies conducted in the U.S. are the focus of this review, but research from other countries is included if it has advanced the study of PM effects on biota. Such studies may include those providing documentation of additional physiological effects of PM toxicity, new techniques for PM assessment, and further characterization of effects on communities and ecosystems. Together with the information available in the 2009 PM ISA, **the body of evidence is sufficient to infer a likely causal relationship between deposition of PM and a variety of effects on individual organisms and ecosystems.**

---

## 15.2 Direct Effects of Particulate Matter on Radiative Flux

The direct effects of particles suspended in the atmosphere on radiative flux and subsequent effects on vegetation were described in previous PM assessments ([U.S. EPA, 2009a](#), [2004](#)). Briefly, increased atmospheric particulates and aerosols can alter radiative flux by both radiation attenuation and by changing the efficiency of radiation interception in the vegetation canopy by converting direct radiation to diffuse radiation ([Hoyt, 1978](#)). Diffuse radiation is more uniformly distributed throughout the vegetation canopy and can reach leaves more evenly than direct radiation, increasing canopy photosynthetic productivity. In a study reviewed in the 2009 PM ISA, decreased crop yield in China was associated with reduction in solar radiation due to regional haze ([Chameides et al., 1999](#)).

More recent studies provide additional evidence of the role of PM in altering radiative flux and plant response. In an assessment of aerosol effects on plant productivity in the eastern U.S., increased canopy photosynthesis due to increases in diffuse radiation, despite a simultaneous decrease in direct radiation due to light scattering by aerosols, was observed on a regional scale ([Matsui et al., 2008](#)). Surface downwelling solar radiation was reduced by 14.9 W/m<sup>2</sup> in 2000 and 16.0 W/m<sup>2</sup> in 2001, while photosynthesis and stomatal conductance increased simultaneously. In a recent study from Beijing, China, the expression of plant proteins important to photosynthesis were shown to be directly impacted by presence of aerosols and PM in the air column ([Yan et al., 2014](#)). Expression

of plant ribulose 1,5-biphosphate carboxylase/oxygenase (RuBisCO), a key enzyme involved in plant photosynthesis, increased in areas with strong diffuse solar radiation, (identified by measurement of aerosol optical depth and particles with diameters of 0.1 to 1.0  $\mu\text{m}$ ). In the same areas, light-harvesting complex II protein and oxygen-evolving enhancer protein decreased. These enzymes play a role in plant responses to direct solar radiation when photosynthesis capacity is exceeded.

---

## 15.3 Particulate Matter Deposition to Ecosystems

Once airborne PM is deposited to aquatic or terrestrial systems, it can elicit additional effects on ecosystem receptors. Large particles tend to be deposited near their sources, such as along roadsides or next to mining, smelting, and other industrial operations, while smaller particles can be transported long distances ([Grantz et al., 2003](#)). Deposition to ecosystems can be in the form of wet, dry, or occult deposition ([U.S. EPA, 2009a](#); [Grantz et al., 2003](#)). Once deposited, PM-associated components may remain on biological surfaces or be transferred between environmental compartments (e.g., water, soil, sediment, biota).

More often, the chemical constituents drive the ecosystem response to PM, rather than size class ([U.S. EPA, 2009a](#); [Grantz et al., 2003](#)). Exposure to a given mass concentration of PM may lead to widely differing phytotoxic and other environmental outcomes depending upon the particular mix of PM constituents involved. Deposition of the metal and organic constituents of PM are discussed below; however, a rigorous assessment of each chemical constituent (e.g., polyaromatic hydrocarbons [PAHs], mercury [Hg], cadmium [Cd]) is not given. An overview of trace metals and organics and their depositional effects in ecosystems was provided in the previous PM assessments ([U.S. EPA, 2009a, 2004](#)) and only summarized below.

---

### 15.3.1 Metals

All but 10 of the 90 elements that comprise the inorganic fraction of the soil occur at concentrations of <0.1% (1,000  $\mu\text{g/g}$ ) and are termed “trace” elements or trace metals. Trace metals with a density greater than 6  $\text{g/cm}^3$ , referred to as “heavy metals” (e.g., Cd, copper [Cu], lead [Pb], chromium [Cr], Hg, nickel [Ni], zinc [Zn]), are of particular interest because of their potential toxicity to plants and animals. For example, plant toxicity to trace metals is most frequently associated with Cu, Ni, and Zn ([U.S. EPA, 2004](#)). Some metals such as Zn, manganese (Mn), Cu, and iron (Fe) play important physiological roles in trace quantities; however, other metals such as Hg, Cd, Cr, and Pb

have no known biological function. Although some trace metals are essential for vegetative growth or animal health, they are all toxic in large quantities. Trace metals are naturally found in small amounts in soils, groundwater, and vegetation. They may enter the ecosystems as both fine and coarse particles. Heavy metals tend to be associated with fine particles. Trace elements exist in the atmosphere in particulate form as metal oxides ([Ormrod, 1984](#)). Aerosols containing trace elements derive predominantly from industrial activities. Once deposited to biological surfaces, metals can be taken up by biota, accumulate in tissues, and elicit toxic effects ([Gall et al., 2015](#)). These responses are highly variable across organisms. Only the bioavailable fraction is available for uptake by biota. In plants, metal uptake is generally via soil to root transfer ([Mcbride et al., 2013](#)), although recent studies reviewed in [Appendix 15.4](#) provide evidence for foliar transfer of metals following atmospheric deposition. The ecological effects of atmospherically deposited Pb, a metal associated with PM, are included in the ISA for Pb ([U.S. EPA, 2013b](#)).

---

### 15.3.2 Organics

Organic compounds can be in the gas phase or in association with particles ([Grantz et al., 2003](#)). Organic compounds that may be associated with deposited PM include persistent organic pollutants (POPs), pesticides, semivolatile organic compounds (sVOCs), PAHs, and flame retardants, among others ([U.S. EPA, 2009a](#)). Dry deposition of organic materials is often dominated by the coarse fraction, but fine PM may act as a carrier for materials such as pesticides. PAHs are widespread in the environment. Of the anthropogenically derived PAHs, 8 are considered carcinogenic and 16 have been classified by the U.S. EPA as priority pollutants. In general, high molecular weight PAHs are more toxic and have a greater tendency to be associated with PM ([Mesquita et al., 2014a](#)). Derived from vehicular traffic and other sources, they are common air pollutants in metropolitan areas. PAHs and other organics can be transferred to higher trophic levels. Some atmospheric contaminants like POPs, polybrominated diphenyl ethers (PBDEs), and other brominated flame retardants have been shown to accumulate in biota in polar regions and at other remote locations where they are carried by long-range atmospheric transport from lower latitudes ([U.S. EPA, 2009a](#)). The Western Airborne Contaminants Assessment Project (WACAP) summarized in the 2009 PM ISA provided evidence for airborne transfer and bioaccumulation of organics to remote national parks and Class I areas ([Landers et al., 2008](#)), and newer studies from this project have added to this information ([Pritz et al., 2014](#); [Landers et al., 2010](#)). Seven ecosystem compartments (air, snow, water, sediments, lichens, conifer needles, and fish) were analyzed for a suite of contaminants to determine where the pollutants were accumulating, identify ecological

indicators, and assess the source of the air masses most likely to have transported the contaminants to the parks. Overall, semivolatile organic compounds and metals were detected throughout park ecosystems, and biomagnification of organics through the food web indicated contaminants were present at multiple trophic levels.

As reviewed in previous PM assessments, vegetation itself is an important source of hydrocarbon aerosols ([U.S. EPA, 2009a, 2004](#)). Terpenes, particularly  $\alpha$  pinene,  $\beta$  pinene, and limonene, released from tree foliage may react in the atmosphere to form submicron particles. These naturally generated organic particles contribute significantly to the blue haze aerosols formed naturally over forested areas ([U.S. EPA, 2004](#); [Geron et al., 2000](#)).

---

## 15.4 Effects of Particulate Matter on Vegetation

Particles deposited to foliar surfaces may lead to both structural and functional alterations in plants. PM may physically obstruct processes associated with the leaf surface or be taken up across the cuticle and into the plant tissues where it affects plant metabolic activities. This section first considers direct impacts of PM deposition to vegetative surfaces. Next, effects following uptake of PM components into plant tissue across leaf surfaces or root uptake via soils are described. Uptake by plants can occur at the soil/plant interface and at the air/plant interface ([Krupa et al., 2008](#)). Once uptake occurs, plant physiological responses may include decreased gas exchange, altered metabolism and photosynthesis, altered pigment and mineral content, and altered enzyme activity ([Naidoo and Chirkoot, 2004](#)). There is some evidence that metals reduce frost hardiness and impair nutrition ([Taulavuori et al., 2005](#); [Kim et al., 2003](#)).

---

### 15.4.1 Vegetative Surfaces

As described in the 2009 PM ISA, foliar surfaces are covered with a waxy cuticle layer that helps reduce moisture loss and ultraviolet (UV) radiation stress ([U.S. EPA, 2009a](#)). This epicuticular wax consists largely of long chain esters, polyesters, and paraffins, which accumulate lipophilic compounds. Organic air contaminants in the particulate or vapor phase can be adsorbed to, and accumulate in, the epicuticular wax of leaf surfaces. Low solubility limits foliar uptake and direct heavy metal toxicity because trace metals must be brought into solution before they can enter leaves or bark of vascular plants ([U.S. EPA, 2009a](#)). Particles embedded in waxes may remain for extended periods of time and remain associated with the leaf while other particles may be removed via precipitation, wind, or leaf-fall. Particle capture efficiency varies by plant species, and the role of vegetative surface characteristics in trapping PM, especially in polluted urban

environments, is extensively reviewed in the literature. PM trapping by vegetation depends on distance from source, leaf shape, canopy structure, leaf surface wettability, presence of hairs, properties of the epidermal layer, and phyllotaxy ([Popek et al., 2015](#); [Popek et al., 2013](#); [Saebo et al., 2012](#)).

The 2009 PM ISA also reviewed studies that show effects of direct deposition of particulates to aboveground plant organs. These effects include altered plant metabolism and photosynthesis by the blocking of sunlight, obstruction of stomatal apertures, increasing leaf temperature, and leaf surface injury ([U.S. EPA, 2009a](#); [Naidoo and Chirkoot, 2004](#); [Grantz et al., 2003](#)). Leaf surface pH can be altered by deposition of alkaline particles, which can hydrolyze epicuticular surfaces ([Grantz et al., 2003](#)). The diverse composition of ambient PM and the effects of other air pollutants confound characterization of the direct effects of PM on foliar surfaces ([Grantz et al., 2003](#)).

A number of recent studies published since the 2009 PM ISA have examined the effects of PM deposition to vegetative surfaces. For example, some have further characterized the effects of particle size and composition on leaf surface processes. Following 60-day experimental application of urban dust collected from roadsides in India to common annual plant species (*Abelmoschus esculentus*, *Celosia cristata*, *Coleus blumei*, *Cyamopsis tetragonolobus*, *Gomphrena globosa*, *Impatiens balsamina*, *Ocimum sanctum*, *Phaseolus vulgaris*, *Solanum melongena*, *Zinnia elegans*), scanning electron micrographs of leaf surfaces indicated that larger particles piled up around the stomata, while finer particles clogged the stomatal openings ([Rai et al., 2010](#)). In the applied dust, about 75% was in the 2.5 to 10  $\mu\text{m}$  size fraction, with particles greater than 10  $\mu\text{m}$  composing approximately 10% of PM and ultrafines (less than 2.5  $\mu\text{m}$ ) comprising 15%. Experimental application of PM (monometallic PM oxides: cadmium oxide [CdO], antimony trioxide [Sb<sub>2</sub>O<sub>3</sub>], and zinc oxide [ZnO] and process PM enriched with Pb) to cabbage (*Brassica oleracea*) and spinach (*Spinacia oleracea*) leaves resulted in a coverage rate of particles on the leaf surface estimated at approximately 2% following washing ([Xiong et al., 2014](#)). Most of the particles were concentrated in stomatal apertures, with up to 12% of the area occupied. The presence of PM in the stomata was correlated to particle size and solubility of the associated metal oxides. Newer studies ([Oguntimehin et al., 2010](#); [Oguntimehin et al., 2008](#)) support observations of visible foliar injury reported in previous PM assessments, with some suggesting that drought may affect the particle capture efficiency of trees, and other studies report that deposited particles on leaf surfaces possibly leads to decreased drought tolerance ([Burkhardt and Pariyar, 2015, 2014](#); [Rasanen et al., 2014](#)).

---

## 15.4.2 Foliar Uptake of Particulate Matter

As reported in the 2009 PM ISA, fine PM has been shown to enter the leaf through the stomata and penetrate into the mesophyll layers where it alters leaf chemistry and physiology ([Da Silva et al., 2006](#); [Naidoo and Chirkoot, 2004](#)). Organic compounds can be deposited as particles on the leaves or be taken up through the cuticle or stomata in the gas phase, although these pathways are not well characterized for most trace organics ([Oguntimehin et al., 2010](#)). As reviewed in the 2009 PM ISA, for lipophilic POPs, such as polychlorinated dibenzodioxins (PCDDs) and polychlorinated biphenyls (PCBs), the air/plant response route generally dominates ([Lee et al., 2003](#); [Thomas et al., 1998](#)), but uptake through aboveground plant tissue also occurs. The pathways depend on the chemical and its physical properties, such as lipophilicity, water solubility, vapor pressure, and Henry's law constant. Environmental conditions can also be important, including temperature and organic content of soil, plant species, and the foliar surface area and lipid content.

([Eichert et al., 2008](#)) demonstrated hydrophilic particle penetration into the substomatal cavity of faba bean (*Vicia faba*) leaves. Since the 2009 PM ISA, development and refinement of techniques such as micro x-ray fluorescence, scanning electron microscopy coupled with energy dispersive x-ray microanalysis, and secondary ion mass spectrometry have been applied toward characterizing particulate transfer from foliar surfaces to the interior of the plant ([Schreck et al., 2014](#); [Burkhardt et al., 2012](#); [Schreck et al., 2012](#)). Repeated deliquescence and efflorescence of soluble PM may have the effect of slowly advancing solutes into the stomatal pore where they may become bioavailable ([Burkhardt et al., 2012](#)). Recently, stomatal uptake of aqueous solutions was confirmed by environmental scanning electron microscopy ([Burkhardt et al., 2012](#)). Deposited aerosols on leaf surfaces may alter surface tension and hydrophobicity, enabling stomatal liquid water transport and facilitating foliar uptake. Several studies provide additional evidence of particles entering plant tissues through stomata openings ([Schreck et al., 2012](#); [Uzu et al., 2010](#)). [Schreck et al. \(2014\)](#) observed particles in stomata and damage to guard cells from Pb-rich particles from a Pb recycling factory. Other pathways of deposited metals to vegetative surfaces may include diffusion across the cuticle ([Schreck et al., 2012](#); [Uzu et al., 2010](#)). Nonstomatal uptake of atmospheric Hg into plant leaves has recently been demonstrated in addition to stomatal pathways ([Stamenkovic and Gustin, 2009](#)). Biogeochemical transformations were observed in metal-rich PM at the leaf surface ([Schreck et al., 2012](#)). The role of the phyllosphere (i.e., the microbial communities on foliar surfaces) on the uptake and chemical transformation of deposited particles and in promoting plant growth is an emerging area of study; however, interactions associated with PM are not well characterized at this time ([Weyens et al., 2015](#); [Xiong et al., 2014](#)).

---

### 15.4.3 Particulate Matter Impacts on Gas Exchange Processes

In earlier assessments of ecological effects of PM, deposition of particles to vegetation was known to interfere with gas exchange processes such as photosynthesis, respiration, and transpiration ([U.S. EPA, 2009a, 2004](#)). Several new studies support observations from previous PM reviews on the exchange of oxygen and carbon dioxide across the leaf surface. Most studies involve the application of dust to leaves. A greenhouse study with lettuce (*Lactuca serriola*) leaves showed decreased gas-exchange parameters (net photosynthetic rate and stomatal conductance) and a change in transpiration rate following PM (dust from vehicular traffic with a dominance of fine particles) application to leaves ([Pavlík et al., 2012](#)). Fly ash dusting of 0.5 to 1.5 g/m<sup>2</sup>/day to rice reduced photosynthesis, stomatal conductance, and transpiration ([Raja et al., 2014](#)). Photosynthesis, transpiration rate, and water use efficiency was decreased in peach (*Prunus persica*) leaves dusted with cement kiln dust, and to a lesser extent with soil dust ([Maletsika et al., 2015](#)). Exposure of the leaves of *Prunus padus* to PM in Poland resulted in decreased photosynthesis and chlorophyll fluorescence, but similar effects on the photosynthetic apparatus were not found in *Prunus serotina* ([Popek et al., 2017](#)). In a study of native and non-native plant species in Argentina, [Gonzalez et al. \(2014\)](#) reported that gas-exchange parameters, including maximum assimilation rate, stomatal conductance, and transpiration rate, were significantly decreased in most plant species by ambient dust accumulation on leaf surfaces compared with those parameters in plants from which deposited dust had been removed. Similarly, decreased photosynthesis rate, increased stomatal resistance, and lower chlorophyll content was observed with increased PM accumulation in plant species growing in the city center of Warsaw, Poland compared to a moderately clean environment ([Przybysz et al., 2014](#)). The photosynthetic apparatus of the lichen species *Evernia prunastri* was significantly affected by dust enriched by calcium (Ca), Fe, and titanium (Ti) near a quarry and cement factory in Slovakia ([Paoli et al., 2015](#)). Photosynthetic rate and chlorophyll content were significantly reduced in cherry tomatoes (*Lycopersicon esculentum*) misted with fluoranthene for 30 days to represent atmospheric wet deposition to the leaf surface ([Oguntimehin et al., 2010](#)).

---

### 15.4.4 Plant Physiology

In the 2009 PM ISA, particulates were associated with phytotoxic responses, including induction of phytochelatins, alteration of pigments, and changes in mineral content and enzyme activity ([U.S. EPA, 2009a](#)). Newly available studies support these findings. Chlorophyll content as well as specific leaf area and relative water content of selected tree species was significantly reduced by the greater dust load associated with a polluted

site in India compared to a low pollution location ([Chaturvedi et al., 2013](#)). Decreased leaf chlorophyll and increased phenol content was also observed in peach leaves with accumulated cement or soil dust ([Maletsika et al., 2015](#)). In lettuce leaves, PM application caused a depletion in amino acids that are metabolized during photosynthesis as well as an increase in proline ([Pavlík et al., 2012](#)). Proline and malondialdehyde concentrations were elevated in maize leaves treated with Hg ([Niu et al., 2014](#)). Recently, the use of foliar fatty acid composition as an indicator of foliar (and root) metal uptake was demonstrated with lettuce leaves exposed to PM from smelter emissions ([Schreck et al., 2013](#)).

---

#### 15.4.5 Uptake of Particulate Matter by Plants from Soils

Plants can also uptake PM that has been deposited to soils. As reviewed in the 2009 PM, ISA uptake from soils varies by the PM component and plant species ([U.S. EPA, 2009a](#)). There was some evidence that shallow-rooted plant species are most likely to take up metals from the soil ([Martin and Coughtrey, 1981](#)). The ability of plants to take up contaminants from soil and water has been applied toward environmental cleanup efforts, a process known as phytoremediation ([Hooda, 2007](#); [Padmavathiamma and Li, 2007](#); [Clemens, 2006](#)). Plants that are hyperaccumulators of metals are especially useful in phytoremediation efforts ([Prasad and DeOliveira, 2003](#)).

Plants respond to high concentrations of metals in soil through a variety of mechanisms, and plant species differ substantially in their response to heavy metal exposure. As reviewed in the 2009 PM ISA, mechanisms of metal tolerance included exclusion, excretion, genetics ([Yang et al., 2005](#); [Patra et al., 2004](#)), mycorrhizal interactions ([Gohre and Paszkowski, 2006](#)), storage capability and accumulation ([Clemens, 2006](#)), various cellular detoxification mechanisms ([Gratao et al., 2005](#); [Hall, 2002](#)), and chelation with phytochelatins ([Memon and Schroder, 2009](#)).

Since the 2009 PM ISA, additional studies have focused on the use of vegetation to remediate sites with both organic and inorganic contaminants and the use of mycorrhizal fungi and bacteria to promote phytoremediation ([Appendix 15.5.4](#)). In addition, soil-bound PAHs associated with soil organic matter, historically thought to be generally not easily available for root uptake, have been shown in recent studies to be readily adsorbed to root surfaces, with some evidence showing translocation to the shoots ([Desalme et al., 2013](#)).

---

## 15.4.6 Effects on Plant Growth and Reproduction

PM effects on plant growth reviewed in the 2009 PM ISA include reduced vigor and impaired root development ([U.S. EPA, 2009a](#)). In general, plant biomass is negatively correlated with organics ([Desalme et al., 2013](#)) and metal concentrations ([Audet and Charest, 2007](#)). Inhibition of aboveground biomass was observed in lettuce leaves with traffic-associated PM applied directly to vegetation ([Pavlík et al., 2012](#)). Increased trace metal concentration along with the decrease in biomass was measured in the treated leaves. Decreased primary root elongation and shoot and root rates were observed in tomatoes (*Solanum lycopersicum*) grown for 18 days with growth solution in a quartz fiber particulate matter filter with particles with a nominal mean aerodynamic diameter less than or equal to 10 µm (PM<sub>10</sub>) collected from an urban background site in Italy ([Daresta et al., 2014](#)). Decreased chlorophyll *a* and increased carotenoids in the exposed plants were noted along with increased reactive oxygen species production in roots from the PM<sub>10</sub> substrate. Phenanthrene, a common PAH in air, applied to soils via simulated atmospheric deposition in an exposure chamber was shown to significantly decrease root length and shoot biomass of leek (*Allium porrum*) seedlings ([Desalme et al., 2012](#)). In a similar study, shoot biomass of red clover (*Trifolium pratense*) exposed to atmospheric phenanthrene decreased by around 30% while ryegrass (*Lolium perenne*) was unaffected ([Desalme et al., 2011a](#)). No effects on root biomass were observed in either plant. With phenanthrene exposure to red clover, more carbon (C) was retained in leaves with decreased C allocation to stems and roots ([Desalme et al., 2011b](#)).

Daily application of urban dust to common annual plant species for 60 days showed reduction in plant growth, number of leaves, and leaf area ([Rai et al., 2010](#)). Growth and yield of rice was significantly influenced at higher rates of fly ash deposition due to increased heat load and reduced intracellular carbon dioxide (CO<sub>2</sub>) concentration ([Raja et al., 2014](#)). Following dusting of the plants by fly ash at 0.5, 1.0, and 1.5 g/m<sup>2</sup>/day, a significant decrease in grain yield of 12.3, 15.7, and 20.2%, respectively, was observed.

[Farahat et al. \(2016\)](#) studied the effects of dust deposition from a rock quarry on old-growth eastern hemlock (*Tsuga canadensis*) in Quebec, Canada. Mean radial growth declined 43% after the construction of the quarry compared with growth rates before construction. Major changes in the hemlock occurred 3–16 years after the quarry was established, indicating that the effect on growth may be indirect through the alteration of soil pH in this forest. In a study from Beijing, China, application of local road dust to *Sophora japonica* seedlings significantly affected growth characteristics such as leaf N, shoot biomass, root-shoot ratio, photosynthesis, and total chlorophyll ([Bao et al., 2016](#); [Bao et al., 2015](#)).

Recently, the effect of air pollutants on the timing and budburst of vegetation has been assessed in several studies ([Jochner et al., 2015](#); [Kozlov et al., 2007](#)). The timing of full flowering of hazel (*Corylus avellana*) was found to be significantly related to PM in ambient air in urban areas of Munich, Germany ([Jochner et al., 2015](#)).

These effects on phenological onset were also observed with ozone (O<sub>3</sub>), nitrogen dioxide (NO<sub>2</sub>), and nitrate (NO<sub>3</sub>) in hazel and additional tree species in the same study. In a field and greenhouse study in Russia with mountain birch (*Betula pubescens*), no impacts of air pollution on phenology were observed between trees surveyed in proximity to a Ni-Cu smelter and trees at further distance from the emission source ([Kozlov et al., 2007](#)).

Some studies have examined the effects of PM on plant reproduction. Some potential effects demonstrated were those in flowering phenology and timing ([Jochner et al., 2015](#); [Rai et al., 2010](#); [Honour et al., 2009](#)). [Jaconis et al. \(2017\)](#) examined the effect of PM on stigmatic clogging in *Cichorium intybus* on roadsides in Cincinnati, OH. The authors reported no relationship between PM levels and pollen germination across all of the roads studied.

---

## 15.5 Effects of Particulate Matter on the Soil Environment

As described in the 2009 PM ISA, the soil is one of the most dynamic environments of biological interaction in nature ([U.S. EPA, 2009a](#)). The upper soil layers where deposited particles accumulate are typically active sites of litter decomposition and plant root uptake. Processes within the rhizosphere, the soil around plant roots that mineral nutrients must pass through, may be affected by PM components. Soil-associated microbial communities of bacteria and fungi such as actinomycetes and basidiomycetes, respectively, break down organic matter for nutrient cycling and make elements available for plant uptake. Soil mycorrhiza, (fungi that colonize plant roots) form a symbiosis to provide nutrients in exchange for carbon from the plant. The effects of PM-associated organics and metals on the soil environment is largely dictated by bioavailability to soil microflora and plant roots.

---

### 15.5.1 Bioavailability in Soils

Soils are heterogeneous and the effects of PM deposition and subsequent bioavailability of PM components depend on soil characteristics (e.g., pH, organic content). PM-associated organics partition between the soil and the atmosphere based on soil properties, such as organic matter content, moisture, porosity, texture, and structure, as

well as the physiochemical properties of the pollutant, including vapor pressure and water solubility ([U.S. EPA, 2009a](#)). These compounds may be taken up by roots or be associated with organic matter ([Fismes et al., 2002](#)). For heavy metals, accumulation in soil is influenced by a variety of soil characteristics, including pH, Fe and aluminum oxide content, amount of clay and organic material, and cation exchange capacity [CEC; ([Hernandez et al., 2003](#))]. Bioavailability depends on metal speciation, soil pH, and degree of binding to dissolved organic matter [DOM; ([Sauvé, 2001](#))].

In the 2009 PM ISA, several models, isotopic studies, and sequential extraction methods for determining metal bioavailability in soils were reported ([Feng et al., 2005](#); [Collins et al., 2003](#); [Shan et al., 2003](#)). However, actual measurement of biological effects is generally regarded as the preferred criterion to assess bioavailability ([Almas et al., 2004](#)). Since the 2009 PM ISA, Biomet biosensors have been used to assess bioavailability of metals in contaminated topsoils and subsoils ([Almendras et al., 2009](#)). Biomet biosensors use genetically engineered bacteria that give off light when exposed to heavy metals that are bioavailable. [Almendras et al. \(2009\)](#) also used sequential extraction to determine solubility. At three sites near a smelter in Chile, they found that Cu and Zn had the greatest solubility, arsenic (As) had less solubility, and Pb and Fe were the least soluble of those heavy metals. Further, as was determined to be the most bioavailable, while Cu and Zn were less bioavailable. The authors were unable to determine bioavailability of Pb using the same technique.

The mobility of heavy metals, an indicator of potential bioavailability, was determined in surface soil using sequential extraction ([Svendsen et al., 2011](#)). In five sites at decreasing distances from a smelter in Norway, Cd was determined to be most mobile and Cu the least mobile ([Svendsen et al., 2011](#)). Zn and Pb were moderately mobile. These results were in contrast to the results of ([Almendras et al., 2009](#)).

---

## 15.5.2 Soil Nutrient Cycling

In previous PM reviews, toxicity of metals, especially Zn, Cd, and Cu, to soil microflora was found to reduce decomposition processes in soils and interfere with nutrient cycling ([U.S. EPA, 2009a](#)). In previous PM reviews, changes to microbial enzymatic activity, soil basal respiration rate, and soil microbial biomass were all associated with increased metal content in soils. Studies reviewed in the 2009 PM ISA report increased leaf litter accumulation near point sources.

Since the 2009 PM ISA, many studies showing the deleterious effects of PM on nutrient cycling have been published. The effect of PM on the microbial coefficient of soils contaminated by atmospheric emissions from an active mining and smelting complex was

determined in one study. The microbial coefficient, which is the ratio of microbial biomass carbon to total organic carbon, was negatively correlated with metal concentrations ([Shukurov et al., 2014](#)). The microbial coefficient gives a measure of substrate bioavailability.

A recent study demonstrated the role of atmospheric deposition of particulate heavy metals in inhibiting C cycling. In this study, a cropping system was exposed to atmospheric deposition while a similar cropping system was designed to exclude it by using a greenhouse. Total organic carbon and water soluble organic carbon increased in the exposed plots and decreased in the greenhouse plots; slow decomposition in soils polluted with heavy metals could have caused the increased levels of total organic carbon and water soluble organic carbon observed in the open plots ([Pandey and Pandey, 2009](#)).

New studies show decreases in enzyme activity and varying sensitivity of enzymes to metal pollution. Soil dehydrogenase activity was diminished in polluted soils compared to control soils ([Bojarczuk and Kieliszewska-Rokicka, 2010](#)). High soil dehydrogenase activity indicates a living microbial community; additionally, dehydrogenase activity increases with microbial biomass C, organic matter levels, and basal respiration ([Bojarczuk and Kieliszewska-Rokicka, 2010](#)). In another study, enzyme activities of alkaline phosphatase and fluorescein diacetate were greater in greenhouse treatments than in open treatments exposed to deposition over the study period, showing that the potential for hydrolysis was elevated in the greenhouse treatments ([Pandey and Pandey, 2009](#)). As a result, organic C was mineralized to carbon dioxide and released from the soil more quickly than it was in the treatments exposed to deposition. [Qu et al. \(2011\)](#) found that enzyme activity was higher at sites farther from an active mining operation than those close to it. However, urease activity was more affected by heavy metals than dehydrogenase and phosphatase activity. Dehydrogenase contributes to many oxidative activities, which degrade soil organic matter ([Qu et al., 2011](#)). Phosphatase conducts hydrolysis to convert organic phosphorus compounds into inorganic phosphorus compounds, and urease converts urea into carbon dioxide and ammonia through hydrolysis ([Qu et al., 2011](#)).

A new study compared soil functional activity measured by the bait-lamina assay and by the Biolog assay. Feeding activity was increased at the less polluted site compared to the more polluted site ([Boshoff et al., 2014](#)). Substrate utilization rate and richness of used substrates were decreased in the more polluted site compared with the less polluted site after 2 and 6 days. On the other hand, diversity of used substrates at all plots resembled one another by the end of the experiment. Feeding activity, substrate utilization rate, richness of used substrates, and diversity of used substrates all decreased as As, Cu, and Pb concentrations increased. The Biolog assay was a better indicator of soil functional

activity than the bait-lamina assay ([Boshoff et al., 2014](#)). The bait-lamina assay indicates the feeding activity of soil fauna; the Biolog assay measures the metabolic use pattern of the culturable microbial community.

The effects of PM on microbial activity and biomass have been widely studied in the literature since the release of the 2009 PM ISA. Additions of Cr and Zn to soils have been found to reduce microbial respiration ([Åkerblom et al., 2007](#)). The highest concentrations of Pb and molybdenum (Mo) decreased respiration, as did higher levels of Ni and Cd. On the other hand, low levels of Ni and Cd increased microbial respiration. In this study, metals were added in low, medium, and high doses to soil from the humus layer of a Swedish forest ([Åkerblom et al., 2007](#)). Similarly, in another study, microbial activity (for all metals except Cu) decreased with increasing metal concentrations, and a negative correlation was also determined between metal concentrations and microbial biomass ([Anderson et al., 2009a](#)). Notably, microbial biomass levels were all similarly reduced among contaminated sites compared to the control site, even though metal concentrations among the contaminated sites varied. At the same time, microbial activity and biomass increased with increasing concentrations of physicochemical variables (such as nitrate, magnesium [Mg], and potassium [K]). Microbial activity, indicated by the amount of carbon substrates used, was measured using the Biolog assay ([Anderson et al., 2009a](#)). Using similar methods, ([Anderson et al., 2009b](#)) found that microbial activity and biomass in polluted sites were reduced compared to activity and biomass in the control site, prior to the experiment, which consisted of adding metals to soils from the sites. Microbial activity and biomass were lower at all sites after metal addition ([Anderson et al., 2009b](#)). In [Azarbad et al. \(2013\)](#), basal respiration and substrate-induced respiration increased with organic matter and pH and decreased as the toxicity index (an indicator of heavy metal contamination) increased. The toxicity index was more important in explaining effects of heavy metal contamination on substrate-induced respiration than basal respiration. In the same study, microbial biomass, represented by total phospholipid fatty acids (PLFAs), increased as toxicity index decreased ([Azarbad et al., 2013](#)). [Chodak et al. \(2013\)](#) found that microbial biomass and basal respiration were affected mainly by environmental variables, such as total nitrogen and organic carbon, and heavy metals impacted them much less. In another study, microbial biomass C and substrate-induced respiration were lower in open treatments exposed to atmospheric deposition than in greenhouse treatments as time progressed ([Pandey and Pandey, 2009](#)).

---

### 15.5.3 Soil Community Effects

At the time of the 2009 PM ISA, toxicity of heavy metals to soil-associated microbes were well characterized in laboratory studies, but less was known about the relative

sensitivity of fungi, bacteria, and actinomycetes and community-level changes. New techniques described in the 2009 PM ISA, such as the use of phospholipid and nucleic-acid biomarkers ([Joynt et al., 2006](#)), have enabled researchers to better characterize microbial community composition and biodiversity. In a recent study, tolerance of microbial communities to heavy metal PM has been shown to vary with ecosystem type. Culturable bacterial communities in contaminated meadow soils experienced greater tolerance to pollution, but the culturable communities in contaminated forest soils did not ([Stefanowicz et al., 2009](#)). The authors suggested that similarities between the degree of heavy metal contamination in control and polluted forest soils, caused by increased pH in polluted soils, may have contributed to the lack of tolerance of bacterial communities in forest soils because pH influences bioavailability of metals. Additionally, the absence of increased tolerance in forest soils might have been caused by a lack of variation in metal sensitivity of bacterial species.

The impact of metal-associated PM on the abundance of microbes has been studied in recently published papers. Total numbers of silver birch (*Betula pendula*) seedling root tips colonized by mycorrhizae decreased in seedlings grown in polluted soils relative to those in control soil ([Bojarczuk and Kieliszewska-Rokicka, 2010](#)). In another study, culturable bacteria were more abundant at the sites farther from an active mining operation than at the sites close to it ([Qu et al., 2011](#)). [Lenart-Boron and Wolny-Koladka \(2015\)](#) found no correlation between metal concentrations and abundance of microbial groups (mesophilic bacteria, fungi, actinomycetes, and *Azotobacter* spp.). The effects of PM from heavy metals on the metabolic quotient of soils that were contaminated by an active mining and smelting complex in Uzbekistan have been studied recently in the literature. Metabolic quotient, an indicator of the influence of environmental variables on microbial communities, increased with increasing heavy metal concentrations ([Shukurov et al., 2014](#)).

Recently published studies show that the response of soil-associated microbial community structure and function to heavy metal PM varies. ([Åkerblom et al., 2007](#)) found that most metals altered community structure in a similar way. Phospholipid fatty acids (PLFAs) can indicate microbial community structure, and different PLFAs are associated with different groups of microbes [e.g., fungi, bacteria; ([Åkerblom et al., 2007](#))]. Relative abundance of PLFAs associated with Gram-positive bacteria had a positive relationship with metal concentrations, but relative abundance of PLFAs associated with Gram-negative bacteria had a negative relationship with metal concentrations. The relative abundance of actinomycetes PLFAs had a positive relationship with metal concentrations. The reaction of the relative abundance of certain PLFAs found in Gram-negative bacteria varied depending on exposure to particular metals, and the reaction differed most between Cr and Cd. Relative abundance of a fungal

PLFA increased with increasing Cr and Zn concentrations ([Åkerblom et al., 2007](#)). [Likar and Regvar \(2009\)](#) determined that ascomycetes fungi were more common in polluted plots, and ectomycorrhizal ascomycetes mainly comprised one taxonomic group. On the other hand, basidiomycetes fungi were more common in control plots and in plots that were less contaminated, and ectomycorrhizal basidiomycetes were more diverse than ectomycorrhizal ascomycetes, comprising several taxonomic groups. Dark septate endophytes in the ascomycete group were common in polluted plots and comprised several taxonomic groups ([Likar and Regvar, 2009](#)). The increased number of DNA sequences from a particular dark septate endophyte genus (*Phialophora*) in plots that contained greater concentrations of Cd and Pb suggests that this genus could help goat willow (*Salix caprea*) take up more nutrients under metal stress ([Likar and Regvar, 2009](#)); however, the authors did not actually measure nutrient uptake of plants in this study. [Anderson et al. \(2009b\)](#) found that before the experiment, which consisted of adding metals to soils with varying levels of initial contamination by an abandoned smelter in Anaconda, MT, the structure and function of the microbial community from each site differed from one another, and after the experiment, the communities remained structurally and functionally different.

In another study, diversity and evenness of soil fungi communities in forest litter and those of arbuscular mycorrhizal fungi communities in forest litter were lower in a site polluted by emissions from an active copper smelter than they were in the reference site; community structure of soil fungi in the polluted site was not similar to that in the control site ([Mikryukov et al., 2015](#)). Spatial autocorrelations existed in both the control and polluted sites for soil fungi communities, but the spatial structure of the communities in the two sites did not resemble one another. Arbuscular mycorrhizal fungi (AMF) community structures at control and polluted sites did resemble one another. Spatial autocorrelation only existed in the polluted sites for arbuscular mycorrhizal fungi communities ([Mikryukov et al., 2015](#)). Spatial heterogeneity tended to be greater in contaminated areas than in uncontaminated areas ([Mikryukov et al., 2015](#)). [Qu et al. \(2011\)](#) found that microbial community diversity increased as distance from an active mining operation increased. In a different study, ecophysiological index values at two long-term contaminated sites were substantially high for oligotrophs and copiotrophs ([Margesin et al., 2011](#)). Both sites contained bacterial communities with high Shannon diversity index values (a common index used to characterize species diversity), and the metabolically active groups at both sites were Proteobacteria and Actinobacteria ([Margesin et al., 2011](#)).

Recent studies have shown the effects of environmental variables in comparison to the effects of heavy metal associated PM. In a study by [Anderson et al. \(2009a\)](#), microbial species richness was influenced by physicochemical characteristics (Mg, CEC, Ca,

ammonium [NH<sub>4</sub><sup>+</sup>]), but was not affected at all by metal concentrations; however, community structure in polluted sites was altered by metal concentrations compared to control sites. In a different study, toxicity index, which represents the degree of heavy metal pollution, had a positive impact on functional diversity of fungi, and nutrient status had a negative impact on functional diversity of fungi ([Azarbad et al., 2013](#)). On the other hand, toxicity index did not influence functional diversity of bacteria, but functional diversity increased as acidity decreased. PLFAs that represent Gram-positive bacteria increased with toxicity index, while the PLFA associated with fungi decreased as toxicity index increased. The level of organic matter and pH were factors that influenced PLFAs as well as degree of metal contamination ([Azarbad et al., 2013](#)). [Chodak et al. \(2013\)](#) determined that pH had the largest impact on bacterial community diversity, but heavy metals also modulated diversity. Bacterial community structure was mainly affected by pH. Although pH was the main factor controlling microbial community structure, heavy metals also influenced microbial community structure ([Chodak et al., 2013](#)).

In addition to soil microbial communities, the effects of metal-associated PM on other soil fauna have been recently published. [Shukurov et al. \(2014\)](#) found that abundance of nematodes was greater at the plots further from the emission source; similarly, the abundance of nematodes, number of bacterivorous nematodes, and number of omnivorous predator nematodes were negatively correlated with heavy metal concentrations.

The harmful effects of organic PM on soil microbes have been published in recent studies. AMF infectivity in the top soils was reduced compared to control soils when exposed to phenanthrene for 2 weeks ([Desalme et al., 2012](#)). In this study, phenanthrene was pumped into an exposure chamber containing soils to simulate atmospheric exposure. However, in another study using a similar experimental setup, mycorrhizal symbiosis in red clover was similar in control and polluted chambers, and mycorrhizal symbiosis in both treatments remained efficient ([Desalme et al., 2011a](#)). In the same study, *Rhizobium* nodule (bacteria) symbiosis in clover was lower in the upper layer of polluted soil than in the upper layer of control soil ([Desalme et al., 2011a](#)).

---

#### **15.5.4 Soil Microbe Interactions with Plant Uptake of Particulate Matter**

In the 2009 PM ISA, the role mycorrhiza in modulating toxicity of deposited metals was reported. This role includes improving nutrient uptake and decreasing metal uptake ([Vogelmikus et al., 2006](#); [Nogueira et al., 2004](#); [Berthelsen et al., 1995](#)) in the plant by acting as a sink for metals ([Carvalho et al., 2006](#); [Berthelsen et al., 1995](#)), often preventing the metals in the roots from allocating to shoots ([Soares and Siqueira, 2008](#);

[Zhang et al., 2005](#); [Kaldorf et al., 1999](#)). In contrast, other studies reviewed in the 2009 PM ISA showed that mycorrhizae may facilitate accumulation of metals in plants and enhance the translocation of metals from the root to the shoot ([Zimmer et al., 2009](#); [Citterio et al., 2005](#); [Vogel-Mikus et al., 2005](#)). There was limited evidence for bacteria and mycorrhiza working together to improve plant tolerance to metals ([Vivas et al., 2006](#); [Vivas et al., 2003](#)).

Since the 2009 PM ISA, additional studies show mycorrhizae modulates metal uptake in plants. Seedlings grown in polluted soil with mycorrhizae preferentially sequestered heavy metals (Cu and Pb) to the roots instead of the shoots ([Bojarczuk and Kieliszewska-Rokicka, 2010](#)). The ratio of mycorrhizal fine roots to nonmycorrhizal fine roots was lower for silver birch seedlings grown in polluted soils (mixture and fully polluted soil near a copper foundry in Poland) than for tree seedlings grown in control soil; however, the mycorrhizae were still able to affect metal uptake by the plants.

Nonmycorrhizal microbes (e.g., bacteria, fungal hyphae, spores from saprobes) may also decrease metal uptake by plants. In a greenhouse experiment using soils collected at varying distances from abandoned smelters in the U.S., wavy hairgrass (*Deschampsia flexuosa*) plants grown in soils with high amounts of contamination and treated with nonmycorrhizal microbial wash accumulated less Zn in the shoots compared to plants without the nonmycorrhizal microbial wash ([Glassman and Casper, 2012](#)). In contrast, although there was an AMF treatment in this experiment, AMF did not impact the amount of Zn in the shoots of plants.

AMF and nonmycorrhizal microbes such as plant growth promoting bacteria can contribute to phytoremediation of polluted soils; much new research on these topics has been published since the release of the previous ISA ([Cabral et al., 2015](#); [Meier et al., 2012](#); [Gamalero et al., 2009](#)).

---

### 15.5.5 Effects of Particulate Matter on Physical Properties of Soils

PM can affect physical properties of soils, such as bulk density, porosity, and water holding capacity. Changes in these properties can decrease plant growth and yield. This topic was not discussed in the previous PM ISA. However, new studies on the effects of PM on physical properties of soils have been published since the release of the previous ISA. [Pandey and Pandey \(2009\)](#) found that bulk density was elevated during the study period in an experimental cropping system open to deposition. Porosity and water holding capacity in the open system were diminished over the same time period. The opposite was the case for the experimental cropping system closed to deposition. The authors suggested that the influx of deposition of particulate matter during the study

period caused a rise in bulk density, and the elevated bulk density caused the decrease in porosity and water holding capacity ([Pandey and Pandey, 2009](#)).

---

## 15.6 Effects of Particulate Matter on Fauna

Toxicity of PM to fauna varies depending upon the PM composition, concentration, bioaccessibility and bioavailability, biological species sensitivity, and organism lifestage. The bioavailability or bioaccessibility of PM-associated trace metals and organics is dependent upon the physical, chemical, and biological conditions under which an organism is exposed at a particular geographic location. Organisms may have detoxification mechanisms that increase tolerance to stressors. Pathways of PM exposure to aquatic and terrestrial organisms include ingestion, absorption, and trophic transfer. Several types of studies have been used to assess the effects of PM on terrestrial and aquatic organisms, including laboratory bioassays and field studies.

---

### 15.6.1 Laboratory Bioassays

The use of ecotoxicity assays to screen and assess PM effects on biota has expanded considerably since the 2009 PM ISA. All but one of the new studies used PM from outside of the U.S., so the pollutant mix may not be representative of exposures occurring in the U.S. These studies are reported below. However, several caveats must be noted in correlating effects in these studies to natural environments. Extracts of PM from air filters may not be representative of exposure routes and conditions in aquatic and terrestrial habitats ([Kováts et al., 2012](#)). Bioavailability of PM in the natural environment is affected by many factors not represented in bioassay techniques. Furthermore, because these studies include a mix of PM constituents, it may be difficult to identify the active component(s). Results from toxicity assays using PM extracts (such as dichloromethane, methanol, or water extracts) should be interpreted with caution because additional compounds might remain unextracted, underestimating or overestimating the whole PM toxicity to aquatic organisms ([Mesquita et al., 2014a](#); [Kováts et al., 2012](#)).

Recently the *Vibrio fischeri* bioluminescence inhibition test (Microtox<sup>®</sup>) has been applied as an ecotoxicological screening tool for PM ([Roig et al., 2013](#); [Kováts et al., 2012](#)). In this bioassay, the rate of inhibition of light emission from the bacteria is measured after exposure to a pollutant. In aqueous PM extracts from air filters from urban, rural, and industrial areas of Catalonia, Spain, no correlation was observed between inhibition of light emission in the in vitro test and PM<sub>10</sub> concentration ([Roig et al., 2013](#)). Metals (except Cr) and PCDD/F congeners in the samples were significantly correlated to the

bioassay results, indicating that PM composition, rather than concentration, explains the experimental observations.

Toxicity of PM extracts to aquatic biota have been assessed in several studies published since the 2009 PM ISA. Acute (24-hour) toxicity of ambient PM with a nominal mean aerodynamic diameter less than or equal to 2.5  $\mu\text{m}$  ( $\text{PM}_{2.5}$ ) extracted from air filters in Atlanta, GA to the freshwater rotifer *Brachionus calyciflorus* was assessed by ([Verma et al., 2013](#)). The toxicity of methanol extracts was much higher than that of water extracts, and there were no conclusive associations of rotifer toxicity with PM chemical composition. In zebrafish (*Danio rerio*) embryos exposed to organic extracts of PM samples from coal-burning particles in a semirural area in Italy, cytochrome P4501A gene expression was significantly induced ([Olivares et al., 2013](#)). In another zebrafish study, urban PM had adverse developmental effects (spinal deformations, malformation of swim bladder, etc.) on embryos ([Mesquita et al., 2014b](#)). These observations correlated with PAH content of the PM samples. In a comparison of PM in rural and urban air particles collected in Spain, induction of AhR signaling pathway correlated with PAH concentrations in all locations ([Mesquita et al., 2015](#)). The greatest dioxin-like activity and embryotoxicity was observed in the finest PM fraction ( $<0.5 \mu\text{m}$ ). During the winter, maximal assay activity occurred in the rural samples due to biomass-burning emissions.

A series of in vivo studies on the effects of  $\text{PM}_{2.5}$  exposure on the nematode *Caenorhabditis elegans* indicated a suite of responses in this organism. [Zhao et al. \(2014b\)](#) observed altered development, lifespan, reproduction, locomotion, and defecation behavior associated with long-term exposure to  $\text{PM}_{2.5}$  collected from a traffic-dense area in Beijing, China. PM components included S, Cd, Pb, Zn, Cu, and PAHs. The insulin signaling pathway was identified as a possible molecular target of the traffic-related  $\text{PM}_{2.5}$  in nematodes ([Yang et al., 2016](#); [Yang et al., 2015](#)). In nematodes exposed to  $\text{PM}_{2.5}$  in coal ash, altered functioning of neurons that control defecation behavior and gene expression patterns required for control of oxidative stress were reported, as were effects on development, reproduction, locomotion behavior, lifespan, and susceptibility to metal toxicity ([Wu et al., 2017](#); [Sun et al., 2016](#); [Sun et al., 2015b](#)). Elemental analysis of the PM from coal combustion indicated Fe, Zn, and Pb were the most common metals followed by As, Cd, Cr, Cu, and Ni. Fluoranthene, pyrene, and 12 additional PAHs were detected in the  $\text{PM}_{2.5}$  in the coal ash.

Earthworms often constitute a large percentage of soil animal biomass and are considered to be relatively sensitive bioindicators of soil contamination by metals and organics. Several studies in the 2009 PM ISA reported uptake of trace metals and organics by earthworms ([Hobbelen et al., 2006](#); [Parrish et al., 2006](#)), while fewer studies reported responses due to atmospheric deposition of PM ([Massicotte et al., 2003](#)). Earthworms can

also modify PM bioavailability and bioaccessibility in soils through bioturbation. For example, the presence of earthworms has been shown to significantly increase soil-to-plant transfer of metals via modifications to soil and increased bioaccessibility of metals to roots ([Leveque et al., 2014](#)).

In a recent study, earthworms (*Eisenia andrei*), directly exposed to powder from PM<sub>10</sub> quartz filters (24.9 mg/g PM<sub>10</sub> and 14 µg/g PAHs) in artificial soil for a range of final concentrations from 15 to 30 µg/g PM<sub>10</sub>, showed genotoxic effects ([Vernile et al., 2013](#)). DNA damage measured by comet assay was observed starting at 22.5 µg/g PM<sub>10</sub> (0.012 µg/g PAHs) in samples collected from an urban site in Italy.

---

### 15.6.2 Wildlife as Biomonitors of Particulate Matter

The 2009 PM ISA reviewed several studies in which resident biota was used to biomonitor urban air pollution including PM. For example, snails (*Helix* spp.) accumulate trace metals and agrochemicals and can be used as effective biomonitors for urban air pollution ([Regoli et al., 2006](#); [Viard et al., 2004](#); [Beeby and Richmond, 2002](#)). Biological effects that have been demonstrated include oxidative stress, growth inhibition, impairment of reproduction, and induction of metallothioneins, which are involved in metal detoxification ([Regoli et al., 2006](#); [Gomot-De Vaufleury and Kerhoas, 2000](#)). Biomonitoring of aquatic species was also reported. For example, [Coelho et al. \(2006\)](#) investigated Hg concentrations in *Scrobicularia plana*, a long-lived, deposit-feeding bivalve in southern Europe. The use of sentinel species to detect the effects of complex mixtures of air pollutants is of particular value because the chemical constituents are difficult to characterize, exhibit varying bioavailability, and are subject to various synergistic effects.

New biomonitoring studies of PM effects on biota include vertebrate and invertebrate organisms. Use of the land snail *Helix aspersa* as a biomonitor for PAHs associated with atmospheric particles in Porto Alegre, Brazil indicated, in general, that higher genotoxicity in this indicator organism was associated with PM size fractions <PM<sub>2.5</sub> ([Janistcki et al., 2009](#)). Various biomarkers of oxidative stress were induced in *Helix* monitored in Kafr El-Zayet, Egypt in response to heavy metals from industrial sources and vehicular traffic ([Abdel-Halim et al., 2013](#)).

Recent biomonitoring studies of PM components include several studies using wild pigeons. Genotoxic endpoints (percentage DNA migrated, tail moment, and damage index), evaluated in pigeons (*Columba livia*) in the city of Milan, Italy showed significant differences when compared with control pigeons living indoors, and the highest values were observed in summer ([Sicolo et al., 2010](#)). In a companion study, porphyrin patterns

in excreta were always higher in the wild urban pigeon population, while methemoglobin levels in blood showed significant differences from season to season, but values in the indoor birds were significantly lower only in summer and autumn ([Sicolo et al., 2009](#)). The authors chose this model because pigeons have a small habitat and high metabolic rate, and the main route of exposure to urban air is through inhalation and intake of contaminated food particles. Assay results were compared with measurements of contaminants in the urban air (carbon monoxide [CO], PM<sub>10</sub>, NO<sub>2</sub>, O<sub>3</sub>, SO<sub>2</sub>, benzene [C<sub>6</sub>H<sub>6</sub>], PAHs in PM<sub>2.5</sub>), and a positive correlation with PAH and protoporphyrin was observed along with a positive correlation between O<sub>3</sub> and DNA damage index ([Sicolo et al., 2010](#); [Sicolo et al., 2009](#)). Feathers, lung, liver, and kidney tissues were sampled from pigeons in two urban areas in the U.S. (Glendora, CA and Midland, TX) to evaluate Hg exposure ([Cizdziel et al., 2013](#)); however, no significant differences were observed between the two locations. In another study in two atmospherically polluted sites in North Texas, Hg was found in the blood and feathers of eastern bluebird (*Sialis sialis*), Carolina wren (*Thryothorus ludovicianus*), wood duck (*Aix sponsa*), great egret (*Ardea alba*), and great blue heron [*Ardea Herodias*; [Schulwitz et al. \(2015\)](#)]. Levels reported in these birds may be high enough to affect fitness ([Schulwitz et al., 2015](#)).

Several species have been evaluated as indicators of metal pollution from a long-term monitoring site near a former Cu-Ni smelter in Harjavalta, Finland. Metal concentrations in bird feces were quantified at the site to measure exposure via atmospheric deposition; however, measured decreases in the excrement did not directly reflect emission patterns ([Berghlund et al., 2015](#)). The authors suggest this is due to uptake of metals from food items in contact with contaminated soils. Plasma carotenoid levels measured in the birds on the site were not directly correlated to metal pollution or nesting survival ([Eeva et al., 2012](#)). Leg deformities of oribatid mites were also evaluated as a biomonitor but determined to be an unreliable indicator of heavy metals in soil at the site ([Eeva and Penttinen, 2009](#)).

---

### 15.6.3 Biomagnification

Biomagnification of PM-associated metals and organics was reviewed in the 2009 PM ISA and are summarized here. The basic understanding of the process of biomagnification has not appreciably changed since the previous assessment. As reported in the 2009 PM ISA, biomagnification is the progressive accumulation of chemicals with increasing trophic level ([Leblanc, 1995](#)). At the time of the 2009 PM ISA, biomagnification had been demonstrated for a few trace metals in terrestrial and aquatic systems ([U.S. EPA, 2009a](#)). Plant uptake is often the first step for a metals to enter higher levels of the food web. Consumers of vegetation may often receive heavy loading of

metals from their diets. Metals may also bioaccumulate in some species, and tissue concentrations are magnified at the higher trophic levels. Organic Hg is the most likely metal to biomagnify, in part because organisms can efficiently assimilate methylmercury and are slow to eliminate it [(Croteau et al., 2005; Reinfelder et al., 1998); [Appendix 12](#)]. There is also evidence that the trace metals Cd, Pb, Zn, Cu, and selenium (Se) biomagnify.

Biomagnification of organics has been extensively documented in aquatic and terrestrial ecosystems, and these compounds are detected in biota at remote locations due to long-range atmospheric transport processes ([U.S. EPA, 2009a](#)). Organics, such as PAHs, can be transferred to higher trophic levels, including fish, and this transfer can be mediated by aquatic invertebrates in the fish diet ([U.S. EPA, 2009a](#)). In high mountain lakes, atmospheric inputs dominate as sources of contamination. In addition, such lakes tend to have relatively simple food webs. In a study reviewed in the 2009 PM ISA, ([Vives et al., 2005](#)) investigated PAH content of brown trout (*Salmo trutta*) and their food items. Total PAH concentrations tended to be highest in organisms that occupy littoral habitats, and lowest in pelagic organisms.

The study of trophic transfer and biomagnification is limited by the difficulty in discriminating food webs and the uncertainty associated with assigning trophic position to individual species ([Croteau et al., 2005](#)). Use of stable isotopes can help establish linkages. However, it is difficult to determine the extent to which biomagnification occurs in a given ecosystem without thoroughly investigating physiological biodynamics, habitat, food web structure, and trophic position of relevant species. Thus, developing an understanding of ecosystem complexity is necessary to determine which species are at greatest risk from toxic metal exposure ([Croteau et al., 2005](#)).

---

## 15.7 Effects of Particulate Matter on Ecological Communities and Ecosystems

Evidence for PM effects on higher levels of biological organization is primarily from field studies conducted in proximity to point sources, such as smelters, mining, and other industrial sources. These areas where PM deposition decreases from the source have been assessed through ecological gradient studies. Several long-term monitoring studies have been conducted on ecosystem responses to atmospheric deposition of metals, including the Harjavalta smelter in Finland where metal-rich dust emissions have decreased by 99% during the 23-year study period ([Eeva and Lehikoinen, 2015](#)). Additional evidence for PM effects on ecological communities include studies from urban areas and model microecosystems.

---

## 15.7.1 Gradient Effects near Smelters

The 2009 PM ISA reviewed multiple studies conducted near a Cu-Ni smelter in Harjavalta, Finland. These studies documented effects on multiple species operating at different trophic levels ([Kiikkilä, 2003](#); [Helmisaari et al., 1999](#); [Malkönen et al., 1999](#); [Pennanen et al., 1996](#)). The species composition of vegetation, insects, birds, and soil microbiota changed, and tree growth was reduced 4 km from the smelter. Within 1 km, very few organisms were documented ([Kiikkilä, 2003](#)).

Since the 2009 PM ISA, additional studies have been published from the long-term monitoring of the ecological communities near the Cu-Ni smelter site in Harjavalta, Finland. Several studies in passerine birds (pied flycatcher [*Ficedula hypoleuca*] and great tit [*Parus major*]) show some biological recovery and a reduction in metal concentration with decreased atmospheric emissions over time, even though metal levels in tissues remain high in birds near the smelter, likely due to contamination of soils and food items ([Berglund et al., 2012](#); [Berglund et al., 2011](#)). Similarly, tissue levels in pied flycatchers remained high near a smelter in Northern Sweden even after a 93 to 99% reduction in metal emissions ([Berglund and Nyholm, 2011](#)). With decreased metal pollution at Harjavalta, breeding parameters in pied flycatchers and great tits have improved since the 1990s. However, clutch size and fledgling number remain below those of birds from a reference area ([Eeva and Lehikoinen, 2015](#); [Eeva et al., 2009](#)). Interruption of egg laying was assessed in passerine birds at the Harjavalta Smelter site and was attributed to both cold weather and pollution ([Eeva and Lehikoinen, 2010](#)). These laying gaps occurred with greater frequency, and most commonly at the beginning of the laying sequence, close to the smelter. The authors suggested that heavy metals at the site interfere with Ca availability and metabolism during the breeding season when extra Ca is needed for eggshell formation and growth.

[Eeva et al. \(2010\)](#) sampled land snail shells from pied flycatcher nests along the Harjavalta smelter pollution gradient to assess effects of air pollution on shell mass, abundance, and diversity of land snail communities. The snails represent an important source of Ca for the birds, especially for eggshell formation and development of nestlings. Shell size decreased near the smelter, indicating snail growth was also impacted at the most highly polluted areas. The highest diversity, largest size, and greatest abundance of snail populations were observed in the moderately polluted areas compared to snails in the vicinity of the smelter and in remote unpolluted areas.

Recent literature continues to show a gradient of response in vegetation to trace metal deposition from smelting operations including evidence from the U.S. The forest surrounding two historical Zn smelters in Palmerton, PA has been used as a study site to assess ecological response and recovery following historic emissions. A portion of this

forest includes the Appalachian National Scenic Trail, and a barren area of approximately 600 to 800 ha remains where Zn, Mn, and Cd were once emitted ([Beyer et al., 2013](#)). Operation at the smelter ceased in 1980, but effects from the contaminated soils persist. In a greenhouse study using seedlings of native tree species, as little as 10% of soil collected in proximity to the smelter site and mixed with reference soil caused reduced growth or mortality of the tree seedlings ([Beyer et al., 2013](#)). Red maple (*Acer rubrum*) was most sensitive, followed by gray birch (*Betula populifolia*), northern red oak (*Quercus rubra*), chestnut oak (*Quercus prinus*), and eastern white pine (*Pinus strobus*). In a field survey relating Zn soil concentrations to forest response, canopy closure and shrub cover was decreased to half at approximately 2,060 mg/kg Zn, while tree-seedling density was reduced by 80% at 1,080 mg/kg Zn ([Beyer et al., 2011](#)). Vegetative communities near the Nikel smelter in Russia near the border with Finland and Norway showed varied response to deposition of heavy metals ([Myking et al., 2009](#)). Epiphytic lichens were most affected followed by decreased abundance and species richness of lichens and bryophytes closer to the smelter. No effects on tree crown condition or growth were observed.

---

## 15.7.2 Urban Environments

Resident biota in urban areas are affected by PM along with other stressors associated with the built environment such as increased temperature due to heat island effects ([Pickett et al., 2011](#)). [McDonnell et al. \(1997\)](#) observed differences in urban forest structure and function compared to rural and suburban areas of New York. Oak forests near the city were characterized by reduced soil fungal and invertebrate populations, elevated soil metals (presumably from air pollution), and lower quality of leaf litter. The removal of PM by urban vegetation to mitigate air pollution has been extensively reviewed, but few of these studies consider ecological impacts of PM ([Escobedo et al., 2011](#); [Pataki et al., 2011](#)).

---

## 15.7.3 Aquatic Ecosystems

In the 2009 PM ISA, PM components in aquatic ecosystems were primarily considered in the context of aquatic food web transfer of organic contaminants ([U.S. EPA, 2009a](#)). In another study reviewed in the 2009 PM ISA, bioassay procedures with green algae were used to provide an initial screening of ambient PM toxicity from two urban/industrial and one rural site near Lake Michigan ([Sheesley et al., 2004](#)). Results suggested that toxicity was not related to the total mass of PM in the extract but to the chemical components of the PM. In a study of the effects of contaminated tunnel wash water runoff in Norway,

growth of sea trout (*Salmo trutta*) was significantly reduced in the stream receiving the wastewater ([Meland et al., 2010](#)). The contaminated wash water had elevated concentrations of traffic-related contaminants including metals, PAHs, and road salt from combustion and highway runoff. Fractionation of water samples indicated some of the metals and PAHs were highly associated with particles. Size ratios of detected PAHs suggested that sources included tire wear and incomplete combustion.

---

#### 15.7.4 Experimental Microecosystems

Since the 2009 PM ISA, several studies have employed a microecosystem to assess effects of air pollutants at the community level of biological organization to see how microbial communities living on terrestrial mosses (bryophytes) respond to atmospheric deposition of PM components (metals, PAHs, NO<sub>2</sub>). In a series of bioindicator studies conducted in France, species-specific responses to PM components and effects on total biomass were observed in the associated microbial communities ([Meyer et al., 2010a](#); [Meyer et al., 2010b](#)). Primary producers, decomposers, and predators responded differently to the pollutants ([Meyer et al., 2010a](#); [Meyer et al., 2010b](#)). Testate amoebae are especially sensitive to changes in atmospheric pollution in these microsystems and were proposed as a biomonitoring tool ([Meyer et al., 2012](#)). Total testate amoebae abundance and the abundance of five species of testate amoebae decreased with increased deposition of the PAH phenanthrene in the experimental microecosystem ([Meyer et al., 2013](#)).

---

### 15.8 Summary of Ecological Effects of Particulate Matter

Since publication of the 2009 PM ISA, new literature builds upon the existing knowledge of ecological effects associated with PM components, especially metals and organics. In some instances, new techniques have enabled further characterization of the mechanisms of PM on soil processes, vegetation, and effects on fauna. New studies provide additional evidence for community-level responses to PM deposition, especially in soil microbial communities. However, uncertainties remain due to the difficulty in quantifying relationships between ambient concentrations of PM and ecosystem response. Overall, **the body of evidence is sufficient to infer a likely causal relationship between deposition of PM and a variety of effects on individual organisms and ecosystems**, based on information from the previous review and new findings in this review.

In regard to direct effects of PM on radiative flux, a newly available research method links changes in expression of proteins involved in photosynthesis to changes in radiation

associated with aerosols and PM. Although this method has not been widely applied, it may represent an important way to study mechanistic changes to photosynthesis in response to more diffuse radiation resulting from PM in the air column.

In general, new studies on PM deposition to vegetation support findings in previous PM reviews on altered photosynthesis, transpiration, and reduced growth. Additional characterization of PM effects at the leaf surface since the 2009 PM ISA has led to a greater understanding of PM foliar uptake. Alterations in leaf fatty acid composition are associated with metals transferred to plant tissues from PM deposition on foliar surfaces ([Schreck et al., 2013](#)).

Several studies published since the 2009 PM ISA show PM effects on soil physical properties and nutrient cycling. Previous findings in the PM ISA of changes to microbial respiration and biomass are further supported by new studies. Microbial community responses to PM vary in tolerance to heavy metals and organics.

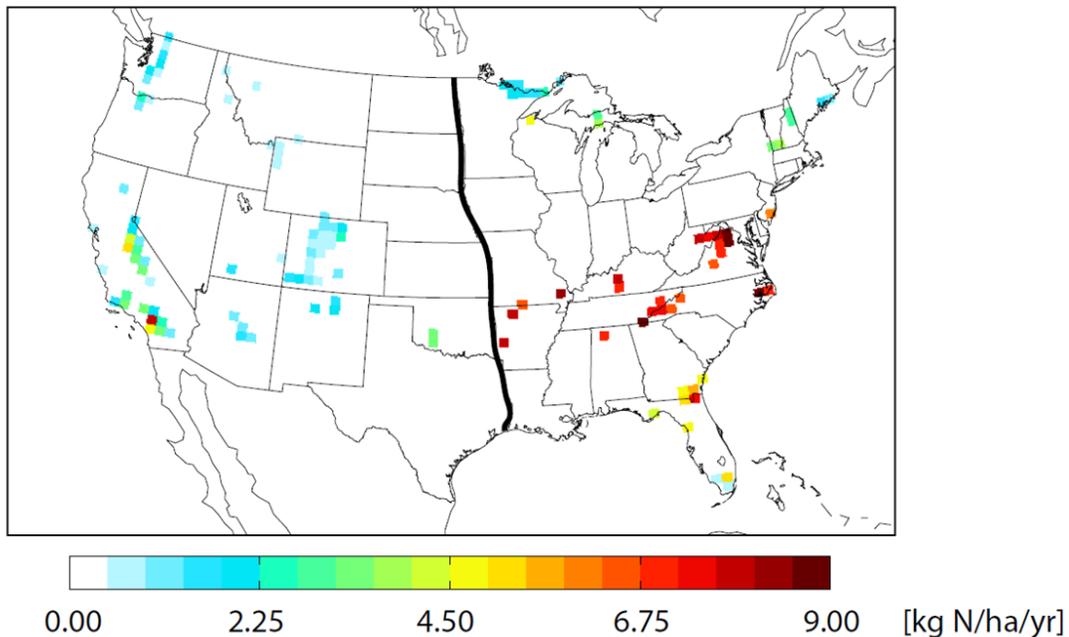

In fauna, results from ecotoxicity assays with PM extracts using bacteria, rotifers, nematodes, zebrafish, and earthworms support findings in the 2009 PM ISA that toxicity is not related to the total mass of PM in the extract, but to the chemical components of the PM. In nematodes exposed to PM from air filters, the insulin-signaling pathway was identified as a possible molecular target. Use of wildlife as PM biomonitors has been expanded to new taxa since the last PM review. Several studies in invertebrates and birds report physiological responses to air pollutants, including PM.

For ecosystem-level effects, a gradient of response with increasing distance from PM source was reported in the 2009 PM ISA. Newly available studies from long-term ecological monitoring sites provide limited evidence for recovery in areas such as those around former smelters due to the continued presence of metals in soils after operations ceased. A novel experimental microecosystem using microbial communities living in terrestrial mosses indicates that PM deposition alters responses of primary producers, decomposers, and predators.

---

## APPENDIX 16 CASE STUDIES

This appendix includes six case studies which are meant to identify the ecological effects of nitrogen (N) and sulfur (S), with a specific focus on national parks, other protected areas, and areas with long-term research. The locations of these case studies were chosen because they are areas for which a substantial amount of published work on ecological response to N and/or S deposition is available. The locations include the northeastern U.S., Adirondack State Park, southeastern Appalachia, Tampa Bay, Rocky Mountain National Park, and southern/central California. These case studies identify current acidification and nutrient status, as well as empirical and modeled critical loads. A recent model of reactive N deposition to Federal Class I areas suggests that reactive nitrogen (Nr) deposition exceeds the most sensitive critical loads in many of these areas [Figure 16-1, from (Lee et al., 2016)]. The scientific characterizations of ecological responses to N and S in these case studies set the scientific foundation for further analysis of risk and exposure.

Notes: color indicates magnitude of the reactive N exceedance. The size of Class I areas is not represented. Air quality model grid cells containing Class I areas are shown as colored regardless of the fraction of grid cell area the Class I area covers. Bold line divides Western and Eastern U.S.

Source: Figure 9 from [Lee et al. \(2016\)](#).

**Figure 16-1      Critical loads (CL) exceedance in Class I areas.**

---

## **16.1 Northeastern U.S. Case Study: Acadia National Park, Hubbard Brook Experimental Forest, and Bear Brook Watershed**

---

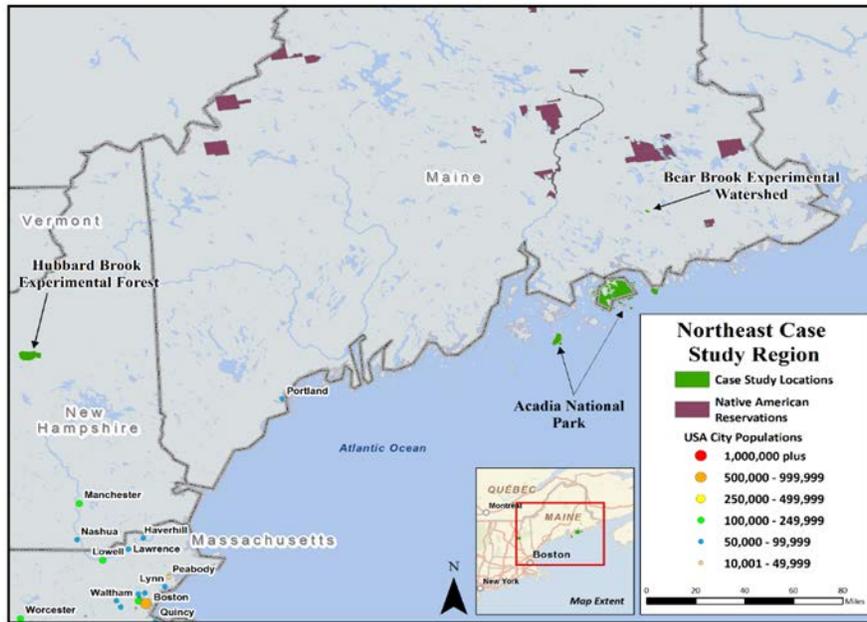

### **16.1.1 Background**

This case study is meant to identify effects of N and S in the northeastern U.S., with a specific focus on national parks and areas with long-term research data. It identifies current acidification and nutrient status and empirical and modeled critical loads (CLs). The 2008 NO<sub>x</sub>-SO<sub>x</sub> ISA included another case study of acidification in the Adirondack region of New York [Section 3.2.2.4 of 2008 ISA ([U.S. EPA, 2008a](#))]. The case study reported here is considered as a supplement to that earlier case study. Further information about the Adirondack region can be found in [Appendix 4](#) and [Appendix 5](#).

---

#### **16.1.1.1 Description of Case Study Region**

Acadia National Park (ACAD) in coastal Maine, the Hubbard Brook Experimental Forest (HBEF) in the White Mountains of New Hampshire, and the Bear Brook Watershed (BBW) in southeastern Maine were chosen for this case study to represent northeastern U.S. ecosystems known historically to be sensitive to acidification and nutrient enrichment from atmospheric S and N deposition ([Figure 16-2](#), [Table 16-1](#)). In this case study, we highlight multiple decades of research and monitoring at these locations to provide insights into the ecosystems' responses to S and N deposition and look for any indications of recovery.

**Figure 16-2** Locations of northeastern U.S. case study areas and nearby human population centers.

**Table 16-1** Selected characteristics of northeastern case study areas.

Case Study Area	Elevation	Geology	Dominant Vegetation	Focus
ACAD	0 to 466 m	Granitic	Red spruce, mixed forest	National Park
HBEF	183 to 1,002 m	Metamorphic	Northern hardwood forest, mixed forest, spruce-fir forest	Experimental forest, site of diverse biogeochemical research and monitoring
BBW	172 to 450 m	Metamorphic	Northern hardwood forest	Site of watershed manipulation experiment

ACAD = Acadia National Park; BBW = Bear Brook Watershed; m = meters; HBEF = Hubbard Brook Experimental Forest.

#### 16.1.1.1 Acadia National Park

Acadia National Park is located at the interface between northern coniferous forests and temperate deciduous woods and hosts plant species from two distinct regions

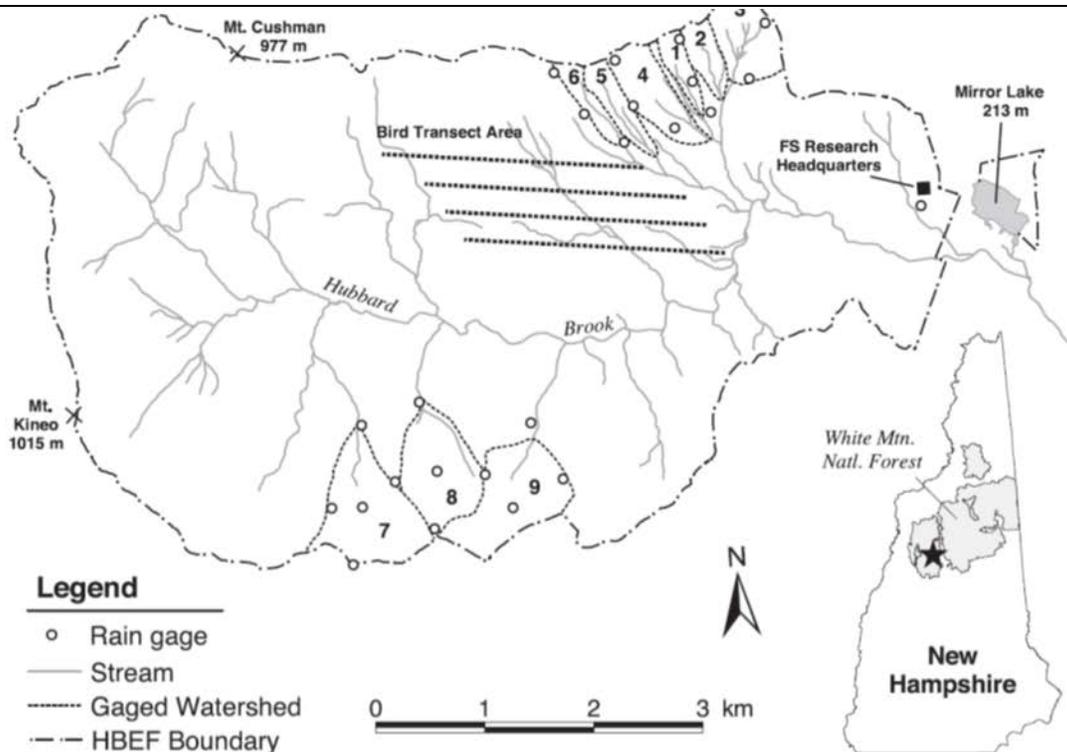

(<https://www.nps.gov/acad/>). ACAD extends over 45,000 acres on two islands and a mainland peninsula on Maine's coast. It receives about 140 cm/year of rainfall (Nielsen and Kahl, 2007). Geologically, the park consists of granite mountains with surrounding sedimentary and metamorphic rock. The soils have low buffering capacity, and steep slopes at high elevations make soil and runoff susceptible to acidification. The park's ecosystems include alpine heath, stunted growth woodlands, jack pine forests that include pitch pine, rocky woodlands of black spruce and heaths, mature spruce, and fir. Red spruce and sugar maple are the predominant tree species.

Eighty freshwater plant species have been documented in ACAD with another 12 semiaquatic shorelines species. Seven of the aquatic and semiaquatic plants are listed or proposed for inclusion on Maine's List of Endangered and Threatened Species. Another 30 of these species are considered "locally rare" (<https://www.nps.gov/acad/learn/nature/plants.htm>).

#### **16.1.1.1.2 Hubbard Brook Experimental Forest**

Hubbard Brook Experimental Forest is located in the southern portion of the White Mountain National Forest in central New Hampshire (Figure 16-3). The Atlantic Ocean is about 116 km to the southeast. Most of the surrounding land is also within the National Forest. The area is hilly and steep in places with coarse-textured acidic soils. The bedrock is dominated by metamorphosed igneous and sedimentary rocks. Bedrock is covered by about 2 m of glacial till.

Northern hardwood forests occupy lower elevation slopes with spruce-fir occurring on upper elevation slopes. Annual average precipitation is about 140 cm (one-third to one-quarter of which falls as snow).

FS = Forest Service; HBEF = Hubbard Brook Experimental Forest; km = kilometer; m = meter; Mt = mount; Mtn = mountain; Natl = national.

Notes: shown are the network of rain gauges, experimental watersheds (1-9), and Mirror Lake.

Source: [Campbell et al. \(2007\)](#).

**Figure 16-3 Site map of Hubbard Brook Experimental Forest in the White Mountains of New Hampshire.**

Glacier-deposited materials vary greatly in degree of sorting and grain size, with thicknesses ranging from zero on ridgetops and in stream valleys to 50 m near Mirror Lake. The principal soils are acidic (pH about 4.5 or less) and relatively infertile. The 20- to 200-mm-thick forest floor allows rapid infiltration of water and acts as insulation to prevent soil freezing before snow accumulates. Streams vary from small ephemeral channels to as large as perennial 5th order. Up to about 60 to 80% of storm precipitation flows by stream. HBEF is entirely forested, predominately with deciduous northern hardwoods including sugar maple (*Acer saccharum*), beech (*Fagus grandifolia*), and yellow birch (*Betula allegheniensis*). High-elevation conifers include red spruce (*Picea rubens*), balsam fir (*Abies balsamea*), and white birch (*Betula papyrifera*). Logging operations ended from around 1915 to 1917. The second-growth forest is about 80 to 90% hardwoods and 10 to 20% conifers. HBEF hosts more than 90 species of birds.

Snowshoe hare, moose, fox, black bear, beaver, and white-tailed deer are also present (<http://www.hubbardbrook.org/overview/sitedescription.shtml>).

HBEF ornithological studies have found that the abundance of birds decreased from more than 200 individuals per 10 ha in the early 1970s to 70 to 100 per 10 ha during the period from the early 1990s to the present. This decrease is unexplained (R.T. Holmes publications—Bird Abundances—<http://www.hubbardbrook.org/data/dataset.php?id=81> and).

#### **16.1.1.1.3 Bear Brook Watershed**

The BBW hosts a long-term, gaged, forested, first-order paired stream watershed. It is located about 40 km from the Atlantic Ocean on the southeast slope of Lead Mountain. It has a total relief of 210 m and a maximum elevation of 450 m. Two nearly perennial, low dissolved organic carbon (DOC), low acid neutralizing-capacity (ANC) streams (East and West Bear Brook [EB and WB]) drain 10.3 and 11.0 ha contiguous watersheds, respectively. BBW is covered predominantly by hardwoods (*Fagus grandifolia*, *Acer rubrum*, *Acer saccharum*, *Betula alleghaniensis*, *Betula papyrifera*, and *Acer pensylvanicum*) and red spruce. Soils are coarse, loamy, mixed, frigid Typic Haplorthods developed on till averaging 1 m in thickness. Bedrock is mainly quartzites and metapelites with local granitic intrusions.

West Bear Brook has received bimonthly additions of ammonium nitrate since November 1989 (~1,800 eq/ha/year—a 300% increase over ambient N deposition at the beginning of the study). East Bear Brook has received no additions and serves as a reference [see [Norton et al. \(1999\)](#)]. BBW has been a research site for three decades with a focus on increasing decadal-scale understanding about northern forested ecosystems' response to chemical and physical change, including whole ecosystem acidification, nitrogen enrichment, and climate change. BBW research has focused on: alterations to nitrogen dynamics, base cation decline, carbon cycling, phosphorus controls on nitrogen cycling, response to decreasing ambient sulfate deposition, sustained elevated experimental sulfate deposition, and changes in forest growth (<https://umaine.edu/bbwm/research/environmental-research/>).

---

#### **16.1.1.2 Class I Areas**

In an effort to preserve pristine atmospheric conditions, the Clean Air Act (42 USC 7470) authorized Class I areas to protect air quality in national parks over 6,000 acres in size and national wilderness areas over 5,000 acres.

Class I areas are subject to the “prevention of significant deterioration (PSD)” regulations under the Clean Air Act. (42 USC 7470). PSD preconstruction permits are required for new and modified existing air pollution sources, and air regulatory agencies are required to notify federal land managers (FLMs) of any PSD permit applications for facilities within 100 km of a Class I area.

ACAD is a PSD Class I Area. HBEF is not in a Class I area, but is near two New Hampshire Class I areas, the Great Gulf and the Presidential Range—Dry River Wilderness Areas. BBW is located southwest of the Moosehorn Wilderness Area in Maine.

---

### 16.1.1.3 Regional Land Use and Land Cover

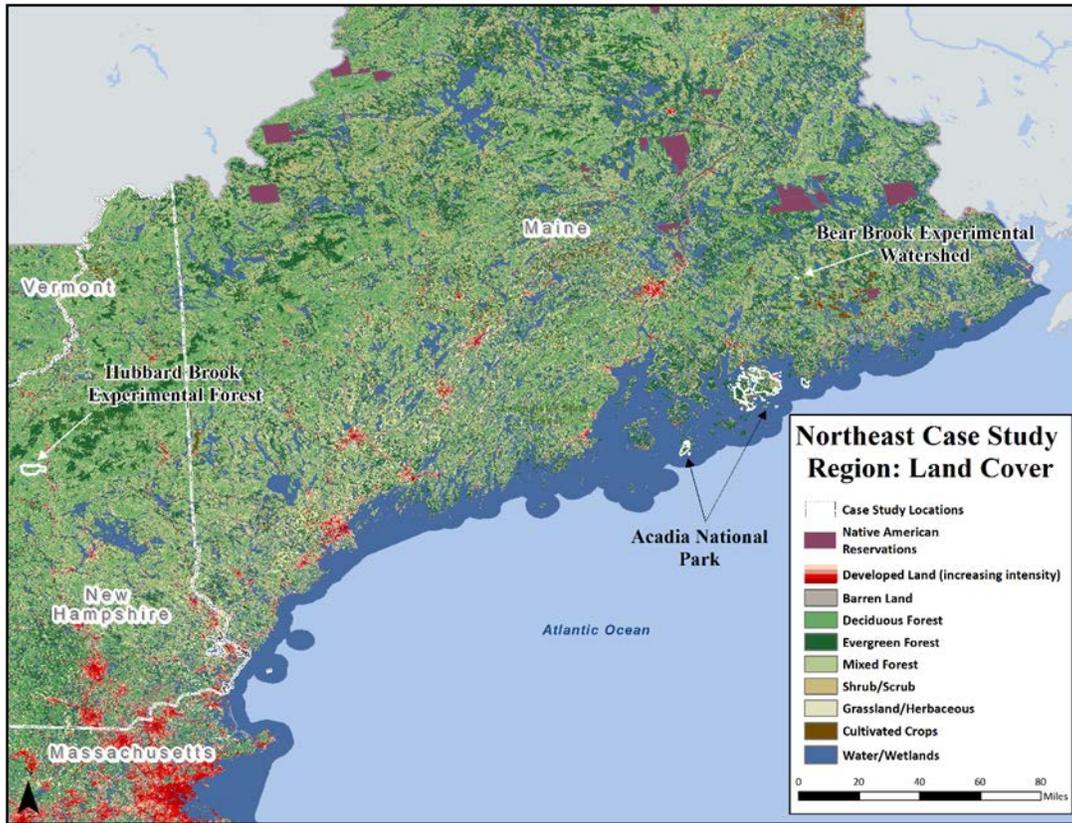

No large population centers are located near HBEF or BBW. Several small towns are interspersed with ACAD lands, including Bar Harbor (pop. 5,235), Southwest Harbor (pop. 1,765), and Trenton (pop. 1,481). The populations of these towns increase substantially with tourists during summer. Bangor (pop. 32,000) lies about 40 miles north from Mount Desert Island. All three study areas are mostly forested, as is much of the Northeast region ([Table 16-2](#), [Figure 16-4](#)).

---

**Table 16-2 Land use/land cover for northeastern case study areas.**

Land Cover	Area Covered (km <sup>2</sup> )		
	ACAD	HBEF	BBW
Developed and barren	83.82	2.96	0.00
Hardwood forest	76.84	159.53	6.64
Conifer forest	592.56	61.88	0.60
Mixed forest and shrubland	300.27	111.49	2.53
Meadow/herbaceous	26.33	0.50	0.00
Wetland	137.05	1.47	0.16

ACAD = Acadia National Park; BBW = Bear Brook Watershed; HBEF = Hubbard Brook Experimental Forest; km = kilometer.

**Figure 16-4** Land cover in the Northeast case study region.

#### 16.1.1.4 Organization of This Case Study

Because this case study addresses the condition of three discrete locations in the Northeast (ACAD, HBEF, and BBW), we developed [Table 16-3](#) to summarize the primary post-2000 research reported in the case study. In addition, we cite relevant research in other areas of the northeastern region. [Appendix 16.1.2](#) presents information about N and S deposition in the Northeast. Discussions of critical load or dose-response research ([Appendix 16.1.3](#)) are each organized around the three case study areas and the Northeast region. [Appendix 16.1.4](#) presents information available on long-term ecological monitoring, and [Appendix 16.1.5](#) contains information on the current status and forecasts for recovery in the case study areas. Key research literature since January 2008 is highlighted in [Table 16-4](#).

## 16.1.2 Deposition

Characteristics of nitrogen and sulfur deposition affecting the ACAD, HBEF, and BBW in the study area are shown in [Figure 16-5](#) and [Figure 16-6](#). [Figure 16-5A](#) and [Figure 16-6A](#) show 3-year average total deposition of N and S for 2011–2013; [Figure 16-5B](#) shows the partitioning between oxidized and reduced N; [Figure 16-6B](#) shows the 25-year-long time series for wet deposition for  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ ,  $\text{SO}_4^{2-}$ , and  $\text{H}^+$  obtained at the NADP/NTN (National Atmospheric Deposition Program/National Trends Network) monitoring site at HBEF (NH02). Surrounding areas in Maine and New Hampshire and inserts showing the coterminous U.S. (CONUS) are shown to place the depositional environment in context. See [Appendix 2.4](#), [Appendix 2.5](#), and [Appendix 2.6](#) for more information on deposition in the U.S. Other maps showing the contributions of individual species to dry and/or wet deposition are given in [Appendix 2.7](#).

Data shown in the map [Figure 16-5](#) and [Figure 16-6A](#) were obtained from the hybrid modeling/data fusion product, TDEP (Total Deposition, <http://nadp.slh.wisc.edu/committees/tdep/tdepmaps/> and described in [Appendix 2.7](#)). However, the time series of wet deposition is taken directly from data on the NADP/NTN ([Figure 16-6B](#)). This was done to track changes in deposition since the passage of the Clean Air Act Amendment (CAAA) because the Community Multiscale Air Quality (CMAQ) model simulations used in TDEP extend back only to 2000.

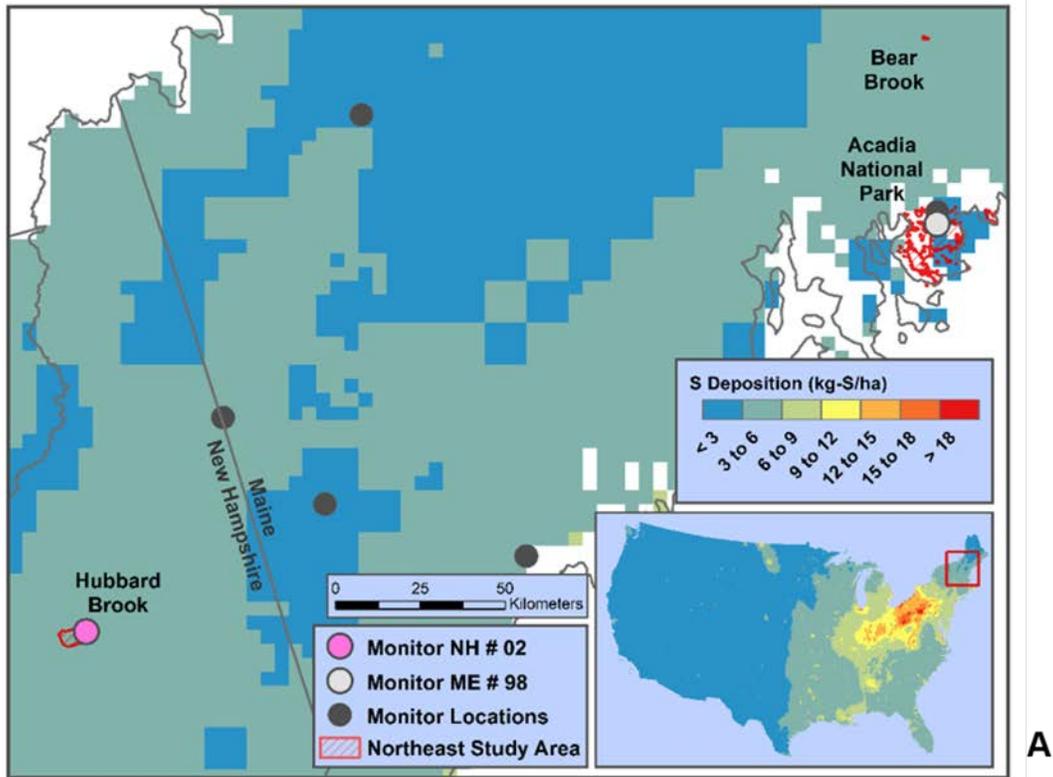

A

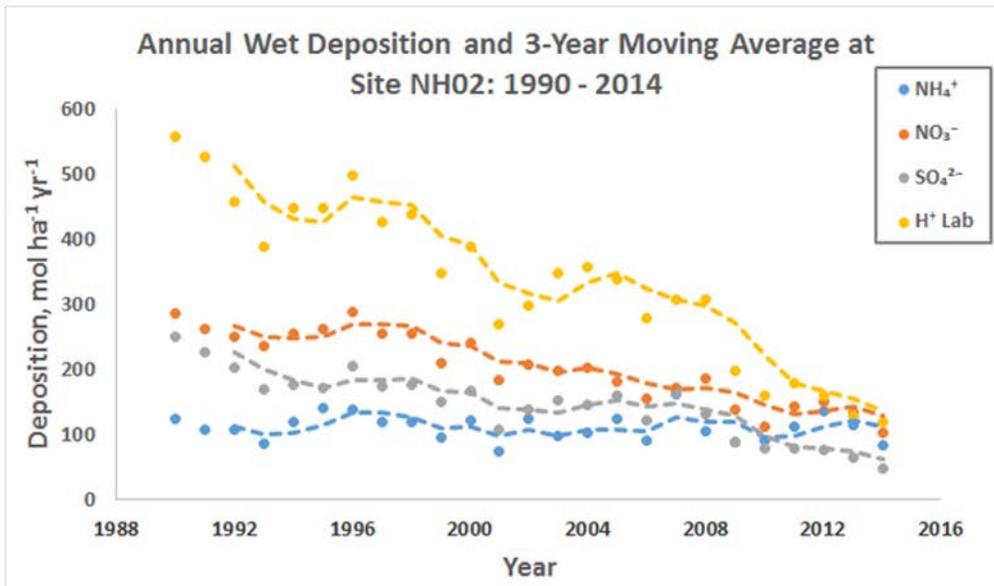

B

ha = hectare; kg = kilogram; N = nitrogen.

**Figure 16-5** Total nitrogen deposition (A) and percentage of oxidized nitrogen deposition (B) for the Northeast case study area estimated by the National Atmospheric Deposition Program Total Deposition Science committee.

A

B

H<sup>+</sup> = hydrogen ion; ha = hectare; kg = kilogram; mol = mole; NH<sub>4</sub><sup>+</sup> = ammonium; NO<sub>3</sub><sup>-</sup> = nitrate; S = sulfur; SO<sub>4</sub><sup>2-</sup> = sulfate; yr = year.

**Figure 16-6** Total sulfur deposition (A) for the Northeast case study area estimated by the National Atmospheric Deposition Program Total Deposition Science committee. Time series of wet deposition (B) from the National Atmospheric Deposition Program/National Trends Network in the Hubbard Brook Experimental Forest, NH.

Comparison of [Figure 16-5A](#) and [Figure 16-6A](#) indicates that the general pattern of deposition of N and S is broadly similar; deposition tends to be higher near the coast and decreases inland. Deposition at ACAD is an exception, with lower values along the coast than elsewhere. As seen in [Figure 16-5A](#), total deposition of N is relatively uniform within the three portions of the study area. In addition, the area surrounding the three sites shows a high degree of regional homogeneity but with higher values in New Hampshire. Deposition of N is not as high as in many areas of the central U.S. or the rest of the Northeast. Deposition of S is considerably lower than along the Ohio River Valley.

[Figure 16-5B](#) shows that the deposition of nitrogen is estimated to be mostly in oxidized form throughout the entire domain. Although most of the area is subject to N deposition in oxidized form with highest percentages surrounding ACAD and BBW, there are areas, principally in central Maine, where N is deposited mostly in reduced form. In [Figure 16-6B](#), wet deposition of all species shows that downward trends in  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ ,  $\text{SO}_4^{2-}$  and  $\text{H}^+$  are consistently found over the past 25 years, although the rate of decrease has been variable. In general, wet deposition typically exceeds dry deposition of N and S in this case study area.

---

## 16.1.3 Critical Loads and Other Dose-Response Relationships

---

### 16.1.3.1 Terrestrial

This section presents post-2000 ACAD, HBEF, and BBW findings on the dose-response relationships of N and S to terrestrial ecology, as well as the critical N and S loads for maintaining ecosystem health. Additional relevant information for the northeastern region is summarized. The section presents findings on both empirical research and modeling analyses.

#### 16.1.3.1.1 Empirical Studies

Post-2000 findings from empirical studies of terrestrial dose-response relationships and critical loads are summarized in this section. [Table 16-5](#) summarizes the body of empirical and modeling research identified.

**Table 16-5 Terrestrial empirical and modeling research on the response of nitrogen and sulfur deposition for the northeastern U.S.**

Tree growth	Red spruce	0	8.4 N (wet + dry)/+25 kg (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub>	1989–2002	BBW	<a href="#">Pardo et al. (2011c)</a>
Mortality		ND				
Foliar %N		+				
Foliar %Ca		–				
NO <sub>3</sub> <sup>-</sup> leaching		+				
Cation loss		+				
Soil C:N		–				
N mineralization		+				
Nitrification		+				
Soil respiration		ND				
Microbial biomass		ND				
Base cation	Sugar maple	Little evidence of BC depletion but confounded by ice storm litter mineralization	8.4 N (wet + dry) + 25 kg (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub>	Not specified	BBW	<a href="#">SanClements et al. (2010)</a>
Mineralization	Not specified	Storm caused increased litterfall, accelerated mineralization, and obstructed temporal trends in soil chemistry (17 yr)	8.4 (wet + dry)/+25 (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub>	1989–1998	BBW	<a href="#">Fernandez et al. (2003)</a>
Soil base saturation	Not specified	ForSAFE-VEG model. Expected future climate change was simulated to cause increase, especially at BBW.	Not specified	Not specified	BBW and HBEF	<a href="#">Phelan et al. (2016)</a>
Soil acid-base chemistry	Not specified	ForSAFE-VEG model. Simulated future climate had a lesser effect at HBEF than BBW, likely due to the overwhelming influences of high S and N deposition.	Not specified	Not specified	BBW and HBEF	<a href="#">Phelan et al. (2016)</a>

**Table 16-5 (Continued): Terrestrial empirical and modeling research on the response of nitrogen and sulfur deposition for the northeastern U.S.**

Variable	Species	Response	Deposition/ Addition (kg N/ha/yr)	Years	Site	Reference
Plant communities and N enrichment	Not specified	ForSAFE-VEG model. Climate futures predicted by the IPCC of increased temperature and precipitation will change plant communities and N enrichment, counteracting the acidifying impacts of S and N deposition on soil acid-base chemistry.	Not specified	Not specified	BBW and HBEF	<a href="#">Phelan et al. (2016)</a>
NO <sub>3</sub> <sup>-</sup> leaching	NA	PnET-BGC Model. Increase due to enhanced net mineralization and nitrification	Not specified	1999–2099	NE	<a href="#">Campbell et al. (2009)</a>
Mineral weathering	NA	PnET-BGC Model. Slight decrease due to reduced simulated soil moisture (negative effect) and increased temperature (positive effect)	Not specified	1999–2099	NE	<a href="#">Campbell et al. (2009)</a>
NO <sub>3</sub> <sup>-</sup> leaching, GHG sequestration, ecosystem C pools	Not specified	DayCent-Chem model. Simulated future high N deposition under climate scenarios had increased ecosystem GHG sequestration. High N increased stream NO <sub>3</sub> <sup>-</sup> fluxes and ecosystem C pools.	Simulated N deposition 3.9 to 9.6 kg/ha/yr for HBEF and 4 to 11.3 kg/ha/yr for ACADr	2001–2075	ACAD and HBEF	<a href="#">Hartman et al. (2014)</a>

BBW = Bear Brook Watershed; BC = base cation; C = carbon; Ca = calcium; ForSAFE-VEG = Soil Acidification in Forest Ecosystems; ha = hectare; GHG = greenhouse gas; HBEF = Hubbard Brook Experimental Forest; IPCC = Intergovernmental Panel on Climate Change; kg = kilogram; Mg = magnesium; N = nitrogen; NA = not applicable; ND = no data; NE = northeastern; (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> = ammonium sulfate; NO<sub>3</sub><sup>-</sup> = nitrate; PnET-BGC = Photosynthesis and Evapotranspiration-Biogeochemical; S = sulfur; WB = West Bear Brook; yr = year; Zn = zinc.

#### 16.1.3.1.1.1 Acadia National Park

[Ellis et al. \(2013\)](#) estimated the CL exceedance for nutrient-N deposition to protect the most sensitive ecosystem receptors in 45 national parks, based on CL ranges compiled by [Pardo et al. \(2011c\)](#). [Ellis et al. \(2013\)](#) estimated the N CL for ACAD in the range of 3–8 kg N/ha/yr to protect hardwood forests and a similar range to protect lichens.

[Cleavitt et al. \(2015\)](#) conducted surveys and used FIA assessments of lichen species in the Northeast, with particular focus on the four Class I wilderness areas in the region (Lye Brook, VT; Great Gulf, NH; Presidential Range—Dry River, NH; and Acadia National Park, ME). In general, cumulative N and S deposition over the course of the modeled period (2000–2013) was a more powerful explanatory factor than annual N or S load for the lichen data. This work determined a critical load of 4.3–5.7 kg total N (oxidized + reduced N)/ha/yr based on lichen species richness, the abundance of sensitive species (higher species richness of cyanolichens and fruticose lichens below CL), and thallus condition. Cumulative S and N deposition were both equally powerful predictors of thallus condition, but no S critical load was determined ([Cleavitt et al., 2015](#)).

[Pardo et al. \(2011c\)](#) estimated that ambient N deposition in parts of ACAD was higher than estimated empirical CL values. Thus, these data suggest the possibility of exceedance of nutrient-N CL in ACAD (see [Table 16-6](#)).

**Table 16-6 Empirical critical loads for nitrogen in Acadia National Park, by receptor, from [Pardo et al. \(2011c\)](#).**

NPS Unit	Ecoregion	N Deposition (kg/ha/yr)	Critical Load (kg/ha/yr)				
			Mycorrhizal Fungi	Lichen	Herbaceous Plant	Forest	Nitrate Leaching
Acadia NP	Eastern Temperate Forests	5.2	5 to 12	4 to 8	17.5	3 to 8	8

ha = hectare; kg = kilogram; N = nitrogen; NP = national park; NPS = National Park Service; yr = year.

Ambient N deposition reported by [Pardo et al. \(2011c\)](#) is compared to the lowest critical load for a receptor to identify potential exceedance. A critical load exceedance suggests that the receptor is at increased risk for harmful effects.

#### 16.1.3.1.1.2 Hubbard Brook Experimental Forest

[Gbondo-Tugbawa and Driscoll \(2002\)](#) used the PnET-BGC model to simulate the responses of soil and surface water chemistry at the reference watershed at HBEF to future emissions controls. Model performance was assessed using the normalized mean absolute error and the efficiency as objective statistical criteria. The focus was on comparing simulated chemistry with observed values between 1980 and 1998. Results showed good agreement for stream Ca and  $\text{SO}_4^{2-}$ . However, stream  $\text{NO}_3^-$  and Al concentrations and soil solution Ca:Al ratios were over-predicted after 1990. Simulation results suggested that emissions controls required by the CAAA will likely not result in

substantial changes in the future in “critical indicators such as soil base saturation, soil solution Ca:Al, or stream ANC and Al concentrations.”

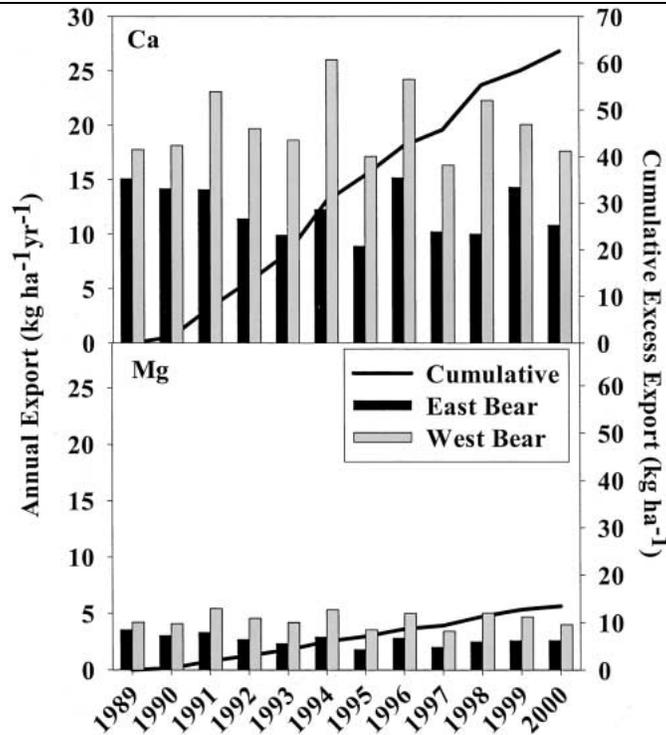

#### 16.1.3.1.1.3 Bear Brook Watershed

[Elvir et al. \(2006\)](#) investigated the effects of increased N deposition on photosynthesis and foliar nutrient content of sugar maple, American beech, and red spruce at the BBW. Trees in the treated WB watershed (an addition of 25 kg N/ha/yr as  $[\text{NH}_4]_2\text{SO}_4$ ) had higher foliar N concentrations than EB reference trees. American beech and red spruce displayed significantly lower foliar concentrations of Ca, Mg, and Zn. Sugar maple did not show decreases in these nutrients and was the only species to have significantly higher photosynthetic rates in the treated watershed as compared with the reference. This result suggested that nutrient imbalances in American beech and red spruce in the treatment watershed may have offset any potential photosynthetic benefits to these species from higher N availability ([Elvir et al., 2006](#)).

During the first 7 years of treatment at WB, sugar maple basal area increment (BAI) was higher in WB compared with EB. After 8 years of treatment, however, the initial higher sugar maple growth rate in WB decreased ([Elvir et al., 2010](#)).

In the WB catchments, the BAI of sugar maple was enhanced 13 to 104% by the addition of 25 kg N/ha/yr as  $(\text{NH}_4)_2\text{SO}_4$ . The BAI of red spruce was not significantly affected ([Elvir et al., 2003](#)).

[Fernandez et al. \(2003\)](#) reported results of quantitative soil excavations in 1998 that measured soil pools of exchangeable base cations after 9 years of treatment at WB. The treated watershed had lower concentrations of exchangeable Ca and Mg in all soil horizons, with greater nutrient cation depletion in the O-horizon as compared with the mineral soil. Depletion was also greater in conifer, as opposed to hardwood, stands. The importance of treatment-caused base cation depletion was reinforced by MAGIC model simulations. Estimates of watershed-wide exchangeable Ca and Mg (66 and 27 kg/ha) were roughly comparable to the total cumulative excess stream Ca and Mg export in WB after 9 years of treatment (55 and 11 kg/ha, respectively; [Figure 16-7](#)).

Ca = calcium; ha = hectare; kg = kilogram; Mg = magnesium; yr = year.  
 Source: [Fernandez et al. \(2003\)](#).

**Figure 16-7 Annual stream calcium and magnesium export (paired bars), and cumulative excess export in West Bear Brook compared with East Bear Brook (line), over the study period 1989–2000 at the Bear Brook Watershed experiment.**

**16.1.3.1.1.4 Other Northeastern Regions**

[Pardo et al. \(2011c\)](#) compiled data on empirical CLs for protecting sensitive resources in Level I ecoregions across the CONUS against nutrient enrichment effects caused by atmospheric N deposition. Available data on empirical CL of nutrient-N in the Northeast suggested that the lower end of estimates of the CL for resource protection was 3 kg N/ha/yr. Values at or above this level of deposition loading are considered to have increased risk of harmful effects for mycorrhizal fungi, lichens, and forest vegetation ([Table 16-7](#)). Keeping levels below this value also helps prevent NO<sub>3</sub><sup>-</sup> leaching into drainage water.

**Table 16-7 Critical loads of nutrient nitrogen for the Northern Forests ecoregion.**

Ecosystem Component	Critical load or N deposition (kg/ha/yr)	Reliability	Response	Comment	Reference
Tree	>3	#	Decreased growth of red pine, and decrease survivorship of yellow birch, scarlet and chestnut oak, quaking aspen, and basswood	None	<a href="#">Thomas et al. (2010)</a>
Lichens	4 to 6	(#)	Community composition shift	Application of model developed for marine West Coast forest to northern forests	<a href="#">Geiser et al. (2010)</a>
Ectomycorrhizal fungi	5 to 7	#	Change in fungal community structure	None	<a href="#">Lilleskov et al. (2008)</a>
Herbaceous species cover	>7 and <21	#	Loss of prominent species	Response observed in low-level fertilization experiment	<a href="#">Hurd et al. (1998)</a>
Northern hardwood and coniferous forest	8	##	Increased surface water NO <sub>3</sub> <sup>-</sup> leaching	None	<a href="#">Aber et al. (2003)</a>
Tree growth and mortality	>10 and <26	#	Decreased growth and/or induced mortality	Response observed in low-level fertilization experiment in old-growth montane red spruce	<a href="#">McNulty et al. (2005)</a>
Arbuscular mycorrhizal fungi	<12	(#)	Biomass decline and community composition change	Observed along a Michigan N gradient	<a href="#">Pardo et al. (2011c)</a>

ha = hectare; kg = kilogram; N = nitrogen; NO<sub>3</sub><sup>-</sup> = nitrate; yr = year.

Reliability rate: ## reliable—a number of published papers show comparable results; # fairly reliable—the results of some studies are comparable; (#) expert judgment—few empirical data are available, Critical Load based on expert judgment of those ecosystems.

Source: [Pardo et al. \(2011c\)](#).

[Thomas et al. \(2010\)](#) analyzed Forest Inventory Analysis (FIA) data in the Northeast to determine tree growth in response to a gradient of atmospheric N deposition from about 3 to 11 kg N/ha/yr. Some tree species showed increased growth across the N input gradient (yellow poplar [*Liriodendron tulipifera*], black cherry [*Prunus serotina*], and white ash [*Fraxinus americana*]). Some showed highest growth at intermediate levels of N deposition (quaking aspen [*Populus tremuloides*] and scarlet oak [*Quercus coccinea*]). Red pine (*Pinus resinosa*) exhibited growth decline across the gradient of increasing N

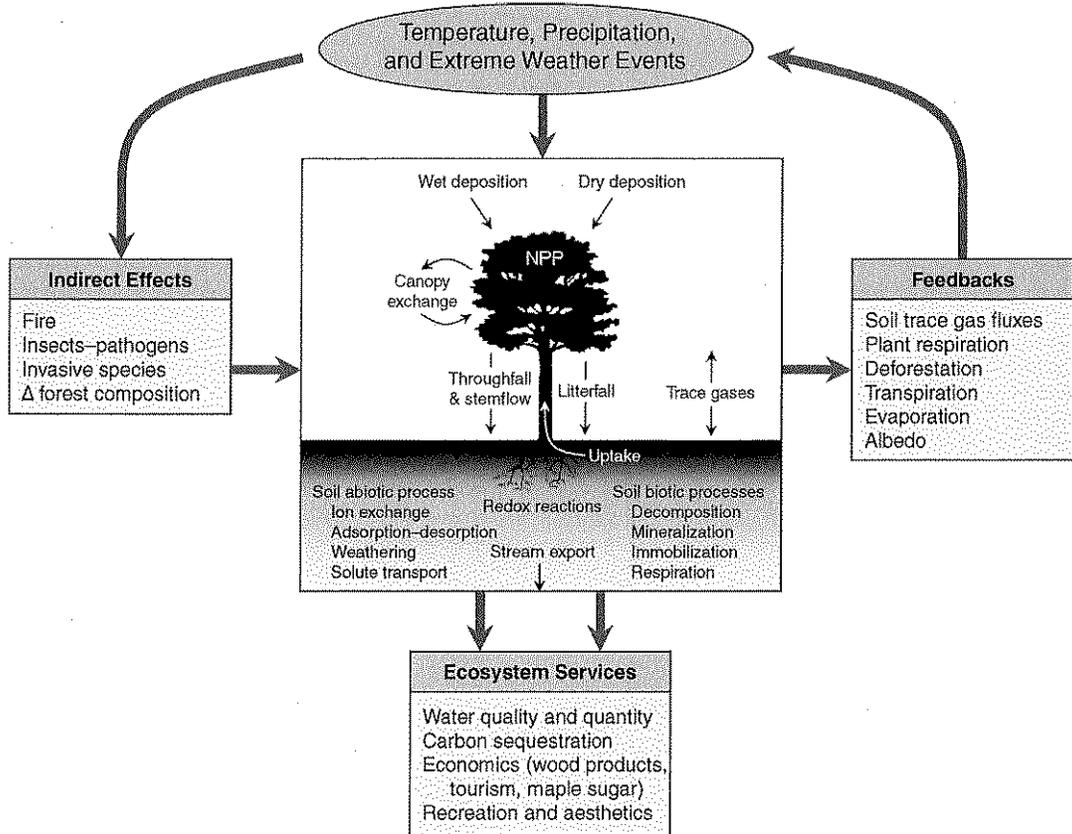

deposition ([Thomas et al., 2010](#)). Thus, it appeared that N deposition at ambient levels can have both positive and negative effects on tree growth, depending on species and deposition level.

In a high-elevation red spruce-balsam fir (*Abies balsamea*) forest in the Northeast, N fertilization over 14 years led to a decrease in live basal area (LBA) with increasing N additions. In control plots, LBA increased by 9% over the course of the study, while LBA decreased by 18 and 40% in plots treated with 15.7 kg N/ha/yr and 31.4 kg N/ha/yr, respectively ([McNulty et al., 2005](#)).

There is little information available regarding the effects of N deposition on herbaceous plants within northern hardwood forests in the Northeast. However, [Hurd et al. \(1998\)](#) reported the results of experimental studies that added N at two and four times the ambient N deposition level at several sites in the Adirondack Mountains. Herbaceous plant coverage decreased after 3 years of fertilization, largely in response to shading caused by enhanced growth of ferns. Additionally, information has been recently published by [Simkin et al. \(2016\)](#) and is discussed in [Appendix 6.2](#) of this ISA.

#### **16.1.3.1.2 Modeling Studies**

Evidence from research in northeastern forests indicates that direct and indirect effects of climate change will cause changes in N and other biogeochemical cycling by altering plant physiology, forest productivity, and soil processes. [Campbell et al. \(2009\)](#) reviewed these relationships ([Figure 16-8](#)) and applied the PnET-BGC model in a northern hardwood forest ecosystem at HBEF to test assumptions about interactions regarding climate change. Model results suggested an increase in primary productivity due to a longer growing season in the future, an increase in  $\text{NO}_3^-$  leaching due to enhanced net mineralization and nitrification, and a slight decrease in mineral weathering due to reduced simulated soil moisture (negative effect) and increased temperature (positive effect).

NPP = net primary production.  
 Source: [Campbell et al. \(2009\)](#).

**Figure 16-8** Conceptual diagram showing the direct and indirect effects of changes in temperature and precipitation on biogeochemical processes in forests and on the services forests provide. Also shown are feedbacks that further influence climatological effects.

### 16.1.3.2 Aquatic

This section presents post-2000 research findings at ACAD, HBEF, and BBW on the dose-response relationships of N and S to aquatic ecology, as well as the critical N and S loads for maintaining ecosystem health. Additional relevant information for the Northeast region is summarized. Both empirical and modeling studies of aquatic dose-response relationships and critical loads are included in this section.

### 16.1.3.2.1 Empirical Studies

Post-2000 findings from empirical studies of aquatic dose-response relationships and critical loads are summarized in this section. [Table 16-8](#) compiles the body of empirical research identified.

**Table 16-8 Aquatic empirical research on the response of nitrogen and sulfur deposition for the northeastern U.S.**

Variable	Response	Deposition	Addition	Years	Site	Reference
Fish community including brook trout ( <i>Salvelinus fontinalis</i> )	Shift in the upper mainstem of HBEF from the presence of at least three fish species to only brook trout ( <i>Salvelinus fontinalis</i> )	Not specified	0	1960s–2007	HBEF	<a href="#">Warren et al. (2008)</a>
SO <sub>4</sub> <sup>2-</sup>	W6 had a 32% decline in the annual volume-weighted concentration (–1.1 µeq/L/yr)	Not specified	0	1963–1994	HBEF	<a href="#">Driscoll et al. (2001b)</a> <a href="#">Likens et al. (2001)</a>
SO <sub>4</sub> <sup>2-</sup> + NO <sub>3</sub> <sup>-</sup>	W6 had declines in stream concentrations of strong acids (–1.9 µeq/L/yr)	Not specified	0	1963–1994	HBEF	<a href="#">Driscoll et al. (2001b)</a>
Sum of base cations	–1.6 µeq/L/yr	Not specified	0	1963–1994	HBEF	<a href="#">Driscoll et al. (2001b)</a>
pH	Small but significant increases in stream pH, from 4.8 to 5.0	Not specified	0	1963–1994	HBEF	<a href="#">Driscoll et al. (2001b)</a>
SO <sub>4</sub> <sup>2-</sup>	Biogeochemical control of SO <sub>4</sub> <sup>2-</sup> export from forested watersheds has shifted from atmospheric S deposition to climatic factors that regulate soil moisture.	Not specified	0	1965–2008	HBEF	<a href="#">Mitchell and Likens (2011)</a>
pH and ANC	Decrease	Not specified	1,800 eq/ha/yr (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub>	7 yr acidification treatment	BBW	<a href="#">Norton et al. (2004)</a>

#### 16.1.3.2.1.1 Acadia National Park

No empirical aquatic critical loads or dose-response studies have been identified in the literature for the ACAD case study area since 2000.

#### 16.1.3.2.1.2 Hubbard Brook Experimental Forest

The cycling of N, S, and other elements in the Northeast is closely linked with aspects of climate. Many recent studies have explored some of those linkages, and many of the empirical studies of aquatic dose-response relationships have included aspects of climate change. The potential for a shift from atmospheric deposition to climatic regulation of watershed S biogeochemistry at HBEF was examined by [Mitchell and Likens \(2011\)](#). More than four decades of continuous long-term data collected from four watersheds were used to evaluate S budgets. “Analyses focused on the role of changing water availability in affecting the amount of S mobilized from internal watershed sources and the resultant changes in the S budget discrepancies over time...The biogeochemical

controls on annual  $\text{SO}_4^{2-}$  export in stream water [appear to have] shifted from atmospheric S deposition to climatic factors that affect soil moisture.”

With declining inputs of atmospheric S, the higher outputs of  $\text{SO}_4^{2-}$  in drainage waters relative to precipitation inputs appear to be driven by the S stored in the soil. These biogeochemical responses at the HBEF might be amplified with further climate change, resulting in greater annual stream discharge and watershed wetness. Such climatic change will potentially increase  $\text{SO}_4^{2-}$  mobilization and hence may slow the recovery of both aquatic and terrestrial ecosystems from acidification.

#### **16.1.3.2.1.3 Bear Brook Watershed**

[Chadwick and Huryn \(2005\)](#) assessed the effects of N additions on secondary stream macroinvertebrate production in BBW. Production did not vary between streams (reference and treatment) but was 35% higher for both streams in the second year of the study. Results suggested that patterns of litter input and channel drying, rather than N input, controlled secondary production in these intermittent streams by altering resource availability and invertebrate community structure. It appeared that these variables overrode the effects of N supply, perhaps because N is not limiting.

Ongoing climate change will likely affect a wide range of biogeochemical processes in northeastern forested ecosystems. Of particular interest are the effects on flow volumes and peak flows. [Kim et al. \(2010\)](#) analyzed a nearly two-decades-long stream flow record at EB and a longer record for the Narraguagus River (a proximate watershed to the BBW). The focus was on improving understanding of high-flow events that have a disproportionate impact on biogeochemical processes and fluxes. A moving window analysis to evaluate the changing flood potential over time suggested upward trends in the occurrence of high-flow events during recent decades.

#### **16.1.3.2.1.4 Other Northeastern Regions**

Considering trends across the Northeast, [Aber et al. \(2003\)](#) found that surface water  $\text{NO}_3^-$  concentrations exceeded  $1 \mu\text{eq/L}$  mainly in northeastern watersheds receiving more than about 9 to 13 kg N/ha/yr deposition. Above this range, mean  $\text{NO}_3^-$  export increased linearly with increasing deposition at a rate of about 0.85 kg  $\text{NO}_3^-$ -N/ha/yr for every 1 kg N/ha/yr increase in deposition, although at higher rates of deposition there was considerable variability in N retention among watersheds ([Aber et al., 2003](#)).

N limitation across the Northeast was evaluated by [Baron et al. \(2011a\)](#) who estimated that 34% of 4,361 New England lakes represented in the Eastern Lakes Survey were

likely to be N limited, based on having dissolved inorganic N (DIN):total P (TP) ratio (by weight) less than 4. Although eutrophication is a concern, there is no published evidence that eutrophication is occurring to any appreciable extent in the lakes in ACAD.

Dissolved organic matter (DOM) is important to a range of processes critical to aquatic ecosystem functioning, including providing a microbial food source, attenuating light, buffering pH, binding metals, and controlling the cycling of C, N, Hg, and P. Shifts in the quality of DOM may affect aquatic ecosystem functioning. A chemical signature of terrestrial DOM was used by [SanClements et al. \(2012\)](#) to support the hypothesis that increased dissolved organic carbon (DOC) concentrations in surface water in the Northeast since about 1993 have been driven mainly by decreasing acidic deposition and increasing solubility of soil organic matter. Fluorescence spectroscopy was used to characterize the quality of DOM of archived samples from nine acid-sensitive lakes in Maine. Decadal decreases in  $\text{SO}_4^{2-}$  in lake water were correlated with increased DOC concentrations and a shift from microbial to terrestrially derived DOM during ecosystem recovery from prior acidification.

Aquatic biota in the Northeast have been affected by acidification at virtually all levels of the food web. Some species and some lifestages are especially sensitive. Decreases in ANC and pH and increases in inorganic Al concentration contributed to declines in species richness and abundance of zooplankton, macroinvertebrates, and fish as documented in the Adirondacks ([Sutherland et al., 2015](#); [Nierzwicki-Bauer et al., 2010](#); [Keller and Gunn, 1995](#); [Schindler et al., 1985](#)). Although some species are favored by increased acidity, the overall species richness typically decreases as surface water acidity increases.

#### **16.1.3.2.2 Modeling Studies**

Post-2000 findings from modeling studies of aquatic dose-response relationships and critical loads are summarized in this section. [Table 16-9](#) compiles the body of research identified.

**Table 16-9 Critical and target load and exceedance modeling studies in the northeastern U.S.**

Reference	Location	Model	Focus
<a href="#">Dupont et al. (2005)</a>	NE region	SSWC	CLs for acidity to protect aquatic biota to pH 6.0
<a href="#">SanClements et al. (2010)</a>	BBW	PnET-BGC	Interactions between climate change parameters and atmospheric deposition
<a href="#">Phelan et al. (2016)</a>	BBW and HBEF	ForSAFE-VEG	Atmospheric deposition to northern hardwood forests
<a href="#">Tominaga et al. (2010)</a>	HBEF	MAGIC, PnET-BGC, SAFE, VSD	Model output comparison
<a href="#">Pourmokhtarian et al. (2012)</a>	HBEF	PnET-BGC	N cycling and climate change

BBW = Bear Brook Watershed; CL = critical load; ForSAFE-VEG = Soil Acidification in Forest Ecosystems; HBEF = Hubbard Brook Experimental Forest; MAGIC = Model of Acidification and Groundwater in Catchments; N = nitrogen; NE = northeastern; PnET-BGC = Photosynthesis and Evapotranspiration-Biogeochemical; SAFE = Soil Acidification in Forest Ecosystems; SSWC = Steady-State Water Chemistry; VSD = Very Simple Dynamic.

#### 16.1.3.2.2.1 Acadia National Park

No modeling studies on aquatic critical loads for ACAD have been identified in the literature.

#### 16.1.3.2.2.2 Hubbard Brook Experimental Forest

[Tominaga et al. \(2010\)](#) evaluated the performance and prediction uncertainty of four dynamic process-based watershed acidification models: MAGIC, PnET-BGC, SAFE, and VSD. Model output was assessed by systematically applying each of the models to data from the HBEF. The models were used to assess future soil and stream chemistry response to reduced levels of atmospheric S deposition. Both hindcast and forecast predictions were qualitatively similar across the four models. Nevertheless, the temporal patterns of projected stream ANC and soil base saturation differed. [Tominaga et al. \(2010\)](#) concluded that these differences can be accommodated by employing multiple models. Nevertheless, these results have implications for individual model applications.

[Pourmokhtarian et al. \(2012\)](#) used “the PnET-BGC model to evaluate the effects of potential future changes in temperature, precipitation, solar radiation, and atmospheric

CO<sub>2</sub> on the pools, concentrations, and fluxes of major elements at the HBEF.” The climate projections were based on downscaled climate output from atmospheric-ocean general circulation models. These climate projections indicated that the average air temperature will likely increase at the HBEF site by 1.7 to 6.5°C over the 21st century, with simultaneous increase in annual average precipitation ranging from 4 to 32 cm above the long-term mean. The PnET-BGC model simulations under expected future climate showed shifts in hydrology from later snowpack development, earlier snowmelt, increased evapotranspiration, and a slight increase in the annual water yield. The model results suggested that net soil N mineralization and nitrification will markedly increase under elevated temperature. This increase resulted in simulated acidification of soil and stream water, altering the quality of water draining from the forested watershed.

#### **16.1.3.2.2.3 Bear Brook Watershed**

No aquatic critical loads modeling studies have been identified for BBW in the literature since 2000.

#### **16.1.3.2.2.4 Other Northeastern Regions**

Studies in the Northeastern region have used a variety of steady-state and dynamic modeling approaches. The Conference of the New England Governors and Eastern Canadian Premiers (NEG/ECP) sponsored a modeling assessment of steady-state CLs for protection of forest soils and lakes against acidification in the Northeast region and in eastern Canada ([Ouimet et al., 2006](#); [Dupont et al., 2005](#); [Ouimet et al., 2001](#)). [Dupont et al. \(2005\)](#) reported the SSWC steady-state aquatic CLs of acidity and associated exceedances for lakes. Atmospheric acid loads were assessed based on atmospheric deposition of both S and N, using a critical limit of pH 6 to protect aquatic biota. This pH level approximately corresponds with ANC = 40 µeq/L in this region ([Small and Sutton, 1986](#)). Estimated S critical loads were exceeded in 2002 for 12.3% of all studied lakes. Lakes having lowest calculated CLs included many in southern Vermont, eastern and northern Maine, northern New Hampshire, and Cape Cod. Exceedances of CLs, based on estimated acidic deposition in 2002, were highest in central and coastal Massachusetts, southern Vermont, much of Maine, and portions of New Hampshire. Eastern Maine and southern Vermont were notable “hot spots” where ambient S + N deposition exceeded CLs by more than 10 meq/m<sup>2</sup>/year ([Dupont et al., 2005](#)).

### 16.1.3.3 Integration

[Table 16-10](#) contains a list of northeastern U.S. critical load determinations by multiple researchers, ranging from 3–8 kg N/ha/yr (forests) to 17.5 kg N/ha/yr (herbaceous plants).

**Table 16-10 Empirical and modeled nitrogen critical loads applicable to the northeastern U.S.**

Critical Load (kg N/ha/yr)	Ecosystem Component	Response	N Deposition (kg/ha/yr)	Site	Reference
5 to 12	Eastern temperate forest	Mycorrhizal Fungi	5.2	ACAD	<a href="#">Pardo et al. (2011c)</a>
4 to 8	Lichens	Epiphytic lichen community change	5.2	ACAD	<a href="#">Pardo et al. (2011c)</a>
17.5	Herbaceous Species	Increases in nitrophilic species, declines in species-richness	5.2	ACAD	<a href="#">Pardo et al. (2011c)</a>
3 to 8	Hardwood forest	Not specified	5.2	ACAD	<a href="#">Pardo et al. (2011c)</a> <a href="#">Ellis et al. (2013)</a>

### 16.1.4 Long-Term Ecological Monitoring

This section summarizes research on the long-term effects of S and N deposition in the case study areas. The focus is primarily on research published since about the year 2000. The acidification and nutrient enrichment subsections are each organized by three case study areas followed by relevant information for the overall Northeast region. Key publications are summarized in [Table 16-11](#).

**Table 16-11 Summary table of observed terrestrial and aquatic acidification long-term trends in Hubbard Brook Experimental Forest and Bear Brook Watershed.**

Variable	Species	Response	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Site	Reference

Acadia National Park is not a federally funded long-term monitoring study area.

#### 16.1.4.1 Long-Term Monitoring of Acidification

Acidic deposition has been shown to be an important factor causing decreases throughout much of the Northeast region in concentrations of exchangeable base cations in soils, which were naturally low historically. Base saturation values less than 12% predominate in the B-horizon in portions of the region where soil and surface water acidification from acidic deposition have been most pronounced ([Sullivan et al., 2006a](#); [Bailey et al., 2004](#); [David and Lawrence, 1996](#)).

[Mitchell et al. \(2011\)](#) evaluated S mass balances for 15 watersheds in the northeastern U.S. and southeastern Canada, including watersheds at HBEF, BBW, and Cone Pond in New Hampshire, for the period 1985 to 2002. Most study watersheds showed evidence of internal watershed sources of  $\text{SO}_4^{2-}$ , likely from mineralization of organic S stored from decades of high S deposition. Mobilization of the mineralized S contributed an estimated 1–6 kg S/ha/yr to the stream fluxes of  $\text{SO}_4^{2-}$ . This mobilization has affected the observed rates of recovery from acidification as S deposition has declined.

Surface water chemistry in the northeastern U.S. has been characterized, surveyed, resurveyed, and monitored in many studies conducted over the last several decades ([Table 16-12](#)).

**Table 16-12 Example surface water acidification chemistry studies in the Northeast case study region.**

Focus	Results	Deposition	Addition	Time Period	Site	Reference
N export	An unburned study watershed exported 10 to 20 times more inorganic N than the burned watershed; in addition, retention of inorganic N was 96% in the burned watershed vs. 72% in the unburned watershed.	Not specified	Not applicable	Pre- vs. post-1947 fire	ACAD	<a href="#">Nelson et al. (2007)</a>
N export	Total N + P exported by watersheds entirely within ACAD were significantly lower than exports in watersheds that were partly or completely outside the park.	Not specified	Not applicable	Not specified	ACAD	<a href="#">Nelson et al. (2007)</a>
Reference stream chemistry	Decline in stream $\text{SO}_4^{2-}$ ( $-1.1 \mu\text{eq/L/yr}$ ) Decline in $\text{SO}_4^{2-} + \text{NO}_3^-$ in stream ( $-1.9 \mu\text{eq/L/yr}$ )	Not specified	Not specified	1963–1994	HBEF	<a href="#">Driscoll et al. (2001b)</a>
S budget	Biogeochemical control of $\text{SO}_4^{2-}$ export has switched from atmospheric deposition to climate factors that regulate soil moisture.	Not specified	Not specified	1965–2008	HBEF	<a href="#">Mitchell and Likens (2011)</a>

**Table 16-12 (Continued): Example surface water acidification chemistry studies in the northeast case study region.**

Focus	Results	Deposition	Addition	Time Period	Site	Reference
Stream trends for reference and treatment catchments	Stream dissolved $\text{SO}_4^{2-}$ , pH, and ANC decrease Base cation and $\text{Al}^+$ increase	Not specified	1,800 eq/ha/yr $(\text{NH}_4)_2\text{SO}_4$	1987–2000	BBW	<a href="#">Norton et al. (2004)</a>
Low-flow and high-flow stream chemistry of reference and treatment catchments	Base cation, $\text{NH}_4^+$ and $\text{Cl}^-$ unchanged	Not specified	1,800 eq/ha/yr $(\text{NH}_4)_2\text{SO}_4$	1987–2006	BBW	<a href="#">Navrátil et al. (2010)</a>
Chronic stream chemistry for reference and treatment catchments	Increased BC export; declined after 7 yr of treatment. Decrease pH and alkalinity Increased dissolved $\text{Al}^+$ , $\text{NO}_3^-$ , $\text{SO}_4^{2-}$	Not specified	1,800 eq/ha/yr $(\text{NH}_4)_2\text{SO}_4$	1987–2007	BBW	<a href="#">Norton et al. (2010)</a>
Episodic stream chemistry for reference and treatment catchments	“18 yr of N and S addition have not affected the natural drivers of episodic acidification. The contribution of $\text{SO}_4^{2-}$ to the ANC decline in WB has been increasing linearly since the beginning of watershed treatment while the role of $\text{NO}_3^-$ has remained relatively constant after an initial increase.”	Not specified	1,800 eq/ha/yr $(\text{NH}_4)_2\text{SO}_4$	1988–2006	BBW	<a href="#">Laudon and Norton (2010)</a>
Lake resurvey	Ubiquitous decreases in the concentration of inorganic Al across the region. Organic monomeric Al also declined region-wide in New England. In 2001, only seven study lakes (representing 130 lakes in the Northeast region) that had Al <sub>i</sub> above the toxic threshold of 2 $\mu\text{M}$ , compared with 20 sampled lakes (representing 449 lakes in the population) in 1986.	Not specified	Not specified	1986 and 1998	NE region	<a href="#">Warby et al. (2009)</a>

**Table 16-12 (Continued): Example surface water acidification chemistry studies in the northeast case study region.**

Focus	Results	Deposition	Addition	Time Period	Site	Reference
Chronic and episodic lake and stream chemistry	Rates of change for individual water bodies ranged from about -1.5 to -3 µeq/L/yr.	Not specified	Not specified	1990–2000	NE and Appalachian Mtns.	<a href="#">U.S. EPA (2003)</a>
Regional lake trends	NO <sub>3</sub> <sup>-</sup> concentrations in New England and the Adirondack Mountains, which had no trend prior to 2000, declined at a rate of -0.05 µeq/L/yr	Not specified	Not specified	2000–2010	New England and Adirondacks	<a href="#">Strock et al. (2014)</a>
Response to deposition reduction	Oa-horizon BS decreased from 56.2 to 33.0% and almost equivalent changes in carbon-normalized exchangeable Ca and exchangeable Al	Not specified	Not specified	1984 to 2001	NE region	<a href="#">Warby et al. (2009)</a>
	Suggested a nascent recovery of soil acid-base chemistry at some locations in the Northeast where six red spruce stands sampled. Exchangeable Al in the Oa-horizons decreased ( $p < 0.05$ ) by 20 to 40% at all New England sites. Evidence of base cation depletion and decreased Ca:Al ratio	Not specified	Not specified	1992–1993 vs. 2003–2004	General	<a href="#">Lawrence et al. (2012)</a>

ACAD = Acadia National Park; Al = aluminum; ANC = acid neutralizing capacity; BBW = Bear Brook Watershed; BC = base cation; BS = base saturation; Ca = calcium; Cl<sup>-</sup> = chloride; ha = hectare; HBEF = Hubbard Brook Experimental Forest; kg = kilogram; L = liter; µeq = microequivalents; µM = micromole; N = nitrogen; NE = northeastern; NH<sub>4</sub><sup>+</sup> = ammonium; (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> = ammonium sulfate; NO<sub>3</sub><sup>-</sup> = nitrate; Oa = well decomposed humus; P = phosphorus; S = sulfur; SO<sub>4</sub><sup>2-</sup> = sulfate; WB = West Bear Brook; yr = year.

These studies have focused on both chronic and episodic responses of reference and (in the case of BBW and HBEF) experimentally treated catchments.

The U.S. EPA's Long-Term Monitoring (LTM) Program has been collecting monitoring data since the early 1980s for many lakes and streams in acid-sensitive areas of the U.S., including within the Northeast region. These data allow evaluation of trends and variability in key components of lake and stream water chemistry prior to, during, and subsequent to 1990 CAAA Title IV implementation. Throughout the Northeast region, the concentration of SO<sub>4</sub><sup>2-</sup> in surface waters has decreased substantially, often by one-third to one-half, subsequent to the 1990 CAAA. These declines in lake and stream

SO<sub>4</sub><sup>2-</sup> concentrations were considered consistent with observed declines in S wet deposition and have been corroborated by other studies showing that SO<sub>4</sub><sup>2-</sup> concentrations in northeastern lakes have decreased steadily since about the late 1970s [e.g., [Driscoll et al. \(1995\)](#); [U.S. EPA \(2003\)](#)]. Regional surface water ANC did not change significantly in New England during the 1990s ([U.S. EPA, 2003](#)).

The impact of the 1990 CAAA relevant to aluminum releases to surface waters was assessed by [Warby et al. \(2008\)](#), who surveyed 113 lakes in the Northeast that had been sampled in 1986 and again in 2001. They “found ubiquitous decreases in the concentration of inorganic Al across the region.” In 2001, there were only 7 study lakes (representing 130 lakes in the Northeast region) that had inorganic Al above the toxic threshold of 2 µM, compared with 20 sampled lakes (representing 449 lakes in the population) in 1986.

[Strock et al. \(2014\)](#) analyzed recent trends in wet deposition and lake chemistry using long-term monitoring data for lakes in New England and the Adirondack Mountains. From 2000 to 2010, lake NO<sub>3</sub><sup>-</sup> concentrations decreased at a rate of -0.05 µeq/L/year (no trend before 2000). There was a shift to nontoxic organic Al. Both ANC and pH exhibited variable trends.

---

#### 16.1.4.2 Long-Term Monitoring of Nitrogen Enrichment

[Table 16-13](#) summarizes the effects of N deposition on watershed nutrient in the three case studies areas and relevant Northeastern regional studies.

---

**Table 16-13 Summary of observed terrestrial and aquatic nutrient enrichment long-term responses in Acadia National Park, Hubbard Brook Experimental Forest, Bear Brook Watershed, and other northeastern regions.**

Variable	Species	Response	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Site	Reference
N export	Not specified	An unburned study watershed exported 10 to 20 times more inorganic N than the burned watershed.	Wet deposition only (value not specified)	Not specified	ACAD (pre- vs. post-1947 fire)	<a href="#">Nelson et al. (2007)</a>

---

**Table 16-13 (Continued): Summary of observed terrestrial and aquatic nutrient enrichment long-term responses in Acadia National Park, Hubbard Brook Experimental Forest, Bear Brook Watershed, and other northeastern regions.**

Variable	Species	Response	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Site	Reference
N mass balance	Sugar maple, American Beech, yellow birch	Stream water export decrease from 4 to 1 kg N/ha/yr Shift to a net N sink storing ~8 kg N/ha/yr; unclear whether N is accumulating or being lost through denitrification.	~7 kg N/ha/yr	0	HBEF	<a href="#">Yanai et al. (2013)</a>
DIN loss	Sugar maple, American Beech, yellow birch	In W6, "losses were elevated in 1960s by a combination of recovery from extreme drought and a significant defoliation event. N deposition alone, in the absence of other disturbances, would have increased DIN losses by 0.35 g N/m <sup>2</sup> /yr."	"0.13 g/m <sup>2</sup> /yr is 20% of wet + dry deposition"	0	HBEF	<a href="#">Aber et al. (2002)</a>
Biogeochemical process	Sugar maple, American Beech, yellow birch	Modeled soil freeze-thaw to year 2100. "Shortened frost covered period has biogeochemical process implications."	Not specified	0	HBEF	<a href="#">Campbell et al. (2010)</a>

**Table 16-13 (Continued): Summary of observed terrestrial and aquatic nutrient enrichment long-term responses in Acadia National Park, Hubbard Brook Experimental Forest, Bear Brook Watershed, and other northeastern regions.**

Variable	Species	Response	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Site	Reference
Biogeochemical process	Sugar maple, American Beech, yellow birch	"A relatively mild freezing event induced significant increases in N mineralization and nitrification rates, solute leaching, and soil N <sub>2</sub> O production and caused significant decreases in soil methane uptake. Soil freezing events may be major regulators of soil biogeochemical processes and solute delivery to streams in forested watersheds."	Not specified	0	HBEF	<a href="#">Groffman et al. (2011)</a>
NO <sub>3</sub> <sup>-</sup> export in 2006	Sugar maple, American Beech, yellow birch	NO <sub>3</sub> <sup>-</sup> retention greater than expected. "Changes over last five decades have reduced impacts of frost events on watershed NO <sub>3</sub> <sup>-</sup> export."	~6 kg N/ha/yr (1999–2008)		HBEF	<a href="#">Judd et al. (2011)</a>
NPP and photosynthetic surface area	Sugar maple, American Beech, yellow birch	Ca nutrition promoted higher aboveground NPP and increased photosynthetic surface area.	Not specified	0	HBEF (15-yr study)	<a href="#">Battles et al. (2014)</a>
Nitrification		Showed greatest response to N treatments.	8.4 kg N/ha/yr (wet + dry)	WB 25.2 kg N/ha/yr (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub> WB 28.8 S	BBW	<a href="#">Jefts et al. (2004)</a>

**Table 16-13 (Continued): Summary of observed terrestrial and aquatic nutrient enrichment long-term responses in Acadia National Park, Hubbard Brook Experimental Forest, Bear Brook Watershed, and other northeastern regions.**

Variable	Species	Response	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Site	Reference
$\beta$ -1,4 glucosidase $\beta$ -1,4-N-acetylglucosaminidase	Sugar maple, American beech, Red spruce	“Greatest leaf N + P contents can increase short-term decomposition, accelerate production of more humic-like water extractable organic matter and thereby potentially influence the distribution of organic matter within the soil C pool.”  Not affected by long-term N enrichment in aquatic and terrestrial habitats.	Not specified	25.2 N since 1989	BBW	<a href="#">Hunt et al. (2008)</a> <a href="#">Mineau et al. (2014)</a>
WB vs. EB streams: Leaf breakdown	Not specified	Little difference found	Not specified	Not specified	BBW	<a href="#">Simon et al. (2010)</a>
WB vs. EB streams: Invertebrate production	Not specified	“Virtually identical”	Not specified	Not specified	BBW	<a href="#">Simon et al. (2010)</a>
WB vs. EB streams: Nutrient uptake	NA	N uptake responsive	Not specified	Not specified	BBW	<a href="#">Simon et al. (2010)</a>
Base cation	Sugar maple, American beech, red spruce	American beech and red spruce lower foliar Ca, Mg, Zn concentrations; nutrient imbalance may offset potential photosynthesis benefits.  Sugar maple higher photosynthesis rates; no decrease in Ca, Mg, Zn concentrations.	8.4 kg N/ha/yr (wet + dry)	WB 25.2 kg N/ha/yr (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub> WB 28.8 S	BBW	<a href="#">Elvir et al. (2006)</a>

## 16.1.5 Recovery

Research to measure and predict recovery in the Northeast indicates that while emission control legislation has resulted in reduced S and N emissions from some stationary and mobile sources, recovery of sensitive northeastern watersheds, including those located at HBEF, BBW, and ACAD, has been limited. From 2000 to 2010, lake  $\text{NO}_3^-$  concentrations in New England and the Adirondack Mountains, which had no trend prior to 2000, declined at a rate of  $-0.05 \mu\text{eq/L/year}$  (Strock et al., 2014). Research by Warby et al. (2008) in the Northeast suggested a nascent recovery of soil acid-base chemistry at some locations where red spruce stands were sampled. In BBW, SanClements et al. (2010) found little evidence of continued depletion or recovery of soil exchangeable base cations. Mitchell and Likens (2011) observed that with declining inputs of atmospheric S, the higher outputs of  $\text{SO}_4^{2-}$  in drainage waters relative to precipitation inputs appear to be driven by the S stored in the soil.

To simulate the future responses of soil and surface water chemistry to potential future emissions controls at the reference watershed at HBEF, Gbondo-Tugbawa and Driscoll (2002) used the PnET-BGC (Photosynthesis and Evapotranspiration-Biogeochemical) model. Simulation results suggested that emissions controls required by the CAAA will likely not result in substantial future changes in critical indicators, such as soil base saturation, soil solution Ca:Al, or stream ANC and Al concentrations. Tominaga et al. (2010) assessed model outputs of four ecosystem models by systematically applying each of the models to data from the HBEF. They predicted that current legislated emissions reductions (13% reduction of  $\text{SO}_4^{2-}$  by 2015) would result in limited recovery and that maximum feasible technology reductions (78% reduction of  $\text{SO}_4^{2-}$  by 2015) would result in a more rapid and greater extent of chemical recovery.

The recovery of sensitive northeastern watersheds appears to be influenced by climate change, which has become increasingly important to consider in understanding the potential for recovery from decades of S and N deposition. For example, climatic change, which increases annual stream discharge and watershed wetness, will potentially increase  $\text{SO}_4^{2-}$  mobilization and hence may slow the recovery of both aquatic and terrestrial ecosystems from acidification (Mitchell and Likens, 2011). Predictive modeling of recovery should, therefore, consider climate change. Two modeling studies reported in this case study are noteworthy for improving scientific understanding of recovery in the Northeast. To test assumptions about interactions that are influenced by climate change, Campbell et al. (2009) applied the PnET-BGC model in a northern hardwood forest ecosystem at HBEF. Results suggested an increase in primary productivity due to a longer growing season in the future, an increase in  $\text{NO}_3^-$  leaching due to enhanced net

mineralization and nitrification, and a slight decrease in mineral weathering. In addition, this warmer climate has contributed to significant declines in snow depth, snow-water equivalents, and snow cover duration. This change has important implications for forest ecosystem processes, such as tree phenology and growth, hydrological flow paths during winter and spring, and soil biogeochemistry. Expected future climate change was also simulated using ForSAFE-VEG (Soil Acidification in Forest Ecosystems model) and found to cause an increase in soil base saturation, especially at BBW ([Phelan et al., 2016](#)). The authors observed that climate had a lesser effect on simulated soil acid-base chemistry at HBEF, likely due to the overwhelming influences of high S and N deposition. They suggested that climate futures predicted by the Intergovernmental Panel on Climate Change (IPCC) of increased temperature and precipitation will change plant communities and N enrichment, counteracting the acidifying impacts of S and N deposition on soil acid-base chemistry.

Finally, increasing attention is being given to developing and implementing practices to restore forest productivity lost to impacts from acidification. Practices such as calcium addition may increase recovery rates in northeastern forests. For example, [Battles et al. \(2014\)](#) added calcium silicate to the HBEF paired watershed to determine whether Ca lost from leaching due to acidification can be restored. Their results suggested tree biomass recovery and reversal of forest decline through greater aboveground net primary production and increased photosynthetic surface area. CO<sub>2</sub> fertilization associated with climate change is also being evaluated for its role in helping mitigate N loss in watersheds ([Pourmokhtarian et al., 2012](#)).

## 16.2 Adirondack Case Study: Adirondack Region of New York

---

### 16.2.1 Background

This case study is meant to identify the effects of nitrogen (N) and sulfur (S) in the Adirondack region and the Adirondack state park in New York. This case study identifies current acidification and nutrient status and empirical and modeled critical loads (CLs). It is a supplement to the case study of acidification in the Adirondack region of New York included in the 2008 NO<sub>x</sub>-SO<sub>x</sub> ISA [Section 3.2.2.4 of 2008 ISA ([U.S. EPA, 2008a](#))]. Further information about the effects in the Adirondack region can be found in [Appendix 4](#), [Appendix 5](#), [Appendix 7](#), and [Appendix 8](#).

---

### 16.2.1.1 Description of Case Study Region

The Adirondack Mountains are in northeastern New York State and are densely forested, have abundant surface waters, and have 46 peaks that extend up to 1,600 m in elevation ([Figure 16-9](#)). This area includes the headlands of five major drainage basins: Lake Champlain and the Hudson, Black, St. Lawrence, and Mohawk rivers. There are more than 2,800 lakes and ponds, and more than 1,500 miles of rivers that are fed by an estimated 30,000 miles of brooks and streams. The Adirondack Park has long been a nationally important recreation area for fishing, hiking, boating, and other outdoor activities.

The Adirondacks, particularly the southwestern Adirondacks, are sensitive to acidifying deposition because they receive high precipitation, have shallow base-poor soils, and are underlain by igneous bedrock with low weathering rates. The Adirondacks are among the most severely acid-affected regions in North America ([Driscoll et al., 2003a](#); [Landers et al., 1988](#)) and have long been used as an indicator of the response of forest and aquatic ecosystems to U.S. policy on atmospheric emissions of SO<sub>2</sub> and NO<sub>x</sub> ([NAPAP, 2011](#); [U.S. EPA, 1995a](#)).

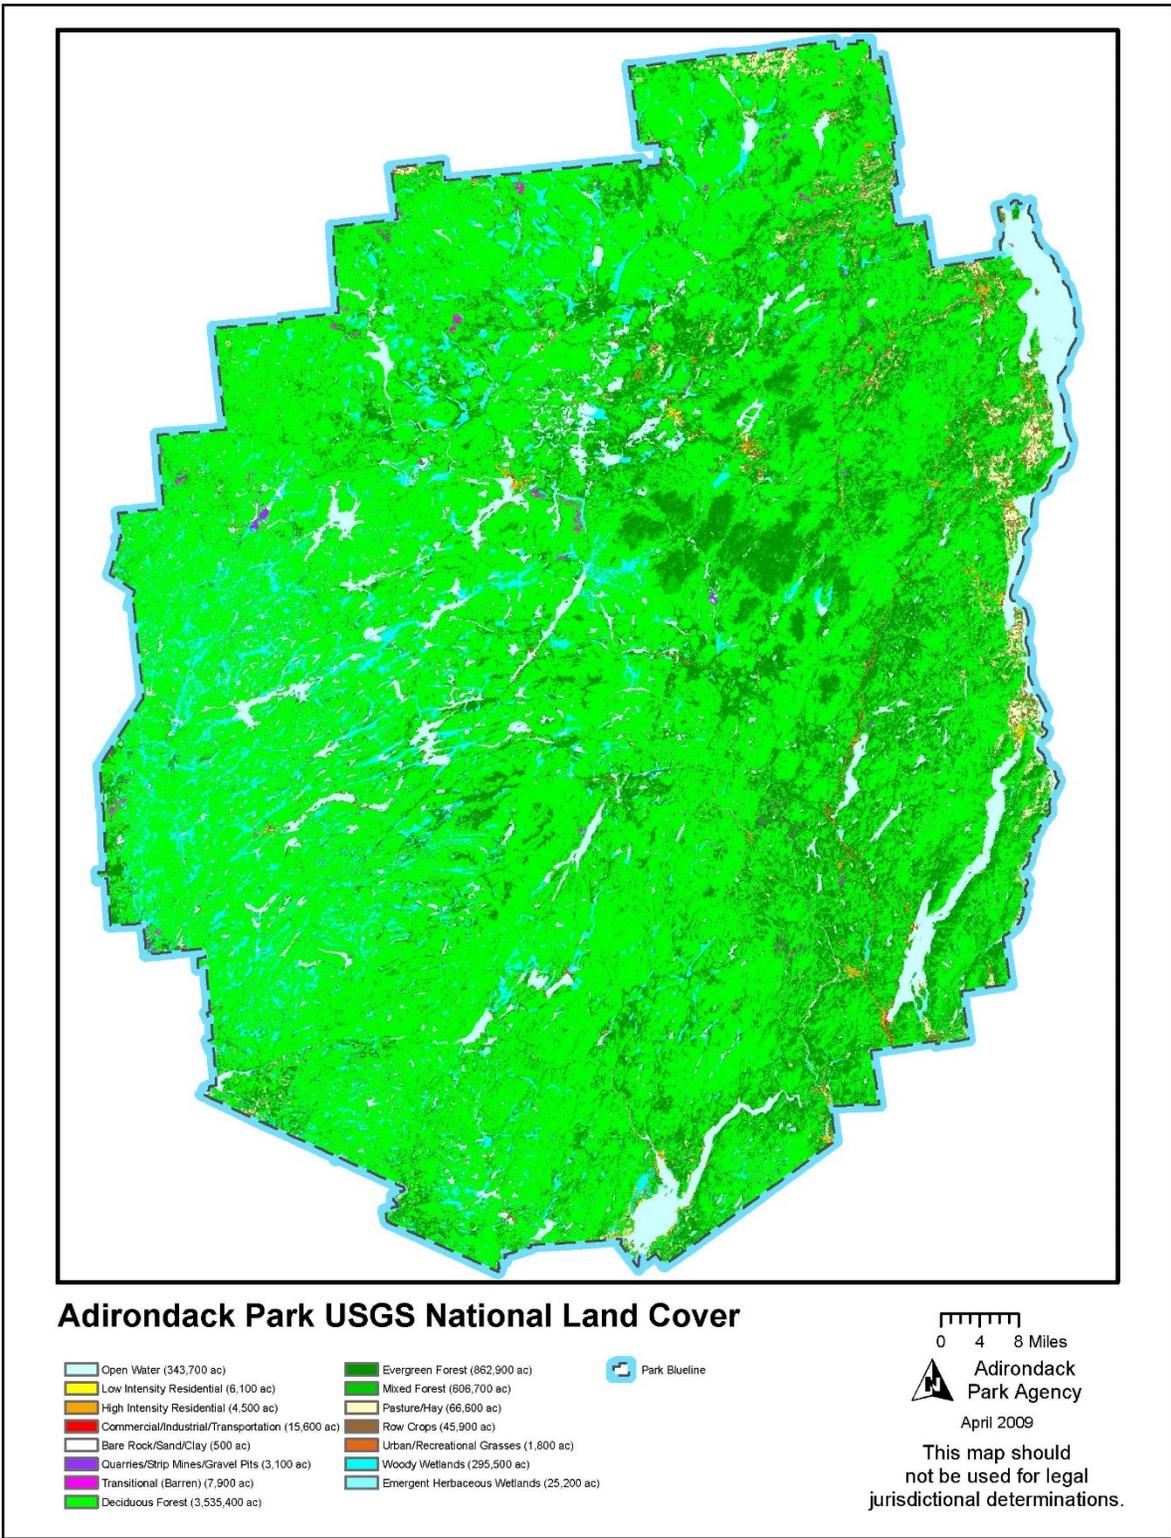

Figure 16-9 Map of Adirondack park land cover.

---

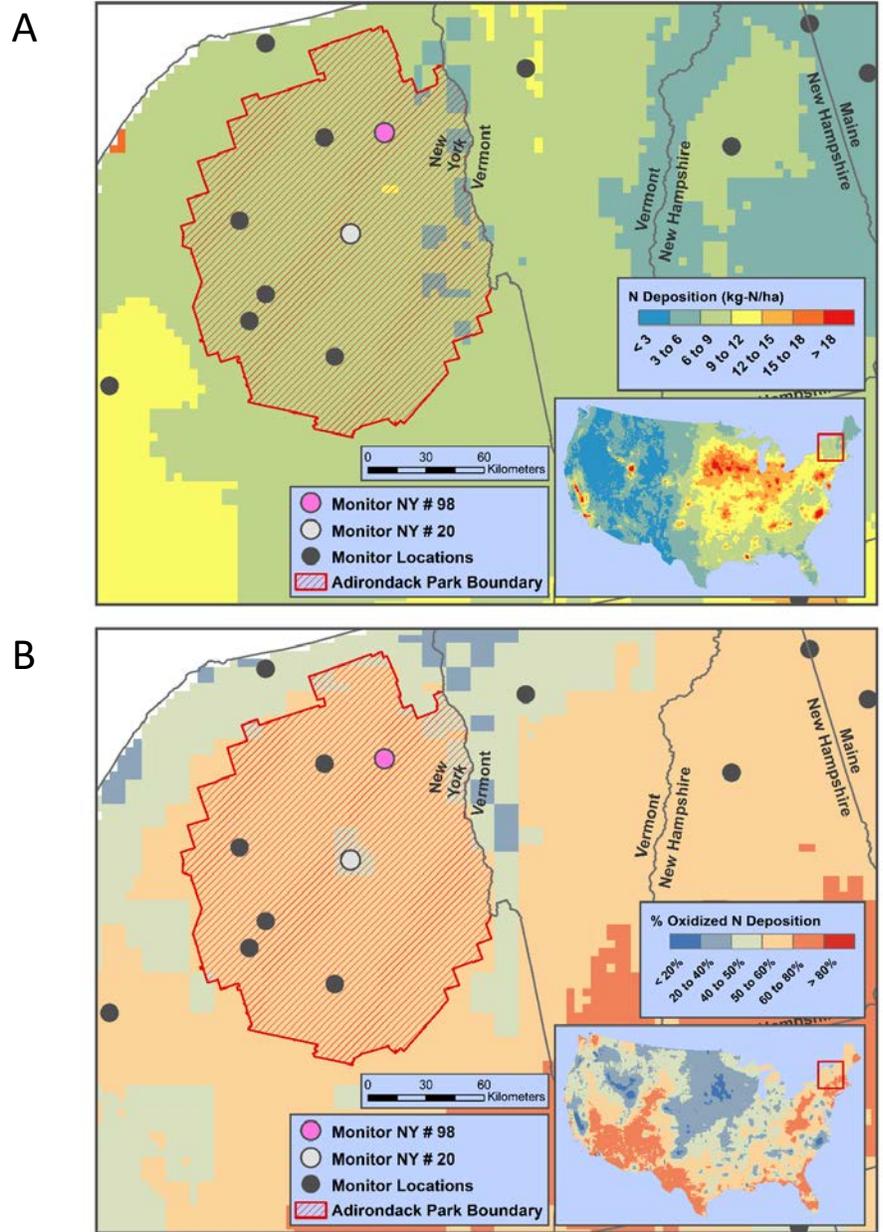

## 16.2.2 Deposition

Characteristics of nitrogen and sulfur deposition affecting the Adirondack region are shown in [Figure 16-10](#) and [Figure 16-11](#). [Figure 16-10A](#) and [Figure 16-11A](#) show 3-year average total deposition of N and S for 2011–2013; [Figure 16-10B](#) shows the partitioning between oxidized and reduced N; [Figure 16-11B](#) shows the 25-year-long time series for wet deposition for  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ ,  $\text{SO}_4^{2-}$  and  $\text{H}^+$  obtained at the NADP/NTN (National Atmospheric Deposition Program/National Trends Network) monitoring site at Whiteface Mountain, NY (NY98). Surrounding areas in Vermont and New Hampshire and inserts showing the coterminous U.S. (CONUS) are shown to place the depositional environment in context. See [Appendix 2.4](#), [Appendix 2.5](#), and [Appendix 2.6](#) for more information on deposition in the U.S. Other maps showing the contributions of individual species to dry and/or wet deposition are given in [Appendix 2.7](#).

Data shown in the map [Figure 16-10](#) and [Figure 16-11A](#) were obtained from the hybrid modeling/data fusion product, TDEP (Total Deposition, <http://nadp.slh.wisc.edu/committees/tdep/tdepmaps/> and described in Annex 2, Section 2.8). The time series of wet deposition is taken directly from data on the NADP/NTN ([Figure 16-11B](#)). This was done to track changes in deposition since the passage of the Clean Air Act Amendment (CAAA) because the Community Multiscale Air Quality (CMAQ) model simulations used in TDEP extend back only to 2000.

Comparison of [Figure 16-10A](#) and [Figure 16-11A](#) indicates that the general pattern of deposition of N and S is broadly similar; deposition estimates tend to be uniform throughout the Adirondack Park. In addition, the area surrounding the park shows a high degree of regional homogeneity but with higher values to the Southwest. Deposition of N is not as high as in many areas of the central U.S. Deposition of S is considerably lower than along the Ohio River Valley.

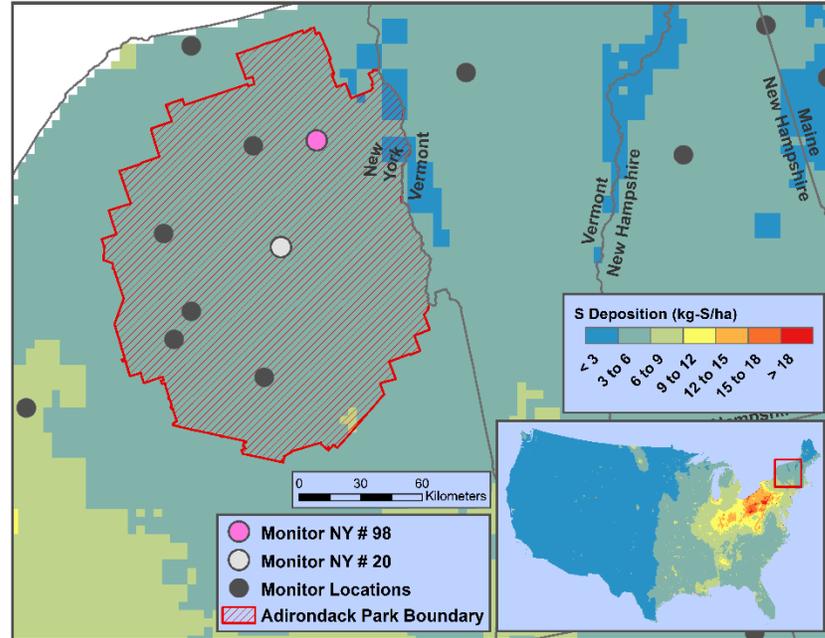

[Figure 16-10B](#) shows that the deposition of nitrogen is estimated to be mostly in oxidized form throughout the entire park. In [Figure 16-11B](#), wet deposition of all species shows that downward trends in  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ ,  $\text{SO}_4^{2-}$ , and  $\text{H}^+$  are consistently found over the past 25 years, although the rate of decrease was variable. In general, wet deposition typically exceeds dry deposition of N and S in this area.

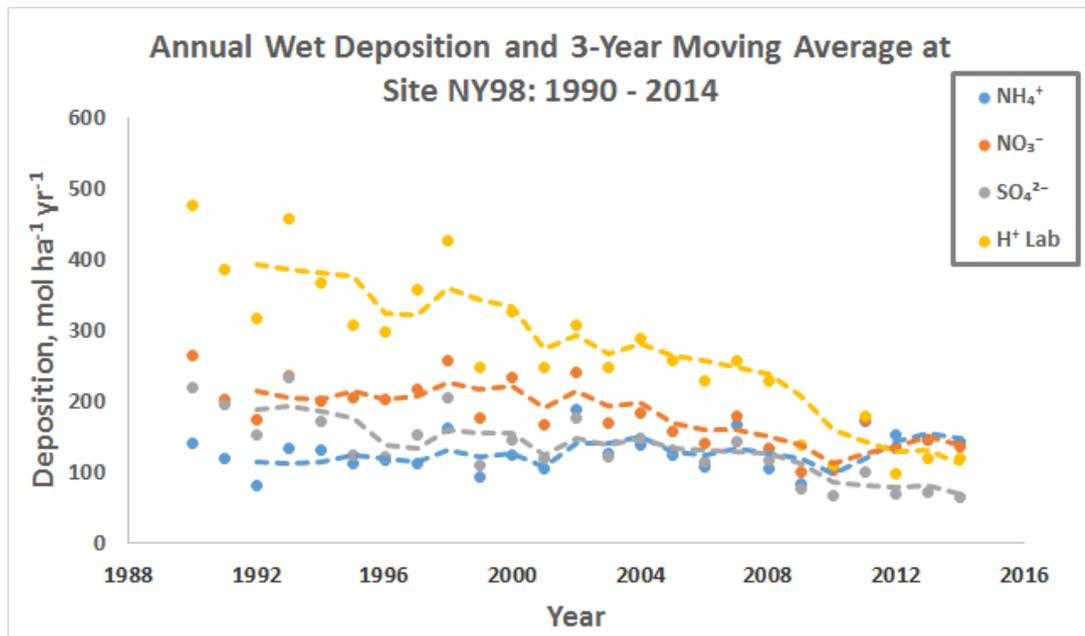

ha = hectare; kg = kilogram; N = nitrogen.

## 16.2.3 Critical Loads and Other Dose-Response Relationships

---

### 16.2.3.1 Terrestrial

This section presents post-2008 Adirondack area findings on the dose-response relationships of N and S to terrestrial ecology, as well as the critical N and S loads for maintaining ecosystem health. Additional relevant information for the Adirondack region is summarized. The section presents findings on both empirical research and modeling analyses.

#### 16.2.3.1.1 Empirical and Modeling Studies

Post-2000 findings from empirical and modeling studies of terrestrial dose-response relationships and critical loads are summarized in this section. [Table 16-14](#) summarizes the body of empirical and modeling research identified.

---

**Table 16-14 Terrestrial empirical and modeling research on the response of nitrogen and sulfur deposition for the Adirondack Mountains.**

Variable	Species	Response	Deposition/ Addition (kg N/ha/yr)	Years	Site	Reference
Community richness and abundance, live biomass	Redback salamanders, calciphilic species of snails	Increasing trends in snail community richness and abundance, live biomass of salamanders, with increasing soil Ca.	14.57 to 19.7 kg/ha/yr as wet NO <sub>3</sub> <sup>-</sup> ; 17.44 to 29.09 kg/ha/yr as wet SO <sub>4</sub> <sup>2-</sup> , modeled ( <a href="#">Ito et al., 2002</a> ) 1990–1999	2009	12 upland hardwood forests	<a href="#">Beier et al. (2012)</a>
Canopy tree basal area	Sugar maple	Sugar maple basal area was positively correlated to forest floor and mineral soil (B-horizon)	14.57 to 19.7 kg/ha/yr as wet NO <sub>3</sub> <sup>-</sup> ; 17.44 to 29.09 kg/ha/yr as wet SO <sub>4</sub> <sup>2-</sup> , modeled ( <a href="#">Ito et al., 2002</a> ) 1990–1999	2009	12 upland hardwood forests	<a href="#">Beier et al. (2012)</a>

---

**Table 16-14 (Continued): Terrestrial empirical and modeling research on the response of nitrogen and sulfur deposition for the Adirondack Mountains.**

Variable	Species	Response	Deposition/ Addition (kg N/ha/yr)	Years	Site	Reference
Tree basal area	Sugar maple, black cherry, American beech, red maple, and yellow birch	Sugar maple basal area was positively correlated with mineral soil pH, and yellow birch basal area was positively correlated with mineral soil exchangeable Ca. Sugar maple basal area was also negatively correlated with stream water DOC.	NA	2008	Ha De-Ron-Dah Wilderness Area in Adirondack Mountains	<a href="#">McEathron et al. (2013)</a>
Tree basal area	Sugar maple, American beech, American basswood, and white ash	Relative basal areas of sugar maple and American basswood were positively correlated with mineral soil exchangeable Ca; American beech was negatively correlated; white ash was not correlated.	NA	2004–2005	Adirondack Park	<a href="#">Page and Mitchell (2008)</a>
Sugar maple regeneration	Sugar maple	Plots with lower soil base saturation did not have sugar maple regeneration (these same plots also received higher N and S deposition levels); proportion of sugar maple seedlings dropped substantially at base saturation levels less than 20%.	750 to 1,120 eq/ha/yr as N + S (NADP wet, CASTNET dry)	2009	Adirondack Park	<a href="#">Sullivan et al. (2013)</a>
Canopy vigor and tree growth	Sugar maple	Canopy vigor was positively correlated with soil pH and exchangeable Ca and Mg. Mean growth rates (BAI) were positively correlated with exchangeable Ca and base saturation at the watershed level.	750 to 1,120 eq/ha/yr as N + S (NADP wet, CASTNET dry)	2009	Adirondack Park	<a href="#">Sullivan et al. (2013)</a>

**Table 16-14 (Continued): Terrestrial empirical and modeling research on the response of nitrogen and sulfur deposition for the Adirondack Mountains.**

Variable	Species	Response	Deposition/ Addition (kg N/ha/yr)	Years	Site	Reference
Tree basal area and woody biomass increments	All major trees	Significant positive overall effect of N deposition on tree growth from 1984–2004, but positive growth effects only for red maple, balsam fir, and red spruce at the species level.	Gradient of 3.5–7 kg N/ha/yr	1984–2004	Adirondack Park	<a href="#">Bedison and McNeil (2009)</a>
NO <sub>3</sub> <sup>-</sup> leaching	NA	PnET-BGC Model. Increase due to enhanced net mineralization and nitrification	Not specified	1999–2099	NE	<a href="#">Campbell et al. (2009)</a>
Mineral weathering	NA	PnET-BGC Model. Slight decrease due to reduced simulated soil moisture (negative effect) and increased temperature (positive effect)	Not specified	1999–2099	NE	<a href="#">Campbell et al. (2009)</a>

BBW = Bear Brook Watershed; BC = base cation; C = carbon; Ca = calcium; ForSAFE-VEG = Soil Acidification in Forest Ecosystems; ha = hectare; HBEF = Hubbard Brook Experimental Forest; IPCC = Intergovernmental Panel on Climate Change; kg = kilogram; Mg = magnesium; N = nitrogen; NA = not applicable; ND = no data; NE = northeastern; (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> = ammonium sulfate; NO<sub>3</sub><sup>-</sup> = nitrate; PnET-BGC = Photosynthesis and Evapotranspiration-Biogeochemical; S = sulfur; WB = West Bear Brook; yr = year; Zn = zinc.

#### 16.2.3.1.1.1 Critical Loads

Target loads of S deposition were calculated for 44 watersheds and extrapolated to 1,320 acid-sensitive watersheds in the Adirondacks using MAGIC and different soil chemical indicator and thresholds of base saturation (5 and 10%), soil solution Bc:Al, and Ca:Al [1.0 and 10.0; [Sullivan et al. \(2011a\)](#)]. In a comparison of target loads (out to years 2050 and 2100) and the 2002 deposition, only 11.6 to 13.5% of the watersheds were simulated to be in exceedance of target loads to protect soil base saturation to 5%. For target loads to protect soils to a base saturation of 10%, 79.7 to 87.5% of the watersheds were in exceedance. For soil solution Bc:Al, 7.8 and 98.1% of watersheds were exceeded by the 2002 deposition for target loads to protect soil solution ratios of 1.0 and 10.0, respectively. For soil solution Ca:Al, 44.1 to 58.2% of watersheds experienced

exceedances of target loads associated with a soil solution ratio of 1.0, and 98.1% of watersheds with target loads to protect Ca:Al ratios of 10.0 were exceeded. Further investigations revealed that 58.2, 85.7, and 93.6% of watersheds could not obtain threshold values of 10% base saturation, Bc:Al = 10, or Ca:Al = 10, respectively, even if acidic deposition was held at zero, thereby demonstrating that these chemical indicator threshold values were not useful for target load calculations using MAGIC in the Adirondack Mountains.

---

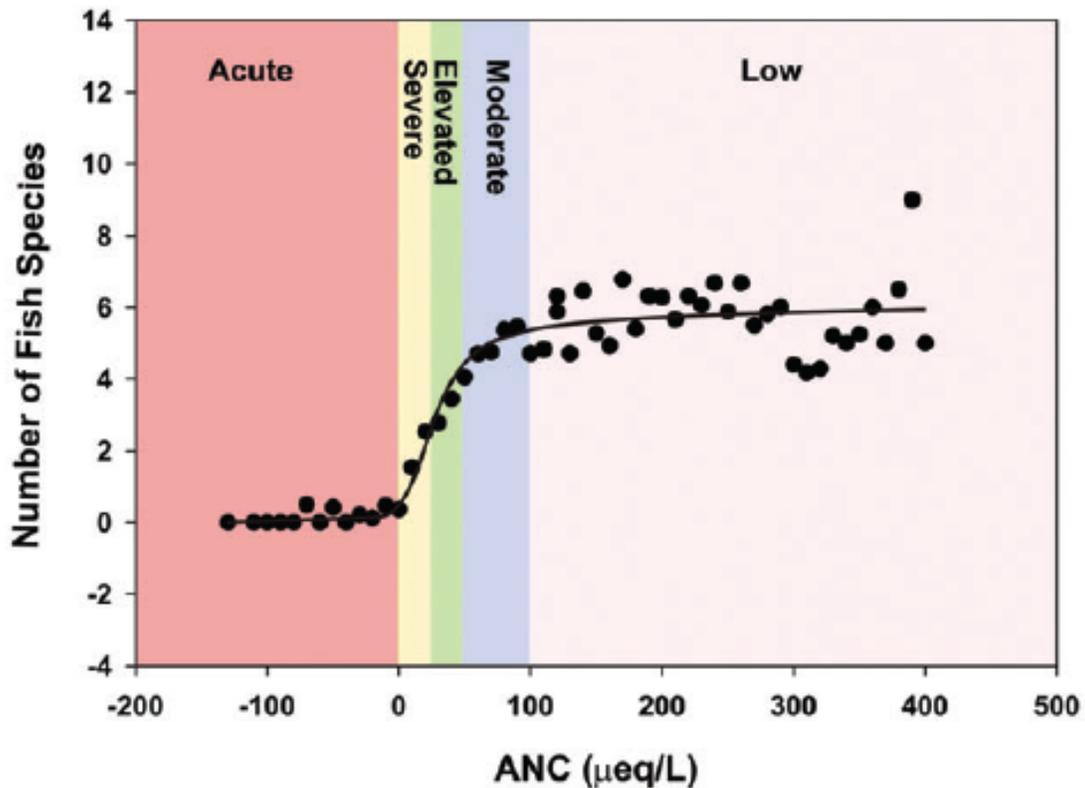

### 16.2.3.2 Aquatic

This section presents research findings at Adirondack Mountains on the dose-response relationships of N and S to aquatic ecology, as well as the critical N and S loads for maintaining ecosystem health. Additional relevant information for the Adirondack region is summarized. Both empirical and modeling studies of aquatic dose-response relationships and critical loads are included in this section.

#### 16.2.3.2.1 Empirical Studies

Studies in the Adirondack Mountains reviewed in the 2008 ISA demonstrated the effect of acidification on fish species richness. Of the 53 fish species recorded in Adirondack lakes, about half (26 species) were absent from lakes with pH below 6.0. Those 26 species included important recreational species plus ecologically important minnows that serve as forage for sport fish ([Baker et al., 1990b](#)). There is often a positive relationship between pH and number of fish species, at least for pH values between about 5.0 and 6.5, or ANC values between about 0 and 50 to 100  $\mu\text{eq/L}$  ([Cosby et al., 2006](#); [Sullivan et al., 2006a](#); [Driscoll et al., 2003b](#); [Bulger et al., 1999](#)).

As summarized in the 2008 ISA, lakes and streams having an ANC < 0  $\mu\text{eq/L}$  generally do not support fish ([Figure 16-12](#)). The analysis shown in this figure suggests that there could be a loss of fish species with decreases in ANC below a threshold of approximately 50 to 100  $\mu\text{eq/L}$  ([Sullivan et al., 2006a](#)).

ANC = acid neutralizing capacity; L = liter;  $\mu\text{eq}$  = microequivalent.

Notes: the data are presented as the mean (filled circles) of species richness within 10  $\mu\text{eq/L}$  ANC categories, based on data collected by the Adirondacks Lakes Survey Corporation.

Source: Modified from [Sullivan et al. \(2006a\)](#).

**Figure 16-12** Number of fish species per lake and acidity status, expressed as acid neutralizing capacity, for Adirondack lakes.

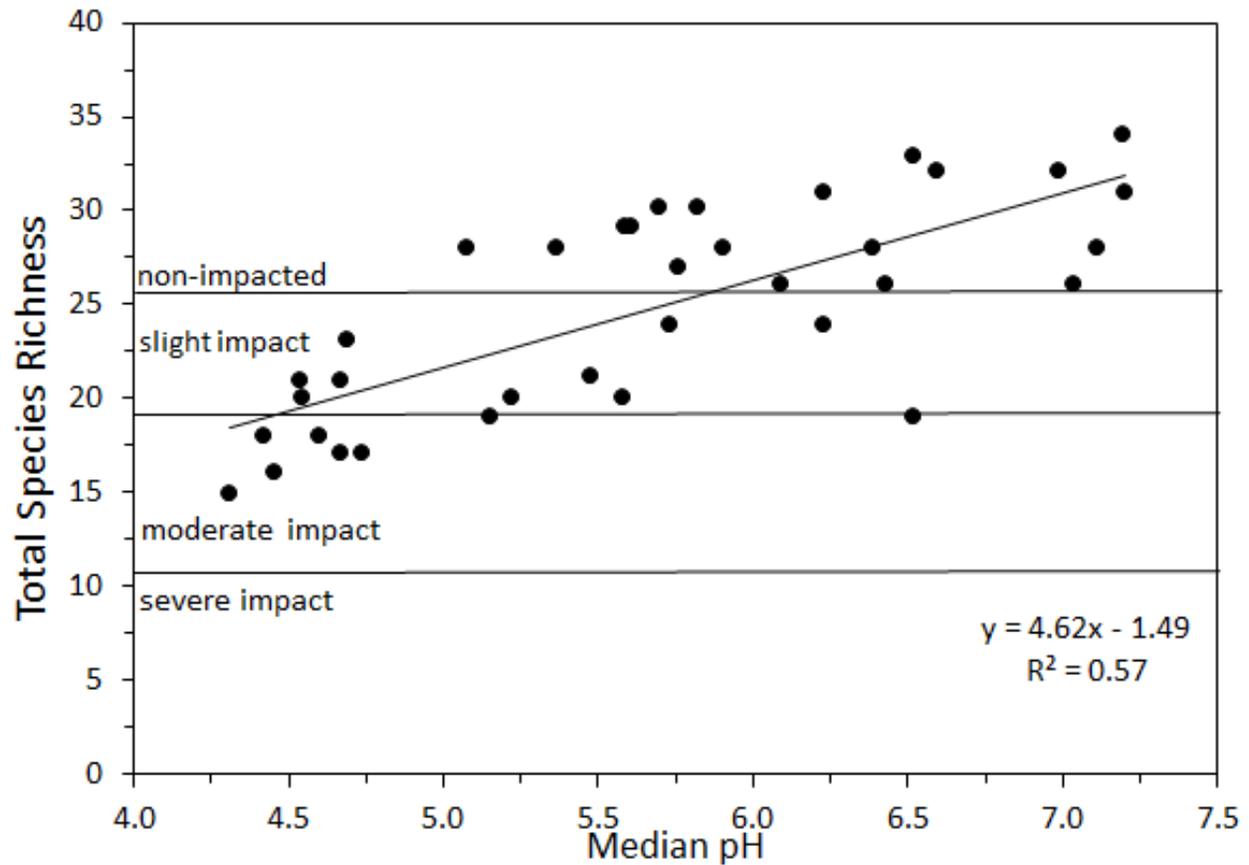

Work by [Baldigo et al. \(2009\)](#) assessed the effects of acidification on benthic macroinvertebrate community dynamics in the southwestern Adirondack Mountains. Water chemistry and benthic macroinvertebrates were surveyed in 36 streams with different levels of acidity to characterize community response and identify thresholds for biological effects ([Figure 16-13](#)). In the study streams, macroinvertebrate assemblages were severely impacted at  $\text{pH} < 5.1$ , moderately impacted at  $\text{pH}$  from 5.1 to 5.7, slightly impacted at  $\text{pH}$  from 5.7 to 6.4 and usually unaffected above  $\text{pH}$  6.4. Inorganic Al concentrations reached potentially toxic levels in two-thirds of the study streams. The authors applied the Acid Biological Assessment Profile [acidBAP] index, which is based on percentage mayfly richness and percentage acid tolerant macroinvertebrate taxa ([Burns et al., 2008b](#)). The acidBAP was strongly correlated with  $\text{pH}$ , ANC, BCS, and the concentration of inorganic Al, indicating the loss of mayflies in the stream as the surface

water's pH declines from pH 7.0 to 4.2. A loss of about 12 species occurred in streams that had a pH between 7 and 4.2. Regression across all 36 streams showed a loss of 4.6 species per unit pH decrease ([Figure 16-13](#)). Inorganic Al toxicity was likely the main cause of the loss of macroinvertebrates. The Al concentration is strongly correlated with surface water pH (as pH decreases, the solubility of inorganic Al increases) and acid-base balance as measured by BCS.

Studies in the Adirondacks have considered effects of species assemblages associated with acid-impacted water bodies. [Nierzwicki-Bauer et al. \(2010\)](#) presented baseline midsummer chemistry and community composition of phytoplankton, bacteria, rotifers, crustaceans, macrophytes, and fish in 30 lakes of the southwestern Adirondacks ([Figure 16-14](#)). Species richness in the lakes was correlated with acid-base chemistry at all trophic levels except bacteria. The decrease in number of taxa per unit pH was similar among groups and ranged from 1.75 (crustaceans) to 3.96 (macrophytes).

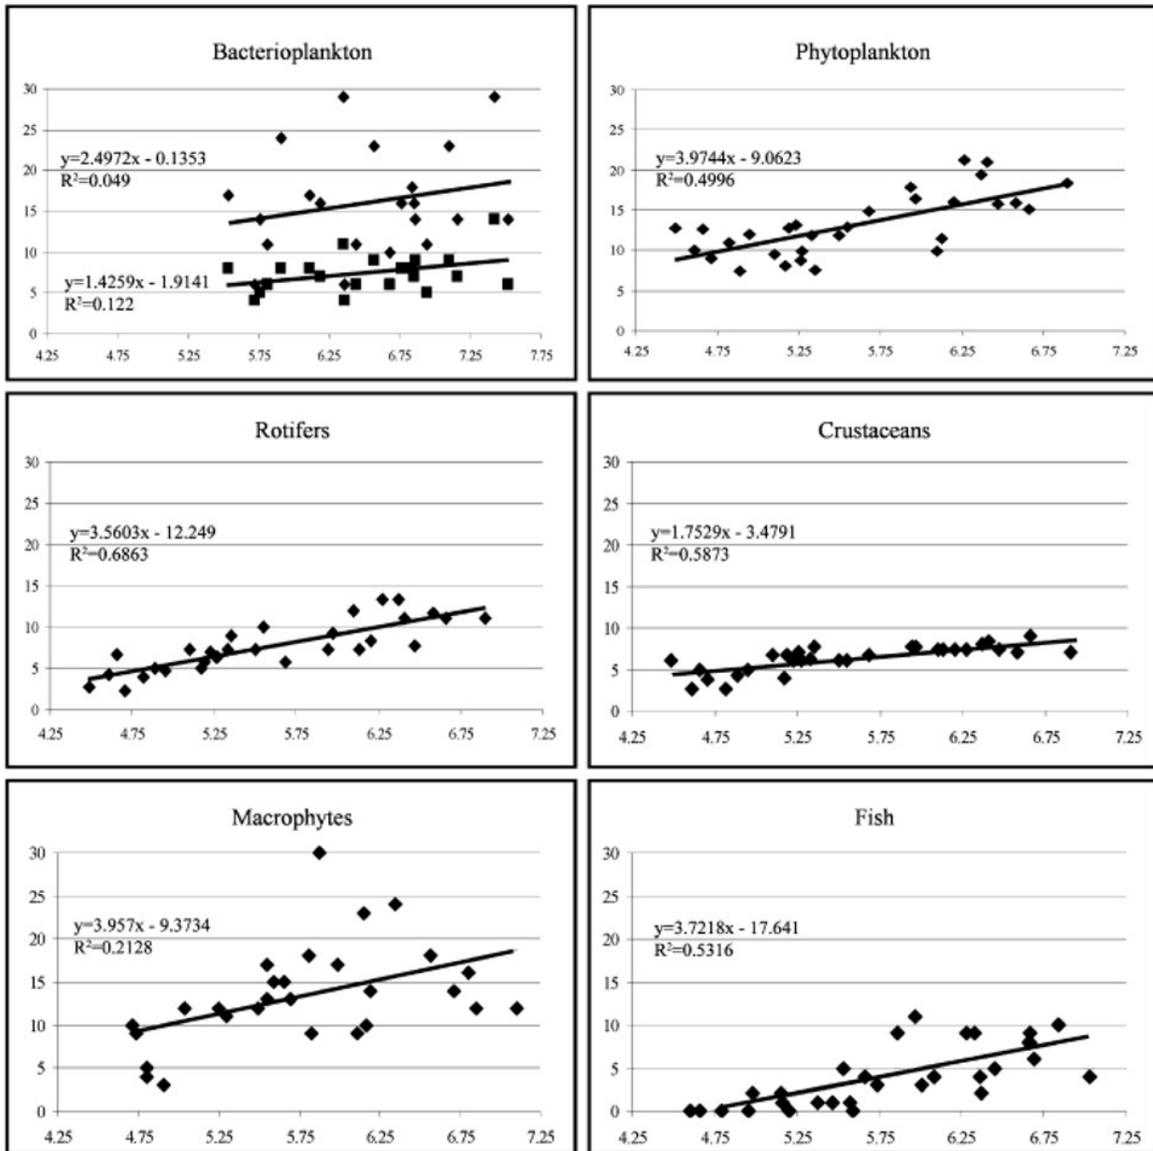

[Percent et al. \(2008\)](#) assessed bacterioplankton community diversity and structure in 18 Adirondack lakes across a range of acid-base chemistry using sequencing and amplified ribosomal DNA restriction analysis of constructed rRNA gene libraries. Based on principal components analysis, pH was positively correlated with bacterioplankton community richness and diversity. The richness of several bacterial classes, including Alphaproteobacteria, was directly correlated with pH. However, other environmental factors, such as lake depth, hydraulic retention time, dissolved inorganic C, and nonlabile (organically bound) monomeric Al, were also important in explaining bacterioplankton community richness and diversity, suggesting that acidity is only one factor that controls community composition.

Post-2008 findings from empirical studies of aquatic dose-response relationships and critical loads are summarized in this section. [Table 16-15](#) compiles the body of empirical research identified.

Source: Modified from [Baldigo et al. \(2009\)](#).

**Figure 16-13** Total macroinvertebrate species (community) richness as a function of median pH in 36 streams sampled in the western Adirondack Mountains of New York, 2003–2005; the four standard (New York State) impact categories for species richness are defined.

## Lake pH

Notes: the y-axis denotes number of groups (bacteria), taxa (phytoplankton) or species (rotifers, crustaceans, macrophytes, fish). The x-axis denotes the pH range that occurred in the 30 study lakes. In the bacterioplankton graph, two regressions were run on the basis of genera (diamonds) and classes (squares).

Source: [Nierzwicki-Bauer et al. \(2010\)](#).

**Figure 16-14** Species richness of biotic groups in 30 Adirondack study lakes relative to midsummer epilimnetic pH during sample years.

**Table 16-15 Aquatic empirical research on the response of nitrogen and sulfur deposition for the Adirondacks.**

Study	Time Period	Focus	Notable Results
<b>Changes to Acidity</b>			
<a href="#">Strock et al. (2014)</a>	1980–2010	Trends in recovery for lakes in the Northeast, including 43 sites in the Adirondack Mountains.	SO <sub>4</sub> <sup>2-</sup> concentration decreased slightly faster in the 2000s than the 1990s—possibly the result of a decline in S emissions that was twice as large in the 2000s than it was in the previous decade. NO <sub>3</sub> <sup>-</sup> concentration did not significantly fall in the 1990s (a decade which had more modest N emissions reductions) but did significantly fall in the 2000s, which saw large N emission reductions.
<a href="#">Mitchell et al. (2013)</a>	1984–2010	S deposition response in 16 Adirondack long-term monitoring Lakes.	SO <sub>4</sub> <sup>2-</sup> concentration has declined significantly along with total S deposition. However, there is a discrepancy in the balance of deposition inputs and discharge outputs. The authors conclude that internal S supplies are likely contributing to high sulfur concentrations and the slow recovery of lakes in the region, and that internal S will become a more important factor as emissions decline.
<a href="#">Waller et al. (2012)</a>	1991–2007	The effectiveness of the Acid Rain Program and Nitrogen Budget Program in the 1990 CAAA in reducing Adirondack lake acidity for 42 lakes.	Sulfate concentration declined by 23.47% over the study period, but nitrate concentration did not significantly decline. ANC has increased over the study period, with the number of lakes with ANC <0 dropping by 46%. ANC <sub>G</sub> was higher than ANC <sub>calc</sub> , suggesting contribution to acidity from naturally occurring organic acids that are not factored into ANC <sub>calc</sub> .
<a href="#">Baron et al. (2011b)</a>	1997–2006	Empirical N loads in 216 northeastern U.S. lakes including Adirondack lakes.	Minimally disturbed Northeast lakes were estimated to have thresholds of 3.5–6.0 kg N/ha/yr for avoidance of acidic episodes.
<a href="#">Lawrence et al. (2011)</a>	1985–2008	Focuses on 12 Adirondack streams rather than lakes.	The pH in streams with lower ANC was more responsive to the 50% reduction in S deposition over the study period than pH in streams with high ANC. Authors noted “a more muted recovery response” in streams compared to what has been reported in lakes.
<a href="#">Inamdar and Mitchell (2008)</a>	2002–2004	Point Peter Brook watershed in Western New York and fluxes of sulfate following storms.	Results suggested that groundwater sources have greater impact on changes to sulfate flux in observed lakes than does deposition through precipitation.
<a href="#">Warby et al. (2008)</a>	1986–2001	Speciation and concentration of Al in 113 northeastern U.S. lakes (including the Adirondacks) and the effect of decreased acid deposition.	The Adirondack lakes had the largest decline in Al concentration of all lakes studied (Adirondacks: 2.01 μmol/L; all: 0.44). For reference, the decline in SO <sub>4</sub> <sup>2-</sup> deposition in the Adirondacks was about the same as the decline in the region as a whole.

**Table 16-15 (Continued): Aquatic empirical research on the response of nitrogen and sulfur deposition for the Adirondacks.**

Study	Time Period	Focus	Notable Results
<b>Changes to Biota</b>			
<a href="#">Sutherland et al. (2015)</a>	1984–2012	Brooktrout Lake acidification and biotic recovery.	Likely as a result of the 1990 Clean Air Act Amendments, $\text{SO}_4^{2-}$ concentrations have dropped 56% or 2 $\mu\text{equiv/L/yr}$ since the 1980s. Plankton species richness has also blossomed, though crustacean species richness has had less impressive growth (possibly due to pressures exerted by the predator-free glassworm, <i>Chaoborus</i> ). Brook trout ( <i>Salvelinus fontinalis</i> ) are now successfully surviving and reproducing after their reintroduction in 2005.
<a href="#">Josephson et al. (2014)</a>	1960–2011	Honnedaga Lake watershed recovery.	There has been significant decline in $\text{SO}_4^{2-}$ and $\text{NO}_3^-$ since 2001, when consistent measurements in surface water chemistry began. There were no notable trends in zooplankton species richness as lake acidity dropped over the observation period, but there was a significant resurgence of adult brook trout in the 2000s compared to catches in the 1970s (a nearly sixfold increase). The authors noted the relationship between acidity and aluminum toxicity for fish. Recovery of adult trout could be improved by lower acidity tributaries that would make a friendlier environment for young-of-year trout.
<a href="#">Yu et al. (2011)</a>	2003–2004	Focused on Hg concentrations in biota of 44 lakes (not $\text{NO}_x\text{SO}_x$ but relevant to acidity).	Lower ANC in surface water was correlated with higher Hg concentrations in the tissues of fish, loons, and zooplankton.
<a href="#">Nierzwicki-Bauer et al. (2010)</a>	1994–2006	Correlation between species richness and acid-base chemistry of 30 Adirondack lakes.	For each unit of pH (toward increased acidity), species richness dropped from 1.4–1.8 (bacterial classes, crustaceans) to above 3.5 (fish, rotifers, phytoplankton, macrophytes). Authors classified species into a system of brackets describing acid sensitivity or tolerance, with most fish species being considered acid sensitive.
<a href="#">Baldigo et al. (2009)</a>	2003–2005	Macroinvertebrate response to acidification of 36 streams in the Adirondack region.	Species richness was measured by acid bioassessment profile (acidBAP) scores. In about half of streams, acidBAP scores were moderately or severely impacted (44%) from low pH—this increased to about two-thirds of streams when including slight impacts (69%).
<a href="#">Percent et al. (2008)</a>	2002–2002	Acidity and bacterial communities in 18 Adirondack lakes.	Authors reported a significant decline in bacterial species richness and species diversity with increasing acidity. However, they did not find the overall bacterial community composition to be significantly affected.

Notes: ANC = acid neutralizing capacity.

### 16.2.3.2.2 Modeling Studies

Post-2008 findings from modeling studies of aquatic dose-response relationships and critical loads are summarized in this section. [Table 16-16](#) compiles the body of research identified.

**Table 16-16 Critical and target load and exceedance modeling studies in Adirondack Mountains.**

Reference	Model	Focus	Notable Results
<a href="#">Sullivan et al. (2012a)</a>	MAGIC and regional extrapolation of model	TL for lakes in 2050 and 2100	To achieve ANC = 50 µeq/L in 2100, about 30% of lakes had simulated TL of S deposition <500 eq/ha/yr and about 600 lakes were in exceedance.
<a href="#">Zhou et al. (2015b)</a>	PnET-BGC	TL link to fish and zooplankton richness	The magnitude of simulated historical acidification represented by ANC loss ranged from about 26 to 100 µeq/L. The amount of historical acidification of the lakes was related to the total ambient deposition of SO <sub>4</sub> <sup>2-</sup> + NO <sub>3</sub> <sup>-</sup> , the Ca weathering rate, and the simulated preindustrial ANC in the year 1850. Adirondack lakes have lost fish and total zooplankton species richness beginning with the onset of acidic deposition. Modeling results suggested that complete recovery to preindustrial conditions may not be possible for most acidified lake ecosystems.
<a href="#">Zhou et al. (2015c)</a>	PnET-BGC	Effects of biophysical factors on the TL in lakes	Model simulations suggested that future decreases in SO <sub>4</sub> <sup>2-</sup> deposition would be more effective in increasing the lake water ANC than equivalent decreases in NO <sub>3</sub> <sup>-</sup> deposition. The difference was a factor of 4.6 during the period 2040 to 2050 but decreased to a factor of 2 by the year 2200. Lakes that had longer hydrologic residence exhibited less historical acidification and therefore could achieve a higher ANC in response to chemical recovery compared with lakes that had short hydrologic residence times.
<a href="#">Fakhraei et al. (2014)</a>	PnET-BGC	TMDLs for 128 acid-impaired lakes	Model simulations suggested that an S TL equal to 79 eq S/ha/yr (representing a 60% decrease from ambient deposition) would lead to ANC recovery at a rate of 0.18 µeq/L/yr through 2050, with reduced rate of recovery thereafter.

**Table 16-16 (Continued): Critical and target load and exceedance modeling studies in Adirondack Mountains.**

Reference	Model	Focus	Notable Results
<a href="#">NAPAP (2011)</a>	SSWC	Combined deposition load of S and N to which a stream and its watershed could be subjected and still have a surface water concentration ANC of 50 µeq/L on an annual basis	To achieve ANC = 50 µeq/L on average, critical load of sulfur and nitrogen for lakes in the Adirondack Mountains is 1,620 eq/ha/yr
<a href="#">Sullivan (2015)</a>	MAGIC and regional extrapolation of model	Development and application of tools to document and quantify TL and their exceedances	To achieve ANC values of 50 and 20 µeq/L in the year 2050 and 2100, the TL to protect against acidification of surface waters was exceeded throughout the Adirondack Mountains.

ANC = acid neutralizing capacity; CL = critical load; ForSAFE-VEG = Soil Acidification in Forest Ecosystems; MAGIC = Model of Acidification and Groundwater in Catchments; N = nitrogen; PnET-BGC = Photosynthesis and Evapotranspiration-Biogeochemical; S = sulfur; SSWC = Steady-State Water Chemistry; TL = target load; TMDL = total maximum daily load; VSD = very simple dynamic.

## 16.2.4 Long-Term Monitoring

This section summarizes research on the long-term effects of S and N deposition in the Adirondacks.

### 16.2.4.1 Long-Term Monitoring of Acidification

Acidic deposition has been shown to be an important factor causing decreases throughout much of the Northeast region in concentrations of exchangeable base cations in soils, which were naturally low historically. Base saturation values less than 12% predominate in the B-horizon in portions of the region where soil and surface water acidification from acidic deposition have been most pronounced ([Sullivan et al., 2006a](#); [Bailey et al., 2004](#); [David and Lawrence, 1996](#)).

At the time of the 2008 ISA, the region of the U.S. most thoroughly studied to ascertain changes in acid-base surface water chemistry over time was the Adirondack Mountains. This has not changed. Several new studies are highlighted here that focused on Adirondack surface waters, three on lakes and one on streams. The Adirondack Lakes Survey Corporation (ALSC) has been monitoring Adirondack lakes for about 30 years. This work has mainly focused on acid-base chemistry but has also involved some fish monitoring and measurement of parameters relevant to nutrient enrichment. Monitoring

data have shown some chemical recovery from lake acidification, reflected in increased pH and ANC and decreased inorganic Al concentrations.

A mass balance study by [Mitchell et al. \(2011\)](#) for 15 watersheds located in the northeastern U.S. and southeastern Canada suggested substantial sources of  $\text{SO}_4^{2-}$  in watershed soils. The internal S sources were attributed mainly to mineralization of S stored in soils in response to decades of atmospheric S deposition. [Mitchell et al. \(2013\)](#) studied 16 of the original Adirondack Long-Term Monitoring lakes that were monitored between 1984 and 2010. Total S deposition significantly declined in all of the study lake watersheds during the monitoring period. Correspondingly, significant decreases were observed over time ( $-2.14 \mu\text{mol/L/year}$ ) in lake  $\text{SO}_4^{2-}$  concentrations. The authors observed discrepancies in the calculated S mass balances that were associated with discharge. These results suggested that internal S sources have become more important to the watershed S budget as atmospheric S deposition has decreased. The watershed supply of  $\text{SO}_4^{2-}$  was lower in those watersheds that contained lakes that had lower ANC. Limited contributions from internal sources of  $\text{SO}_4^{2-}$  to the low-ANC lakes will allow ANC recovery. [Mitchell et al. \(2013\)](#) further concluded that the effects of future increases in precipitation might become more important in regulating the amount of  $\text{SO}_4^{2-}$  mobilized from internal watershed sources.

Surface water ANC and pH recovery has been documented by [Lawrence et al. \(2013\)](#) and [Lawrence et al. \(2011\)](#) in studies of Adirondack streams and lakes. [Lawrence et al. \(2011\)](#) reported results of Adirondack Mountain stream monitoring from the early 1980s to 2008. During that period, there was an approximate 50% reduction in atmospheric deposition of S in the Adirondack region. On average, the pH increased by only 0.28 pH units and ANC by  $13 \mu\text{eq/L}$  in 12 streams that were monitored over a period of 23 years. Larger increases in ANC and pH occurred in the monitored streams that had lower initial ANC. In the north tributary of Buck Creek that had a relatively high DOC concentration, the  $\text{SO}_4^{2-}$  concentration decreased between 1999 and 2008 at a rate of  $2 \mu\text{mol/L/year}$ . In the adjacent south tributary, which had a lower DOC concentration, the decrease in  $\text{SO}_4^{2-}$  concentration was substantially smaller, only  $0.73 \mu\text{mol/L/year}$ . [Driscoll et al. \(2016\)](#) observed increases in ANC and pH and marked decreases in dissolved inorganic Al in 45 of 48 study lakes in the Adirondack region from 1982 to 2015, corresponding to decreases in acidifying deposition.

[Michelena et al. \(2016\)](#) reported changes in the water chemistry of 30 Adirondack lakes, in response to reductions in acidic deposition from 1994 to 2012. The water quality of the study lakes generally improved during the study period, but the responses were sporadic and complex. Lake pH values increased until about 2002 and then fluctuated. Inorganic Al concentrations generally decreased throughout the period of record. During the early

years of monitoring, the average pH increased dramatically from about 5.5 to 6.0. This increase was followed by a period of reacidification for about 5 years, followed by another period of increased pH. This 5-year cycle was then repeated to a muted extent, even though acidic deposition continued to decline.

Chemical recovery from surface water acidification, and associated CL exceedance, in the Adirondack Mountains has been accompanied by increasing concentrations of DOC and organic acids, which have complicated and restricted recovery from acidification. [Lawrence et al. \(2013\)](#) reported the chemistry of 42 Adirondack lakes from samples collected between 1994 and 2011. They evaluated long-term changes in DOC and BCS (which reflects the calculated ANC and includes an adjustment for strong organic acid anions). Increases in DOC concentration during the study period contributed to organic complexation of Al. This reduced the fraction of monomeric Al that was in the inorganic (and potentially toxic) form from 57% in 1994 to 23% in 2011. Thus, the higher DOC found during the latter sampling period increased the organic acidity of the lake water and limited ANC recovery, but at the same time it decreased the toxicity of dissolved Al to aquatic biota. Similarly, [Strock et al. \(2014\)](#) reported trends in recovery from acidification of northeastern U.S. surface waters associated with Al chemistry. They analyzed recent trends in lake chemistry using long-term data from lakes in the Adirondack Mountains and New England. During the 2000s, the wet deposition of  $\text{NO}_3^-$  declined more than 50%. The lake  $\text{NO}_3^-$  concentration, which showed no trend prior to 2000, declined subsequent to 2000 at a rate of  $-0.05 \mu\text{eq/L/year}$ . There was a shift to nontoxic (organic) forms of Al. Despite the Al recovery, both the ANC and pH in the study lakes failed to show evidence of appreciable chemical recovery; rather, the lakes continued to exhibit variable trends in ANC and pH.

[Waller et al. \(2012\)](#) also evaluated the response of lake watersheds in the Adirondack Mountains to changes in  $\text{SO}_2$  and  $\text{NO}_x$  emissions and deposition, in this case using data from the TIME monitoring program collected during the period 1991 to 2007. The percentage of Adirondack lakes that were acidic decreased from an estimated 15.5 to 8.3%. Decreases in lake water  $\text{SO}_4^{2-}$  concentrations, and to a lesser extent  $\text{NO}_3^-$  concentrations, generally were accompanied by increases in lake ANC. However, the calculated ANC increased more than twice as much as the Gran titrated ANC. This discrepancy is important for assessing lake recovery from acidification. It appeared to be due mainly to increases in DOC (and associated organic anions) that accompanied decreases in concentrations of the strong mineral acid anions,  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$ . The difference between calculated ANC and Gran titrated ANC was generally consistent with trends of increasing DOC. [Waller et al. \(2012\)](#) concluded that assessments of surface water recovery from previous acidification should consider differences in DOC concentration and in the manner in which ANC is calculated and quantified.

Interpretation of long-term trends in Adirondack surface water chemistry, as summarized above, has also been augmented by results of repeated surveys of the chemistry of lakes initially surveyed several decades previously. [Warby et al. \(2008\)](#) resurveyed 113 lakes throughout the Northeast in 2001 that had previously been sampled by the U.S. EPA in 1986 to assess chemical recovery from lake acidification. Decreases in total Al and inorganic Al concentrations were widespread and largest in the Adirondack Mountains (−2.59 to −4.60  $\mu\text{mol/L}$ ). In 2001, only 7 study lakes (representing 130 lakes in the population) had inorganic Al concentrations above a toxic limit of 2  $\mu\text{mol/L}$ , compared with 20 sampled lakes (representing 449 lakes in the population) in 1986. Thus, it was estimated that in 2001 more than 300 northeastern lakes no longer had summer inorganic Al concentrations at levels considered harmful to aquatic biota.

---

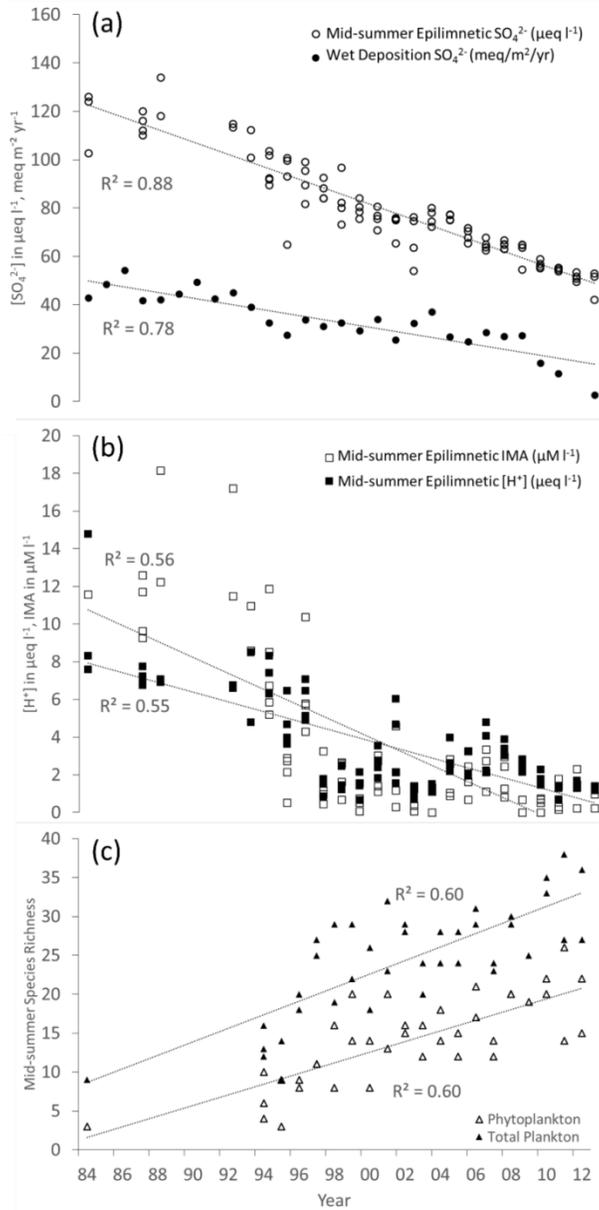

#### 16.2.4.2 Recovery

Biological recovery from past acidification is a process affected by chemical, climatic, biological, and hydrologic influences over time. It may, under certain conditions, follow chemical recovery of such water quality constituents as pH, ANC, and the concentrations of  $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ , inorganic Al, and DOC. Both chemical and biological recovery can, and often does, lag behind changes in the levels of S and/or N emissions and deposition because of chemical, hydrological, and biological processes and constraints. Studies at Honnedaga Lake and Brooktrout Lake in the Adirondacks show evidence for return of biota to levels approaching preacidification levels ([Sutherland et al., 2015](#); [Josephson et al., 2014](#)). In Brooktrout Lake, biological recovery of the food web structure has begun, in part, due to reintroduction and re-establishment of brook trout in the lake. However, ongoing biological recovery cannot necessarily be expected to conclude with the return of the biological community to preacidification conditions. The reason is due to factors such as differences in the rate of recovery of aquatic organisms, permanent loss of some acid-sensitive species, and irreversible chemical and physical alterations to aquatic environments during acidification ([NAPAP, 2011](#)).

Since the 2008 ISA, some paleolimnological studies have been conducted that documented historical acidification and subsequent recovery (see [Appendix 8](#)). In one study from the U.S., diatom shifts were linked to historical changes in pH at Brooktrout Lake in the Adirondacks. *Fragilariforma acidobiontica*, a diatom that is often abundant at pH <5.0, was present in lake sediments deposited since the 1950s, and shifts in *Mallomonas* and *Synura* were also observed ([Sutherland et al., 2015](#)). In this study, phytoplankton and rotifer taxonomic richness showed substantial increases ([Figure 16-15](#)) in association with pronounced decreases in lake  $\text{SO}_4^{2-}$ ,  $\text{H}^+$ , and inorganic Al concentrations. In contrast, species richness of crustaceans changed little. [Sutherland](#)

[et al. \(2015\)](#) suggested that the absence of crustacean recovery may have been due to the severity of the initial stress and continuing toxic pH conditions during some seasons, and/or to a large population of predatory *Chaoborus* larvae present since the early 1980s when fish were absent from the lake. In another study, [Arseneau et al. \(2016\)](#) concluded that Adirondack lakes that were not previously acidified by acidic deposition will likely not recover to predisturbance chrysophyte community structure because of the influence of other stressors, including changes in climate.

Despite observed reductions in acidic deposition and improvement in water quality of New York lakes, [Baldigo et al. \(2016\)](#) found no evidence of widespread or substantial biological recovery of brook trout populations or broader fish communities in the Adirondack Mountains. The study focused on 43 lakes sampled by the Adirondack Lakes Survey Corporation during three time periods (1984–1987, 1994–2005, and 2008–2012). Metrics reflecting fish species richness, abundance of fish species, and abundance of brook trout did not change significantly over the 28-year period across the group of study lakes despite a significant average ANC increase and a decrease in inorganic Al over time. Fish species richness and catch of all fish species per net-night were positively related to lake chemistry reflecting some limited degree of biological recovery. The authors speculated that additional time may be needed for fish recolonization.

H<sup>+</sup> = hydrogen ion; IMA = inorganic monomeric aluminum;  $\mu\text{eq}$  = microequivalent;  $\mu\text{M}$  = micromolar; m = meter;  $\text{SO}_4^{2-}$  = sulfate; yr = year.

## 16.3 Southeastern Appalachia Case Study

---

### 16.3.1 Background

This case study focuses on the Great Smoky Mountain National Park and on several closely located Class I areas in North Carolina (Joyce Kilmer Forest, Linville Gorge, Shining Rock). These areas are representative of the southern Appalachian region and also have been the focus of research on the ecological impacts of historical and current NO<sub>x</sub> and SO<sub>x</sub> deposition. The case study summarizes literature published since 2008, although older studies are included when relevant (e.g., conducted in Class I areas for the purpose of investigating critical loads). The southern Appalachians are in the Eastern Temperate Forests ecoregion, so critical loads for the broader Level I ecoregion are also presented.

---

#### 16.3.1.1 Description of Case Study Region

This case study focuses on the southern Appalachian Mountains, with special emphasis on Great Smoky Mountains National Park (GRSM), located on the border between eastern Tennessee and western North Carolina. The park consists of 2,100 km<sup>2</sup> of mountain ridges and valleys and ranges over an elevation of 267 to 2,025 m ([Thornberry-Ehrlich, 2008](#)), with peaks at the highest elevations in the eastern U.S. The wide range in elevation, annual precipitation [140 cm in valleys and 215 cm on ridges and peaks; [Thornberry-Ehrlich \(2008\)](#)], and temperature [growing season temperatures are 10–15°C cooler on ridge tops and peaks than in valleys; [Lesser and Fridley \(2016\)](#)] within the park has allowed distinct terrestrial and aquatic communities to form at different elevations.

Geologically, the park is in the Blue Ridge physiographic province, where Cambrian crystalline quartzite forms ridges, and Precambrian metamorphic rocks underlie the valleys, particularly in the eastern part of the park. Carbonates and shales of the Valley and Ridge province underlie valleys in the western part of the park where deposits of dolomite provide substantial base cations to drainage water. The Anakeesta Formation sits at the highest elevation of the Great Smoky Group, which forms the crest of the mountains. The Anakeesta Formation contains iron sulfide minerals that contribute to soil solution and surface water sulfate; it has outcroppings at Clingmans Dome, Newfound Gap, and Chimney Tops, as well as at other high-elevation locations in the north-central section of the park.

Soils of the Blue Ridge tend to be thin and shallow, overlying steep terrain ([Thornberry-Ehrlich, 2008](#)). Park soils are highly weathered and, particularly on mountain tops and ridges, have substantial soil S adsorption capacity and limited base cation supply ([Elwood, 1991](#)). Linville Gorge Wilderness is also within the Blue Ridge Province, with soils that formed with low Ca, Mg, and K concentrations, in which base cation concentrations have further declined in response to acid deposition ([Elliott et al., 2013](#)).

There are 3,200 km of streams within the park's boundaries ([Nichols and Langdon, 2007](#)). Streams in the park are first through sixth order, and their chemistry is strongly influenced by geology and storm events, as well as by acidic deposition. In 2006, Tennessee listed 12 streams (67 km stream length) within GRSM as impaired under the Clean Water Act Section 303d, because mean stream pH was below 6.0 ([Fakhraei et al., 2016](#)). Streams in GRSM that have ANC between 50 and 200  $\mu\text{eq/L}$  (41%) are mostly influenced by limestone weathering and tend to be located in the western portion of the park ([Neff et al., 2009](#)). Most stream ANCs in the park (54.2%) are in the 0–50  $\mu\text{eq/L}$  range. Streams that have ANC near or below 0  $\mu\text{eq/L}$  (2.4%) are influenced by weathering of the Anakeesta Formation and are mainly located in the north-central portion of the park ([Neff et al., 2009](#); [Flum and Nodvin, 1995](#)). Within the park, hindcasting by PnET-BGC model simulations suggested that ANC in park streams in 1850 ranged from 28 to 107  $\mu\text{eq/L}$ , with lower ANC at higher elevations ([Zhou et al., 2015a](#)). In the broader southern Blue Ridge province, MAGIC model simulations hindcasted to 1860 suggested that 66 modeled streams had preindustrial ANC > 30  $\mu\text{eq/L}$ ; in 2005, 30% of the streams had ANC below that level ([Sullivan et al., 2011c](#)). Streams in the Blue Ridge region with ANC < 20  $\mu\text{eq/L}$  were underlain by siliceous bedrock, including sandstone and quartzite ([Sullivan et al., 2007b](#)).

Storm events cause episodic acidification in streams, with decreases in pH of 0.5 to 1.6 pH units in streams with ANC of <20  $\mu\text{eq/L}$  under high-flow conditions ([Lawrence et al., 2015b](#); [Deyton et al., 2009](#)). Stream chemistry responses to storm events varies by elevation within the park. At high elevations, stream pH decreased by as much 0.5–2.0 pH units during storm events in 1990–2008 ([Neff et al., 2009](#); [Cook et al., 1994](#)), and streams above 975 m in elevation had significantly lower pH and ANC and higher nitrate concentrations during storm events than did lower elevation streams ([Neff et al., 2013](#)). High-elevation streams (823–966 m elevation) in the Little Pigeon River watershed had lower ANC and pH during storm events and higher sulfate, nitrate, and organic acid anion concentrations than at low flow ([Deyton et al., 2009](#)). Streams in watersheds influenced by the Anakeesta Formation also had significantly lower pH and higher Al concentrations during storm flow ([Neff et al., 2013](#)).

GRSM historically received some of the highest deposition loads of NO<sub>x</sub> and SO<sub>x</sub> in the U.S. In the late 1980s, a monitor at 1,740 m elevation within the park estimated S deposition of approximately 2,200 kg S/ha/yr, about half of which was occult deposition ([Johnson and Lindberg, 1992](#)); long-term trends in deposition from a monitor placed at a lower elevation within the park are shown in [Figure 16-18](#) and [Figure 16-19](#). Much of the historically deposited N and S remains stored within park ecosystems, with N stored in soils, biomass, and coarse woody debris ([Cai et al., 2011b](#); [Creed et al., 2004](#)), and S adsorbed to soil ([Fakhraei et al., 2016](#); [Cai et al., 2011b](#)). The capacity of these compartments for storing N and S are not infinite, and the capacity to retain N has been exceeded in some areas (ecosystems have reached N saturation), as evidenced by increased nitrate leaching and acidification of some surface waters. This suggests that ecosystems are impaired by N deposition, and that there may be a lag time in ecosystem recovery if deposition is reduced ([Fakhraei et al., 2016](#); [Cai et al., 2011a](#)).

The range of elevation and precipitation within the park has allowed distinct terrestrial and aquatic communities to form at different elevations, making the park one of the most biologically diverse areas in North America. Furthermore, because the park remained unglaciated during recent ice ages, it served as a refugium for northern plant and animal species, as well as an evolutionary generator of new species. The All Taxa Biodiversity Initiative is an ongoing project that seeks to document all species within the park's boundaries, and as of March 2016, there were 19,260 species across all domains documented within the park (<https://www.dlia.org/smokies-species-tally>).

Land cover in this case study region is mostly hardwood forest; coniferous forest occurs primarily at the higher elevations in and around GRSM ([Figure 16-17](#)). Distributed in elevational zones from highest elevation to lowest, forest types in the park include spruce-fir forest, beech-yellow birch forest, pine-oak forest, hemlock forest, and cove hardwood forest. Different forest types may support endemic animal, plant, fungal, and lichen species, as well as more broadly distributed species. There are 831 species of lichens documented within the park (<https://www.dlia.org/smokies-species-tally>); lichens are some of the most sensitive organisms in terrestrial ecosystems to atmospheric deposition (see [Appendix 6.3.7](#)), and work in Eastern Temperate forests ([Cleavitt et al., 2015](#); [Will-Wolf et al., 2015](#)) suggests that high atmospheric deposition can negatively impact their condition, species richness, and community composition. The forests in the park support rich understory plant communities, which are sensitive to deposition effects such as shifts in mycorrhizal communities, competitive exclusion, and increases in herbivory, all of which can lead to declines in herbaceous species richness ([Simkin et al., 2016](#)).

A number of threatened and endangered species occur within the park ([Table 16-17](#)). GRSM is a key preserve for North American amphibian species ([Nickerson et al., 2002](#); [Hyde and Simons, 2001](#)), including salamander species which have seen their North American populations decline over the past half century ([Caruso and Lips, 2013](#)). The park's high biodiversity has been recognized by its designation as a UNESCO World Heritage Site and International Biosphere Reserve. The broader Tennessee-Cumberland region contains the highest diversity of freshwater mussel and crayfish species and the highest levels of aquatic species endemism in North America ([Abell et al., 1999](#)). Within the park, sampling between 1993 and 2001 found 90–168 genera of benthic macroinvertebrates in 13 different streams ([Milner et al., 2016](#)). A national analysis of federally listed species identified 49 aquatic and 4 terrestrial threatened or endangered species impacted by anthropogenic N in the U.S. Fish and Wildlife Service Region 4, which encompasses 10 southeastern states, including Tennessee and North Carolina ([Hernández et al., 2016](#)).

**Table 16-17 Species in the Southeast case study region that are listed as threatened or endangered or as a species of concern.**

Threatened and endangered species known or believed to occur in Great Smoky Mountains NP
<b>Mammals</b>
<ul style="list-style-type: none"> <li>• <i>Myotis septentrionalis</i>, northern long-eared bat—threatened</li> <li>• <i>Myotis sodalis</i>, Indiana bat—endangered</li> <li>• <i>Glaucomys sabrinus coloratus</i>, Carolina northern flying squirrel—endangered</li> </ul>
<b>Birds</b>
<ul style="list-style-type: none"> <li>• <i>Picoides borealis</i>, red-cockaded woodpecker—endangered</li> </ul>
<b>Fish</b>
<ul style="list-style-type: none"> <li>• <i>Etheostoma sitikuense</i>, Citico darter—endangered</li> <li>• <i>Noturus baileyi</i>, smoky madtom—endangered</li> <li>• <i>Noturus flavipinnis</i>, yellowfin madtom—threatened</li> </ul>
<b>Arthropods</b>
<ul style="list-style-type: none"> <li>• <i>Microhexura montivaga</i>, spruce-fir moss spider—endangered</li> </ul>

NP = national park.

Source: National Park Service <https://home.nps.gov/grsm/learn/nature/te-species.htm>.

A number of disturbances in the park can interact with acidic deposition to affect biodiversity. Invasive species alter the distribution of native species within the park; for example, native brook trout (*Salvelinus fontinalis*) have been displaced from approximately 75% of their historical range within park streams by rainbow trout (*Oncorhynchus mykiss*) introduced to the park in the early twentieth century for recreational fishing (Kanno et al., 2017). Recent eradication campaigns of rainbow trout and reintroduction of brook trout within a set of park streams showed that brook trout quickly re-established populations (Kanno et al., 2016). Both introduced and native pathogens are also changing plant communities within the park. Fraser fir is endemic to the Southeast and sensitive to acidic deposition, and 74% of remaining Fraser fir (*Abies fraseri*) forests are within GSMNP boundaries (Kaylor et al., 2017). The invasive balsam woolly adelgid (*Adelges piceae*) killed mature stands of Fraser fir which historically dominated the highest elevations of the park (Kaylor et al., 2017; Van Miegroet et al., 2007). The most recent survey of Fraser fir was conducted in the park in 2010 and found the highest elevation stands regenerating despite the continuing presence of the adelgid, suggesting some population recovery following reductions in acid deposition (Kaylor et al., 2017). Ongoing damage from the invasive hemlock woolly adelgid (*Adelges tsugae*) may kill the mature hemlock (*Tsuga* spp.) stands which grow along streams in the park and which regulate stream temperature by the dense shading they provide (Martin and Goebel, 2012). Recent research suggests that N deposition may alter beech (*Fagus grandifolia*) bark chemistry, making the trees more susceptible to mortality caused by beech bark disease (attack by beech scale, *Cryptococcus fagisuga*, followed by infection by fungal pathogens in the *Neonectria* genus), which was first detected in the park in 1993 (Cale et al., 2017). In addition to disturbances caused by plant pathogens, shifting wildfire frequency affects the distribution of plant communities within the park and the wider region. In late November 2016, a fire burning at Chimney Tops spread rapidly

north across the park and into the nearby cities of Gatlinburg and Pigeon Forge. The fire, aided by drought conditions and strong winds, burned 17,140 acres (<https://www.nps.gov/grsm/learn/chimney-tops-2-fire.htm>). Wildfire suppression was the policy of the Park from its founding in 1931 until 1996, when a program of prescribed burns was instituted in order to regenerate forests of fire-dependent oak and pine species on dry ridges ([Schwartz et al., 2016](#)).

Precipitation and temperature alter the responses of terrestrial and aquatic ecosystems to N and S deposition. Between 1900 and 2011, annual precipitation increased 10 cm while there was no overall trend in temperature over the same period of time at stations within GSMNP ([Lesser and Fridley, 2016](#)). At nearby Grandfather Mountain, NC, summer temperature increased by more than 1.4°C between 1956 and 2011 ([Soulé, 2011](#)). Changes in temperature may alter species distributions. For example, native brook trout inhabit about 970 km of stream length in GRSM, most of which is above 900 m elevation ([Neff et al., 2009](#)). Brook trout have disappeared from six high-elevation streams in the Little Pigeon River watershed ([Deyton et al., 2009](#); [Neff et al., 2009](#)). Simulation modeling by [McDonnell et al. \(2015\)](#) showed that acidification of streams may hinder the movement of southern Appalachian aquatic species (including brook trout) to colder, higher elevation habitats if stream temperatures rise.

Like GSMNP, Linville Gorge Wilderness (LGW) contains plant communities structured by elevation. LGW comprises 43.9 km<sup>2</sup> of mountain ridges and gorges that range over an elevation of 426 to 1,250 m. Forest cover in the gorge is 43% coniferous tree species and 55% deciduous tree species, in plant communities from low to high elevation of acidic cove, mesic oak-hickory, and xeric pine-oak or oak heath zones ([Kantola et al., 2016](#)). Soils in LGW formed from parent material with very low concentrations of Ca, Mg, and K; and historic acidic deposition has further depleted these nutrients while decreasing soil pH and increasing soluble aluminum ([Elliott et al., 2013](#)). Experimental addition of dolomitic limestone resulted in transient improvements in soil Ca:Al ratios, while wildfire, which can release base cations from biomass into the soil, had no measurable impact on Ca pools in soils ([Elliott et al., 2013](#)). Between 1992 and 2011, forest structure in LGW shifted towards trees in younger age classes, as outbreaks of beetles and hemlock wooly adelgid, drought, and wildfire caused mortality in older and larger age classes of trees ([Hagan et al., 2015](#)).

---

### 16.3.1.2 Legal Authorities

GRSM is a Prevention of Significant Deterioration (PSD) Class I Area. The CAA (42 USC 7470) authorized Class I areas to protect air quality in national parks over

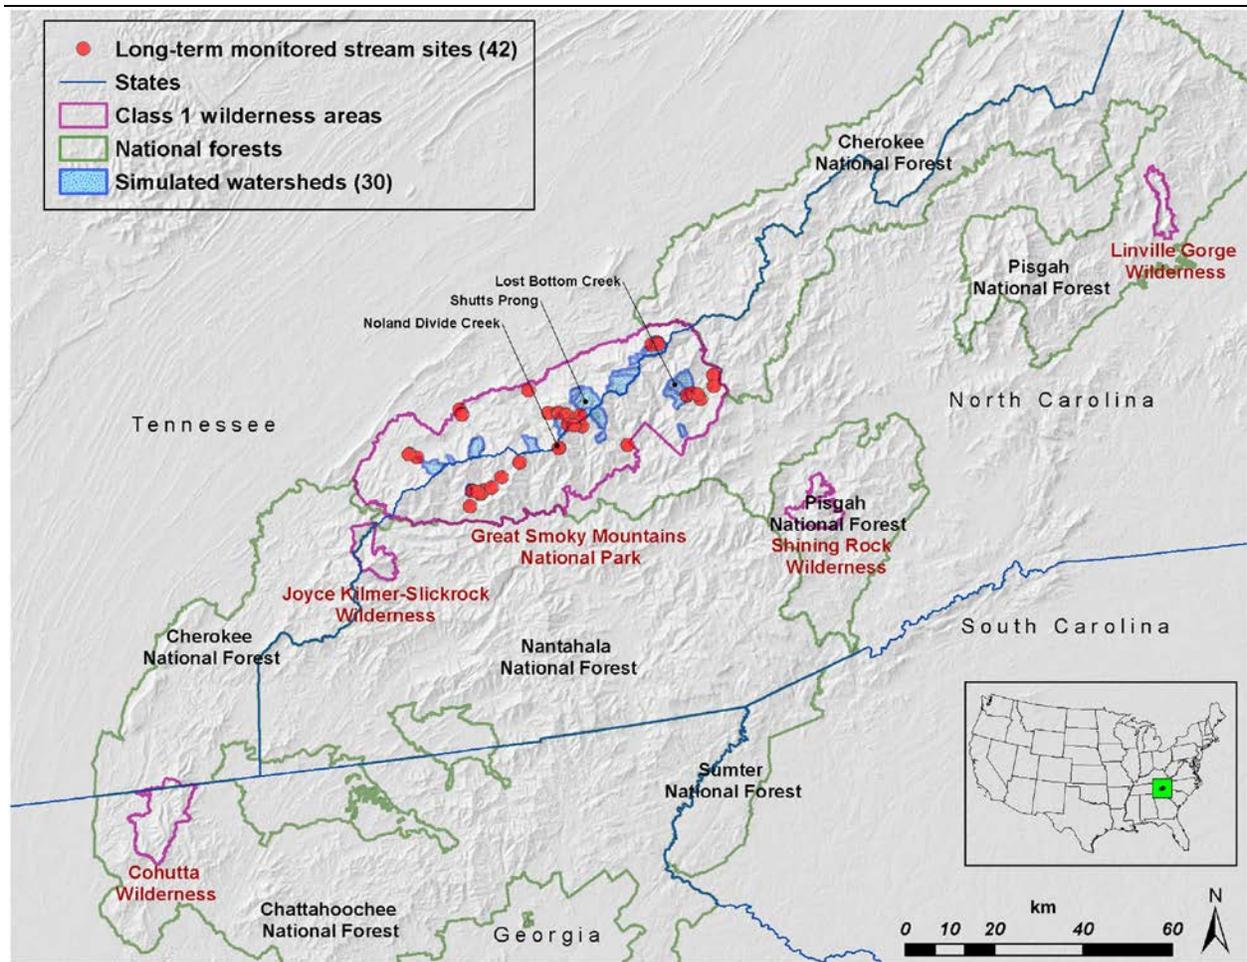

6,000 acres and national wilderness areas over 5,000 acres in an effort to preserve pristine atmospheric conditions and air quality related values (AQRVs).

Wilderness areas in North Carolina located in the vicinity of GRSM that also have been designated PSD Class I include Shining Rock, Linville Gorge, and Joyce Kilmer Memorial Forest. All are managed by the USDA's U.S. Forest Service. Shining Rock consists of 74 km<sup>2</sup> of high elevation (1,450–1,550 m) hardwood forests dominated by yellow birch and red maple on soils formed in gneissic bedrock. Linville Gorge is 43.9 km<sup>2</sup> of acidic cove and slope forests at intermediate elevations (1,090–1,160 m) dominated by chestnut oak and red maple on quartzite parent material. Joyce Kilmer Memorial Forest is 68.1 km<sup>2</sup> of low elevation (250–450 m) cove hardwoods, dominated by tulip poplar, oaks, and eastern hemlock stands, on metasandstone parent material. Additional information on these three wilderness areas is in [Elliott et al. \(2008\)](#). The geography of the Class I wilderness areas described in this case study are shown in [Figure 16-16](#); further details on this study can be found in [Appendix 16.2.3.2](#).

Class I areas are subject to the PSD regulations under the CAA. PSD preconstruction permits are required for new and modified existing air pollution sources. Air regulatory agencies are required to notify federal land managers (FLMs) of any PSD permit applications for facilities within 100 km of a Class I area.<sup>1</sup> The FLMs are entitled to review and comment on PSD Class I permit applications with the authorized permitting agency. Information on air quality monitoring by NPS within GRSM is available at the GRSM Air Quality website (<https://www.nps.gov/grsm/learn/nature/air-quality.htm>).

**Figure 16-16** Great Smoky Mountains National Park and nearby Class I wilderness areas, with emphasis on water sampling locations within GSMNP and critical loads for watersheds described in [Appendix 16.2.3.2](#).

### 16.3.1.3 Regional Land Use and Land Cover

Land cover in this case study region is mostly hardwood forest; coniferous forest occurs primarily at the higher elevations in and around GRSM ([Figure 16-17](#)). Although located generally downwind of populous areas, GRSM has only a few human population centers of any magnitude nearby. They include Knoxville, TN, 30 mi from the park (pop. 181,000); Asheville, NC, 30 mi (pop. 87,000); Johnson City, TN, 70 mi (pop. 64,000); and Greenville, SC, 90 mi (pop. 61,188).

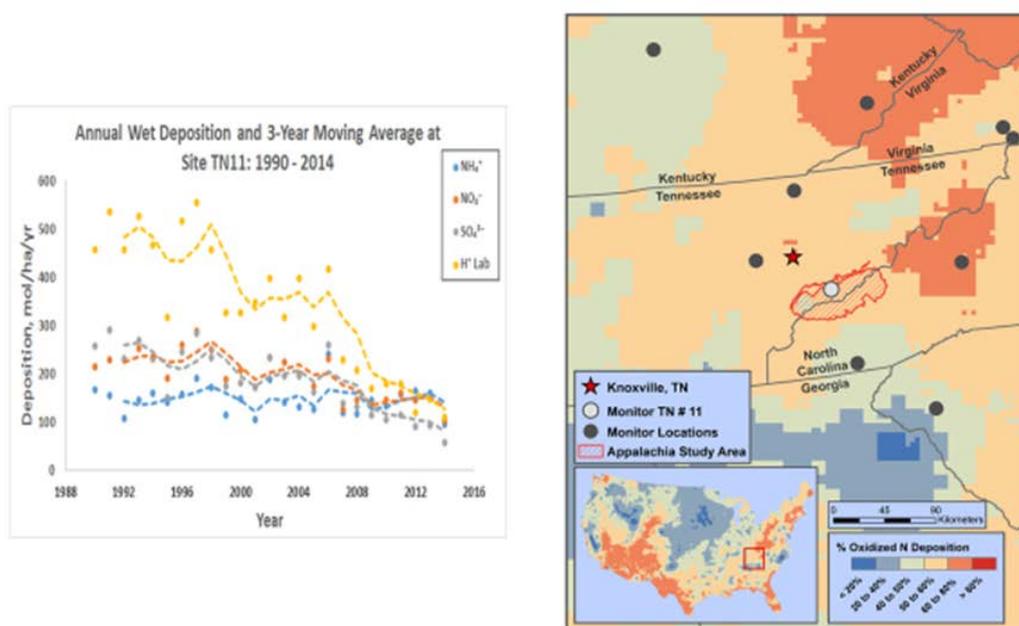

**Figure 16-17** Land cover in the southern Appalachian Mountains case study region.

### 16.3.2 Deposition

The highest elevations of the park have received some of the highest rates of acidic deposition in the U.S. (Weathers et al., 2006; Herlihy et al., 1993) due largely to the location of upwind power plants, major agricultural regions, and the substantial amount of annual precipitation.

Characteristics of nitrogen and sulfur deposition affecting the Great Smoky Mountains Study Area are shown in [Figure 16-18](#)–[Figure 16-21](#). Data shown in [Figure 16-18](#)–[Figure 16-23](#) were obtained from the hybrid modeling/data fusion product, TDEP, <http://nadp.slh.wisc.edu/committees/tdep/tdepmaps/> and described earlier in

[Appendix 2.7](#). However, the time series of wet deposition is taken directly from data on the NADP/NTN website. This was done to use the long-term record of wet deposition to illustrate trends in deposition since the passage of the Clean Air Act Amendment, because the CMAQ dry deposition simulations involved in estimating TDEP total deposition extend back only to 2000. [Figure 16-18](#) shows the 25-year-long time series for wet deposition for  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ ,  $\text{SO}_4^{2-}$ , and  $\text{H}^+$  measured at the NADP/NTN monitoring site Great Smoky Mountain NP (TN11), as well as the partitioning between oxidized and reduced N Deposition of nitrogen, which is estimated to be mostly in oxidized form in the study area. Although most of the area in [Figure 16-18](#) is subject to N deposition in oxidized form, there are areas, principally in northern Georgia, where N is deposited mainly in reduced form. The graph of wet deposition of all chemical species shows that downward trends in  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ ,  $\text{SO}_4^{2-}$ , and  $\text{H}^+$  are consistently found over the past 25 years, although the rate of decrease has been irregular, with occasional increases.

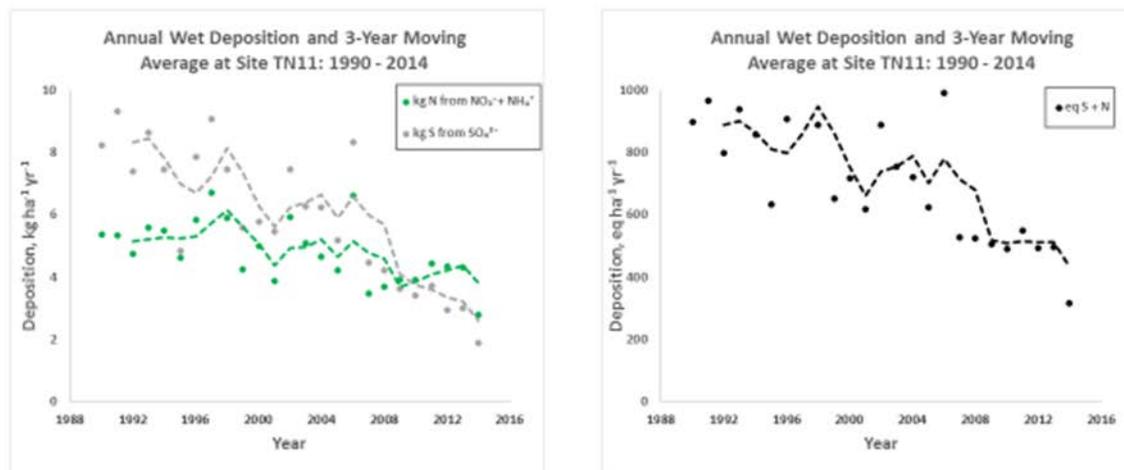

$\text{H}^+$  = hydrogen ion; ha = hectare; mol = mole; N = nitrogen;  $\text{NH}_4^+$  = ammonium;  $\text{NO}_3^-$  = nitrate;  $\text{SO}_4^{2-}$  = sulfate; yr = year.

Notes: on the left, trends in wet deposition, 1990–2014. On the right, partitioning between reduced and oxidized forms of N in deposition in 2011–2013.

Source: NCEA based on data from TDEP.

**Figure 16-18 Deposition over Great Smoky Mountain National Park.**

[Figure 16-19](#) shows the 25-year-long time series for wet deposition of N and S in terms of units commonly used to determine critical loads within GSMNP. Critical loads for eutrophication are commonly expressed in terms of kg N/ha/yr. Critical loads for acidification are commonly expressed in terms of kg S/ha/yr, or because both N and S deposition can contribute to acidification, in terms of eq/ha/yr.

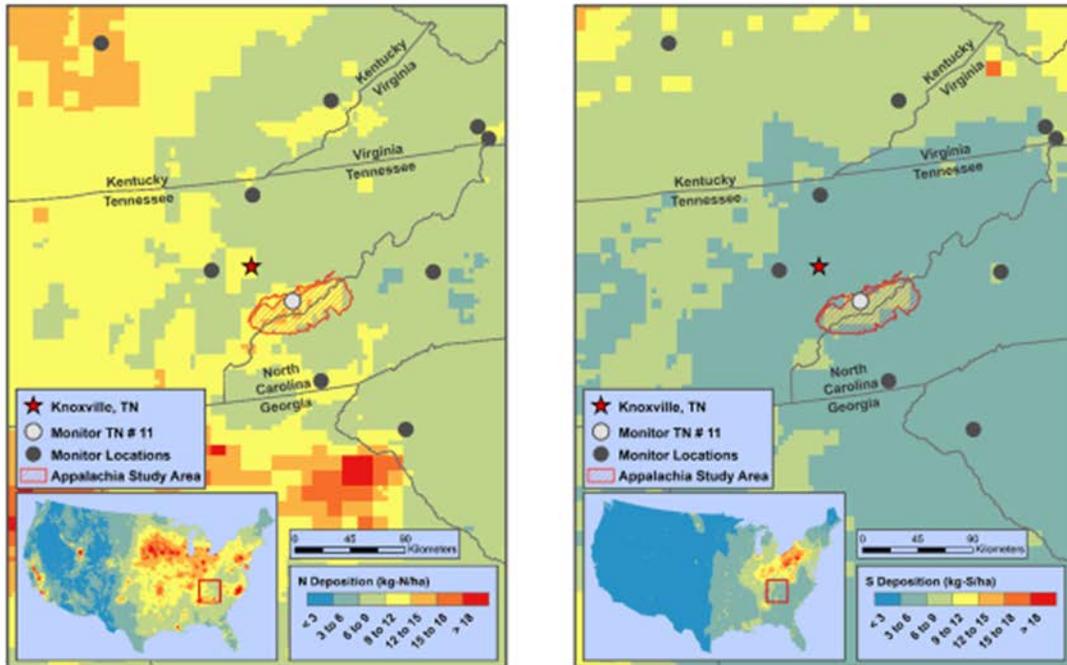

eq = H<sup>+</sup> equivalents; ha = hectare; kg = kilogram; N = nitrogen; NH<sub>4</sub><sup>+</sup> = ammonium; NO<sub>3</sub><sup>-</sup> = nitrate; S = sulfur; SO<sub>4</sub><sup>2-</sup> = sulfate; yr = year.

Notes: On the left, N and S deposition are shown in units of kg/ha/yr of N or S. On the right, N and S deposition are combined into units of acidifying deposition, eq/ha/yr of S + N.

Source: NADP/NTN.

**Figure 16-19 Trends in wet deposition of nitrogen and sulfur in Great Smoky Mountain National Park, 1990–2014.**

[Figure 16-20](#) shows the 3-year average total deposition of N and S for 2011–2013. Surrounding areas in southern states and inserts showing the coterminous U.S. are shown to place the depositional environment in context. Comparison of maps indicates that the general pattern of deposition of N and S is broadly similar, with higher values within the study area than outside of it. Current rates of deposition of S are considerably lower than along the Ohio River Valley, which might be expected given that the Ohio River Valley is a major industrial region, and GRSM is a national park. Wet and dry deposition of S were roughly equal across the study area. See [Appendix 2.4](#), [Appendix 2.5](#), and [Appendix 2.6](#) for more information on deposition in the U.S. Other maps showing the contributions of individual species to dry and/or wet deposition, based on TDEP are given in [Appendix 2.7](#).

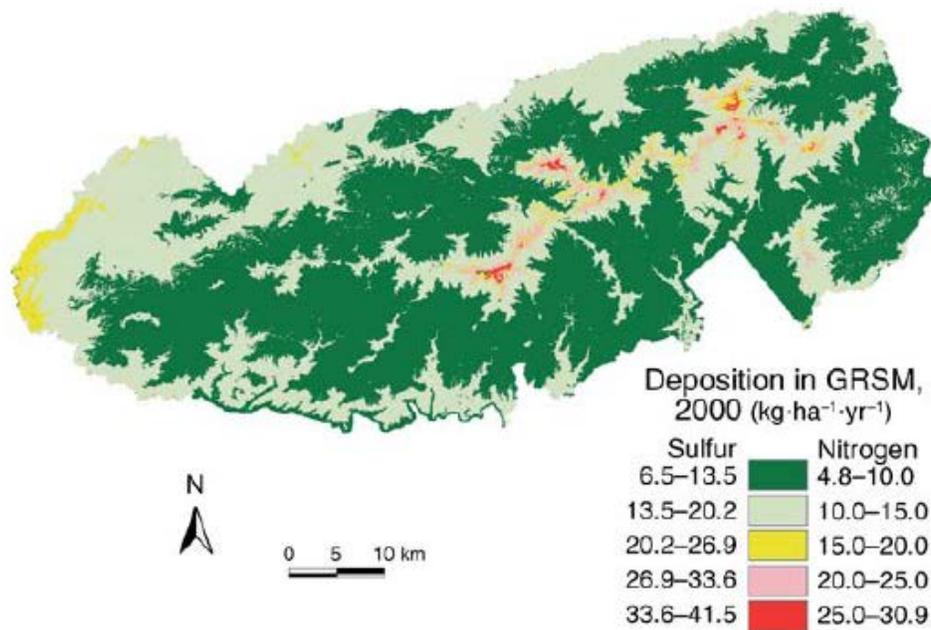

ha = hectare; kg = kilogram; N = nitrogen; S = sulfur.

**Figure 16-20** Total nitrogen deposition on left, total sulfur deposition on right, for the 3-year average, 2011–2013 in Great Smoky Mountain National Park.

The Great Smoky Mountain National Park NADP/NTN monitoring site (TN11) was chosen to characterize long-term wet deposition of N and S species in the study area. [Figure 16-18–Figure 16-20](#) are based on data for wet deposition from the TN11 monitor, which is located in low-elevation hardwood forest within the park. [Weathers et al. \(2006\)](#) mapped deposition in 2000 in the park at a finer scale and showed that deposition rates at higher elevations (see [Figure 16-21](#)) were roughly two to five times higher than at the low-elevation NADP monitor site.

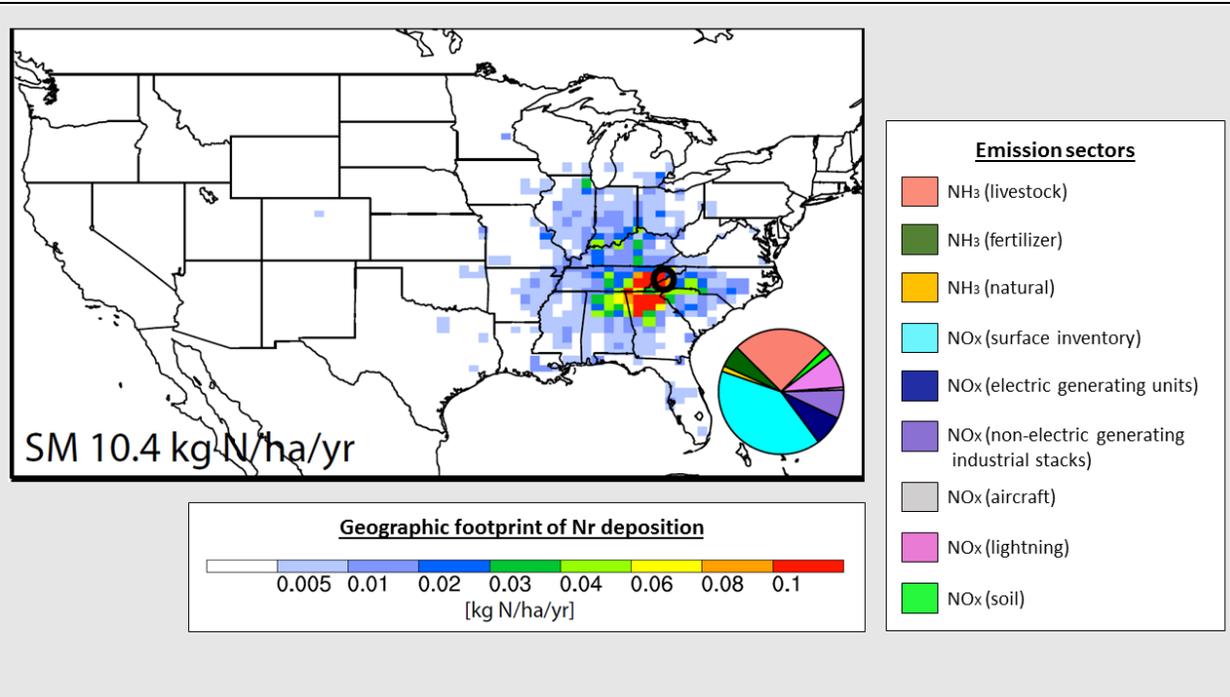

A recent modeling study of Class I areas, including GSMNP, used a GEOS-Chem adjoint model to identify the geographic sources of reactive N deposition, as well as the emission sector sources of reactive N deposition within the park ([Lee et al., 2016](#)). Emissions of Nr that affect GSMNP originate as far as 1,500 km from the park, and mobile sources of NO<sub>x</sub> are the major emission source (40%) to N deposition within GSMNP (see [Figure 16-22](#)).

GRSM = Great Smoky Mountain National Park; ha = hectare; kg = kilogram; yr = year.

### 16.3.3 Critical Loads and Other Dose-Response Relationships

The following sections describe critical loads determined for the Great Smoky Mountains National Park, for the larger southern Appalachian region, or for the Level I ecoregion in which the park resides, the Eastern Temperate Forests.

#### 16.3.3.1 Empirical Studies

Thresholds of deposition are quantified for GRSM and the broader region. Sampling of soil and streams at high elevations in the park in the mid-1990s found elevated extractable inorganic N concentrations at high elevations ([Garten, 2000](#)), as well as substantial nitrate leaching in streams from these watersheds ([Van Miegroet et al., 2001](#)). Because NO<sub>x</sub> deposition was determined by [Van Miegroet et al. \(2001\)](#) in the watersheds

to be 32 kg N/ha/yr, [Gilliam et al. \(2011a\)](#) stated that the nitrate leaching critical load would be <32 kg N/ha/yr. Additional water quality critical loads for the park are based on models (see below). The comparable critical load set for leaching in the Eastern Temperate Forests is 8 kg N/ha/yr, which is lower than the [Gilliam et al. \(2011a\)](#) value. This critical load is set to protect hardwood forest soils from NO<sub>3</sub><sup>-</sup> leaching to surface water and is based on a synthesis of data across northeastern forests ([Aber et al., 2003](#)). This quantity is in agreement with an earlier recommendation for Class I wildernesses in the Forest Service's eastern region that N deposition should not exceed 5–8 kg N/ha/yr to protect terrestrial biota ([Adams et al., 1991](#)). That report also recommended an annual load for total sulfur deposition not to exceed 5–7 kg S/ha/yr to protect terrestrial biota ([Adams et al., 1991](#)). The critical loads set by [Adams et al. \(1991\)](#) were based on observations across Class I wildernesses in the Forest Service eastern region; the deposition limits were based on the deposition loads of three Class I areas where eutrophication and acidification were not observed.

A number of additional empirical critical loads have been set for the Eastern Temperate Forests ecoregion based on protection of sensitive biota from the effects of nitrogen deposition ([Gilliam et al., 2011a](#); [Pardo et al., 2011a](#)). A critical load of >3 kg N/ha/yr protects growth rates or survivorship of sensitive tree species, including red pine, yellow birch, scarlet and chestnut oaks, quaking aspen, and basswood. A critical load of 4–8 kg N/ha/yr was set for Eastern Temperate Forests based on extrapolation from data collected in Northwest forests to preserve sensitive lichen species and prevent lichen community composition shifts towards more eutrophic species. A critical load of 5–10 kg N/ha/yr protects ectomycorrhizal fungi associated with coniferous tree species from community composition change. A critical load of <12 kg N/ha/yr protects arbuscular mycorrhizal fungi associated with hardwood tree species from decreases in abundance and community composition change. A critical load of <17.5 kg N/ha/yr protects forest understory communities from herbaceous species loss and shifts in plant community composition. These critical loads (3–17.5 kg N/ha/yr) represent protection for a broad range of sensitive terrestrial species within the Eastern Temperate Forest ecoregion ([Gilliam et al., 2011a](#); [Pardo et al., 2011a](#)).

Two more recent studies document empirical critical loads for the broad Eastern Temperate Forest ecoregion. [Cleavitt et al. \(2015\)](#) conducted surveys and used FIA assessments of lichen species in the Northeast, with particular focus on the four Class I wilderness areas in the region (Lye Brook, VT; Great Gulf, NH; Presidential Range—Dry River, NH; and Acadia National Park, ME). In general, cumulative N and S deposition over the course of the modeled period (2000–2013) was a more powerful explanatory factor than annual N or S load for the lichen data. This work determined a critical load of 4.3–5.7 kg total N (oxidized + reduced N)/ha/yr based on lichen species richness, the

abundance of sensitive species (higher species richness of cyanolichens and fruticose lichens below CL), and thallus condition. Cumulative S and N deposition were both equally powerful predictors of thallus condition, but no S critical load was determined (Cleavitt et al., 2015). A study by Simkin et al. (2016) used FIA data to determine critical loads for herbaceous species in a national assessment. The critical load for this analysis was placed to prevent any loss of herbaceous species richness and was determined to be 7.8–19.3 kg N/ha/yr for closed-canopy forest herbaceous communities in the Eastern Temperate Forest ecoregion. The critical load determined for open-canopy (grassland, shrubland, and woodland) herbaceous communities in this ecoregion was lower, 6.6–9.7 kg N/ha/yr (Simkin et al., 2016). These critical load estimates may be too high for GRSM, as Simkin et al. (2016) determined that critical loads tended to decrease under conditions of low soil pH, high precipitation, and high temperatures, all of which affect park ecosystems (Appendix 6.2.3.2).

---

### 16.3.3.2 Modeling Studies

Some of the critical loads modeled for GSMNP are aimed to protect terrestrial ecosystems from N saturation and associated acidification. The Integrated Forest Study sampled forests across North America, and several plots were located at high elevations within GSMNP. A critical load of 2.5–9 kg N/ha/yr was determined for the park using SMB modeling (Oja and Arp, 1998). A decade later, Pardo and Duarte (2007) used SMB and data from GRSM to determine critical loads for different forest types within the park. Critical loads of 2.7–2.8 kg N/ha/yr to prevent terrestrial ecosystem eutrophication were determined for low- and mid-elevation hardwood forests within the parks, while the critical load for high-elevation spruce-fir forests was 3.4–7 kg N/ha/yr. Pardo and Duarte (2007) also developed critical loads to protect GSMNP forests from acidification based on pH, Al, and base cation threshold values. In low-elevation hardwood forests, the most protective critical load was 1,080 eq S + N/ha/yr; in mid-elevation hardwood forest, the most protective critical load was 1,650 eq S + N/ha/yr; and in high-elevation spruce-fir forest, the most protective critical load was 2,000 eq S + N/ha/yr (Pardo and Duarte, 2007).

Critical loads of N and S deposition to protect aquatic ecosystems depend upon underlying geology, elevation, and sensitivity of streams (i.e., preindustrial ANC) in the southern Appalachian Mountains (Sullivan et al., 2011b). A recent application of the PnET-BGC model was used to determine target loads to protect aquatic ecosystems in 12 streams within GSMNP from acidification. The target load to achieve a target ANC of 50 µeq/L by 2050 was deposition of 270–1,400 eq (S + N)/ha/yr in streams at <1,000 m elevation and which did not drain watersheds within the Anakeesta Formation (Zhou et

[al., 2015a](#)). In an acid-sensitive, high-elevation watershed with drainage from the Anakeesta Formation, no reduction in deposition was sufficient to reach a target of ANC = 50  $\mu\text{eq/L}$ , but a target load of 270 eq (S + N)/ha/yr resulted in ANC recovery to 0 by 2050 ([Zhou et al., 2015a](#)). In a follow-up analysis, [Fakhraei et al. \(2016\)](#) and [Fakhraei et al. \(2017a\)](#) determined total maximum daily loads of acid deposition for each of the twelve 303(d)-listed stream watersheds at high elevations within the park. The target date for recovery to pH of 6.0 was 2150 for these model runs, and critical loads ranged between 240 and 960 eq/ha/yr of  $\text{SO}_4^{2-} + \text{NO}_3^- + \text{NH}_4^+$  deposition to eight of the twelve watersheds. For the remaining four watersheds, no reduction in deposition was sufficient to achieve pH of 6 by 2150; recovery in these streams is projected to take centuries ([Fakhraei et al., 2017a](#)). These target loads are in good agreement with critical loads set for S only deposition based on MAGIC and Steady-State Water Chemistry (SSWC) modeling for the broader southeastern Appalachian region ([McDonnell et al., 2014b](#)). The S only critical load was based on achieving a target stream ANC of 50  $\mu\text{eq/L}$ , and for high elevations in the park, the critical load was 0–250 eq S/ha/yr. Most of the low-elevation area within the park had a critical load of 250–500 eq S/ha/yr by this method ([McDonnell et al., 2014b](#)).

---

#### 16.3.4 Characterization and Long-Term Monitoring

The majority of studies conducted in this case study region have evaluated the effects of acidification on ecosystems rather than the effects of eutrophication (see [Table 16-18](#)). Acidification has been considered to be the dominant result of air pollution stress in the region. Biogeochemical processes that govern watershed responses to acidification are generally similar between the Northeast and the southern Appalachian Mountains in most respects. The major exception is that soils in the southern Appalachians are unglaciated and therefore more weathered, with greater sulfate adsorption capacity, than soils in northeastern forests. [Cai et al. \(2010\)](#) used long-term monitoring data to generate an input-output budget to identify processes that have influenced stream pH and ANC at the Noland Divide watershed in Great Smoky Mountains NP during the period 1991–2006. The majority (about 61%) of the net  $\text{SO}_4^{2-}$  entering the watershed was retained, confirming that S adsorption on soil is an important biogeochemical process in this watershed. However, during large precipitation events,  $\text{SO}_4^{2-}$  in wet deposition moved more directly and rapidly to streams, contributing to episodic stream acidification. [Fakhraei et al. \(2016\)](#) projected that GRSM streams in watersheds with a low capacity to adsorb  $\text{SO}_4^{2-}$  and low N retention will respond positively (increase stream pH and ANC) to additional reductions in S and N deposition, while streams in watersheds with high  $\text{SO}_4^{2-}$  adsorption and low N retention (typically higher elevation watersheds) are less

responsive (or unresponsive) to reduced S and N deposition. In these watersheds, increases in soil pH due to reduced deposition are projected to increase desorption of accumulated  $\text{SO}_4^{2-}$  from soils, resulting in a  $\text{SO}_4^{2-}$  pulse to streams that will slow recovery of stream ANC and pH (Fakhraei et al., 2016). Monitoring data from the Great Smoky Mountains NP indicated that the high S absorption in watershed soils delayed recovery from previous stream acidification. Stream chemistry at 42 monitoring sites in the park did not show substantial changes over the recent period of long-term monitoring, 1991–2014 (Fakhraei et al., 2016).

## 16.4 Tampa Bay Case Study

### 16.4.1 Background

This case study provides an overview of the Tampa Bay estuary’s ecology and research related to nutrient impairments and nitrogen (N) deposition. It also reports on the improvements to the bay’s ecology being realized from strategies to reduce nutrient loading to the bay. Years of historical data going back to the 1950s and unique partnerships among government, industry, and citizen groups make Tampa Bay an interesting example of the varied issues involved in monitoring and managing water quality and N loading in an urban estuary. During the 1970s and early 1980s eutrophic conditions were commonly observed in Tampa Bay. Contrary to many other estuaries suffering from eutrophication worldwide, Tampa Bay appears to be recovering since the mid-1980s as a result of the nutrient management strategy defined by the community ([Greening et al., 2014](#); [Morrison et al., 2011](#)). These approaches have included upgraded sewage treatment, reduction of atmospheric N emissions, and controls on stormwater and point sources. Atmospheric deposition continues to be a source of N to Tampa Bay and, with the decreases in N loading from point sources, represents a greater proportion of total N loading to the bay ([Greening et al., 2014](#)). Estimates from both modeling and measurement indicate that direct atmospheric N deposition to Tampa Bay is between 14 and 30% while total (direct plus indirect) atmospheric deposition is between 35 and 71% ([Poor et al., 2013b](#); [Poor et al., 2013a](#); [Greening and Janicki, 2006](#)).

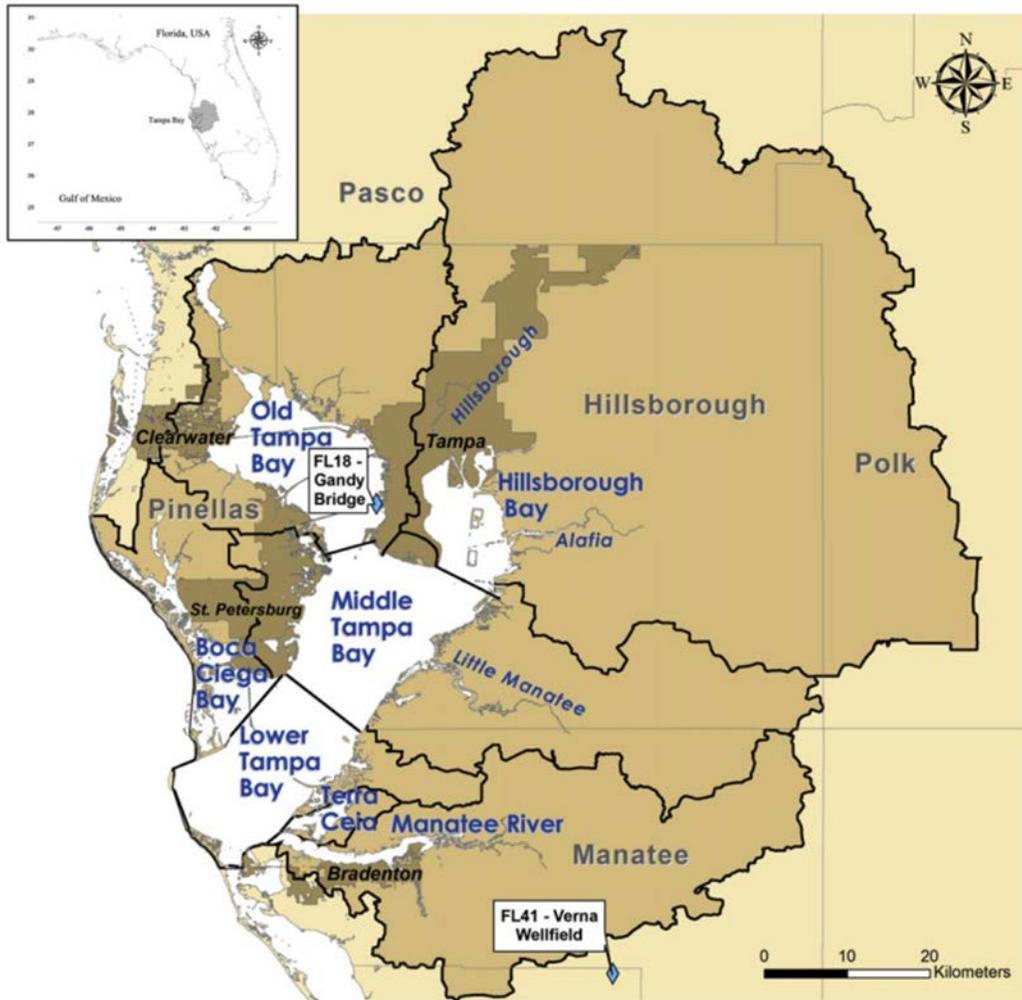

Information regarding sulfur deposition is not included in this case study because N is a primary contributor to nutrient enrichment and the focus of the monitoring studies used to compile this case study.

---

#### 16.4.1.1 Description of Case Study Region

The Tampa Bay estuary ([Figure 16-23](#)) is located on the eastern shore of the Gulf of Mexico in Florida. At more than 1,000 km<sup>2</sup>, it is Florida's largest open water estuary, with an average water depth of just 4 m and annual average rainfall rate of more than 125 cm ([TBEP, 2015](#); [Poor et al., 2013a](#); [TBEP, 2012b](#)). It lies in the Northern Gulf of Mexico marine ecoregion near the South Florida/Bahamian Atlantic marine ecoregion ([Wilkinson et al., 2009](#)). This transition zone between warm-temperate and tropical ecoregions, combined with its shallow waters, large size, and gradient of fresh water to salt water, allows the bay to support a diversity of organisms and habitats ([Greening et al., 2014](#); [USGS, 2011](#); [USFWS, 1990, 1988](#)).

Seagrass, a type of submerged aquatic vegetation (SAV), and mangrove forests are the most prominent estuarine habitats within Tampa Bay ([TBEP, 2015](#)). Tidal marshes and mud flats are also found throughout the estuary ([USGS, 2011](#)). Collectively, these habitats support a large biodiversity of flora and fauna and play a role in nutrient cycling. Seagrasses stabilize sediments, are a food source for wildlife, provide habitat, and serve as a nursery for large numbers of fish and shellfish species ([Greening et al., 2014](#)). Mangrove roots help to stabilize the shoreline and provide nursery habitat for important fishery species. Mud flats and salt marshes in the bay provide habitat for wading birds, while oyster reefs near river mouths serve to naturally filter the water and attract recreational fish species, making them popular fishing spots ([TBEP, 2015](#)). Federally endangered West Indian manatees (*Trichechus manatus*), a migratory species, visit Tampa Bay seasonally to feed in the seagrass meadows. Other endangered species in the bay documented to be impacted by N enrichment include green turtle (*Chelonia mydas*) and Atlantic sturgeon [*Acipenser oxyrinchus*; [Hernández et al. \(2016\)](#)]. Three national wildlife refuges (Egmont Key, Passage Key, and Pinellas) are located in Tampa Bay and support populations of nesting birds.

Source: [Poor et al. \(2013a\)](#).

**Figure 16-23 Tampa Bay mainstem segments and watershed. Also shown are the National Atmospheric Deposition (NADP) National Trends Network wet deposition monitoring site FL41 at Verna wellfield in Sarasota County and the NADP Atmospheric Integrated Research Monitoring Network site FL18 in Hillsborough County.**

The Tampa Bay watershed, located in the Eastern Temperate Forest ecoregion, is highly urbanized. It is now the second largest metropolitan area in Florida with a population of over 2 million people ([TBEP, 2015](#)). Pinellas, Hillsborough, and Manatee counties border directly on Tampa Bay while Pasco, Polk, and Sarasota counties are also within the estuary's 6,000-km<sup>2</sup> watershed ([Poor et al., 2013a](#)). Activities in Tampa Bay linked to the local and regional economy include shipping, tourism, and commercial and recreational fishing ([Poor et al., 2013a](#); [TBEP, 2006](#); [Tomasko et al., 2005](#)). More than 80 miles of

deep-water shipping channels carry water traffic to the three seaports along the bay's borders, in Tampa, St. Petersburg, and in northern Manatee County. The largest of these, the Port of Tampa, consistently ranks among the busiest ports in the nation.

Mangroves, salt marshes, and SAV habitats in Tampa Bay have all experienced significant reductions in extent since the 1950s, due to physical disturbance (dredge and fill operations) and water quality degradation ([TBEP, 2015](#)). Excess N enrichment in the bay is one of the main factors impacting water clarity and quality. The excess N leads to increased algal biomass and reduced light availability for shallow-water (less than a 3-m depth) SAV ([TBEP, 2015](#)). Numerous studies have shown that the waters of Tampa Bay are strongly N limited, due to a high concentration of phosphorus (P) from natural leaching and from active P mining in the watershed ([Greening et al., 2014](#)). Therefore, the primary focus for managing eutrophication in Tampa Bay has been the reduction of N loading to the bay ([Greening et al., 2014](#)).

Tampa Bay was designated an “estuary of national significance” by Congress in 1990. In 1998, the Tampa Bay National Estuary Program (TBNEP) partnership (consisting of the Florida Department of Environmental Protection [FDEP]; the U.S. Environmental Protection Agency; the counties of Hillsborough, Manatee, and Pinellas; the cities of Tampa, St. Petersburg, and Clearwater; and the Southwest Florida Water Management District) signed a formal Inter-local Agreement in support of a Comprehensive Conservation and Management Plan (CCMP) for Tampa Bay. Upon adoption of the Inter-local Agreement, the TBNEP became simply the Tampa Bay Estuary Program (TBEP). TBEP continues to finance research projects in support of the CCMP and coordinates the overall protection and restoration of the bay with assistance and support from its many formal and informal partners ([TBEP, 2015](#); [Morrison et al., 2011](#)). TBEP also coordinates the Tampa Bay N Management Consortium (TBNMC), a public-private partnership working to reduce nitrogen loading to the bay and whose members include local governments (Tampa, St. Petersburg, and others) along with key industries bordering the bay, such as electric utilities, fertilizer manufacturers, and agricultural operations.

The Tampa Bay watershed's human population is expected to increase over the next decade and a 7% increase in N loading is projected to occur ([TBEP, 2012a](#)). To account for these increases, the TBEP and TBNMC have adopted a new 17-ton/year reduction target for total N loading, to offset expected increases in total nitrogen (TN) loading and maintain TN loading rates at average annual rates for 1992–1994.

#### **16.4.1.2 Class I Areas**

The Tampa Bay area is not a Clean Air Act Prevention of Significant Deterioration (PSD) Class I area.

---

#### **16.4.1.3 Regional Land Use and Land Cover**

Land use within the Tampa Bay watershed is mixed among undeveloped, agricultural, urban, and mining uses, including phosphate mining and fertilizer manufacturing. [Figure 16-24](#) shows the land coverage within the bay's border communities and watershed.

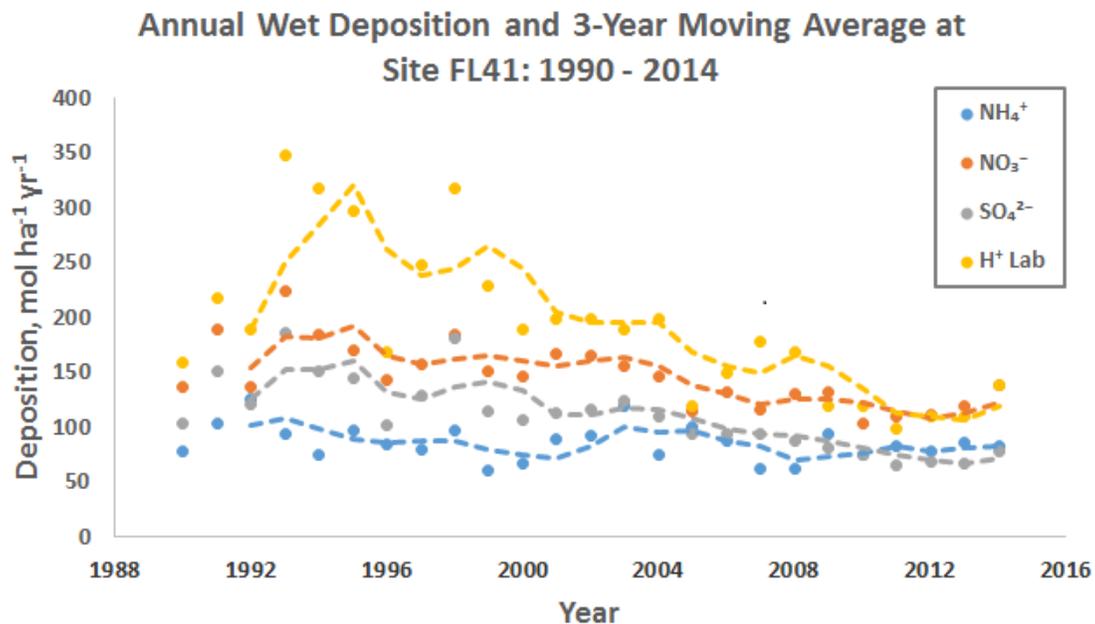

Source: [Sherwood et al. \(2016\)](#).

**Figure 16-24** Tampa Bay overview map highlighting watershed development and land use.

## 16.4.2 Deposition

Both direct atmospheric deposition of N to surface waters and indirect deposition to the watershed with subsequent transport to the Tampa Bay represent important sources of N to the case study area. In a 25-year time series with deposition data from the nearest National Atmospheric Deposition Program (NADP) National Trends Network (NTN) monitoring site ([Figure 16-23](#), Verna wellfield in Sarasota, FL), wet deposition of  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ ,  $\text{SO}_4^{2-}$ , and  $\text{H}^+$  show strong interannual variability, but downward trends in wet deposition of all these species are consistently found over the past 25 years ([Figure 16-25](#)).

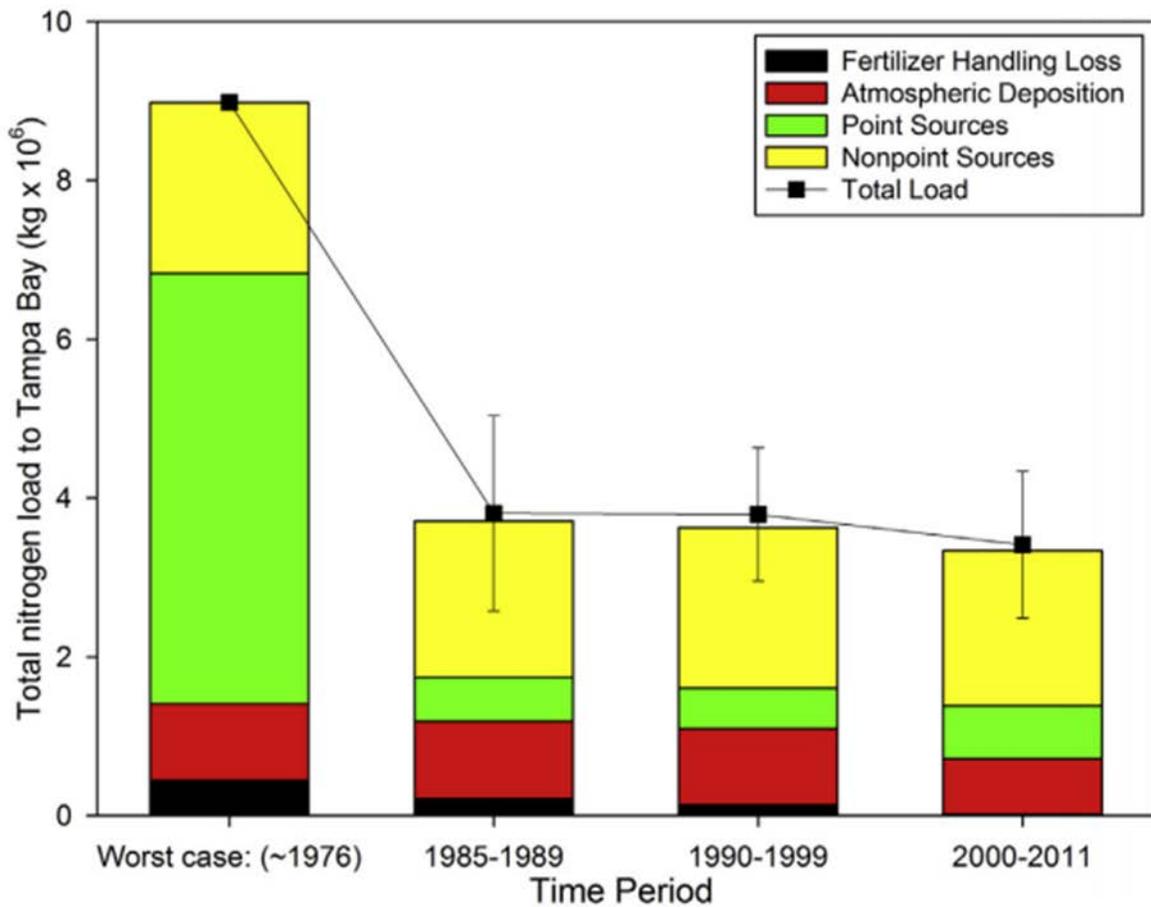

$\text{H}^+$  = hydrogen ion; ha = hectare; mol = mole;  $\text{NH}_4^+$  = ammonium;  $\text{NO}_3^-$  = nitrate;  $\text{SO}_4^{2-}$  = sulfate; yr = year.

Source: National Center for Environmental Assessment, U.S. EPA.

**Figure 16-25 Annual wet deposition of ammonium, nitrate, sulfate, and acidity at the National Atmospheric Deposition National Trends Network monitoring site closest to the Tampa Bay case study area.**

Between 2002 and 2007, U.S. EPA and Tampa Bay area scientists conducted an air quality modeling and measurement project called the Bay Region Atmospheric Chemistry Experiment (BRACE) in order to improve estimates of atmospheric N deposition to Tampa Bay ([Poor et al., 2013a](#); [Atkeson et al., 2007](#)). This project was also

established to identify sources of N deposition in the local Tampa Bay area and assess the impact of air quality regulations (Poor et al., 2013a). Although total nitrogen (TN) loading to Tampa Bay has trended downward over the past 20 years, the percentage of N from different sources has fluctuated. Direct atmospheric deposition has accounted for a greater average percentage of the TN loading in recent years (from 2007–2011) than in previous years [Greening et al. (2014); Poor et al. (2013a); Figure 16-26]. Mainstem segments of the bay vary widely in the percentage of total N loading attributable to direct atmospheric deposition (Janicki Environmental, 2013).

Source: [Greening et al. \(2014\)](#).

**Figure 16-26** Estimated annual loads of total nitrogen from various sources to Tampa Bay summarized from 1976 to 2011.

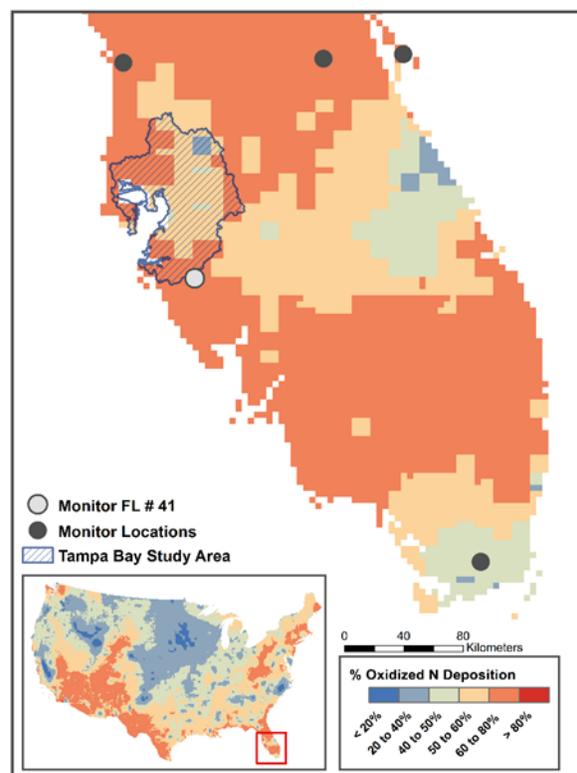

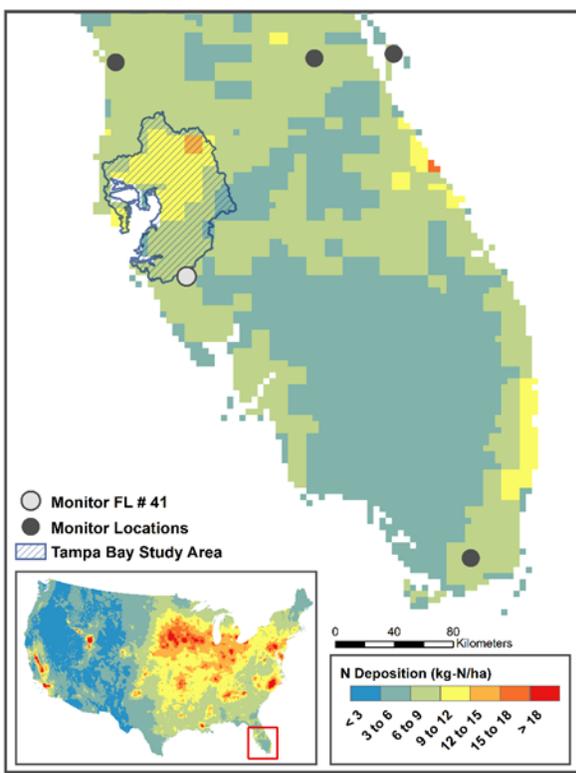

BRACE also investigated the primary sources of N deposition to the bay, which included power plants and mobile sources such as cars and trucks. Power plants had recently reduced N emissions through upgrades made as a result of TBEP's work with the TBNMC ([Poor et al., 2013a](#)). The sensitivity results suggested that, per unit of emission, mobile sources had a disproportionately higher contribution than power plant sources to atmospheric N deposition to Tampa Bay (over the watershed, the mobile NO<sub>x</sub> emissions were responsible for four times more oxidized-N deposition than the power plant emissions; over the bay, the mobile NO<sub>x</sub> emissions were responsible for twice as much oxidized-N deposition as the power plants). According to BRACE, reductions in N emissions from mobile sources must be a part of the strategy to reduce N loading to the bay, and that control of atmospheric N emissions both within and outside the Tampa Bay watershed is important to restore and maintain good water quality and a healthy ecosystem within the bay ([Poor et al., 2013a](#)).

The U.S. EPA recently modeled atmospheric deposition in Tampa Bay using TDEP with monitoring data from 2000 to 2013 (see [Appendix 2.7](#)). The general pattern of wet + dry deposition of N (NO<sub>y</sub> and NH<sub>x</sub>) for 2011–2013 shows that fluxes are higher in the northern half of the study area than the southern half ([Figure 16-27A](#)). The deposition of N varies by roughly a factor of two across the study area with higher deposition of N to the north and west of Tampa Bay and a maximum in the northeast corner of the study area. Fluxes are typically higher than those for the rest of Florida. However, they are not as high as in many areas of the central and northeastern U.S. Dry deposition of NO<sub>2</sub> accounts for approximately 1/6 of total deposition of oxidized N. At Tampa Bay (and some other NADP sites), dry fluxes are directed upward using the Community Multiscale Air Quality (CMAQ) model, due to the implementation of bidirectional exchange of NH<sub>3</sub>. (However, the net flux of NH<sub>x</sub> in CMAQ is still directed downward from wet deposition.).

Most N deposition in the case study area except for the northeastern corner is estimated to be mostly in oxidized form throughout the study area and in most of Florida, which is consistent with many areas in the eastern and southern U.S. ([Figure 16-27B](#)). This is generally in agreement with findings from BRACE modeling where oxidized forms of N made up 60% of the total atmospheric loading to Tampa Bay, compared to 40% for reduced forms such as ammonia [NH<sub>3</sub>; [Poor et al. \(2013a\)](#); [TBEP \(2012b\)](#)]. In the study area dry deposition dominates over wet deposition of N, which contrasts with many areas in southern Florida where wet deposition dominates ([Poor et al., 2013a](#)).

**A. Total Wet and Dry N Deposition in Southern Florida 2011-2013 (12 km resolution)**

**B. Percent Oxidized N Deposition in Southern Florida 2011-2013 (12 km resolution)**

ha = hectare; kg = kilogram; km = kilometer; N = nitrogen.

Notes: the Verna Wellfield National Atmospheric Deposition Program/National Trends Network monitoring site, FL41, was chosen to characterize long-term wet deposition of N species, because it is closest to the Tampa Bay study area. The site is located at the southern edge of the study area in Sarasota, FL and is shown as the grey dot on the maps.

Source: Data shown in the figures were obtained from the hybrid modeling/data fusion product, total deposition, <http://nadp.slh.wisc.edu/committees/tdep/tdepmaps/>, and described earlier in [Appendix 2.7](#).

**Figure 16-27 (A) Wet and dry nitrogen deposition in Tampa Bay and the surrounding area. (B) Percentage of oxidized nitrogen deposition in Tampa Bay and the surrounding area.**

**16.4.3 Long-Term Ecological Monitoring**

Tampa Bay has been intensively studied over the years due to its significance as a natural resource and its susceptibility to degradation from eutrophication. There is monthly ambient water quality data going back to 1972 ([Sherwood et al., 2016](#)). Phytoplankton biomass and primary production have been assessed regularly in the bay from the 1980s

and benthic organisms since 1993 ([Greening et al., 2014](#)). Aerial photography of the Tampa Bay shoreline is available from the early 1950s showing the extent of seagrass coverage prior to rapid human population increases in the watershed ([Greening et al., 2014](#)). A consistent monitoring program of seagrass extent (every 2 years) was started in 1988 ([Greening et al., 2014](#)).

Eutrophication symptoms were observed in Tampa Bay as early as the 1970s. These included phytoplankton and macroalgal blooms and areas of low dissolved oxygen ([Greening et al., 2014](#)). According to [Bricker et al. \(2007\)](#), algal blooms were common in the 1970s and caused foul odors and aesthetic impairment. In the late 1970s, hypoxic and anoxic conditions along the shoreline of the most urbanized segment of Tampa Bay caused extensive mortality of benthic organisms in the late summer months ([Greening et al., 2014](#)). Fish kills have also been observed in and near Tampa Bay. Historically, the most obvious symptom of eutrophication in Tampa Bay was the loss of light at depth due to elevated algal biomass. The loss of SAV from reduced light availability was dramatic. In 1950, approximately 16,000 hectares of SAV were present. By the early 1980s, over half of this area had been lost [[Figure 16-28](#); [Bricker et al. \(2007\)](#); [Haddad \(1989\)](#)].

Tampa Bay is somewhat unique in that the bay waters have historically exhibited a high level of P from local phosphate deposits, P mining, and fertilizer manufacturing and shipping operations. The high phosphorus concentrations have resulted in an unusually low N:P ratio in comparison to other estuaries, making N the limiting nutrient for phytoplankton growth ([Greening et al., 2014](#); [Greening and Janicki, 2006](#)). Numerous nutrient limitation studies using natural Tampa Bay phytoplankton populations and cultured test organisms have confirmed N limitation ([Greening et al., 2014](#)).

km = kilometer; mi = mile.

Notes: Red indicates area of submerged aquatic vegetation lost from 1950 to 1990.

**Figure 16-28** Submerged aquatic vegetation cover loss in Tampa Bay.

---

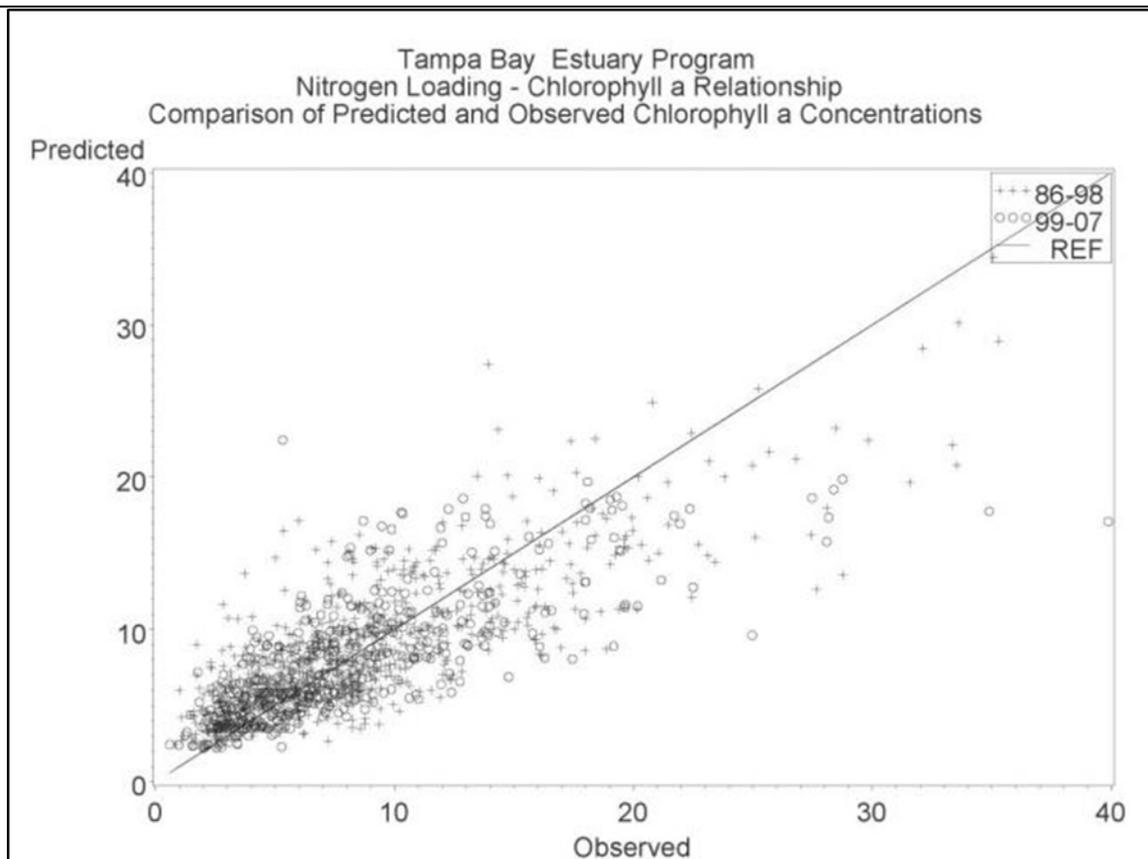

### 16.4.3.1 Indicators of Enrichment and Eutrophication in Tampa Bay

Indicators of historical water quality trends in the bay include chlorophyll *a* concentration and seagrass coverage ([Greening et al., 2014](#)).

### 16.4.3.1.1 Chlorophyll *a*

Phytoplankton biomass as measured by chlorophyll *a* concentration is one of the most effective indicators of eutrophication in the bay ([Sherwood et al., 2016](#)). Chlorophyll *a* is directly linked to nutrient inputs and has been measured in the bay since 1972. Increased algal biomass results in reduced light penetration in the water, thereby harming seagrass and ultimately resulting in the loss of SAV area.

The TBEP has developed water quality models to quantify linkages between N loads and bay water quality. N is generally the primary limiting nutrient, and chlorophyll *a* variation in the bay responds most significantly to watershed TN loads [[Figure 16-29](#); [Greening and Janicki \(2006\)](#)].

Source: [Janicki Environmental \(2011\)](#).

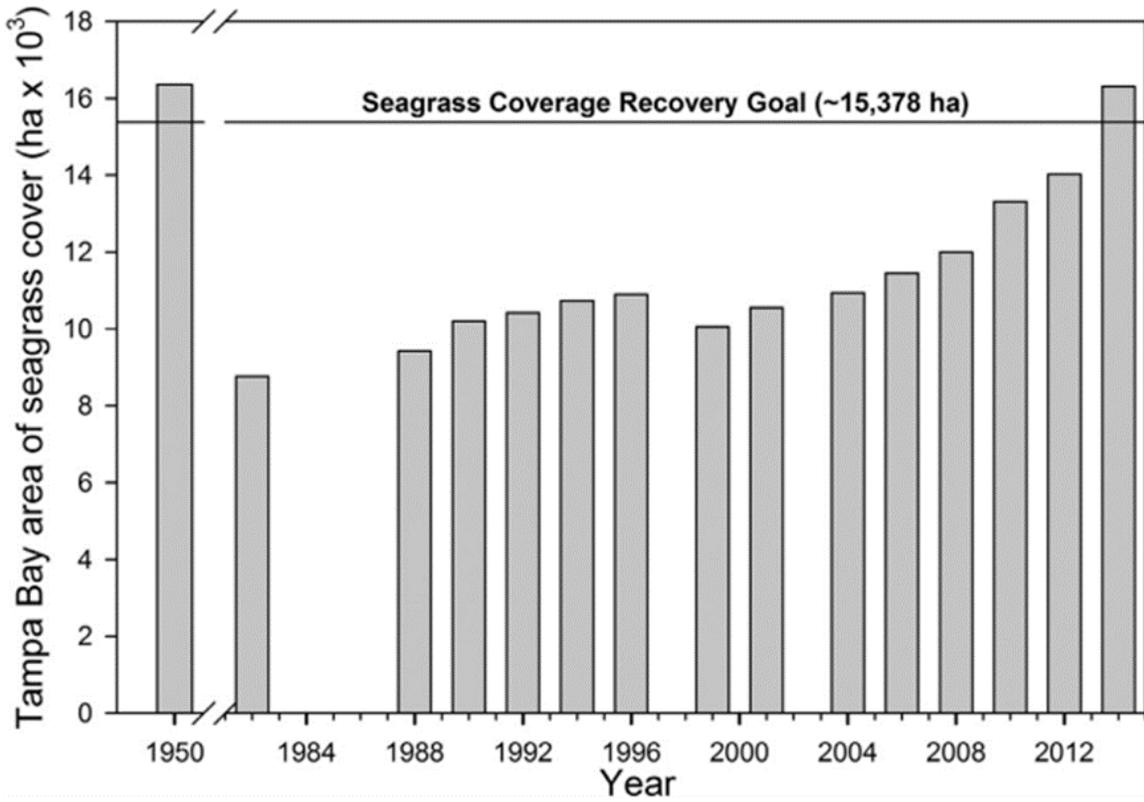

**Figure 16-29 Comparison of observed chlorophyll *a* and that predicted from the total nitrogen load—chlorophyll *a* relationships for all four mainstem Tampa Bay segments, for 1986–1998 and 1999–2007.**

Data show that, with the exception of the Old Tampa Bay segment in 2009 and 2011, chlorophyll *a* thresholds were not exceeded in all four major bay segments over the 2007–2011 period ([TBEP, 2012a](#)). The chlorophyll *a* threshold values are used as indicators of impairment and vary slightly for each different segment of the bay, ranging from 5.1 µg/L for Lower Tampa Bay, to 8.5 µg/L for Middle Tampa Bay, 9.3 µg/L for Old Tampa Bay, and 15 µg/L for Hillsborough Bay [expressed as annual averages; [TBEP \(2012a\)](#)].

#### 16.4.3.1.2 Seagrass Coverage

Five species of seagrasses, turtle grass (*Thalassia testudinum*), manatee grass (*Syringodium filiforme*), shoal grass (*Halodule wrightii*), star grass (*Halophila engelmannii*), and widgeon grass (*Ruppia maritima*), are found in Tampa Bay ([USGS, 2011](#)). These shallow-water grasses need sufficient light for photosynthesis and are sensitive to reduced water clarity associated with increased algal growth. Scientists have been tracking seagrass coverage as far back as the 1950s in Tampa Bay. Between the 1950s and 1980s seagrass coverage declined by about 50% or 9,000 ha in conjunction with decreased water quality and physical impacts to the bay such as dredging and filling ([Poor et al., 2013a](#); [Haddad, 1989](#)). Between 1999 and 2010, bay water clarity improved, chlorophyll *a* concentrations decreased, and seagrass coverage area steadily increased, coinciding with the reductions to N inputs to the bay [[Figure 16-30](#); [Greening and Janicki \(2006\)](#); [Poor et al. \(2013a\)](#); [TBEP \(2011\)](#); [TBEP \(2015\)](#)]. The most recent surveys of seagrasses (2014) exceeded the recovery goal set in 1995 [95% of estimated seagrass coverage of the 1950s; [Sherwood et al. \(2016\)](#)].

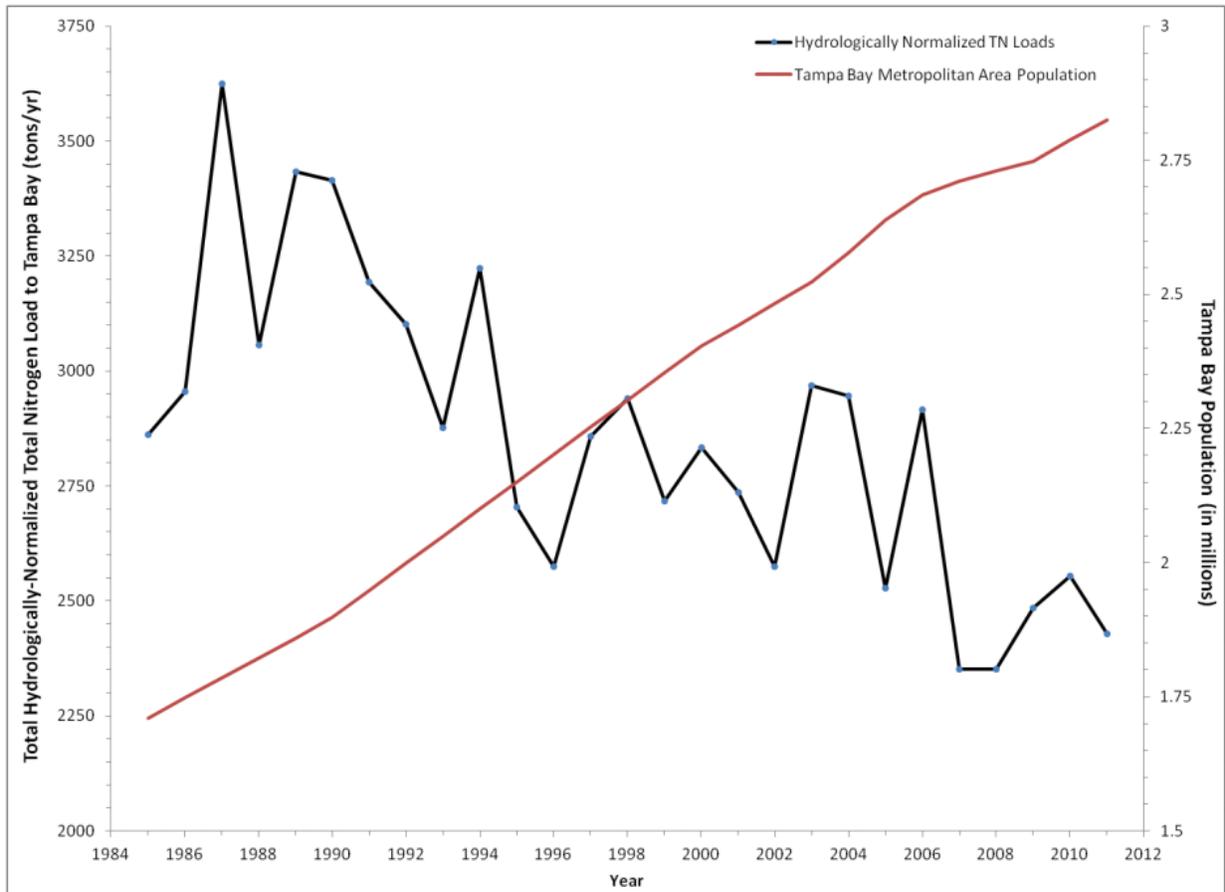

Through management actions, including an agreement with a power company to install air pollution control systems and the completion of more than 250 projects to reduce N inputs from the watershed, TN loadings to the bay have declined from previous annual average estimates despite an ever-increasing population in the Tampa Bay metropolitan area ([Figure 16-31](#)). Data compiled by the TBNMC indicate that continuing efforts to reduce N loading are resulting in more-than-sufficient water quality for the expansion of seagrasses ([TBEP, 2012a](#)).

ha = hectare.

Source: [Sherwood et al. \(2016\)](#).

**Figure 16-30 Total seagrass coverage in Tampa Bay circa 1950 through 2014.**

TN = total nitrogen; yr = year.

Source: [TBEF \(2012a\)](#).

**Figure 16-31** Trend in hydrologically normalized total nitrogen load to Tampa Bay relative to population increases in the Tampa Bay metropolitan area.

[Russell and Greening \(2015\)](#) estimated a potential relative cost savings of \$22 million per year in avoided wastewater treatment plant costs due to nutrient reductions associated with restoration and recovery of seagrass, marsh, and mangrove habitats in Tampa Bay. Ecosystem services benefits of over \$365 million estimated over an 18-year period from 1990 to 2008 include C sequestration and nutrient reductions via denitrification.

---

## 16.4.4 Nitrogen Management

---

### 16.4.4.1 Numeric Nutrient Criteria

In 1998, the U.S. EPA published the *National Strategy for the Development of Regional Nutrient Criteria* to promote the use of nutrient concentration levels in state water quality standards ([U.S. EPA, 1998b](#)). Historically, Florida had a narrative nutrient water quality criterion in place to protect waters against nutrient enrichment. In 2011, the state adopted the first set of statewide numeric nutrient standards for Florida's waters. By 2015, almost all of the remaining waters in Florida had numeric nutrient standards. Numeric nutrient criteria in Florida are established for all estuary segments and include criteria for TN, total phosphorus (TP), and chlorophyll *a*. For open ocean coastal waters, numeric criteria are derived from satellite remote sensing techniques and established for chlorophyll *a* only. Numeric nutrient criteria covering all of the mainstem segments and estuarine segments in Tampa Bay were approved by the U.S. EPA in November 2012 ([U.S. EPA, 2012c](#)). A map of the bay segments is provided in [Figure 16-23](#). The numeric nutrient criteria for chlorophyll *a* for the mainstream segments of Tampa Bay are shown in [Table 16-19](#).

---

**Table 16-19 Numeric nutrient criteria for chlorophyll *a* for the four mainstem segments of Tampa Bay adopted by the Florida Department of Environmental Protection.**

Bay Segment	Chlorophyll <i>a</i> (µg/L)
Old Tampa Bay	9.3 as annual mean
Hillsborough Bay	15.0 as annual mean
Middle Tampa Bay	8.5 as annual mean
Lower Tampa Bay	5.1 as annual mean

L = liter; µg = microgram.

Modified from [Sherwood et al. \(2016\)](#).

Tampa Bay's numeric nutrient criteria for TN ([Table 16-20](#)) is expressed as tons/million cubic meters of water as an annual total not to be exceeded more than once in a 3-year period and represents an unorthodox approach to developing nitrogen nutrient criteria

([Florida DEP, 2016](#); [Sherwood et al., 2016](#)). These values are based on previously adopted total maximum daily loads (TMDLs) or nutrient targets developed by TBEP. Usually, the U.S. EPA’s numeric nutrient criteria are expressed as a concentration, but TMDLs are typically expressed as loads. The N management strategy for Tampa Bay linked seagrass growth to external N loadings based on evidence that TN loads, resultant chlorophyll and light attenuation, and seagrass response were closely correlated ([Sherwood et al., 2016](#); [Janicki Environmental, 2011](#)). The TBNMC also found that when freshwater inputs are greater, TN moves through the system more quickly; therefore, residence time was an important consideration. TN loads and hydrologic loads affect both the chlorophyll within the bay, and the amount of TN delivered per unit water was used to set the numeric nutrient criteria for Tampa Bay. The FDEP and the U.S. EPA both agreed that this framework, although unique for numeric nutrient criteria, would provide reasonable assurance that the state water quality criteria would be met in Tampa Bay ([Sherwood et al., 2016](#); [Greening et al., 2014](#)).

**Table 16-20 Numeric nutrient criteria for total nitrogen for the four mainstem segments of Tampa Bay.**

Segment	Nitrogen Delivery Ratio Threshold (tons/million m <sup>3</sup> )
Old Tampa Bay	1.08
Hillsborough Bay	1.62
Middle Tampa Bay	1.24
Lower Tampa Bay	0.97

m = meter; TBEP = Tampa Bay Estuary Program; TN = total nitrogen.

TBEP estuarine numeric nutrient criteria expresses as nitrogen delivery ratio (tons TN per million m<sup>3</sup> hydrologic load) based on 1992–1994 conditions.

Source: [Florida DEP \(2016\)](#), [Janicki Environmental \(2011\)](#).

#### **16.4.4.2 Nitrogen Management Consortium Efforts**

The TBEP was established in 1992 as a part of the U.S. EPA’s National Estuary Program ([Sherwood et al., 2016](#)). TBEP coordinates TBNMC, a public-private partnership working to reduce N loading to the bay and whose members include 40+ local governments (Tampa, St. Petersburg, and others) along with key industries bordering the bay, such as electric utilities, fertilizer manufacturers, and agricultural operations.

In recent years, one focus of the TBNMC's strategy has been to allocate N loads for major point and nonpoint sources in order to meet state and federal requirements. The governments and industries participating in the TBNMC voluntarily committed to cap their N loads at average annual levels recorded in 2003–2007, which also meets the 1998 federally recognized TMDL for N. These capped allocations have been adopted by the state of Florida and incorporated into NPDES discharge permits ([TBEP, 2014](#)). One example of the Consortium's work is the reconfiguration of coal-fired plants in the Tampa Bay watershed to reduce NO<sub>x</sub> emissions ([Poor et al., 2013a](#)).

Every 5 years, the TBNMC must submit a Reasonable Assurance Update document to FDEP for approval to document progress toward water quality and seagrass management goals. The most recent reasonable Assurance Update (2012) presented data to show that reasonable progress has been made towards the attainment of designated uses of Tampa Bay. Based on this conclusion, FDEP upgraded Hillsborough Bay and Old Tampa Bay segments to assessment Category 4b for nutrients (adequate management in place) from Category 5 (impaired), and segments in Lower Tampa Bay were moved from Category 4b to Category 2 (attains standards), signifying the state's recognition of significant improvements in water quality and seagrass expansion ([TBEP, 2014](#)). The Consortium members share the cost of the data collection and analysis to prepare the Reasonable Assurance Update document, and the next update will cover progress made during the 2013–2017 time period.

---

#### **16.4.4.3 Response to Nitrogen Management Strategies**

A recent paper reviewing the response of Tampa Bay to N management strategies presented evidence of the ecosystem's recovery constituting a "regime shift" trajectory ([Duarte et al., 2015](#); [Duarte et al., 2009](#)). Since the mid-1980s Tampa Bay has shifted back to a clear water seagrass system from a phytoplankton-dominated system that was characteristic of the bay under previously eutrophic conditions. Following recovery from an El Niño heavy rainfall period (1997–1998), water clarity in Tampa Bay increased significantly, and seagrass expanded at a rate significantly different than before the event, suggesting a feedback mechanism observed only in a few other systems. The authors observed that too often these estuarine ecosystems are not able to recover even when eutrophication stressors are mitigated because of the concurrent changes in environmental conditions, that affected ecosystem dynamics occurring over the time period from the onset of eutrophication to the reduction of nutrient levels. [Greening et al. \(2014\)](#) noted four specific elements of the Tampa Bay management strategy that have resulted in a successful recovery trajectory: (1) development of numeric water quality targets in consultation with stakeholders, (2) citizen involvement in calling for action from

regulatory agencies, (3) collaborative actions such as the TBNMC, and (4) state and federal regulatory programs. BRACE scientists concluded that declines in atmospheric N deposition to the estuary and its watershed were likely part of the historical improvement in water clarity and increases in seagrass acreage ([Poor et al., 2013a](#); [TBEP, 2011](#)).

---

## 16.5 Rocky Mountain National Park Case Study

---

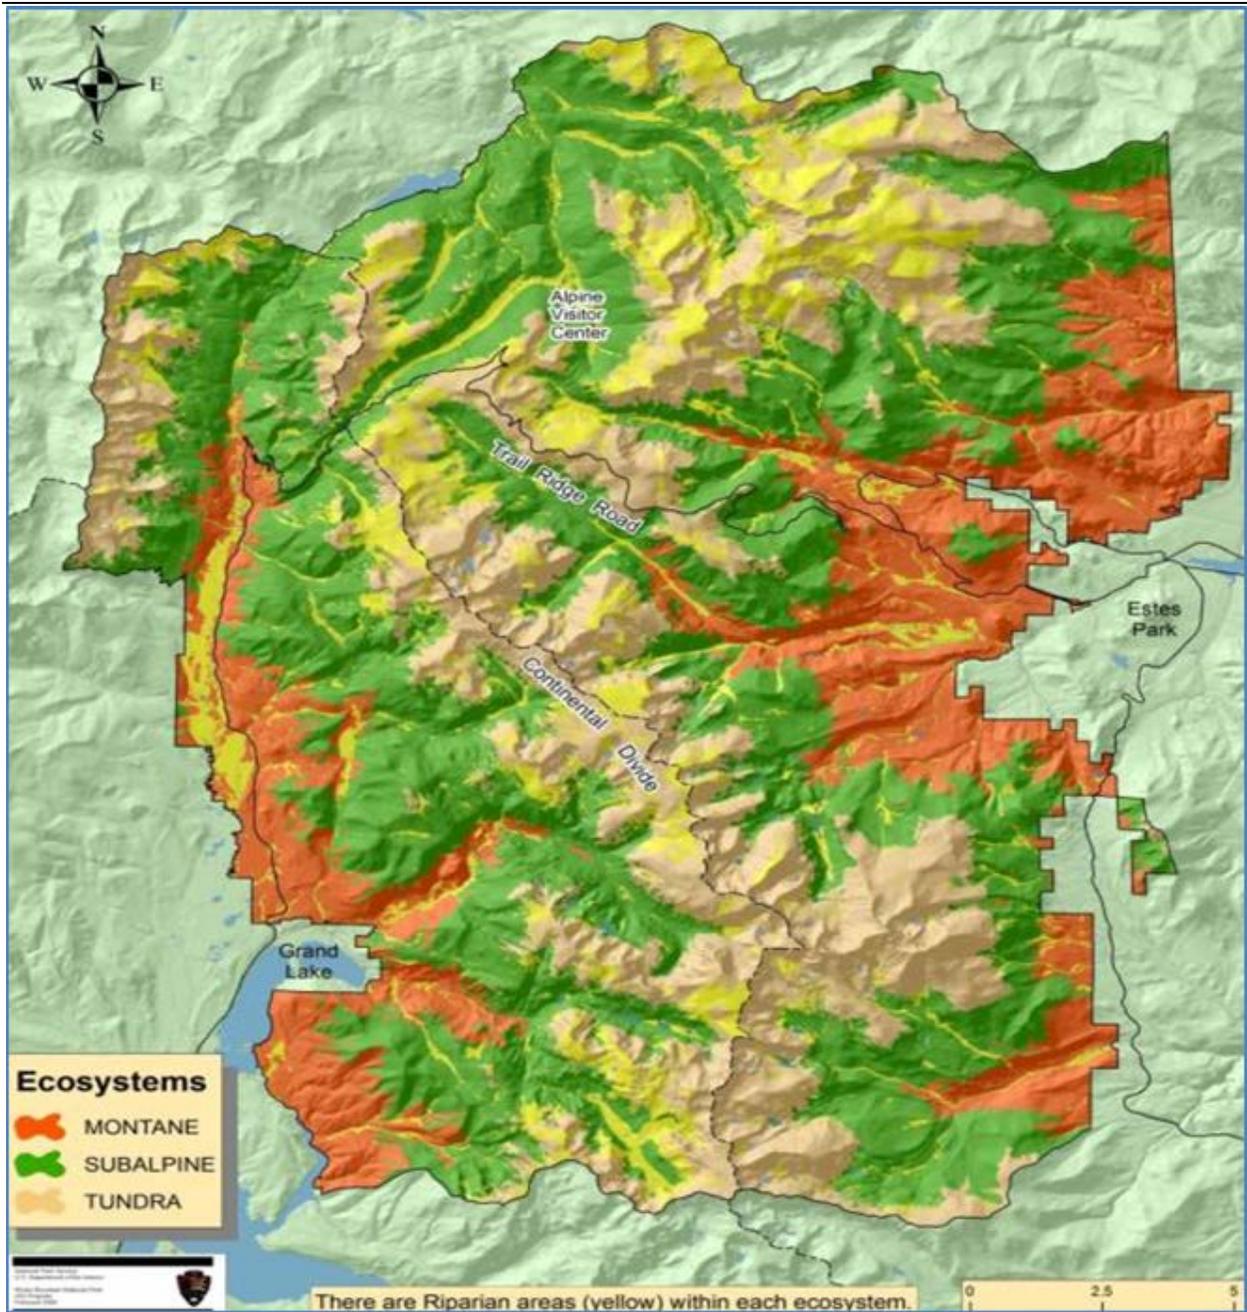

### 16.5.1 Background

This case study describes the environment and ecology of Rocky Mountain National Park (ROMO) and summarizes research that provides insight into the impacts of atmospheric nitrogen and sulfur deposition on terrestrial and aquatic ecosystems in ROMO. This includes atmospheric deposition research from within ROMO, the surrounding area of the Rocky Mountains, as well as other portions of the Northwestern Forested Mountains ecoregion. Although the focus is on research published since 2008, publications prior to 2008 are used to establish context and identify long-term trends.

---

#### 16.5.1.1 Description of Case Study Region

Rocky Mountain National Park (ROMO) was established by Congress in 1915 and is located in the Front Range of the Rocky Mountains in north-central Colorado, about 80 km northwest of Denver. Straddling the Continental Divide, the western side of ROMO serves as the headwaters for the Colorado River and eastern slope feeding the South Platte River Basin ([Wolfe et al., 2003](#)). The land within ROMO contains steep elevation gradients and diverse ecosystem types, ranging from talus slopes at high elevations and permanent glaciers above 4,000 m to grassy meadows at 2,400 m. Over 25% of ROMO is above the tree line (about 3,500 m), and ROMO contains large areas of alpine tundra. In addition, there are more than 60 peaks above 3,600 m in elevation ([Porter and Johnson, 2007](#)). Ecologically, ROMO is part of the Northwestern Forested Mountains ecoregion ([Figure 16-32](#)).

Source: [Clarke \(2013\)](#).

**Figure 16-32 Rocky Mountain National Park ecosystems.**

The ecoregion hosts extremely diverse vegetation and well-defined community zones along elevation gradients. Winter snow cover averages 1.5 m annually in the Rocky Mountains, and is a strong determinant of both plant and soil biodiversity ([Clow et al., 2016](#)). More than 1,000 species of vascular plants have been documented in ROMO ([NPS, 2013](#)). Within the alpine tundra, plant communities contain willow (*Salix* spp.) and a variety of grasses, sedges, and forbs such as alpine sunflower (*Rydbergia grandiflora*) and alpine forget-me-nots (*Polemonium viscosum*). The subalpine zone is composed primarily of forests, dominated by Engelmann spruce (*Picea engelmannii*), subalpine fir (*Abies lasiocarpa*), and limber pine (*Pinus flexilis*), whereas forests in the montane zone vary from lodgepole pine (*Pinus contorta*) at cold high elevation sites, trembling aspen (*Populus tremuloides*) in moist sites, and Douglas fir (*Pseudotsuga menziesii*) and ponderosa pine (*Pinus ponderosa*) at more moderate and xeric sites, respectively ([Beidleman et al., 2000](#)).

More than 270 species of birds, including migratory species, have been reported in this area over the last 100 years. Many are unique to mountainous habitats—aspens, ponderosa pine, high-elevation willow, and spruce-fir vegetation types—found in the southern Rocky Mountains. Seven native fish and four exotic fish inhabit the aquatic systems of ROMO. Sixty-seven mammal species are known to be native to the area, but grizzly bears (*Ursus arctos*), gray wolves (*Canis lupus*), and bison (*Bison bison*) were locally extirpated in the 19th and early 20th centuries. The lynx (*Lynx canadensis*) and wolverine (*Gulo gulo*) are either extirpated or extremely rare. Moose (*Alces alces*) are now common but were not historically recorded as part of this area of the Rocky Mountains. A select group of four amphibian and two reptile species survive the high elevations and cold temperatures in ROMO. They are all considered species of concern due to apparent low numbers, lack of information about their status, and/or declining population trends. There are 141 confirmed species of butterflies, but arthropod (insects, spiders, centipedes, etc.) communities in ROMO have not been as well documented as other taxonomic groups.

The NPS maintains a list of species known to occur in ROMO that are considered endangered, threatened, or candidates for protection by the Endangered Species Act ([NPS, 2013](#)):

- Boreal toad (*Bufo boreas boreas*)—candidate
- Yellow-billed cuckoo (*Coccyzus americanus*)—candidate
- Canada lynx (*Lynx canadensis*)—threatened
- Greenback cutthroat trout (*Oncorhynchus clarki stomias*)—threatened

[Pardo et al. \(2011c\)](#) reported that responses to elevated N deposition in the Northwestern Forested Mountains ecoregion include alteration of soil carbon:nitrogen (C:N) ratios, base cation composition, and accelerated N cycling rates, including increased

mineralization and nitrification. Further changes described in this case study and in other Appendices include plant, lichen, and algal chemistry; surface water chemistry (including N concentration and acid neutralizing capacity); catchment N leaching rate; and changes in the community composition of plants, lichens, and phytoplankton.

---

### **16.5.1.2 Class I Areas**

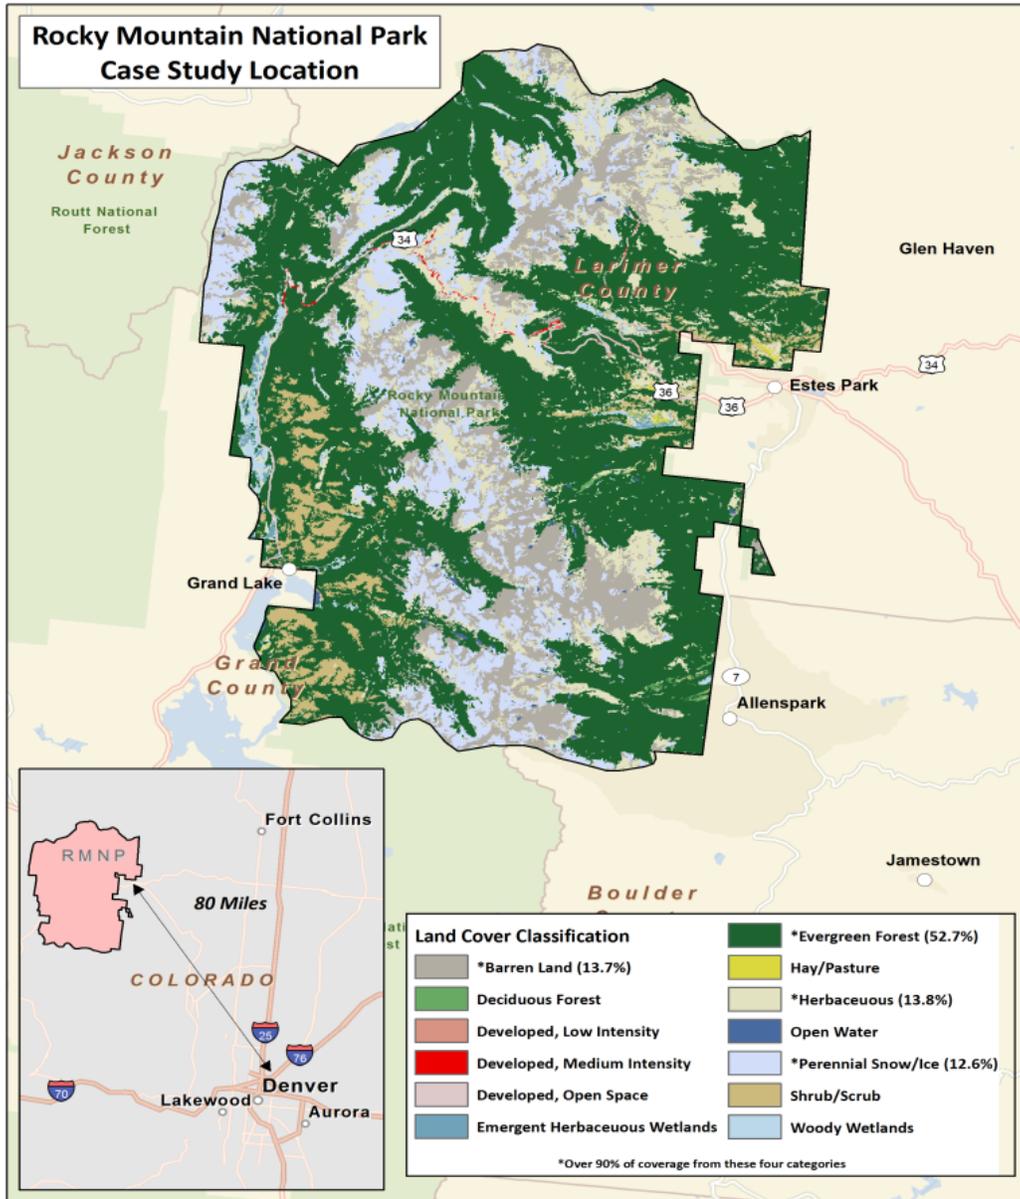

Rocky Mountain National Park is designated as a federal Class I area. The Clean Air Act (42 USC 7470) authorized these Class I areas to protect air quality in national parks over 6,000 acres and national wilderness areas over 5,000 acres in an effort to preserve pristine atmospheric conditions. Class I areas are subject to the “prevention of significant deterioration (PSD)” regulations under the Clean Air Act (42 USC 7470). New and modified existing air pollution sources are required to have PSD preconstruction permits and air regulatory agencies are required to notify federal land managers (FLMs) of any PSD permit applications for facilities within 100 km of a Class I area.

---

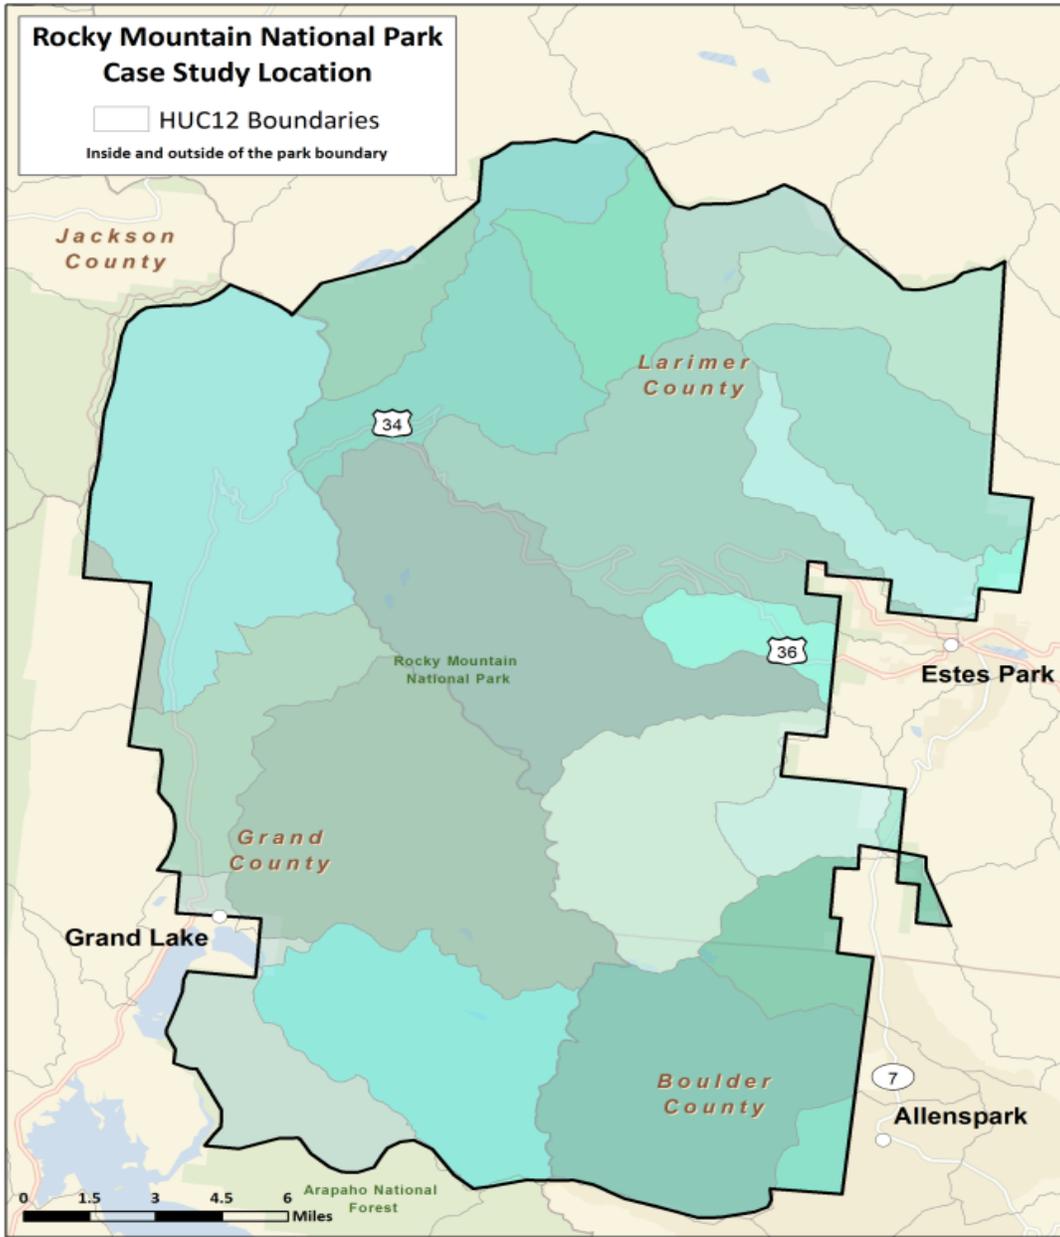

### **16.5.1.3 Regional Land Use and Land Cover**

The land area within the ROMO region falls predominantly into four land cover classifications: evergreen forest, barren land, herbaceous cover, and perennial snow/ice ([Figure 16-33](#)). The remainder of the land coverage categories account for less than 7% of the total area. The area immediately surrounding ROMO is largely forested. Regionally, the land to the north, west, and south of ROMO is predominantly forested, with some grasslands used as grazing land. The region to the east and southeast contains more grassland, agricultural, and urban land use. The smaller towns of Estes Park, Allenspark, and Grand Lake are close to the boundaries of ROMO ([Figure 16-34](#)), while the larger population centers of Fort Collins and the Denver metropolitan area are further to the east and southeast, respectively ([Figure 16-33](#) inset).

There are 29 total watersheds at the U.S. Geological Survey level-12 hydrological unit code (HUC12s) scale that fall completely or partially inside ROMO ([Figure 16-34](#)).

**Figure 16-33 Rocky Mountain National Park land coverage using the land cover classifications as mapped by the National Land Cover Dataset. Percentage of cover is shown for the four dominant cover types.**

HUC = hydrologic unit code.

## 16.5.2 Deposition

Based on TDEP calculations (see [Appendix 2](#) of the ISA), most of ROMO is estimated to receive deposition between 3–9 kg N/ha/yr and 3–6 kg S/ha/yr ([Figure 16-35](#)). In contrast to the low rates observed throughout much of the western U.S., rates of N deposition within ROMO are relatively high, and areas to the east of ROMO experience deposition rates similar to areas in the north-central U.S. (see [Figure 16-35](#) N deposition inset). However, the estimated rates of S deposition are consistent with the low rates observed elsewhere in the western U.S. and considerably lower than the S deposition rates observed within the Ohio Valley. Within these TDEP estimates, the inorganic N deposition in ROMO is relatively evenly balanced between oxidized and reduced forms, with the northeastern portion of the region receiving predominantly reduced forms of N ([Figure 16-36](#)). There are three National Atmospheric Deposition Program (NADP) measurement sites within ROMO ([Figure 16-36](#)), including measurements stretching back more than 30 years at the Loch Vale and Beaver Meadows sites. Over the past 25 years, sulfate ( $\text{SO}_4^{2-}$ ) and hydrogen ion ( $\text{H}^+$ ) deposition have declined slightly at the Beaver Meadows site (CO19), whereas deposition of ammonium ( $\text{NH}_4^+$ ) and nitrate ( $\text{NO}_3^-$ ) has been relatively constant ([Figure 16-35](#)). See [Appendix 2.4](#), [Appendix 2.5](#), and [Appendix 2.6](#) for more information on deposition in the U.S. Other maps showing the contributions of individual species to dry and/or wet deposition are given in [Appendix 2.7](#).

Atmospheric N deposition generated from anthropogenic sources is a significant influence on many ecosystems within ROMO ([Wolfe et al., 2003](#); [Baron et al., 2000](#); [Williams and Tonnessen, 2000](#); [Williams et al., 1996a](#); [Caine, 1995](#)). For this reason, atmospheric N deposition has been the focus of considerable research, including the Rocky Mountain Airborne Nitrogen and Sulfur (RoMANS) study ([Beem et al., 2010](#)). The RoMANS study was designed to characterize the sources as well as the transport, transformation, and deposition processes of oxidized S and oxidized and reduced forms of N ([Beem et al., 2010](#)).

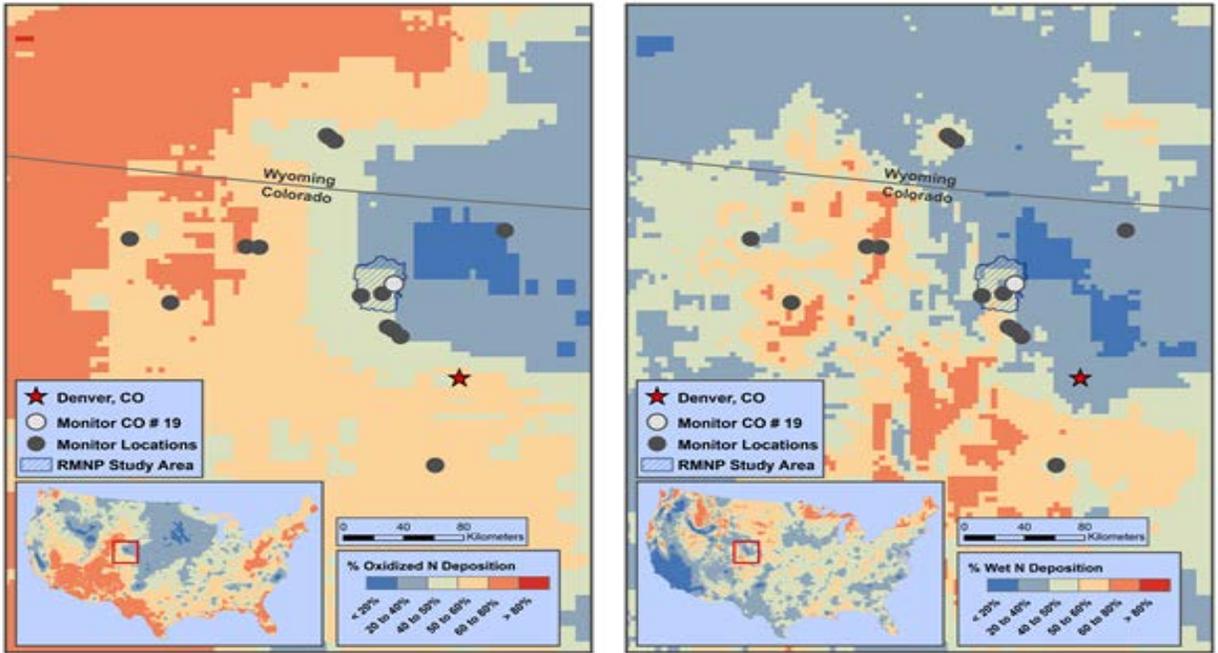

Primary atmospheric transport to ROMO is from the west and northwest. However, atmospheric circulation patterns along the Colorado Front Range can be complex, and significant quantities of precipitation can fall on the east side of ROMO when easterly upslope events occur ([Porter and Johnson, 2007](#); [Mast et al., 2003](#); [Baron and Denning, 1993](#)). For instance, although prevailing pattern of atmospheric circulation brings relatively clean air from west of ROMO, anthropogenic N can be transported to ROMO from urban and agricultural areas along the Front Range when convective heating over the plains produces easterly upslope winds ([Figure 16-37](#)). Higher than 3,000 m above sea level (masl), westerly air flow dominates over the upslope pollution ([Sievering et al.,](#)

1996), but coal-fired power plants located in Hayden and Craig, CO approximately 150 km west of ROMO, emit NO<sub>x</sub> that may reach ROMO with prevailing westerly winds.

H<sup>+</sup> = hydrogen ion; ha = hectare; kg =kilogram; mol = mole; N = nitrogen; NH<sub>4</sub><sup>+</sup> = ammonium; NO<sub>3</sub><sup>-</sup> = nitrate; RMNP = Rocky Mountain National Park; S = sulfur; SO<sub>4</sub><sup>2-</sup> = sulfate; yr = year.

Source: [Benedict et al. \(2013\)](#).

**Figure 16-38 National Park from November 2008 to November 2009, including organic nitrogen and particulate organic nitrogen.**

Modeling conducted by [Gebhart et al. \(2011\)](#) suggests that the majority of the ammonia measured in ROMO during the RoMANS study was emitted within Colorado. Modeling conducted by [Lee et al. \(2016\)](#) suggested that reduced N deposition comes mostly from sources east of the park, and oxidized N deposition comes primarily from sources west of the park. Major emission sources of N to deposition in ROMO include ammonia from livestock and oxidized N from mobile sources ([Figure 16-39](#)).

Aeolian dust deposition from the Colorado Plateau mitigates some of the acidifying effects of S and N deposition in ROMO. Between 1993 and 2014, dust deposition increased by as much as 81% in the southern Rocky Mountains. [Clow et al. \(2016\)](#) estimated that deposition of dust has altered snowpack chemistry by increasing its alkalinity (annual change of 0.32 μeq Ca<sup>2+</sup>/L/year) over the same time period in which smaller magnitude decreases in acid deposition to the snowpack (annual changes of -0.10 μeq SO<sub>4</sub><sup>2-</sup>/L/year and -0.07 μeq NO<sub>3</sub><sup>-</sup>/L/year) have occurred.

### 16.5.3 Critical Loads and Other Dose-Response Relationships

This section focuses on studies that describe dose-response functions and/or critical loads (CL) for atmospheric deposition effects on ecological endpoints. Terrestrial effects are discussed first, followed by aquatic effects and a discussion on integration.

#### 16.5.3.1 Terrestrial Critical Loads and Dose-Response Relationships

Among terrestrial ecosystems impacted by N deposition, alpine ecosystems are particularly sensitive to increased availability of N due to inherently low rates of N cycling, low rates of primary production, and thin, poorly weathered soils ([Fenn et al., 1998](#)). Among taxonomic groups in this ecoregion, the impact of atmospheric deposition

on epiphytic lichens is concerning because their strong dependence on atmospheric deposition for nutrients and unique symbiotic physiology makes them highly vulnerable to N and S pollution and because lichens are important contributors to ecosystem services (Brodo et al., 2001). Among lichens, the structure and physiology of oligotrophic species makes them especially important components of winter food webs, hydrologic and nutrient cycles, and wildlife habitat (McCune and Geiser, 1997).

**16.5.3.1.1 Empirical Studies**

In the Pardo et al. (2011c) critical loads assessment, most of the studies examining the responses of alpine ecosystems were conducted in the Colorado Front Range of the Rocky Mountains, either in ROMO or in adjacent ecosystems such as the Niwot Ridge Long-Term Ecological Research site. Critical load values for these alpine ecosystems ranged from 1.2 to >20 kg N/ha/yr, excluding two values from Fenn et al. (2008) which were determined for southwestern forested ecosystems in California (Table 16-21).

**Table 16-21 Terrestrial empirical critical loads of nutrient nitrogen for the Northwestern Forested Mountains ecoregion.**

Reliability rating: ## = highly reliable—a number of published papers show comparable results; # fairly reliable—the results of some studies are comparable; (#) expert judgment—few empirical data are available, Critical Load based on expert judgment of those ecosystems.

Source: [Pardo et al. \(2011c\)](#).

Since the publication of [Pardo et al. \(2011c\)](#) assessment, there have been several new studies on terrestrial CLs ([Table 16-22](#)). New studies find CLs for soil N concentration changes and leaching at 9.0–14.0 kg N/ha/yr, CLs to protect lichens at 4.0–4.1 kg N/ha/yr, and CLs to protect vascular plant biodiversity (species richness, abundance, or community composition) at 1.0–8.7 kg N/ha/yr.

**Table 16-22 Montane forest and alpine ecosystem critical loads for nitrogen deposition research published since the critical load assessment by [Pardo et al. \(2011c\)](#).**

CL (kg N/ha/yr)	Vegetation	Response	Method	Deposition/Addition	Site	Reference
1.0	Composite montane plant communities	5% change in alpine and subalpine plant community composition	ForSAFE-VEG modeled change in future (to 2500) vegetation	Deposition: ~4 kg N/ha/yr, 1 kg S/ha/yr	Northern and central Rocky Mountains region	<a href="#">Sverdrup et al. (2012)</a>

### 16.5.3.1.2 Modeling Studies

Elevated lake and stream  $\text{NO}_3^-$  concentrations have been observed in ROMO since the mid-1980s. To understand the source of these elevated  $\text{NO}_3^-$  concentrations and the role of atmospheric N deposition, [Baron et al. \(1994\)](#) used the CENTURY terrestrial biogeochemistry model to estimate N uptake by plants and soils in alpine forest and subalpine tundra within the Loch Vale watershed in ROMO. Based on the model output, N uptake in the subalpine tundra was considerably lower than in the alpine forest. Increased export of  $\text{NO}_3^-$  into stream water occurred at low N deposition rates (3 to 4 kg N/ha/yr) because much of this atmospheric N was deposited in the tundra or on exposed rock surfaces, providing little N uptake. This work by [Baron et al. \(1994\)](#) was the first N deposition CL research within the Northwestern Forested Mountains ecoregion and aside from two CL estimates for lichens ([Geiser et al., 2010](#)), the CL estimate produced from this research is the lowest among the CL estimates reviewed by [Pardo et al. \(2011c\)](#) for this ecoregion ([Table 16-21](#)).

Terrestrial biogeochemistry models have also played a role in the development of some CL estimates for the ROMO region published since the [Pardo et al. \(2011c\)](#) assessment. [Sverdrup et al. \(2012\)](#) and [McDonnell et al. \(2014a\)](#) used the ForSAFE-VEG model to evaluate potential long-term effects of climate change and atmospheric N deposition on alpine/subalpine ecosystems. Critical loads in both studies were defined as the rate of N deposition at which plant diversity was protected from a change of 5 to 10 Mondrian units (Mu; i.e., 5–10% change in plant species cover). [Sverdrup et al. \(2012\)](#) focused on a “generalized” alpine/subalpine site, with vegetation composition constructed from plant community data from ROMO and other national parks in the northern and central Rocky Mountains region. [Sverdrup et al. \(2012\)](#) simulated plant responses to a future climate (IPCC A2) and four levels of N and S deposition (preindustrial background, Clean Air Act [CAA] controls, no CAA controls, and no CAA controls + high deposition). Soil base saturation and soil solution base cation (Bc)-to-aluminum (Al) ratios (Bc:Al) were predicted to decrease to less than 1% and less than 10% after year 2100, respectively, with the scenarios of no CAA emission controls and no CAA controls + high deposition (indicating soil acidification). Future plant species coverages were predicted to change in successively greater amounts in response to the altered climate, CAA emission controls, no CAA emission controls, and no CAA emission controls + high deposition. Calculated CLs (based on a change of 5 Mu) for N deposition were 1 kg N/ha/yr. Critical loads related to S deposition were not discussed. All future N deposition scenarios (except preindustrial background N) resulted in CL exceedance.

The approach of [McDonnell et al. \(2014a\)](#) was similar to that of [Sverdrup et al. \(2012\)](#) because both applied the ForSAFE-VEG model to a subalpine ecosystem to determine

CLs for long-term vegetation composition shifts caused by climate change and atmospheric N deposition. The former study differed from the latter by using the Loch Vale watershed within ROMO as the study area and also back-projecting the model to 1900. [McDonnell et al. \(2014a\)](#) estimated that the N deposition CL to avert a 10% (5 Mu) change in future (2010–2100) plant biodiversity was 1.9 to 3.5 kg N/ha/yr, which had already been exceeded. Future air temperature increases were predicted to further change plant community composition and exacerbate changes caused by N deposition alone. In the simulations between 1900 and 2010, the authors found that subalpine fir (*Abies lasiocarpa*) sapling coverage had increased by more than 25%, graminoid response was mixed, and forbs generally had decreased in abundance ([Table 16-23](#)). By 2010, *Geum rossii* was reduced by more than 50% of its simulated historical cover. In scenarios using ambient N deposition and 0.5 times ambient N deposition, pronounced increases in the abundance of the moss *Aulacomnium palustre* would occur in 2065 and 2080, respectively, while the dominant graminoid (*Carex rupestris*) decreased. They also found that higher total N deposition scenarios would suppress moss cover near the end of the simulation period. Projected future tree responses were similar between the lowest two and highest three total N deposition scenarios. Future forb and *Carex rupestris* cover remained relatively constant under higher total N deposition rate scenarios.

**Table 16-23 Hindcast absolute and percentage changes in species abundance between 1900 and 2010 in response to historical reconstructions of nitrogen deposition ([Sullivan et al., 2005](#)) and historical climate change ([IPCC, 2007b](#)).**

Growth Form	Species	Relative Abundance %		Absolute Change	% Change

### 16.5.3.2 Aquatic Critical Loads

Nitrogen limitation of algal productivity is widespread in remote and undisturbed freshwater lakes, such as the high-elevation lakes located throughout the Rocky Mountains ([Baron et al., 2011b](#)). Based on surveys conducted in the 1980s that quantified the ratio of dissolved inorganic N to total phosphorus, alpine lakes in the Rocky Mountains region are predominantly N limited (45% of lakes) or colimited by both N and

P [22% of lakes; [Pardo et al. \(2011c\)](#)]. This may underestimate the previous extent of N limitation in these systems because lake sediment records indicate that N deposition began impacting biogeochemistry in some alpine lakes during the 1950s ([Das et al., 2005](#); [Wolfe et al., 2003](#); [Wolfe et al., 2001](#)). [Pardo et al. \(2011c\)](#) summarized CLs for ROMO surface waters ([Table 16-24](#)) with empirical and modeled CL estimates ranging from 1.5 to 2.5 kg N/ha/yr. Within ROMO, eastern slope surface waters commonly have higher dissolved inorganic N (DIN) than western slope surface waters ([Wolfe et al., 2001](#); [Baron et al., 2000](#)).

While the majority of ROMO aquatic research since 2000 focused on eutrophication, [Vertucci and Corn \(1996\)](#) and [Wolfe et al. \(2003\)](#) described the potential for aquatic acidification in the Colorado Rocky Mountains. Neither [Vertucci and Corn \(1996\)](#) nor [Wolfe et al. \(2003\)](#) found evidence for acidification, citing the influence of catchment sources of base cation neutralization. However, [Wolfe et al. \(2003\)](#) suggested that persistent N deposition threatened to cause chronic surface water acidification, particularly given that episodic declines of pH and acid neutralizing capacity (ANC) have been well documented in east slope headwaters of the Front Range ([Williams and Tonnessen, 2000](#); [Williams et al., 1996b](#)). [Vertucci and Corn \(1996\)](#) found that although episodic acidification occurred during snowmelt, at no point was  $ANC < 0$  in the northern Colorado and southern Wyoming lakes and streams that were sampled. Importantly, the observed acidification episodes did not coincide with the presence of amphibian embryos, meaning that amphibians in the region were not threatened by acidification (including the boreal toad, a candidate species for Endangered Species Act protection).

**Table 16-24 Critical loads for nitrogen for eutrophication for surface water (high-elevation lakes) in the Rocky Mountains.**

CL kg N/ha/yr	Species	Response	Method	Deposition/ Addition	Site	Reference
1.5	Diatom community composition	Eutrophication	Used exponential equations correlating with NO <sub>x</sub> emissions from CO and 11 western U.S. states to reconstruct historic N deposition. 1950–1964 wet N deposition correlated with alteration of ROMO diatom assemblages.	Wet deposition 2.94 kg N/ha/yr Dry deposition 0.94 kg N/ha/yr	Southern Rockies/ Loch Vale ROMO	<a href="#">Bowman et al. (2006)</a>

### 16.5.3.2.1 Empirical Studies

[Pardo et al. \(2011c\)](#) compiled a list of N deposition studies in high-elevation lakes that have observed changes in the growth, biomass, or composition of phytoplankton ([Table 16-25](#)). Within these studies, there was a relatively narrow range of lake water nitrate concentrations at which these phytoplankton responses were observed ([Table 16-25](#)). In paleolimnological studies of alpine lakes in this region that experienced increased rates of deposition, there were pronounced shifts in the composition and productivity of phytoplankton communities that occurred around 1950 ([Table 16-26](#)).

**Table 16-25 Lake water nitrate concentrations in nitrogen deposition studies observing phytoplankton responses.**

ha = hectare; kg = kilogram; N = nitrogen; NP = national park; ROMO = Rocky Mountain National Park; yr = year.

Source: ([Pardo et al., 2011c](#)).

Since the [Pardo et al. \(2011c\)](#) CLs synthesis, [Baron et al. \(2011b\)](#) synthesized aquatic N cycling research for lakes in several regions of the U.S., including alpine lakes in the Rocky Mountains. Using existing water chemistry measurements and modeled estimates of wet and dry N deposition, [Baron et al. \(2011b\)](#) observed that lake nitrate concentrations increased where N deposition exceeded 2.0 kg N/ha/yr. This threshold was similar to previous CLs of 1.5–4 kg N/ha/yr for lakes in this region ([Table 16-24](#)). ([Baron et al., 2011b](#)) also sought to develop a CL for N driven episodic aquatic acidification, but found little data apart from that used to generate the [Williams and Tonnessen \(2000\)](#) CL estimate of 4.0 kg N/ha/yr. Using phytoplankton biomass N to P limitation shifts as the basis for CL calculations, [Williams et al. \(2017b\)](#) determined an empirical CL of 4.1 kg/TN/ha/yr for remote high-elevation lakes across the western U.S. The CLs were calculated as the total (wet + dry) N deposition rate at which point below the CL, N limitation is more likely than P limitation and above the CL, P limitation is more likely than N limitation. DIN:TP and DIN response categories yielded an average critical load of 3.8 kg/TN/ha/yr for the lakes.

### 16.5.3.2.2 Modeling Studies

In addition to the empirical estimates of aquatic CLs, [Sullivan et al. \(2005\)](#) and [Hartman et al. \(2007\)](#) modeled CL estimates for aquatic acidification in ROMO. [Sullivan et al. \(2005\)](#) used the MAGIC model to evaluate the sensitivity of two water bodies in the Loch Vale watershed within ROMO—the Loch and Andrews Creek—to N and S deposition based on ANC. [Hartman et al. \(2007\)](#) also modeled deposition scenarios for changes in ANC at Andrews Creek, but used the DayCent-Chem model. Beginning with 1996 deposition rates of 2.2 kg S/ha/yr and 4.2 kg N/ha/yr, [Sullivan et al. \(2005\)](#) estimated CLs for N or S in order to reach ANC of 0, 20, or 50  $\mu\text{eq/L}$  by 2046 in the Loch and Andrews Creek, which had 1996 ANC values of 53 and 34, respectively. Acidification of the watershed to ANC to 0 or 20 by 2046 in either water body would require doubling of either N or S deposition ([Sullivan et al., 2005](#)). However, increasing ANC to 50 in Andrews Creek was not achievable by 2046 in any deposition scenario considered by [Sullivan et al. \(2005\)](#). [Hartman et al. \(2007\)](#) took a somewhat different approach, modeling 47-year scenarios beginning in 2000 where N deposition increased at rates that were low (+60%), moderate (+120%), and high (+240%) relative to the contemporary deposition rate. In these scenarios, episodic acidification (ANC = 0  $\mu\text{eq/L}$ ) of Andrews Creek occurred at 6.3–7.1 kg N/ha/yr. Estimates for persistent (chronic) changes in ANC of Andrews Creek were similar to those of [Sullivan et al. \(2005\)](#), within 1 kg N/ha/yr for ANC = 20  $\mu\text{eq/L}$  and within 3 kg N/ha/yr for ANC = 0  $\mu\text{eq/L}$  ([Table 16-27](#)). Notably, the Loch does not represent the most acid-sensitive lakes in the Front Range, with approximately 1/5th of the alpine lakes in the Colorado Front Range having a similar or lower ANC ([Eilers et al., 1989](#)). [Williams et al. \(2017b\)](#) modeled CLS for remote high-elevation lakes across the Western U.S. based on nutrient limitation shift thresholds. Modeled critical loads ranged from 2.8 to 5.2 kg/TN/ha/yr and correctly predicted exceedances in 69% of lakes using  $\text{NO}_3^-$ -N.

### 16.5.3.3 Integration

Together, there is a considerable amount of research available on the effects of atmospheric N deposition on ecological processes and characteristics within ROMO. Assembled together, the CL estimates developed in and around ROMO ([Figure 16-40](#)) show a continuum of effects as atmospheric N loads increase from natural background rates (0.2 kg N/ha/yr) to levels several times greater than the current estimates of 3–9 kg N/ha/yr ([Figure 16-35](#)). Broadly, the chemistry and biota of aquatic systems appear to be the most sensitive to N deposition, followed by alpine plant communities ([Figure 16-39](#)). It is notable that many of the published CLs ([Table 16-21](#), [Table 16-22](#), and [Table 16-24](#)) are near or below the rates of atmospheric N deposition currently observed in ROMO. Thus, there is considerable evidence that current rates of atmospheric N deposition are influencing the composition and function of aquatic and terrestrial ecosystems within ROMO [[Figure 16-41](#); [Porter and Johnson \(2007\)](#); [RMNP Initiative \(2014\)](#)].

ha = hectare; kg = kilogram; N = nitrogen; P = phosphorus; RM = Rocky Mountain; ROMO = Rocky Mountain National Park; RR = relative response to changes in N or P; yr = year.

**Figure 16-40 The continuum of ecological sensitivity to nitrogen deposition.**

ha = hectare; kg = kilogram; N = nitrogen; yr = year.

Notes: Current rates of N deposition impact terrestrial and aquatic ecosystems and relatively small increases in deposition may cause further ecological change.

## 16.5.4 Highlights of Additional Research Literature and Federal Reports since January 2008

A number of studies documenting the effects of N or S deposition on terrestrial and aquatic systems in ROMO or the ROMO region have been published since 2008. We discuss these studies briefly here but refer readers to the appropriate portion of the main body of the ISA for a more detailed review of this work.

### 16.5.4.1 Terrestrial

A number of the studies reviewed in [Appendix 4](#) and [Appendix 6](#) of the current NO<sub>x</sub>-SO<sub>x</sub> ISA as part of the body of terrestrial N deposition research published since 2008 were conducted in and around ROMO. [Farrer et al. \(2013\)](#) and [Bowman et al. \(2012\)](#) both conducted N addition studies in alpine tundra ecosystems to understand the response of

plants to N deposition. [Farrer et al. \(2013\)](#) did not find an increase in net primary productivity, but found both positive and negative effects on the aboveground biomass of individual plant species. [Bowman et al. \(2012\)](#) did not find any significant overall effect on aboveground plant biomass, plant tissue N concentration, or plant diversity; but the abundance of an important sedge (*Carex*) species almost quadrupled. This contrasts with [Farrer et al. \(2015\)](#) and [Yuan et al. \(2016\)](#), who found that N additions decreased plant species diversity. In mixed grass meadows near ROMO, an experiment that recreated historical, low N deposition conditions (soil N availability reduced by 63%, winter precipitation reduced 50%) reduced biomass of invasive cool-season grass *Bromus tectorum* ([Concilio et al., 2016](#)).

There are no published CLs for changes in soil microbial communities in the ROMO area, but several studies in alpine tundra ecosystems have quantified microbial responses to N additions ranging from 8 to 288 kg N/ha/yr. [Dean et al. \(2014\)](#) observed decreased ericoid fungi abundance and decreased richness and diversity of root-associated fungi, while [Farrer et al. \(2015\)](#) and [Boot et al. \(2016\)](#) observed decreased microbial biomass, fungal biomass, and bacterial biomass. [Farrer et al. \(2013\)](#), [Nemergut et al. \(2008\)](#), and [Yuan et al. \(2016\)](#) documented shifts in microbial community composition.

[Lieb et al. \(2011\)](#) found that a decade of N additions to alpine ecosystems lowered soil acid buffering capacity, decreased concentrations of base cation  $Mg^{2+}$ , and increased concentrations of  $Mn^{2+}$  and  $Al^{3+}$ . After 15 years of N additions, [Boot et al. \(2016\)](#) found that N addition reduced soil pH, soil percentage of C, and soil C:N in the O-horizon.

---

#### 16.5.4.2 Aquatic

As with terrestrial ecosystems, there have been a number of new studies quantifying the effects of N deposition on aquatic ecosystems in the Rocky Mountains since 2008 ([Table 16-28](#)). [McCrackin and Elser \(2012\)](#) measured denitrification in sediments of alpine lakes in the Colorado Rocky Mountains that received elevated (5–8 kg N/ha/yr) or low (<2 kg N/ha/yr) N deposition inputs. In high-deposition lakes, the  $NO_3^-$ -N concentration was significantly higher than in low-deposition lakes, but there was also evidence that denitrifying bacteria could remove a meaningful portion of N inputs to the lakes. While current levels of N deposition have not saturated the microbial capacity for denitrification, the abundance of denitrifying bacteria has not increased in response to additional N.

**Table 16-28 Summary of freshwater eutrophication studies in the Rocky Mountains since 2008.**

Species	Response	Method	Deposition/ Addition	Site	Reference
Not applicable	Diatom assemblages already dominated by species indicative of moderate N enrichment	Diatom calibration from surface sediment samples	Wet deposition: 1 to 3.2 kg N/ha/yr	46 high-elevation lakes in the Rocky Mountains	<a href="#">Arnett et al. (2012)</a>
Not applicable	Average lake DIN:TP of 16.3 + 2.76, suggesting widespread N saturation, but unclear if this is a new or historical condition	Mesocosms amended with NO <sub>3</sub> <sup>-</sup> , PO <sub>4</sub> <sup>3-</sup> , or PO <sub>4</sub> <sup>3-</sup> + NO <sub>3</sub> <sup>-</sup>	Ambient deposition not specified Addition: 930 mg/L NO <sub>3</sub> <sup>-</sup>	Colorado Front Range	<a href="#">Gardner et al. (2008)</a>
Chlorophyll a	Greater N deposition increased the N:P ratio in lakes. Phytoplankton growth P limited in high N deposition lakes (~7 kg N/ha/yr), but N limited in low-N deposition lakes (~2 kg N/ha/yr)	N and P enrichment bioassay experiments in high- and low-deposition lakes	Deposition: 2 to 7 kg N/ha/yr	14 eastern Colorado alpine lakes	<a href="#">Elser et al. (2009a)</a>
Chlorophyll a	Chl a conc. increase. Responses indicated a range from P limitation to N-P colimitation with one N limited outlier lake.	Enrichment bioassay	Wet deposition >6 kg N/ha/yr	14 eastern Colorado alpine lakes	<a href="#">Elser et al. (2009b)</a>
<i>A. formosa</i>	Maximum diatom growth rate at 0.5 μM of NO <sub>3</sub> <sup>-</sup>	Growth kinetics experiments	Total deposition >3 kg N/ha/yr	Rocky Mountains	<a href="#">Nanus et al. (2012)</a>

Chl a = chlorophyll a; DIN = dissolved inorganic nitrogen; ha = hectare; kg = kilogram; L = liter; μM = micromolar; mg = milligram; N = nitrogen; NO<sub>3</sub><sup>-</sup> = nitrate; P = phosphorus; PO<sub>4</sub><sup>3-</sup> = phosphate; TP = total phosphorus; yr = year.

[Mast et al. \(2011\)](#) examined trends in precipitation chemistry and other factors that influence long-term changes in chemistry of high-elevation lakes in three Colorado wilderness areas. [Mast et al. \(2011\)](#) observed that sulfate concentrations in precipitation decreased at rates of -0.15 to -0.55 μeq/L/year during the years 1985 through 2008 at 10 monitoring stations in Colorado. In high-elevation lakes where SO<sub>4</sub><sup>2-</sup> was primarily derived from atmospheric sources, the lake SO<sub>4</sub><sup>2-</sup> concentrations decreased by -0.12 to -0.27 μeq/L/year. In lakes where watershed sources were the dominant source of SO<sub>4</sub><sup>2-</sup>, the SO<sub>4</sub><sup>2-</sup> concentrations in lake water increased during this time period. [Mast et al. \(2011\)](#) attributed this trend to the effects of climate warming on pyrite weathering. Similarly, [Heath and Baron \(2014\)](#) observed increases in summer (June–August) fluxes and concentrations of cations, SiO<sub>2</sub>, SO<sub>4</sub><sup>2-</sup>, inorganic N, and ANC in stream water from

1984–2010 within the Loch Vale watershed in ROMO and attributed these trends to climate change effects on nitrification, mineral weathering, and the release of elements entrained in snow and ice. In comparison, wet N deposition rates were relatively constant and wet  $\text{SO}_4^{2-}$  deposition decreased.

[Mast et al. \(2014\)](#) measured long-term changes in stream  $\text{NO}_3^-$  concentration over three decades at the Loch Vale watershed in RMNP. The concentrations of  $\text{NO}_3^-$  in stream water increased during the early 1990s, peaked in the mid-2000s, and then declined by more than 40%. [Nanus et al. \(2012\)](#) developed a surface water  $\text{NO}_3^-$  threshold for growth of the diatom *A. formosa* for high-elevation lakes in the Rocky Mountains. [Arnett et al. \(2012\)](#) tried to develop a CL for diatom community composition change along a gradient of 46 high-elevation lakes receiving 1 to 3.2 kg N/ha/yr in wet deposition, but observed that diatom communities were dominated by a species associated with moderate N enrichment even in lakes where  $\text{NO}_3^-$  concentrations were at the detection limit (<1  $\mu\text{g/L}$ ).

New information on relative  $\text{NO}_3^-$  inputs from glacial versus snowpack meltwaters indicate water of glacial origin has higher  $\text{NO}_3^-$ , which may influence interpretation of biological data from high-altitude lakes and streams in some regions of the U.S., including the Rocky Mountains ([Slemmons et al., 2015](#); [Slemmons et al., 2013](#); [Saros et al., 2010](#); [Baron et al., 2009](#)). In the central Rockies and Glacier National Park, fossil diatom richness in snowpack-fed lakes was found to be higher relative to lakes fed by both glacial and snowpack meltwaters ([Saros et al., 2010](#)). Sedimentary diatom analysis of alpine lakes in the Rocky Mountains indicated that increases in *A. formosa* occurred at least a century ago in glacially fed lakes whereas shifts in the planktonic diatom communities occurred after 1970 in snow-fed lakes ([Slemmons et al., 2017](#)).

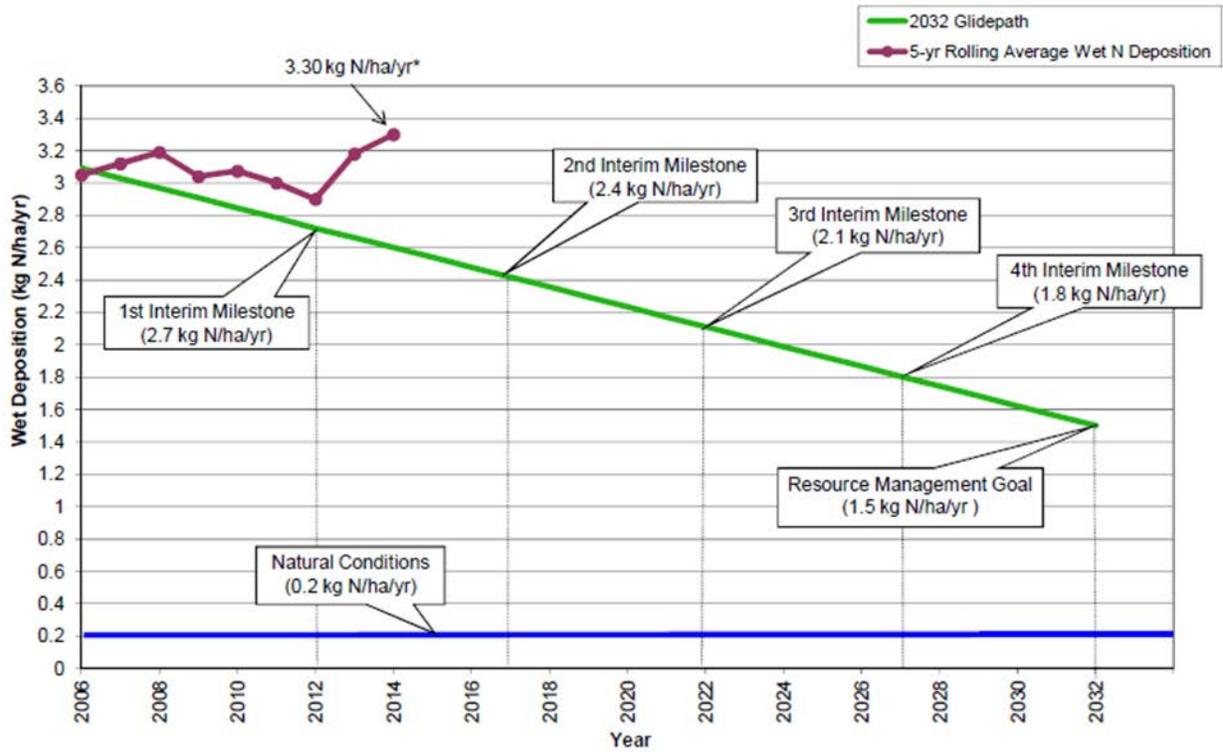

---

### 16.5.5 Rocky Mountain National Park Initiative

The large body of research on the effects of atmospheric deposition on terrestrial and aquatic ecosystems in ROMO and the relatively low CLs has led the National Park Service (NPS) to partner with the Colorado Department of Public Health and Environment and the U.S. EPA to develop a plan in 2005 to decrease atmospheric N pollution within ROMO ([Porter and Johnson, 2007](#)). Formally, this collaboration is organized as the Rocky Mountain National Park Initiative (RMNPI). The goal of the collaboration is to understand the impacts of N deposition in ROMO and the sources of N emissions, and resolve the N deposition issue in ROMO ([RMNP Initiative, 2014](#)). The three agencies developed the Nitrogen Deposition Reduction Plan, which intended to

decrease N wet deposition in ROMO from a 2006 baseline of 3.1 kg N/ha/yr to a 2032 target of 1.5 kg N/ha/yr.

The Nitrogen Deposition Reduction Plan aims for a linear decrease in deposition between 2006 and 2032, with interim milestones of 0.3 kg N/ha reductions in annual deposition every 5 years. In 2012, the 5-year rolling average of wet deposition was 2.9 kg N/ha/yr, a number that was 0.2 kg N/ha/yr above the interim milestone target, but also reflective of a 4-year trend toward decreased wet N deposition ([RMNP Initiative, 2014](#)). However, in the most recent status report ([Morris, 2016](#)), the 5-year rolling average has increased in each of the last 2 years and is now 3.3 kg N/ha/yr ([Figure 16-42](#)), well above the intended target. There has been no overall trend in wet N deposition or nitrate deposition since 2007, but the ammonium concentration has increased at four of the five monitoring sites since 2009. Within the nine-county Denver Metropolitan and Northern Colorado Front Range region, the two largest estimated sources of ammonia emissions were livestock (75% of emissions) and fertilizer use [14%; [RMNP Initiative \(2015\)](#)]. However, considerable uncertainty remains in ammonia emissions and transport estimates, and the members of RMNPI have dedicated resources to research ammonia in the region. The agency partners within the RMNPI are working with the agricultural industry in Colorado to decrease ammonia emissions by adopting a set of best management practices for agricultural N ([Figure 16-43](#)).

Figure 16-43 Rocky Mountain National Park Initiative accomplishment timeline.

### 16.5.6 Interactions between Nitrogen Deposition, Precipitation, and Large-Scale Ecological Disturbances

Precipitation patterns have changed over the past decades in ROMO, with consequences for biodiversity responses to N deposition. Spring snowfall has diminished over the last two decades (Clow et al., 2016), while winter snowfall has increased over the last century (Concilio et al., 2016). As a consequence, snowmelt occurs 7–18 days earlier than in 1993 (Clow et al., 2016), which extends the growing season. In a review of Niwot Ridge research, Bowman et al. (2014) suggested that N additions tend to have the opposite effect that high snowpack has on soil properties and processes (i.e., if N deposition accelerates soil N cycling, higher snowpack slows soil N cycling). Long-term trends in decreasing snowpack caused by changes in temperature and dust deposition (Clow et al., 2016), will intensify the effects of N deposition upon biodiversity.

Most forests within ROMO are composed of lodgepole pine or a mixture of Engelmann spruce and subalpine fir. Historically, these forests have been vulnerable to two natural mortality agents: bark beetles and wildfire ([Ehle and Baker, 2003](#)). Bark beetles can kill more than 90% of mature trees in heavily infested areas ([Rhoades et al., 2013](#)), while wildfires in these types of forests tend to burn at high intensities and kill trees across large landscapes ([Sibold et al., 2006](#); [Buechling and Baker, 2004](#); [Veblen et al., 1994](#); [Romme and Knight, 1981](#)). The large number of trees killed in these disturbances radically alters many ecological processes, including N cycling.

After tree mortality events, the decrease in biotic demand for N results in higher levels of inorganic N in the soil and increased concentrations of N in the leaves of surviving or recolonizing plants ([Dijkstra and Adams, 2015](#); [Mikkelsen et al., 2013](#); [Rhoades et al., 2013](#)). These changes in N cycling are similar to those caused by N deposition ([Fenn et al., 1998](#)) and those in experiments in and near ROMO simulating N deposition ([Rueth et al., 2003](#)). Although these disturbances increase N availability, beetle epidemics or wildfires in Rocky Mountain lodgepole pine and spruce-fir forests have not historically caused large increases in soil nitrate leaching or high concentrations of N in stream water ([Dunnette et al., 2014](#); [Morris et al., 2013](#); [Rhoades et al., 2013](#)), processes associated with excess N availability and the state of “N saturation” that occurs in ecosystems receiving large amounts of N deposition ([Fenn et al., 2003a](#)). However, there is concern that N deposition along the Colorado Front Range will enhance N availability to the point where disturbances will lead to large N leaching losses ([Rhoades et al., 2013](#)). This means that there is potential for N deposition to interact with bark beetles and wildfire to increase stream and lake water N content and degrade ecosystem function.

Nitrogen deposition can increase insect attack on plants ([Throop and Lerdau, 2004](#)) and there is some evidence that bark beetle activity and the bark beetle-caused tree mortality can be increased by N deposition ([Jones et al., 2004](#)). Unlike in other parts of the western U.S. where N deposition has allowed fires to occur more frequently by increasing fuels through greater plant growth ([Fenn et al., 2003a](#)), there is unlikely to be a large effect of N deposition on fire occurrence in ROMO. Fires in ROMO occur mostly during extreme weather conditions and are not as directly influenced by the amount of fuel available ([Sibold et al., 2006](#)). Notably, warm climate conditions increase fire frequency in lodgepole pine and spruce-fir forests in the Rocky Mountains ([Westerling et al., 2006](#)) and support bark beetle outbreaks in these forests ([Bentz et al., 2010](#); [Hebertson and Jenkins, 2008](#)).

---

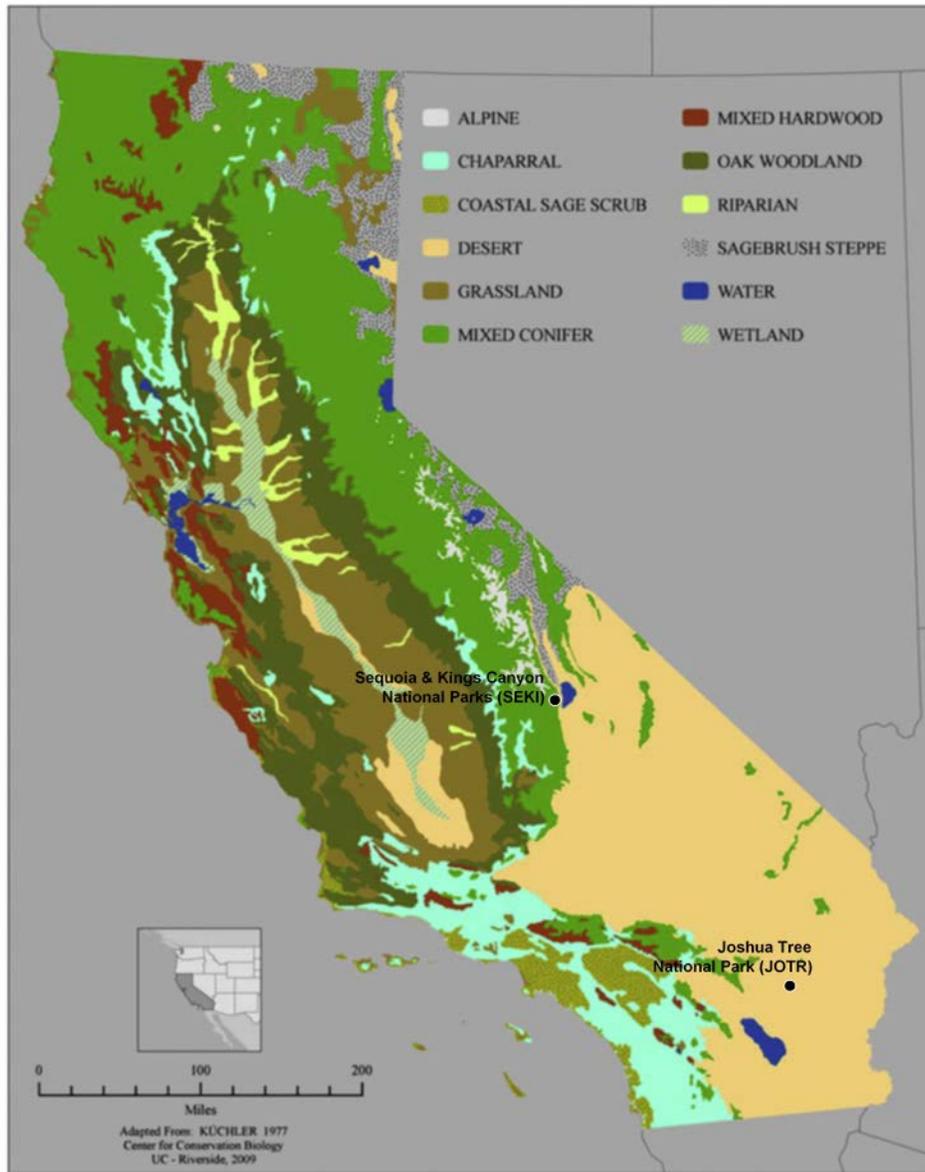

## 16.6 Southern and Central California

---

### 16.6.1 Background

This case study focuses on the impact of N and S deposition on aquatic and terrestrial ecosystems in southern and central California. Two areas are considered that have abundant information on ecological effects: the Sierra Nevada and southern California arid land ecosystems. Here we focus on the national parks located in both of these ecosystems, the Sequoia and Kings Canyon national parks (SEKI), located in the southern Sierra Nevada Mountains in central California, and Joshua Tree National Park (JOTR), located in the desert to the southeast ([Figure 16-44](#)). SEKI and JOTR were selected to emphasize Class I areas in the Sierra Nevada (SEKI) and southern California arid land ecosystems (JOTR). In addition, research from surrounding ecoregions relevant to these ecosystems is included because more work has been conducted within the surrounding areas than within the park boundaries.

The majority of the information provided in this case study represents the Sierra Nevada Mountains/SEKI. Limited research conducted in JOTR was found in the peer-reviewed literature. Yosemite National Park (YOSE) to the north shares many commonalities with SEKI regarding air pollution exposure, sensitivities, and impacts. Thus, research conducted in YOSE is relevant and included here. Background information is provided below, including a general description of the region, protected status designation (e.g., Class I, Wilderness Area), and regional land use. This case study includes atmospheric deposition to the parks and surrounding areas, dose-response relationships, and critical loads.

Notes: Land cover presented in this figure represents potential natural vegetation before urbanization and modern agricultural development.

### 16.6.1.1 Description of Case Study Region

Sequoia and Kings Canyon national parks are located in the Mediterranean California ecoregion (Level I Omernick classification) and are part of the Sierra Nevada Mountains. These parks are known for exceptionally large trees, high mountain peaks and ridges, and deep canyons and include the highest point in the contiguous U.S. (CONUS), Mount Whitney at 14,494 ft (4,418 m) above sea level. There are more than 200 marble caverns, many with endemic cave invertebrates. Sequoia National Park was originally created in 1890 to protect the giant sequoia trees (*Sequoiadendron giganteum*) from logging. It was the second national park, and the first formed to protect a particular living organism. In 1940, Congress created the contiguous Kings Canyon National Park to include the glacially formed Kings Canyon. These parks have increased in size to encompass 1,353 mi<sup>2</sup> (3,504 km<sup>2</sup>); 97% is designated and managed as wilderness.

Ecosystems in SEKI include chaparral vegetation at low elevation, extending up to alpine areas in the high mountains. Mycorrhizae, lichens, and herbaceous species communities are susceptible to declines in species richness/biodiversity due to the effects of N deposition. Likewise, high-elevation lakes and streams as well as low-order streams are susceptible to eutrophication and acidification driven by N deposition. Five rivers begin in SEKI, and past and present glaciers contributed to more than 3,000 lakes (many at high elevation) and 2,000 miles of streams, generally of low Strahler order ([Boiano et al., 2005](#)). Landscape variation contributes to diverse habitats that contain various assemblages of terrestrial, aquatic, and subterranean biota. As of 2005, of the more than 1,500 taxa of vascular plants in SEKI, 138 were deemed special status; 24 were listed by the California Native Plant Society as rare, threatened, or endangered. Fifty-one taxa of the parks' 312 terrestrial and aquatic vertebrate species had special status designations. Five extant native vertebrate species were federally listed in 2005: Sierra Nevada bighorn sheep (*Ovis canadensis sierrae*), bald eagle (*Haliaeetus leucocephalus*), Little Kern golden trout (*Oncorhynchus mykiss whitei*), mountain yellow-legged frog (*Rana muscosa*), and Yosemite toad (*Anaxyrus canorus*). As of 2005, the state listed the peregrine falcon (*Falco peregrinus*), great gray owl (*Strix nebulosa*), and willow flycatcher (*Empidonax traillii*) as endangered and the red fox (*Vulpes vulpes*), wolverine (*Gulo gulo*), and Swainson's hawk (*Buteo swainsoni*) as threatened. Forty extant native vertebrate species were listed as sensitive, including: white-tailed jackrabbit (*Lepus townsendii*), fisher (*Martes pennanti*), ring-tailed cat (*Bassariscus astutus*), Townsend's big-eared bat (*Corynorhinus townsendii*), western mastiff bats (*Eumops perotis*), merlin (*Falco columbarius*), northern harrier (*Circus cyaneus*), California spotted owl (*Strix occidentalis*), California legless lizard (*Anniella pulchra*), western pond turtle (*Actinemys marmorata*), Mount Lyell salamander (*Hydromantes platycephalus*), San Joaquin roach

fish (*Lavinia symmetricus*), and Kern River rainbow trout [*Oncorhynchus mykiss gilberti*; [Boiano et al. \(2005\)](#)].

Joshua Tree National Park is in the North American Desert ecoregion (Level I ecoregion by Omernick classification). The park was initially dedicated as a U.S. National Monument in 1936 and later declared a national park in 1994 when the U.S. Congress passed the California Desert Protection Act (Public Law 103-433). The park covers 1,235 mi<sup>2</sup> (3,200 km<sup>2</sup>), more than half designated as wilderness. It straddles the San Bernardino County/Riverside County border, including parts of two deserts: the higher, wetter Mojave Desert and the lower, drier Colorado Desert. The Little San Bernardino Mountains cross the southwestern edge of the park. JOTR is covered primarily by semiarid and arid vegetation types, including Joshua tree (*Yucca brevifolia*) woodlands. While rainfall is less than 10 cm/year, JOTR's groundwater supplies 200 surface water sources (e.g., springs, oases, ephemeral streams, or washes).

Joshua Tree National Park was preserved to protect the natural resources found at the junction of three California ecosystems. The Colorado Desert is a western extension of the Sonoran Desert. It occupies the southern and eastern portions of the park and is characterized by ocotillo (*Fouquieria splendens*) shrubs and cholla (*Opuntia* spp.) cacti. The Mojave Desert crosses the northern portions of the park and contains Joshua tree woodlands. The third ecosystem type in JOTR is a community of California juniper (*Juniperus californica*) and pinyon pine (*Pinus* spp.) located in the westernmost portion of the park, above 1,220 m elevation, in the Little San Bernardino Mountains.

There are several threatened and endangered species found within JOTR. Plant species include the triple-ribbed milkvetch (*Astragalus tricarinatus*) and Coachella Valley milkvetch (*A. lentiginosus* var. *coachellae*), which are federally endangered; as well as the Parish's daisy (*Erigeron parishii*), which is federally threatened. The desert tortoise (*Gopherus agassizii*), California's state reptile, is on both California's and the federal threatened lists. Twenty-six other species are listed as "special concern." JOTR was originally inhabited by the Serrano, the Chemehuevi (sometimes called the Southern Paiutes), and the Cahuilla people, and the park contains over 500 archaeological sites. (<https://www.nps.gov/jotr/index.htm>).

---

### 16.6.1.2 Class I Areas

The 1964 Wilderness Act and the NPS Organic Act are both used as tools to protect SEKI and JOTR from air pollution impacts. SEKI and JOTR (as well as nearby YOSE) are also Prevention of Significant Deterioration (PSD) Class I areas. They receive the highest level of protection under the Clean Air Act (CAA) against air pollution

degradation. The CAA (42 USC 7470) authorized designation of Class I areas to protect air quality in national parks (over 6,000 ac [2,428 hectares]) and national wilderness areas (over 5,000 ac [2,023 hectares]) in an effort to preserve pristine atmospheric conditions and air quality-related values (AQRVs). Class I areas are subject to the PSD regulations under the CAA. PSD preconstruction permits are required for new and modified existing air pollution sources. Air regulatory agencies are required to notify federal land managers (FLMs) of any PSD permit applications for facilities within 100 km of a Class I area.<sup>1</sup> The FLMs are authorized to review and comment on PSD Class I permit applications with the permitting agency.

---

### 16.6.1.3 Regional Land Use and Land Cover

Land cover in SEKI is largely forested and mountainous terrain in and near the Sierra Nevada Mountains. The westernmost portions of the park are covered by mixed conifer and chaparral vegetation. Further to the west is a zone of intensive agriculture ([Table 16-29](#)).

---

**Table 16-29 Land coverages of Sequoia, Kings Canyons, and Joshua Tree national parks.**

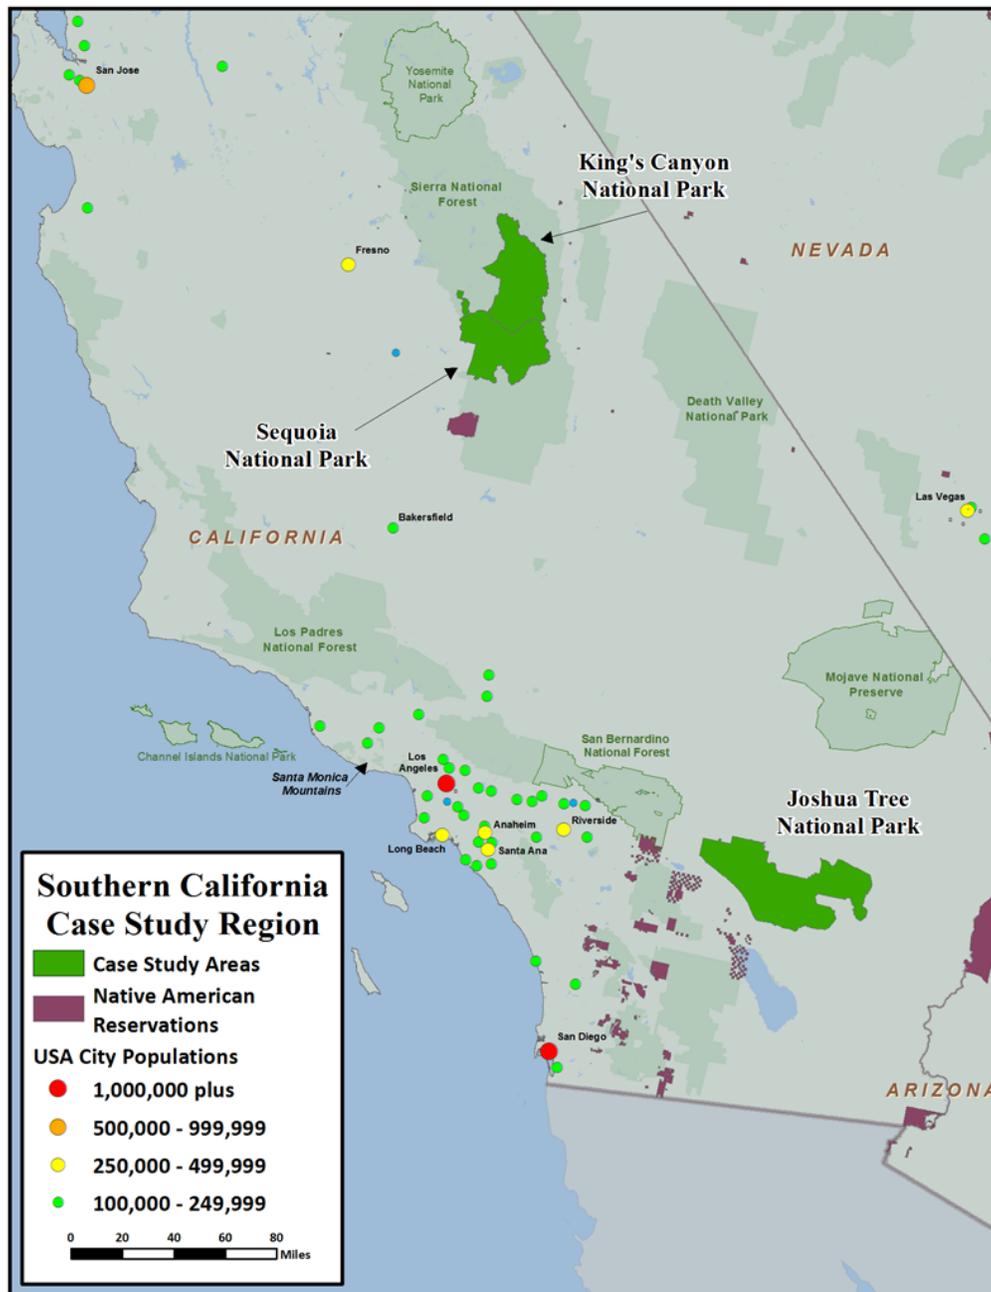

Land Cover Category	Sequoia National Park (km <sup>2</sup> )	Joshua Tree National Park (km <sup>2</sup> )	Kings Canyon National Park (km <sup>2</sup> )
Developed	5	7	4
Barren land and exposed rock	416	207	690
Deciduous forest	12	0	2
Evergreen forest	736	5	519
Mixed forest	8	0	1
Shrub/scrub	390	2,936	516
Grassland/herbaceous	68	54	100
Wetland	2	0	2

km = kilometer.

---

<sup>1</sup> <http://webcam.srs.fs.fed.us/psd>.

Land cover in JOTR is largely desert and semiarid land ([Table 16-29](#), [Figure 16-44](#)). Nearby human population centers ([Figure 16-45](#)) include the Coachella Valley (~350,000 people, including the cities of Palm Springs and Indio), as well as the towns of Twentynine Palms (25,600 people) and Joshua Tree (7,400).

**Figure 16-45** Southern and central California case study region showing locations of human population centers.

---

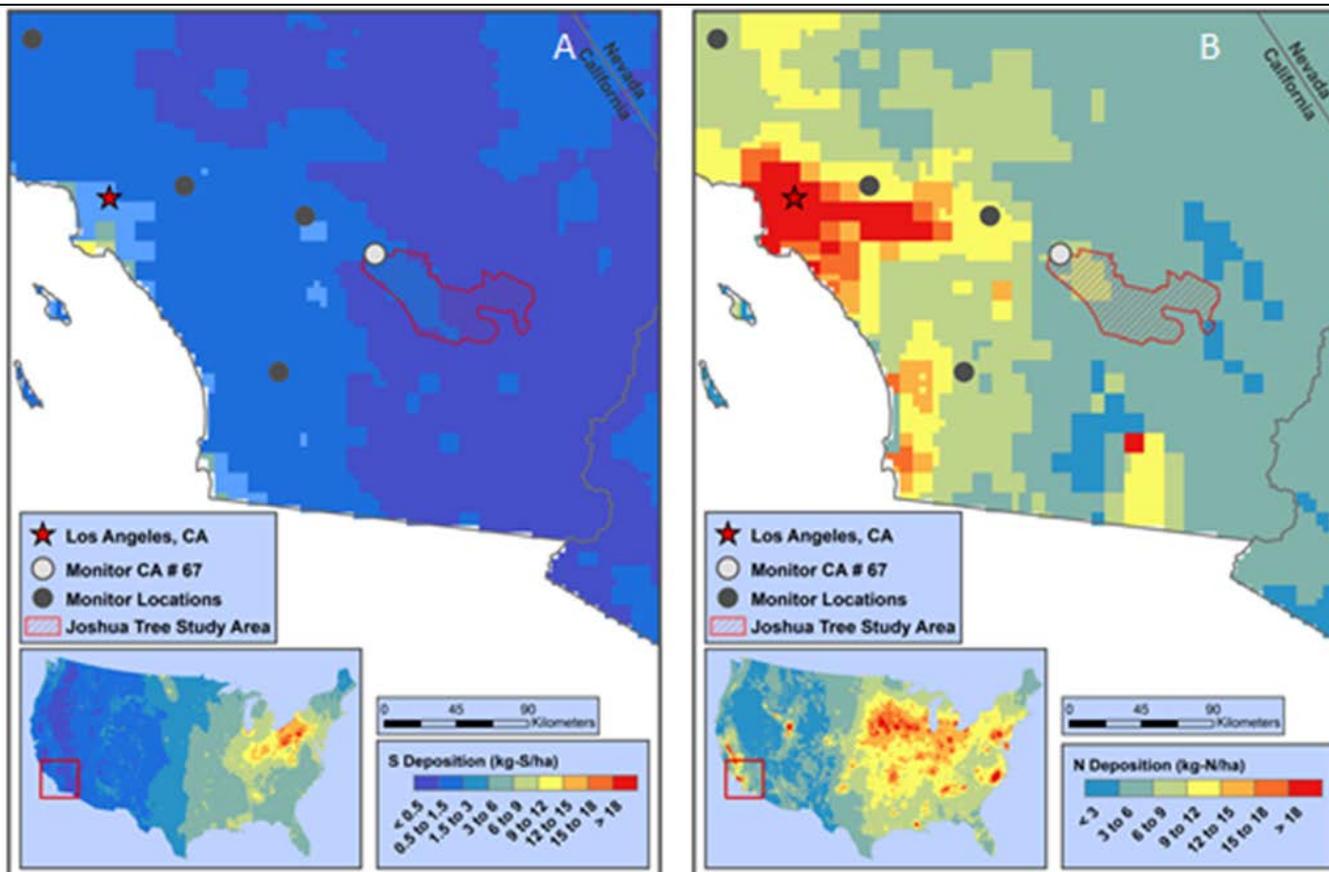

## 16.6.2 Deposition

Characteristics of N and S deposition are shown in [Figure 16-46](#) through [Figure 16-48](#) for JOTR and [Figure 16-49](#) through [Figure 16-51](#) for SEKI. Data shown in the figures were obtained from the hybrid modeling/data fusion product, TDEP (<http://nadp.slh.wisc.edu/committees/tdep/tdepmaps/>), and described earlier in [Appendix 2](#). However, the time series of wet deposition is taken directly from data on the NADP/NTN website. This was done to track changes in deposition since the passage of the Clean Air Act Amendment because the CMAQ simulations involved in TDEP extend back only to 2000. See [Appendix 2.4](#), [Appendix 2.5](#), and [Appendix 2.6](#) for more information on deposition in the U.S. Other maps showing the contributions of individual species to dry and/or wet deposition are given in [Appendix 2.7](#).

[Figure 16-46](#) indicates that the general pattern of deposition in JOTR of N and S is broadly similar, tending to be higher near the NADP site located in the NW corner of the study area and decreasing inland. As expected, N deposition is highest in and surrounding Los Angeles. The park is often subject to transport of emissions from the Los Angeles Basin. However, as can be seen from [Figure 16-46B](#), this influence decreases substantially towards the southeast. In addition, the area surrounding JOTR shows a high degree of regional heterogeneity. Deposition of S is consistent with the rest of the western U.S., but is considerably lower than in the eastern U.S.

As shown in [Figure 16-47A](#), deposition of N in JOTR is estimated by TDEP to be mostly in oxidized forms. NADP measurements of wet deposition at the park as seen in [Figure 16-48](#) are inconsistent with these simulation results. Although wet deposition is small in the arid environment of JSTOR, the difference suggests that processes occurring at spatial scales below that of TDEP may result in localized conditions different from those depicted in [Figure 16-47](#). In [Figure 16-48](#), wet deposition of  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ ,  $\text{SO}_4^{2-}$ , and  $\text{H}^+$ , apart from being lower than at many other sites, has not shown consistent trends over the past 25 years. Comparison of [Figure 16-46](#) and [Figure 16-47](#) suggests that dry deposition dominates over wet deposition of N and S in the JOTR study area.

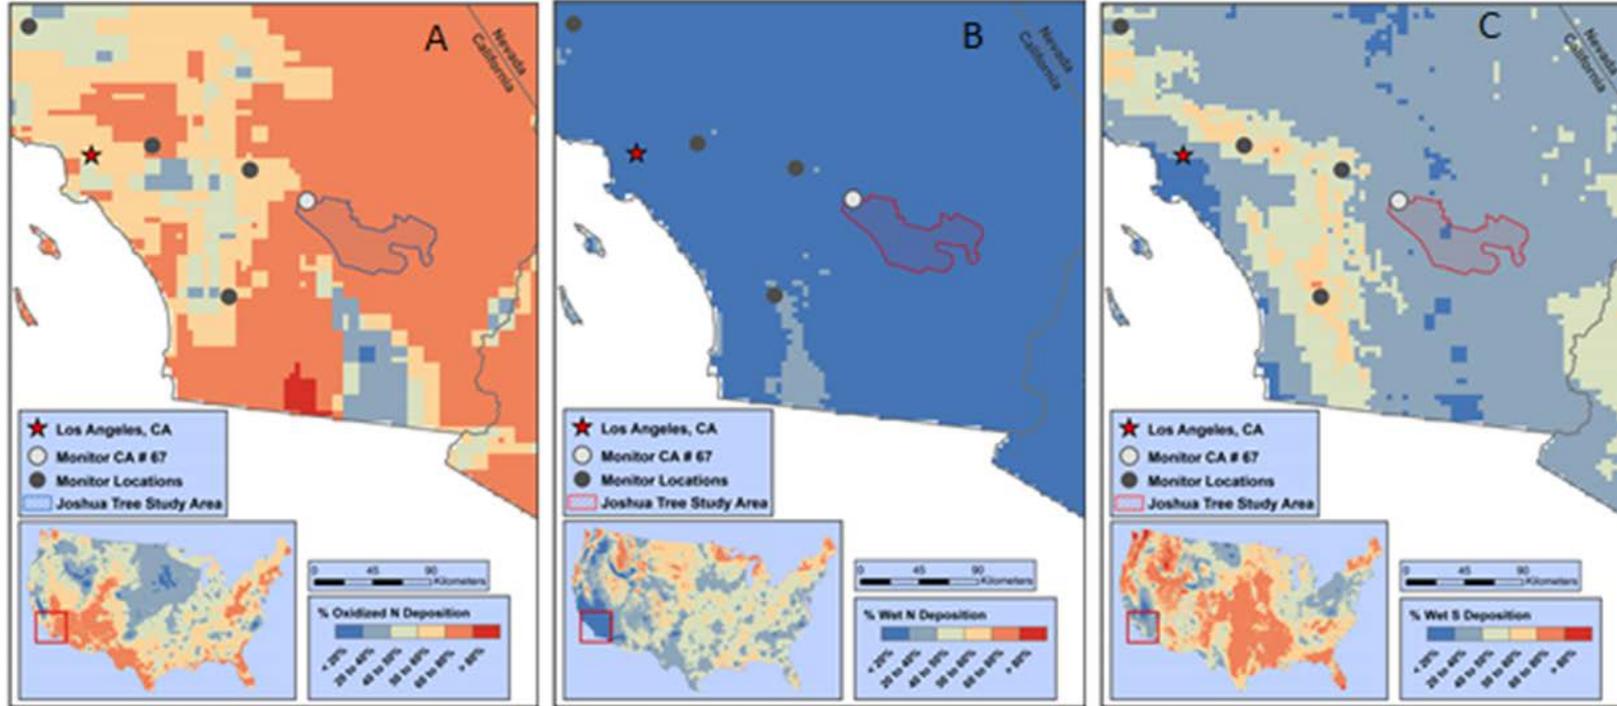

In SEKI, [Figure 16-49](#) shows a 3-year average total deposition of N and S for 2011–2013; [Figure 16-50](#) shows the partitioning between oxidized and total N; [Figure 16-51](#) shows the 25-year time series for wet deposition of  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ ,  $\text{SO}_4^{2-}$ , and  $\text{H}^+$  obtained at the NADP/NTN monitoring sites near SEKI.

CONUS = contiguous U.S.; ha = hectare; kg = kilogram; N = nitrogen; S = sulfur.

Surrounding areas in California and Nevada and inserts showing the whole CONUS are shown to place the depositional environment for both portions of the study area in context. Other maps showing the contributions of individual species to dry and/or wet deposition are given in [Appendix 2.7](#).

**Figure 16-51** Patterns and temporal trends of nitrogen and sulfur deposition of Sequoia and Kings Canyons and in Yosemite national parks and surrounding regions in California. A and B show the 25-year time series for wet deposition of nitrate, ammonium, sulfate, and hydrogen obtained from the National Atmospheric Deposition Program/National Trends Network monitoring sites CA99 and CA75.

As modeled by TDEP simulations, which may carry additional uncertainty when considered at smaller spatial scales, deposition of N is much higher in SEKI than JOTR, and its spatial variability is greater in SEKI than JOTR. On the other hand, S deposition is similar in magnitude between the two sites; S is also characterized by relatively low spatial variability at the two sites. In contrast to JOTR, deposition of N is estimated by TDEP simulations to be mostly in reduced forms in SEKI (see [Figure 16-50](#)), although this is not consistent with the wet portion of deposition measured by NADP at sites within those respective parks. Given the proximity of SEKI to the San Joaquin Valley, however, a higher proportion of reduced as opposed to oxidized N at that park would be expected. There is considerable variability in the percentage of N deposition as either in oxidized or reduced forms. Wet deposition of  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ ,  $\text{SO}_4^{2-}$ , and  $\text{H}^+$  is larger over SEKI than over JOTR, but still lower than at some NADP sites in the eastern U.S. Similar to JOTR, dry deposition dominates over wet deposition of both N and S in SEKI.

A recent modeling study of Class I areas, including SEKI and JOTR, used a GEOS-Chem adjoint model to identify the geographic sources of reactive N deposition, as well as the emission sector sources of reactive N deposition within the parks ([Lee et al., 2016](#)). Ninety percent of emissions of  $\text{N}_r$  that affect SEKI originate within 400 km of the park, with livestock ammonia as the major emission source (>50%) of N deposition within SEKI (see [Figure 16-52](#)). At JOTR, 90% of N emissions originate within 600 km of the park, and mobile sources of  $\text{NO}_x$  are the major emission source (>60%) of N deposition to JOTR (see [Figure 16-52](#)).

Source: Adapted from Figure 5 in [Lee et al. \(2016\)](#).

**Figure 16-52** Annual-averaged monthly footprint of reactive N deposition in Joshua Tree National Park (3.2 kg N/ha/yr) and Sequoia National Park (5.7 kg N/ha/yr). Also shown for each park is a pie chart of fractional contribution from emission sectors, as estimated by GEOS-Chem adjoint model.

## 16.6.3 Critical Loads and Other Dose-Response Relationships

### 16.6.3.1 Terrestrial

The communities of terrestrial species with well-documented effects caused by N deposition include lichens, mycorrhizae, grasses, and trees. While well studied ecosystems include mixed conifer forest, alpine/subalpine, and chaparral/semiarid shrubland.

Data on the effects of N deposition on mixed conifer forest ecosystems in the Mediterranean California ecoregion (Omernick Level I), including the Sierra Nevada region, are well summarized by [Fenn et al. \(2011b\)](#). A more recent overview of empirical

and modeled CLs for mixed conifer forests was provided by [Fenn et al. \(2015\)](#). Nitrate leaching from soil in combination with high evapotranspiration rates lead to high nitrate concentrations in surface waters in this area.

In general, the alpine and subalpine plant communities, such as those found in SEKI and YOSE, are sensitive to eutrophication, an observation based largely on research conducted in alpine ecosystems in the Rocky Mountains ([Bowman et al., 2006](#)). Alpine and subalpine communities are high-elevation plant communities that have developed under conditions of low nutrient supply, in part because soil-forming processes tend to be poorly developed at high elevations. This contributes to N sensitivity. Consequently, changes in alpine plant productivity and species composition have been reported in response to increased N inputs ([Bowman et al., 2006](#); [Vitousek et al., 1997](#)).

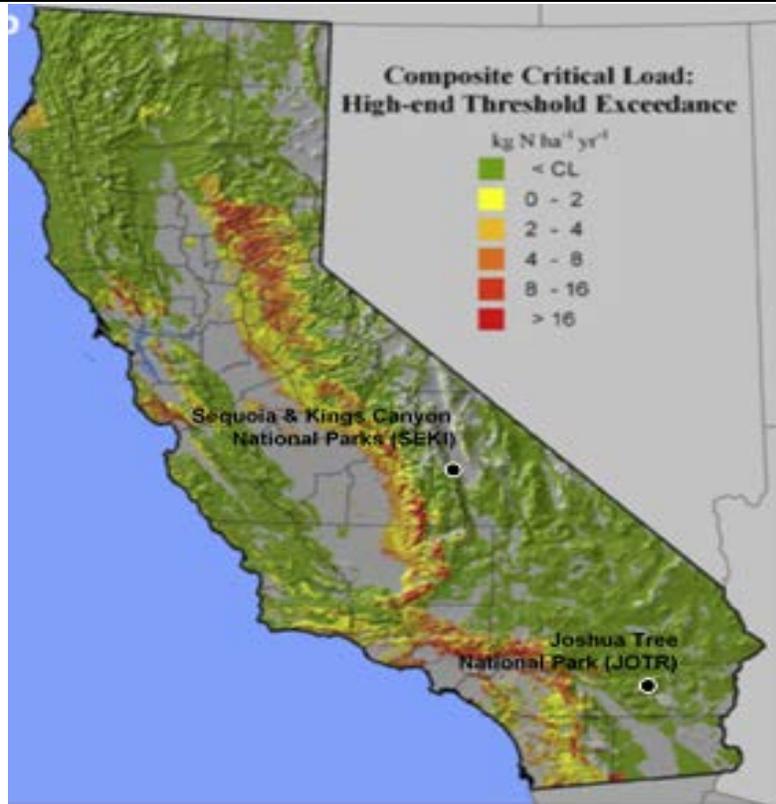

In chaparral and other semiarid shrublands in southern California, nitrogen enrichment can contribute to an increase in net primary productivity; however, water availability is often limiting to growth ([Vourlitis, 2012](#)). Arid ecosystems represent an extreme in terms of water availability and water is the principal limiting resource. Therefore, long-term (many years) experiments and the potential for interactions among water, fire, and nutrient supply in governing plant responses to N additions should be considered. Based on N addition experiments, [Vourlitis and Pasquini \(2009\)](#) suggested that dry-season addition of N significantly changes the community composition of coastal sage scrub (CSS) vegetation, but not chaparral. The impacts of such changes on the plant community may magnify over time. It has been proposed that the increase in the growth of invasive annual forbs and non-native grasses induced by nitrogen deposition leads in turn to greater fire frequency and destructiveness, particularly in arid ecosystems including JOTR ([Rao et al., 2010](#)). [Talluto and Suding \(2008\)](#) on the other hand proposed that increases in both fire frequency and N deposition over the last several decades in southern California may have promoted the conversion of CSS land to non-native grasslands. Both empirical and modeling studies suggest that loss of biodiversity in response to N input and climate change can be greater than the effects of either stressor alone ([Porter et al., 2013](#)).

#### **16.6.3.1.1 Empirical Studies**

A number of empirical studies (N gradient and N experimental additions) have been conducted to identify tipping points and to define areas of CL exceedance. Key studies conducted in the southern and central California case study region are listed in [Table 16-30](#).

[Fenn et al. \(2010\)](#) reported empirical CL exceedance maps for seven major vegetation community types in California ([Figure 16-53](#)). Thirty-five percent of the land area covered by these vegetation types (100,000 km<sup>2</sup>) was estimated to be in exceedance of the nutrient-N CLs (3–8 kg N/ha/yr) that were estimated for mixed conifer forests, chaparral, and oak woodlands. Nearly half of the area covered by CSS (54%) and grasslands (44%) was judged by the authors to be in exceedance of the CLs for protecting the ecosystem against changes associated with invasive grasses. Substantial chaparral (53%) and oak woodland (41%) cover was estimated to be in exceedance for impacts on epiphytic lichens. About 30% of the desert area investigated was in exceedance, based on the presence of invasive grasses and increased fire risk. An estimated 30% of the mixed conifer forest, based on lichens, was in exceedance of the CL. Forested and chaparral communities were less sensitive. Only 3–15% of the forested and chaparral areas were estimated to be in exceedance of the CL for NO<sub>3</sub><sup>-</sup> leaching. By combining the exceedance areas of the seven vegetation types, [Fenn et al. \(2010\)](#) estimated that 25% of the land area of the vegetation types included in the study were in exceedance for protecting against nutrient enrichment.

[Pardo et al. \(2011c\)](#) conducted a synthesis study that evaluated published data to identify the empirical CLs for N in Level I ecoregions across the U.S. The authors estimated CL values as low as 3 kg N/ha/yr to protect sensitive resources in the southern and central California case study area. [Table 16-30](#) lists the CLs identified by [Pardo et al. \(2011c\)](#) for North American Desert and Mediterranean California ecoregions (Omernick Level I) and new studies published after [Pardo et al. \(2011c\)](#). If deposition exceeds the CL, the risk of harmful effects increases.

CL = critical load; ha = hectare; kg = kilogram; N = nitrogen; yr = year.

When CLs based on two different N responders were used within a given vegetation type (e.g., lichen effects and nitrate leaching), only the more sensitive responder was used (lowest CL). The higher value of two CLs, when two values were available, was used in the case of coastal sage scrub, mixed conifer forest (lichen community effects), desert scrub and pinyon-juniper, and the lichen effects CL was used for chaparral.

Source: [Fenn et al. \(2010\)](#). Adapted to show case study locations.

**Figure 16-53** Composite critical load exceedance maps for all seven vegetation types included in the study of [Fenn et al. \(2010\)](#) showing the combined exceedance areas and the level of exceedance (kg N/ha/yr).

Study	Terrestrial	Aquatic	Location	Focus	CL/Exceedance
<b>Mediterranean California Ecoregion Level I (Omernick)</b>					
<a href="#">Pardo et al. (2011a)</a>	•		Mediterranean California Ecoregion Level I (Omernick); mixed conifer forest ecosystem	Lichen chemistry and community changes, nitrate leaching, soil acidification, reduced fine root biomass	3.1–39 kg N/ha/yr The lowest critical load is 3.1 based on lichen tissue chemistry above the clean site threshold. Nitrate leaching and fine root biomass critical load is 17, soil acidification is 26 kg N/ha/yr, and susceptibility to beetle infestation is 39 kg N/ha/yr
<a href="#">Pardo et al. (2011a)</a>	•		Mediterranean California Ecoregion Level I (Omernick); chaparral ecosystem	Nitrate leaching and changes in the lichen community	3.1–14 kg N/ha/yr 3.1 kg N/ha/yr is a modeled value for lichens, while 10 kg N/ha/yr is the value for nitrate leaching
<a href="#">Pardo et al. (2011a)</a>	•		Mediterranean California Ecoregion Level I (Omernick); coastal sage scrub ecosystem	Exotic invasive grass cover, native forb richness, arbuscular mycorrhizal richness	7.8–10 kg N/ha/yr
<a href="#">Pardo et al. (2011a)</a>	•		Mediterranean California Ecoregion Level I (Omernick); serpentine grassland ecosystem	Annual grass invasion replacing native herbs	6 kg N/ha/yr
<a href="#">Clark et al. (2013)</a>	•		Mediterranean California and North American Desert	Loss of herbaceous plant species	Species loss 1–30%
<a href="#">Ellis et al. (2013)</a>	•		SEKI and YOSE	Protection of lichens	Estimated CL 2.5 to 7.1 kg N/ha/yr

**Table 16-30 (Continued): Summary of recent empirical dose response and critical load studies focused on the southern California case study area and published since Pardo et al. (2011c).**

Study	Terrestrial	Aquatic	Location	Focus	CL/Exceedance
<a href="#">Cox et al. (2014)</a>	•		Mediterranean California Ecoregion Level I (Omernick); coastal sage scrub ecosystem	Conversion from coastal sage scrub to annual grassland	Estimated CL 11 kg N/ha/yr to conserve coastal sage shrub vegetation
<a href="#">Bytnerowicz et al. (2015)</a>	•		Mediterranean California Ecoregion Level I (Omernick); chaparral ecosystem	Lichens in chaparral, San Bernardino Mountains	Exceedances of CL = 5.5 kg N/ha/yr for lichens occurred mostly in western and northern portions of the study area
<a href="#">Bytnerowicz et al. (2015)</a>	•		Mediterranean California Ecoregion Level I (Omernick); mixed conifer forest ecosystem	Mixed conifer forest	Exceedances of CL = 3.1 kg N/ha/yr for mixed conifer forest covered much of San Bernardino Mountains
<a href="#">Allen et al. (2016)</a>	•		Mediterranean California Ecoregion Level I (Omernick); coastal sage scrub ecosystem	Rapid decline in mycorrhizal biodiversity	CL = 11 kg N/ha/yr
<b>North American Desert Ecoregion Level 1 (Omernick)</b>					
<a href="#">Pardo et al. (2011a)</a>	•		North American Desert Ecoregion Level I (Omernick)	Protect herbaceous plants and shrubs	CL 3 to 8.4 kg N/ha/yr
<a href="#">Simkin et al. (2016)</a>	•		North American Desert Ecoregion Level I (Omernick)	Grass and forb decreasing species richness	CL open canopy: 8.3–9.9 (mean = 9.2, n = 240) CL closed canopy: 13.5–17.0 (mean = 16.5, n = 32)
<a href="#">Clark et al. (2013)</a>	•		Mediterranean California and North American Desert	Loss of herbaceous plant species	Species loss 1–30%

CL = critical load; ha = hectare; kg = kilogram; N = nitrogen; SEKI = Sequoia and Kings Canyons National Parks; YOSE = Yosemite National Park; yr = year.

Data compiled by [Pardo et al. \(2011c\)](#) suggested that ambient N deposition is higher than the lower limit of the expected CL to protect against nutrient enrichment effects in some of the national parks in the Sierra Nevada, mainly SEKI, and to a lesser extent, YOSE. Potential CL exceedances were reported for the protection of mycorrhizal fungi, lichens, herbaceous plants, and forest vegetation, and also to restrict  $\text{NO}_3^-$  leaching in drainage waters. [Fenn et al. \(2010\)](#) estimated low CL values (3–8 kg N/ha/yr) for mixed conifer forests, chaparral, and oak woodlands. These low critical load estimates were driven by the presence of highly N sensitive species (lichens) and N poor vegetation (annual grasslands and desert scrub plant communities). [Fenn et al. \(2010\)](#) concluded that N deposition at or above these critical load values might cause vegetation community changes because the increased availability of N tends to favor invasion by non-native grasses into arid land ecosystems.

[Clark et al. \(2013\)](#) estimated the loss of herbaceous plant species caused by atmospheric N deposition based on a national CL database. Using the lower and more conservative estimates of CLs, the ambient N deposition was judged to be in exceedance of nutrient N CLs over extensive portions of the Mediterranean California and North American Desert ecoregions. Estimated plant species losses ranged from less than 1 to 30%, but variability was high and uncertainty in these estimates was substantial.

#### **16.6.3.1.2 Modeling Studies**

Dynamic and steady-state models have been used to estimate critical or target loads in the southern/central California case study region. Key studies, highlighted in [Table 16-31](#), have focused on CLs of nutrient N and acidity.

**Table 16-31 Terrestrial critical and target load and exceedance modeling studies in southern/central California.**

Study	Location	Model	Focus
<b>Mixed Conifer</b>			
<a href="#">Hurteau et al. (2009)</a>	Teakettle Experimental Forest and YOSE	STELLA <sup>®7</sup>	Modeled how changing precipitation and N deposition levels affect shrub and herb biomass production. Herb cover growth rate greater at 12 kg N/ha/yr than 24 kg N/ha/yr. Precipitation was more important driver for shrub cover.
<a href="#">Fenn et al. (2015)</a>	Sierra Nevada and San Bernardino Mts.	DayCent	Modeled CL to protect against NO <sub>3</sub> <sup>-</sup> leaching; CL ranged from 17 to 30 kg N/ha/yr.
<b>Semiarid</b>			
<a href="#">Li et al. (2006)</a>	SEKI	DayCent	Simulated N deposition of 7.7 kg N/ha/yr; increased loss of N to NO <sub>3</sub> <sup>-</sup> export and gaseous NO.
<a href="#">Rao et al. (2010)</a>	JOTR	DayCent	Effects on fire risk in creosote bush and pinyon-juniper vegetation types. CL = 3.2 kg N/ha/yr (creosote bush) and 3.9 kg N/ha/yr (pinyon-juniper). Wet areas having low soil clay (6–14%) may have CL as low as 1.5 kg N/ha/yr.
<a href="#">Rao et al. (2010)</a>	JOTR	DayCent	Modeled CL was determined as the N deposition load at which fire risk began to increase exponentially above the background fire risk. The CL for creosote bush scrub was 2.1 kg N/ha/yr and for pinyon-juniper woodland was 3.6 kg N/ha/yr.

CL = critical load; ha = hectare; JOTR = Joshua Tree National Park; kg = kilogram; Mts. = mountains; N = nitrogen; NO = nitric oxide; NO<sub>3</sub><sup>-</sup> = nitrate; SEKI = Sequoia and Kings Canyons National Parks; YOSE = Yosemite National Park; yr = year.

#### 16.6.3.1.2.1 Mixed Conifer

[Hurteau et al. \(2009\)](#) developed and tested a model to determine how changes in precipitation and N deposition might affect shrub and herb biomass in mixed conifer forests in Teakettle Experimental Forest (located between SEKI and YOSE) and YOSE. They estimated the prescribed fire intervals needed to counteract high fuel loads. Increased understory (especially grass) biomass enhances fuel connectivity and fosters larger and more severe fires. Under a model scenario that specified higher interannual variability in precipitation and increased N deposition, model results suggested that implementing fire treatments at an interval approximately equivalent to the historical

range (15–30 years) would likely be needed to maintain understory vegetation fuel loads at levels comparable to the control.

Based on 28 streams draining California mixed conifer forests studied by [Fenn and Poth \(1999\)](#), [Fenn et al. \(2015\)](#) estimated that peak  $\text{NO}_3^-$  concentrations in runoff were usually less than  $14.3 \mu\text{eq/L}$ ; therefore, this level of  $\text{NO}_3^-$  leaching was identified as the likely critical threshold value to identify watersheds that exhibit signs of N saturation. [Fenn et al. \(2015\)](#) specified the empirical CL for protecting against  $\text{NO}_3^-$  leaching in California mixed conifer forests equal to the N deposition level at which this identified critical surface water  $\text{NO}_3^-$  concentration is exceeded ([Fenn et al., 2015](#); [Fenn et al., 2008](#)). The CL was derived using linear regression of stream water  $\text{NO}_3^-$  concentrations during the winter high flow period and annual throughfall N deposition at 11 locations in the southern Sierra Nevada and San Bernardino mountains. The calculated CL to protect against  $\text{NO}_3^-$  leaching at the sites (6–71 kg N/ha/yr deposition) was 17 kg N/ha/yr (95% CI 15–19 kg N/ha/yr).

#### 16.6.3.1.2.2 Semiarid Shrublands

[Li et al. \(2006\)](#) used the DayCent model to quantify water, C, and N fluxes for a chaparral ecosystem in SEKI that received about 7.7 kg N/ha/yr of atmospheric N deposition. Simulated  $\text{NO}_3^-$  export and gaseous N emissions (mostly as nitric oxide [NO]) generally agreed with observations. The model projections suggested that increased N deposition would likely increase the flux of N from terrestrial ecosystems as  $\text{NO}_3^-$  in streams and gaseous NO. The authors concluded that the representations within the DayCent model of N mineralization, runoff, and  $\text{NO}_3^-$  export in chaparral or similar semiarid vegetation needed improvement.

[Rao et al. \(2010\)](#) used DayCent to estimate CLs of N deposition in JOTR, with focus on the effects of N input on fire risk in creosote bush (*Larrea tridentata*) and pinyon-juniper vegetation communities. Fire risk was expressed as the probability that annual biomass production would exceed the risk threshold of 1,000 kg/ha of biomass available for burning. Critical load was calculated as the N deposition at the point along the deposition gradient where modeled fire risk began to increase exponentially. Mean estimated CLs across multiple soil types, receiving precipitation of less than 21 cm/year, were 3.2 and 3.9 kg N/ha/yr for creosote bush and pinyon-juniper plant communities, respectively. Critical loads decreased (more nutrient-sensitive) with decreasing soil clay content and increasing precipitation. The wettest areas that had low clay content (6 to 14%) had estimated low CLs, as low as 1.5 kg N/ha/yr ([Rao et al., 2010](#)). These values fall at the lower end of the CL range identified by [Pardo et al. \(2011c\)](#) and [Pardo et al. \(2011a\)](#) for herbaceous vegetation in North American Deserts. Fire risks in the two vegetation types

were highest under moderately high N deposition (9.3 and 8.7 kg N/ha/yr, respectively); above those deposition levels, modeled fire risk was influenced more by precipitation amount than by N supply.

#### 16.6.3.1.2.3 Arid/Semiarid

DayCent modeling results suggested a CL less than 8.2 kg N/ha/yr for low-elevation desert containing invasive Mediterranean grass (*Schismus barbatus*) and less than 5.7 kg N/ha/yr at higher elevation sites containing non-native red brome [*Bromus rubens*; [Rao et al. \(2010\)](#)]. Invasive non-native grass production in JOTR was simulated under varying levels of N input and precipitation. Results suggested changing fire frequency. Simulated fire risk was higher when N deposition was above 3 kg N/ha/yr, but then stabilized at N deposition above 5.7 kg N/ha/yr in pinyon-juniper and at 8.2 kg N/ha/yr in creosote bush scrub plant communities ([Rao et al., 2010](#)). Model results of this study also suggested that fire risk is controlled more by precipitation than by grass productivity ([Allen and Geiser, 2011](#)).

---

### 16.6.3.2 Aquatic

This section highlights recent monitoring, dose-response, and critical load studies of N and S deposition to aquatic systems in SEKI, JOTR, and similar southern and central California ecosystems.

#### 16.6.3.2.1 Acidification

In the Sierra Nevada, both S and N deposition can contribute mobile acid anions ( $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ ) to watershed soil solution, streams, and lakes. Many aquatic and terrestrial ecosystems in the Sierra Nevada are generally sensitive to acidification. Lakes in these mountains are highly sensitive to impacts from acidic deposition because of the granitic bedrock, thin acidic soils, large amounts of precipitation, coniferous trees, and dilute surface waters ([Melack and Stoddard, 1991](#); [Melack et al., 1985](#); [McColl, 1981](#)). Because the levels of acidic deposition at the higher elevations have been relatively low, however, acidification effects to date have been minimal.

During the fall of 1985, about one-third of the lakes sampled by the Western Lake Survey (WLS) in and near SEKI had acid neutralizing capacity (ANC) < 50  $\mu\text{eq/L}$ , and two of the lakes in the park had ANC < 20  $\mu\text{eq/L}$  ([Landers et al., 1987](#)). The possibility of recovery from lake acidification during the period 1985–1999 was evaluated by another

chemical survey conducted by the U.S. Geological Survey (USGS) during the fall of 1999 (Clow and Sueker, 2000). Clow et al. (2003) reported that the resampled lakes were generally low in ionic strength and had pH between about 6.0 and 7.0; the median ANC was 59  $\mu\text{eq/L}$  in SEKI and 32  $\mu\text{eq/L}$  in YOSE located to the north. The observed lake chemistry further confirmed the high sensitivity to acidification.

Key acidification characterization and monitoring studies conducted in the Sierra Nevada are listed in Table 16-32. None of these studies are recent (post-2008) other than the study of Clow et al. (2010) in YOSE. The current condition of these waters is probably similar to what was found during previous decades with no additional recovery.

The weight of evidence suggests that many high-elevation lakes in SEKI have in the past received N deposition high enough to cause some chronic  $\text{NO}_3^-$  leaching. This can contribute to both acidification and eutrophication. Widespread chronic lake or stream acidification has not occurred to any degree, although Sullivan (2000) concluded that some episodic acidification has likely occurred. Acid anion concentrations (mainly  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$ ) in most high-elevation lakes were low during summer and fall, but higher during spring when there are commonly pulses of high  $\text{NO}_3^-$  concentrations in surface waters during snowmelt (Melack et al., 1989), which is seldom sampled due to logistical and safety constraints. Acid-base chemistry is not expected to have changed appreciably in recent years.

**Table 16-32 Example surface water acidification studies in Sequoia and Kings Canyons National Parks and other Sequoia and Kings Canyons National Parks—relevant areas in the southern/central California case study region.**

Study	Location	Time Period	Focus
<a href="#">Clow et al. (2003)</a> <a href="#">Clow and Sueker (2000)</a>	National parks in western U.S., including SEKI	1999	Resurvey of WLS lakes
<a href="#">Clow et al. (2003)</a>	Sierra Nevada region	1985 and 1999	Decrease in ANC in lakes in SEKI partly due to climatic differences at time of sampling
<a href="#">Clow et al. (2010)</a>	YOSE	2003	Multiple linear regression modeling to predict $\text{NO}_3^-$ concentrations and ANC in lakes across the park

ANC = acid neutralizing capacity;  $\text{NO}_3^-$  = nitrate; SEKI = Sequoia and Kings Canyons National Parks; WLS = Western Lake Survey; YOSE = Yosemite National Park.

The hydrology of alpine and subalpine ecosystems in the Sierra Nevada is controlled by snowmelt because more than 90% of the annual precipitation in this region falls as snow. The relatively small loads of acidic deposition can contribute to moderately high concentrations of  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  in lakes and streams during the early phase of snowmelt ([Stoddard, 1995](#)). Potential biological effects of acidic deposition on surface waters in the Sierra Nevada are most likely caused by acidification attributable to high  $\text{NO}_3^-$  concentrations, which tend to be episodic rather than chronic ([Wigington et al., 1990](#)).

Climatic fluctuations that control the amount and timing of precipitation, melting of the snowpack, growth of plants, depth to groundwater, and concentration by evaporation of constituents in solution all influence soil and surface water chemistry. These factors regulate interactions between air pollutants and the aquatic and terrestrial biological receptors. Because conditions vary over time, many years of data might be required to establish the existence of trends in episodic surface water chemistry ([Sullivan, 2000](#)).

Effects of acidification on vertebrate animals in the Sierra Nevada have not been documented. However, declines and elimination of frogs and toads due to uncertain causes have been documented throughout the western U.S., including in the national parks in California. Possible impacts of air pollution on aquatic amphibians is noteworthy because amphibians are especially sensitive to environmental change or degradation ([Bradford and Gordon, 1992](#); [Blaustein and Wake, 1990](#)).

Arid and semiarid ecosystems in southern California are generally not known to be sensitive to acidification from either S or N deposition. Precipitation to these ecosystems is limited. There are relatively few surface waters, and it appears that they have appreciable acid buffering capacity. However, semiarid chaparral soils under very high N deposition in the San Gabriel Mountains have decreased considerably in pH between the 1970s and 1990s, and so have soils of mixed conifer forests in the San Bernardino Mountains ([Fenn et al., 2011a](#); [Pardo et al., 2011c](#)).

#### **16.6.3.2.1.1 Empirical Studies**

Empirical studies have shed light on dose-response relationships in lakes and streams of southern/central California. Several new studies are addressed here. [Heard et al. \(2014\)](#) investigated CLs to protect against lake acidification in the Sierra Nevada. An experimental study by [Kratz et al. \(1994\)](#) investigated responses of macroinvertebrates. Earlier studies of effects of N deposition in this region (mainly before 2008) addressed aspects of water chemistry and the response of algae to nutrient addition. More recent

publications include the reviews of [Baron et al. \(2011a\)](#), [Pardo et al. \(2011c\)](#), and [Fenn et al. \(2015\)](#).

[Heard et al. \(2014\)](#) investigated the likelihood that paleoreconstructed changes in ANC in lakes of the Sierra Nevada had been caused by atmospheric deposition of  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  during the 20th century. The deposition estimates suggested that the CL at Moat Lake was exceeded in about 1920 and the chemical recovery started in about 1970. The initial inferred decline in the ANC of Moat Lake occurred between 1920 and 1930. This time period corresponded with estimated acidic deposition ( $\text{SO}_4^{2-} + \text{NO}_3^-$ ) equal to about 74 eq/ha/yr. This was taken by [Heard et al. \(2014\)](#) to be the critical load (CL) to protect this lake against acidification. Diatom-reconstructed ANC values changed from near 100  $\mu\text{eq/L}$  before 1920 to near 60  $\mu\text{eq/L}$  during the 1970s. Recovery of ANC after 1970 was attributed by [Heard et al. \(2014\)](#) to decreased deposition of S. In addition, during the late 20th century, warmer air temperatures may have contributed to higher ANC via increased weathering rates.

#### 16.6.3.2.1.2 Modeling Studies

Some limited work has been conducted on modeling of aquatic critical loads using steady-state approaches for acidity. Data from over 12,500 streams and lakes were used by the Critical Loads of Atmospheric Deposition (CLAD) science committee of the NADP (<http://nadp.slh.wisc.edu/committees/clad/>) to model steady-state CLs for acidity of surface waters based on multiple approaches for estimating base cation weathering. [Shaw et al. \(2014\)](#) used the Steady-State Water Chemistry (SSWC) model to estimate the steady-state CL of acidity for 208 Sierra Nevada lakes. Study lakes were generally dilute (mean specific conductance 8  $\mu\text{S/cm}$ ) and had relatively low ANC (mean 57  $\mu\text{eq/L}$ ). Most were located in Forest Service wilderness areas, some in proximity to Sierra Nevada national parks. Using a critical ANC limit of 10  $\mu\text{eq/L}$  to protect aquatic biota from effects caused by water acidification, the model predicted a CL of 149 eq/ha (14.9  $\text{meq/m}^2$ ) of acidity for Sierra Nevada watersheds situated on granitic bedrock. More than one-third of the study lakes received acidic deposition that was in exceedance of the estimated CL. The median study lake showed a CL exceedance of about 80 eq/ha (8  $\text{meq/m}^2/\text{year}$ ). Based on these CL calculations, [Shaw et al. \(2014\)](#) concluded that high-elevation lakes in the Sierra Nevada have not fully recovered from effects of acidifying deposition despite large decreases in S and N air pollution and reduced S deposition over the last several decades.

### 16.6.3.2.2 Aquatic Nutrient Enrichment

There have been several studies of water chemistry dose-response relationships that pertain to nutrient enrichment in the Sierra Nevada case study area. These have included studies of N retention and release, critical loads, and N saturation. A meta-analysis of lakes from 42 regions of Europe and North America concluded that atmospheric N deposition has caused higher concentrations of  $\text{NO}_3^-$  in lake water and increased phytoplankton biomass ([Bergström and Jansson, 2006](#)). [Bergström et al. \(2005\)](#) found N limitation in lakes that received N deposition below approximately 2.5 kg N/ha/yr, limitation of N and P at N deposition between ~2.5 and 5.0 kg N/ha/yr, and P limitation in lakes that had N deposition higher than about 5.0 kg N/ha/yr. These findings may be relevant to remote lakes in the Sierra Nevada, including those in SEKI.

[Sickman et al. \(2002\)](#) reported yields and retention of dissolved inorganic N (DIN) at 28 high-elevation lakes, including those within SEKI. Net DIN retention was 1.2 kg N/ha/yr, an estimated 55% of annual DIN loading. [Sickman et al. \(2001\)](#) calculated that the annual yield of N from the Emerald Lake watershed varied by a factor of 8 (0.4 to 3.2 kg N/ha/yr), which explained 89 and 74% of the variation in DIN and organic N, respectively. The N content of runoff was higher during years that experienced high runoff and was lower during dry years. Increases in  $\text{NO}_3^-$  concentration were larger during years with deep, late-melting snowpacks. Therefore, it is expected that climate warming, with associated earlier snowmelt, might increase N retention in high-elevation watersheds ([Sickman et al., 2001](#)).

Nutrient enrichment of Sierra Nevada lakes is not solely a function of N inputs. Atmospheric P deposition can also be important. [Sickman et al. \(2003\)](#) proposed that atmospheric P deposition and enhanced cycling of P due to climate change were the most likely sources of the observed increase in P loading to the Sierra Nevada lakes. It is not known why atmospheric deposition of P to these lakes has increased over time. Possibilities include increased use of organo-phosphate pesticides ([Kegley et al., 2000](#)) and wind-blown transport of soils and dust that are high in P from the agricultural San Joaquin Valley to the mountains ([Sickman et al., 2003](#); [Lesack and Melack, 1996](#); [Bergametti et al., 1992](#)).

Based on results of bioassay experiments and application of coarse nutrient limitation indices, [Sickman et al. \(2003\)](#) concluded that phytoplankton growth in Emerald Lake in SEKI during the early 1980s was limited by P supply. During subsequent years, in response to increased atmospheric P input, the nutrient balance shifted into a pattern of colimitation by N + P, and finally N limitation. [Sickman et al. \(2003\)](#) observed that the total P concentration in the lake doubled from 1983 to 1999. Particulate C concentration in the lake in 1999 was four times higher than the average during the period 1983–1998.

Together with the observed increase in total P in lake water, this suggested that eutrophication had occurred during that time ([Sickman et al., 2003](#)). It was proposed that increased P loading to Sierra Nevada lakes decreased  $\text{NO}_3^-$  concentration in lake water and promoted N limitation. The increased P loading may have been due to increased emissions and deposition of P and/or accelerated internal P cycling that might be caused by changes in climatic conditions and the timing of snowmelt and runoff ([Sickman et al., 2003](#); [Johnson, 1998](#); [Dettinger and Cayan, 1995](#)).

[Baron et al. \(2011a\)](#) synthesized CLs of N deposition for protecting against nutrient enrichment of high-elevation lakes. Relationships between  $\text{NO}_3^-$  concentrations and N deposition suggested a CL near 2 kg N/ha/yr to prevent  $\text{NO}_3^-$  leaching to lakes in the Sierra Nevada. [Fenn et al. \(2011a\)](#) also summarized data reflecting the relationship between atmospheric N deposition and stream  $\text{NO}_3^-$  concentration, in this case for chaparral vegetation in the San Dimas Experimental Forest in the San Gabriel Mountains ([Meixner et al., 2006](#); [Riggan et al., 1994](#); [Riggan et al., 1985](#)), Devil Canyon watershed in the western San Bernardino Mountains ([Meixner and Fenn, 2004](#); [Fenn and Poth, 1999](#)), and Chamise Creek in SEKI ([Fenn et al., 2003a](#); [Fenn et al., 2003c](#)). Stream water  $\text{NO}_3^-$  concentrations in streams draining chaparral vegetation were among the highest reported in North America, with concentrations in some streams higher than 200  $\mu\text{eq/L}$  ([Fenn et al., 2011a](#); [Fenn et al., 2003a](#); [Fenn et al., 2003c](#); [Fenn and Poth, 1999](#); [Riggan et al., 1994](#); [Riggan et al., 1985](#)). Evaluation of N saturation in chaparral must also consider the prevalence of fire in this ecosystem type because the stand-replacing fire interval is only about 40 to 60 years ([Minnich and Bahre, 1995](#)). Much of the atmospherically deposited N that has accumulated in the litter and aboveground vegetation over the intervening years is released suddenly to the atmosphere during fire. In contrast, much of the accumulated N in the mineral soil generally remains on-site after a fire ([Fenn et al., 2011a](#)), and fire contributes to increased  $\text{NO}_3^-$  concentrations in stream water ([Riggan et al., 1994](#); [Anderson and Poth, 1989](#)).

The recent work that has been conducted on aquatic ecosystems has focused mostly on the Sierra Nevada region. Analogous nutrient enrichment work has not been conducted in or around JOTR, in part, because there are few surface waters in that region.

#### **16.6.3.2.2.1 Algae**

Changes in nutrient supply can affect aquatic biota at all trophic levels, but algae are perhaps most likely to show eutrophication effects from N deposition. Studies have shown an increase in lake phytoplankton biomass in response to increases in N deposition in the Sierra Nevada region ([Sickman et al., 2003](#)), Wyoming ([Lafrancois et al., 2003b](#)), Sweden ([Bergström et al., 2005](#)), and across Europe ([Bergström and Jansson, 2006](#)).

Increases in algal biomass have been associated with changes in algal assemblages that favor certain species over others. A widespread increase in the relative abundance of *Asterionella formosa* and *Fragilaria crotonensis* occurred in oligotrophic lakes across the western U.S.; these changes have been documented from both lake sediment cores and limnological surveys ([Saros et al., 2003](#); [Wolfe et al., 2001](#); [Interlandi et al., 1999](#); [Goldman, 1988](#)). In Lake Tahoe to the north of YOSE, there has been an increase since about 1950 in the ratio of araphidinate pennate diatoms to centric diatoms. This was largely due to increased abundance of *Fragilaria crotonensis*. This change in diatom relative abundance was associated with higher N loading to the lake ([Goldman, 1988](#)). [Jassby et al. \(1994\)](#) showed that atmospheric deposition supplies most of the N to Lake Tahoe.

Because high-elevation lakes in the Sierra Nevada tend to be highly oligotrophic, small changes in nutrient supply can affect algal productivity ([Sickman et al., 2003](#)). Chamise Creek in SEKI was reported to have high NO<sub>3</sub><sup>-</sup> leaching in response to throughfall N deposition near 10 kg N/ha/yr, suggesting N saturation ([Fenn et al., 2003a](#); [Fenn et al., 2003c](#)). The U.S. Forest Service has suggested a policy threshold of 2 µeq/L for stream NO<sub>3</sub><sup>-</sup> concentration in N limited ecosystems in the western U.S. This load has been suggested as a tipping point to trigger management concern for possible over-enrichment of aquatic ecosystems with N ([Fenn et al., 2011b](#)).

### 16.6.5 Summary

This case study focuses on the ecosystems found in two national parks in southern/central California, SEKI, and JOTR. SEKI largely consists of forested and mountainous terrain in and near the Sierra Nevada Mountains. JOTR is covered largely by desert and semiarid land. Both are generally downwind of air pollution (mainly N) sources. The majority of the information provided in this case study is applicable to ecosystems found within SEKI. Limited research conducted in JOTR was found in the peer-reviewed literature. A summary of studies relevant to evaluating CLs is shown by [Figure 16-54](#).

ha = hectare; JOTR = Joshua Tree National Park; kg = kilogram; Mtns. = mountains; N = nitrogen; N. = north; NO = nitric oxide; NO<sub>3</sub><sup>-</sup> = nitrate; SEKI = Sequoia and Kings Canyons National Parks; So = southern; YOSE = Yosemite National Park; yr = year.

**Figure 16-54 Continuum of critical loads in southern/central California case study area and relevant surrounding region.**

The Sierra Nevada Mountains, in which SEKI is located, contain many acid-sensitive aquatic resources. Limited monitoring studies indicated that the current condition of these waters is probably similar to that found during previous decades with no additional recovery. Aquatic acidification effects to date on SEKI's condition have been minimal at higher elevations due to low acidic deposition, and widespread lake or stream acidification has not occurred to any degree, although some episodic acidification has likely occurred. There are expectations for N retention in high-elevation watersheds as snowmelt changes temporally due to climate warming. Small changes in nutrient supply to high-elevation, oligotrophic lakes in the Sierra Nevada can affect algal productivity and increase abundance of *Asterionella formosa* and *Fragilaria crotonensis* ([Saros et al., 2003](#)). Amphibian decline and the possible association with air pollution is noteworthy. However, one of the most pronounced effects of N deposition in the Sierra Nevada has been shown to be an alteration of the lichen community which has CLs ranging from 3.1 to 5.2 kg N/ha/yr ([Bowman et al., 2011](#); [Fenn et al., 2008](#)).

JOTR's arid and semiarid ecosystems are not known to be sensitive to acidification because there is limited precipitation, few surface waters, and high acid buffering capacity. N deposition may increase productivity of invasive grasses after fire, and deposition and climate change may promote an altered fire cycle that does not allow sufficient time for Joshua tree woodlands to re-establish between fires. It has been suggested that N deposition may have already exceeded JOTR's critical load of 8.4 kg N/ha/yr for terrestrial plant communities ([Pardo et al., 2011c](#)).
