<b>EXECUTIVE SUMMARY</b>	<b>1</b>
--------------------------	----------

ES.1	Purpose and Scope of the Integrated Science Assessment	1
	Figure ES-1 Roadmap of the Integrated Science Assessment (ISA) linking atmospheric concentrations and deposition, soil and aquatic biogeochemistry, and biological effects.	4
ES.2	Emissions, Ambient Air Concentrations, and Deposition	4
	Figure ES-2 Wet plus dry deposition of (A) oxidized nitrogen, (B) reduced nitrogen, (C) total nitrogen, and (D) total sulfur over the 3-year periods 2000–2002 and 2016–2018.	6
ES.3	Ecological Effects	7
	Table ES-1 Causal determinations for relationships between criteria pollutants and ecological effects from the 2008 NO <sub>x</sub> /SO <sub>x</sub> Integrated Science Assessment (ISA) or the 2009 ISA for Particulate Matter (PM), for other effects of PM, and the current draft ISA.	8
	Figure ES-3 Causal relationships between the criteria pollutants and ecological effects.	12
ES.4	Direct Phytotoxic Effects of Gas-Phase Oxides of Nitrogen (NO <sub>y</sub> ) and Oxides of Sulfur (SO <sub>x</sub> )	13
ES.5	Ecological Effects of Nitrogen and Sulfur Deposition	13
	ES.5.1 Acidification of Terrestrial and Freshwater Ecosystems	13
	ES.5.2 Nitrogen Enrichment/Eutrophication of Terrestrial, Wetland, and Aquatic Ecosystems	15
	Figure ES-4 Summary of critical loads for nitrogen in the U.S. for shrubs and herbaceous plants (yellow), trees (blue), lichens (green), and mycorrhizae (gray). Values expressed by major U.S. ecoregions.	17
	ES.5.3 Sulfur (S) Enrichment of Wetland and Freshwater Ecosystems	19

ES.5.4	Ecological Effects of Particulate Matter Other Than Those Associated with Nitrogen and Sulfur Deposition	20
ES.6	Ecosystem Services	20
ES.7	Integrating across Ecosystems	21
	Figure ES-5 Causal relationships between the criteria pollutants and ecological effects organized under ecosystem type.	22

## **INTEGRATED SYNTHESIS** \_\_\_\_\_ **1**

IS.1	Introduction to This Integrated Science Assessment (ISA)	1
	IS.1.1 Purpose	1
	IS.1.2 Process and Development	4
	Figure IS-1 Workflow for collecting relevant literature for the 2017 Integrated Science Assessment for Oxides of Nitrogen, Oxides of Sulfur, and Particulate Matter—Ecological Criteria.	5
IS.2	Connections, Concepts, and Changes	7
	IS.2.1 Connections	7
	Figure IS-2 Overview of atmospheric chemistry, deposition, and ecological effects of emissions of oxides of nitrogen, oxides of sulfur, and reduced nitrogen.	8
	IS.2.2 Concepts	8
	Figure IS-3 An example of the matrix of information considered in defining and calculating critical loads (see discussion in text). Note that multiple alternative biological indicators, critical biological responses, chemical indicators, and critical chemical limits could be used.	13
	IS.2.3 Changes: New Evidence and Causal Determinations	20
	Table IS-1 Causal determinations for relationships between criteria pollutants and ecological effects from the 2008 NO <sub>x</sub> /SO <sub>x</sub> Integrated Science Assessment (ISA) or the 2009 Particulate Matter (PM) ISA, for other effects of PM, and the current draft ISA.	22
	Figure IS-4 Causal relationships between the criteria pollutants and ecological effects.	25
IS.3	Emissions and Atmospheric Chemistry	27
	IS.3.1 Sources and Atmospheric Transformations	28
	IS.3.2 Measurement and Modeling Techniques	29
	IS.3.3 Spatial and Temporal Variability in Deposition	29
	Figure IS-5 Wet plus dry deposition of total nitrogen over 3-year periods. Top: 2000–2002; Bottom: 2016–2018.	31
	Figure IS-6 Wet plus dry deposition of oxidized nitrogen over 3-year periods. Top: 2000–2002; Bottom: 2016–2018.	32
	Figure IS-7 Wet plus dry deposition of reduced (inorganic) nitrogen over 3-year periods. Top: 2000–2002; Bottom: 2016–2018.	33
	Figure IS-8 Wet plus dry deposition of total sulfur over 3-year periods. Top: 2000–2002; Bottom: 2016–2018.	35

<b>APPENDIX 1 QUALITY ASSURANCE AND INTRODUCTION TO APPENDICES</b>			<b>1-1</b>
<b>APPENDIX 2 SOURCE TO DEPOSITION</b>			<b>2-1</b>
2.1		Introduction	2-1
2.2		Sources of Nitrogen and Sulfur Compounds and Particulate Matter to the Atmosphere	2-5
	2.2.1	National Emissions by Source	2-6
		Table 2-1 Emissions of NO <sub>x</sub> (nitric oxide + nitrogen dioxide), sulfur dioxide, and ammonia by source category for 2017 (Teragrams N, S/yr).	2-7
	2.2.2	Methods of Estimating Emissions	2-8
		Figure 2-1 Modeling system used to compute 2014 Fertilizer Application Emissions.	2-11
		Figure 2-2 Process to produce specific location and practice specific daily emission factors for livestock waste.	2-13

2.2.3	Evaluation and Uncertainty	2-13
2.3	Atmospheric Chemistry of Nitrogen and Sulfur Species and Particulate Matter (PM)	2-16
2.3.1	Nitrogen Oxides	2-16
	Figure 2-3 Schematic diagram showing pathways for reactive nitrogen species in ambient air.	2-18
	Table 2-2 Henry's law coefficients for selected reactive nitrogen species at 25°C in water.	2-19
2.3.2	Sulfur Oxides	2-21
	Figure 2-4 Rate of conversion of sulfur (IV) to sulfur (VI) by different oxidation paths as a function of pH.	2-22
2.3.3	Acid Neutralization by Ammonia	2-23
2.3.4	Organic Nitrogen and Sulfur	2-25
2.3.5	Organic Acids	2-26
2.3.6	Particulate Matter (PM)	2-27
	Figure 2-5 Contributions of organic carbon (OC), elemental carbon (EC), sulfate, nitrate, sea salt, and crustal components to PM <sub>2.5</sub> at selected sites (A) 2003–2005 (B) 2013–2015.	2-28
2.4	Concentration and Deposition Measurements	2-29
2.4.1	Monitoring Networks	2-29
	Table 2-3 Summary of monitoring networks used by Schwede and Lear (2014a).	2-31
2.4.2	NO <sub>2</sub> , NO <sub>x</sub> , and NO <sub>y</sub>	2-33
2.4.3	Ammonia	2-35
2.4.4	Sulfur Dioxide	2-38
	Table 2-4 Sources of uncertainty for individual Ozone Monitoring Instrument measurements in the study of Nowlan et al. (2014).	2-39
2.4.5	Filter-Based Concentration Measurements	2-39
	Figure 2-6 Clean Air Status and Trends Network filter pack.	2-40
	Figure 2-7 Comparison between weekly average measurements of sulfur dioxide using the Clean Air Status and Trends Network filter pack and the trace ultraviolet pulsed fluorescence monitor in 2014.	2-42
2.4.6	Deposition Measurements	2-43
2.5	Modeling Chemistry, Transport, and Deposition	2-46
2.5.1	Advances in Chemistry-Transport Model (CTM) Modeling	2-46
2.5.2	Modeling Deposition	2-48
	Figure 2-8 Schematic diagram showing mechanisms for transferring pollutants from the atmosphere to the surface.	2-49
	Table 2-5 Average dry deposition velocities (cm/s) for several gases over land surfaces.	2-50
	Table 2-6 Deposition velocity (cm/s) for sulfur dioxide averaged over different land use types for summer and winter.	2-50
	Figure 2-9 Modeled and measured deposition velocities over grass (left figure) and coniferous forest canopies (right figure) for particles of density 1 gm/cm <sup>3</sup> depositing under similar friction velocity ( $u^*$ ) ( $35 < u^* < 56$ cm/s).	2-52
	Figure 2-10 Schematic of the interactions involved in the exchange of nitrogen oxides between the atmosphere and the forest canopy as identified by Min et al. (2014).	2-55
	Figure 2-11 Scatterplots showing transference ratios for oxidized nitrogen and sulfur oxides comparing the Community Multiscale Air Quality model to the Comprehensive Air Quality Model with Extensions in (a) and (c) and comparing 2005 to 2014 in (b) and (d).	2-60
2.5.3	Model Evaluation and Uncertainty	2-61

	Table 2-7	Reported comparisons of chemical transport models and observations of nitrogen and sulfur wet deposition _____	2-62
2.6	Geographic Distribution of Concentration and Deposition _____		2-62
2.6.1	pH and H <sup>+</sup> Equivalents _____		2-65
	Figure 2-12	(Left) pH of rainwater, 1989–1991; (Right) pH of rainwater, 2016–2018. _____	2-66
	Figure 2-13	Difference in wet deposition of nitrate, ammonium, and sulfate expressed as hydrogen ion equivalents (eq/ha/yr) over the contiguous U.S. between 1989 to 1991 and 2016 to 2018. _____	2-67
2.6.2	Total Nitrogen _____		2-68
	Figure 2-14	Total (wet + dry) deposition of nitrogen (kg N/ha/yr) over the contiguous U.S. 2016–2018. _____	2-69
	Figure 2-15	(A) Percentage of total nitrogen deposition as reduced inorganic nitrogen over the contiguous U.S. 2016–2018. (B) Percentage of total nitrogen deposition as oxidized nitrogen over the contiguous U.S. 2016–2018. _____	2-70
	Figure 2-16	Trends in U.S. total deposition flux of total nitrogen, oxidized nitrogen, reduced nitrogen, and major nitrogen species 2000–2017. _____	2-71
	Figure 2-17	Three-year average percentage of total nitrogen deposition by species (i.e., those species that are not measured in the networks) simulated by the Community Multiscale Air Quality modeling system for 2016–2018. _____	2-72
	Figure 2-18	Wet deposition of ammonium + nitrate (kg N/ha/yr) over the contiguous U.S. in two, 3-year periods, 2016 to 2018 and 1989 to 1991. Also shown are active National Trends Network sites in either period. _____	2-73
2.6.3	Oxidized Nitrogen _____		2-74
	Figure 2-19	Geographic distribution of annual U.S. NO <sub>x</sub> emissions in 2017. _____	2-75
	Figure 2-20	Distribution of annual average total oxidized nitrogen species concentrations for 2011 simulated by Community Multiscale Air Quality modeling system. _____	2-76
	Figure 2-21	Seasonal average surface nitrogen dioxide mixing ratios in parts per billion for winter (upper panel) and summer (lower panel) derived by the Ozone Monitoring Instrument/GEOS-Chem model for 2009–2011. The Ozone Monitoring Instrument has an overpass at approximately 1:30 p.m. local standard time. _____	2-77
	Figure 2-22	Three-year average (2016–2018) surface concentrations of nitric acid based on monitoring data obtained at Clean Air Status and Trends Network sites (black dots). _____	2-79
	Figure 2-23	Three-year average (2016–2018) surface concentrations of particulate nitrate based on monitoring data obtained at Clean Air Status and Trends Network sites (black dots). _____	2-80
	Figure 2-24	Trends in particulate nitrate concentration 1990–2017: (A) average eastern U.S. concentration based on 34 sites; (B) average western concentration based 16 sites. _____	2-81
	Figure 2-25	Total oxidized nitrogen deposition over the contiguous U.S. 2016–2018. _____	2-82
	Figure 2-26	(Left) nitrate wet deposition, 1989–1991; (Right) nitrate wet deposition, 2016–2018. _____	2-83
	Figure 2-27	Difference in wet deposition of nitrate (kg N/ha/yr) over the contiguous U.S. between 1989 to 1991 and 2016 to 2018. The range of positive values is smaller than that for negative values. _____	2-84
	Figure 2-28	Trends in oxidized nitrogen emissions and deposition 2000–2017: (A) total national emissions; (B) national average total deposition flux. _____	2-85
2.6.4	Reduced Nitrogen _____		2-85

	Figure 2-29	Geographic distribution of annual U.S. ammonia (NH <sub>3</sub> ) emissions in 2017. _____	2-86
	Figure 2-30	Average (2017) surface concentration of ammonia obtained by the Ambient Ammonia Monitoring Network at select Clean Air Status and Trends Network sites. Concentrations of ammonia (µg/m <sup>3</sup> ) can be converted to mixing ratios (parts per billion) to rough approximation at normal temperature and pressure by multiplying by 1.4. _____	2-87
	Figure 2-31	Three-year average (2016–2018) surface concentrations of particulate ammonium (µg/m <sup>3</sup> ) based on monitoring data obtained at Clean Air Status and Trends Network sites (black dots). _____	2-88
	Figure 2-32	Total reduced inorganic nitrogen deposition over the contiguous U.S. 2016–2018. _____	2-89
	Figure 2-33	(Left) ammonium wet deposition, 1989–1991; (Right) ammonium wet deposition, 2016–2018. _____	2-90
	Figure 2-34	Difference in wet deposition of ammonium (kg N/ha/yr) over the contiguous U.S. between 1989 to 1991 and 2016 to 2018. _____	2-91
	Figure 2-35	Trends in reduced nitrogen emissions and deposition 2000–2017: (A) total national NH <sub>3</sub> emissions; (B) national average reduced nitrogen deposition flux. _____	2-92
2.6.5	Sulfur Oxides	_____	2-92
	Figure 2-36	Geographic distribution of annual U.S. sulfur dioxide (SO <sub>2</sub> ) emissions by county from the 2017 National Emissions Inventory. _____	2-93
	Figure 2-37	Trends in total national sulfur dioxide emissions. _____	2-93
	Figure 2-38	Three-year average (2016–2018) surface concentrations of sulfur dioxide obtained by fusion of monitoring data obtained at Clean Air Status and Trends Network sites (black dots) and Community Multiscale Air Quality model system results. Concentrations (µg/m <sup>3</sup> ) can be converted to mixing ratios (parts per billion) at normal temperature and pressure) to rough approximation by multiplying by 0.37. _____	2-95
	Figure 2-39	Three-year average (2016–2018) surface concentrations of particulate sulfate based on monitoring data obtained at Clean Air Status and Trends Network sites (black dots). _____	2-96
	Figure 2-40	Trends in oxides of sulfur oxides concentrations 1990–2017: (A) average eastern U.S. SO <sub>2</sub> concentration based on 34 sites; (B) average western U.S. SO <sub>2</sub> concentration based on 16 sites; (C) average eastern U.S. sulfate concentration based on 34 sites; (D) average western U.S. sulfate concentration based on 16 sites. _____	2-97
	Figure 2-41	Total deposition of sulfur (kg S/ha/yr) over the contiguous U.S. 2016–2018. _____	2-98
	Figure 2-42	Percentage of deposition of total sulfur as dry deposition over the contiguous U.S. 2016–2018. _____	2-99
	Figure 2-43	(Left) sulfate wet deposition, 1989–1991; (Right) sulfate wet deposition, 2016–2018. _____	2-100
	Figure 2-44	Difference in wet deposition of sulfate (kg S/ha/yr) over the contiguous U.S. between 1989 to 1991 and 2016 to 2018. The range of positive values is much smaller than for negative values. _____	2-100
	Figure 2-45	Trends in average sulfur deposition flux for 34 monitoring sites in the eastern U.S. 1989–2017. _____	2-101
2.6.6	Particulate Matter (PM)	_____	2-101
	Figure 2-46	Three-year average concentrations of particulate matter smaller than 2.5 µm diameter (PM <sub>2.5</sub> ) 2013–2015. _____	2-102

	Figure 2-47	National monthly average concentrations of particulate matter smaller than 2.5 $\mu\text{m}$ diameter ( $\text{PM}_{2.5}$ ; top) and sulfate in $\text{PM}_{2.5}$ (bottom) from 2000–2016 (concentrations in $\mu\text{g}/\text{m}^3$ ). _____	2-103
	Figure 2-48	98th percentile concentrations for $\text{PM}_{10-2.5}$ between 2013–2015. ____	2-104
2.6.7	Distributions of Dry Deposition of Nitrogen Dioxide and Sulfur Dioxide Derived Using Satellite-Based Measurements and Chemistry Transport Models _____		2-104
	Figure 2-49	Top panel: modeled deposition velocities for nitrogen dioxide and sulfur dioxide for 2005 to 2007; middle panel satellite-model estimates of annual mean dry deposition fluxes of nitrogen dioxide and sulfur dioxide; bottom panel: uncertainties in estimates. _____	2-106
2.6.8	Background Concentrations and Deposition _____		2-107
	Figure 2-50	Contributions to oxidized and reduced nitrogen deposition from U.S.: anthropogenic (top), foreign anthropogenic (middle), and natural sources (bottom). _____	2-108
2.7	Supplemental Material on Changes in Deposition since 2000 _____		2-112
	Figure 2-51	Wet plus dry deposition of total nitrogen over 3-year periods. Top: 2000–2002; Bottom: 2016–2018. _____	2-114

### **APPENDIX 3 DIRECT PHYTOTOXIC EFFECTS OF GASEOUS OXIDIZED NITROGEN AND SULFUR ON VEGETATION** **3-1**

3.1	Introduction	3-1	
	Figure 3-1	The microarchitecture of a dicot leaf. While details among species vary, the general overview remains the same. Light that drives photosynthesis generally falls upon the upper (adaxial) leaf surface. Carbon dioxide, oxides of sulfur, oxides of nitrogen, and ozone gases generally enter by diffusion through the guard cells (or stomata) on the lower (abaxial) leaf surface, while water vapor exits through the stomata (transpiration).	3-3
3.2	Direct Phytotoxic Effects of Sulfur Dioxide on Vegetation	3-3	
	Figure 3-2	Map of maximum 3-hour daily max average sulfur dioxide concentration reported at Air Quality System monitoring sites for 2016.	3-5
3.3	Direct Phytotoxic Effects of Nitric Oxide, Nitrogen Dioxide, and Peroxyacetyl Nitrate	3-7	
	Figure 3-3	Map of U.S. annual average nitrogen dioxide concentrations for 2013.	3-8
3.4	Direct Phytotoxic Effects of Nitric Acid	3-13	
3.5	Direct Phytotoxic Effects of Reduced Nitrogen Gases	3-15	
3.6	Summary	3-16	
	3.6.1	Sulfur Dioxide	3-16
	3.6.2	Nitrogen Oxide, Nitrogen Dioxide, and Peroxyacetyl Nitrate	3-17
	3.6.3	Nitric Acid	3-17

### **APPENDIX 4 SOIL BIOGEOCHEMISTRY** **4-1**

4.1	Introduction	4-1	
4.2	Nitrogen and Sulfur Sources to Soil	4-2	
	Figure 4-1	Dominant sources of nitrogen across the U.S. at 8-digit hydrologic unit codes.	4-3
	Figure 4-2	Percentage of nitrogen input from nitrogen deposition at 8-digit hydrologic unit codes.	4-3

<b>APPENDIX 5 BIOLOGICAL EFFECTS OF TERRESTRIAL ACIDIFICATION _____</b>			<b>5-1</b>
5.1	Introduction _____		5-1
	Figure 5-1	Diagram based on Fenn et al. (2006) showing indicators of forest physiological function, growth, and structure that are linked to biogeochemical cycles through processes that control rates of calcium supply. Calcium affects plant physiological processes that influence growth rates and the capacity of plants to resist environmental stresses, such as extremes of temperature, drought, insects, and diseases. Therefore, acidifying deposition, which can deplete soil calcium or interfere with calcium uptake through mobilization of soil aluminum, can affect forest health. _____	5-3
	Table 5-1	Relationships between soil chemistry indicators and biological endpoints that have been evaluated in the literature since the 2008 Integrated Science Assessment. _____	5-4

	Table 7-9 Summary of studies quantifying atmospheric nitrogen contribution to total nitrogen in coastal areas via watersheds and/or direct deposition to estuary surface waters.	7-73
7.2.2	The Estuary Environment	7-77
	Figure 7-7 Schematic diagram illustrating sources, transformations, and fate of nitrogen along the estuary-to-ocean continuum. Surface, subsurface, and atmospheric pathways of externally supplied or new nitrogen inputs attributable to anthropogenic activities are shown as internal nitrogen cycling. The combined anthropogenic nitrogen inputs are shown as a thick arrow (upstream), which decreases in thickness downstream as a portion of the nitrogen inputs settles to the bottom sediments and is buried and/or denitrified. Nitrogen (N <sub>2</sub> ) fixation is a biologically mediated new nitrogen input. The linkage of anthropogenically enhanced nitrogen inputs to accelerated primary production or eutrophication and its trophic and biogeochemical fate are also shown.	7-78

10.1.2		Trends in Atmospheric Deposition of Nitrogen _____	10-6
10.1.3		Nitrogen Limitation _____	10-6
10.1.4		Characteristics of Coastal Systems Sensitive to Eutrophication _____	10-8
10.2		Indicators of Nutrient Enrichment _____	10-11
	Table 10-1	Indicators of Estuarine Eutrophication. _____	10-12
	Figure 10-3	Biological indicator responses to nutrient enrichment. _____	10-13
10.2.1		Chlorophyll a _____	10-13
	Table 10-2	Chlorophyll a thresholds used in methods to evaluate the status of phytoplankton in U.S. coastal and estuarine water bodies. _____	10-14
10.2.2		Harmful/Nuisance/Toxic Algal Blooms _____	10-16
	Table 10-3	Levels and forms of nitrogen at which effects on phytoplankton are manifest in U.S. coastal waters evaluated in the literature since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur—Ecological Criteria. _____	10-20
10.2.3		Macroalgal Abundance _____	10-25
10.2.4		Dissolved Oxygen _____	10-26
	Figure 10-4	The range of ecological impacts exhibited as dissolved oxygen levels drop from saturation to anoxia. _____	10-27
	Figure 10-5	Coastal eutrophic and hypoxic areas of North America and the Caribbean. _____	10-29
10.2.5		Submerged Aquatic Vegetation _____	10-32
	Table 10-4	Nitrogen loading thresholds from multiple watershed sources versus eelgrass loss. _____	10-34
	Figure 10-6	Extent of submerged aquatic vegetation in the Chesapeake Bay 1978–2016. _____	10-36
10.2.6		Indices of Estuarine Condition _____	10-37
10.3		Effects on Biodiversity _____	10-39
10.3.1		Paleontological Diversity _____	10-39
10.3.2		Phytoplankton Diversity _____	10-40
10.3.3		Diversity of Phytoplankton Under Different Forms of Nitrogen (Reduced vs. Oxidized) _____	10-41
	Figure 10-7	Summary conceptual schematic illustrating the effect of changes in the proportion of $\text{NH}_4^+$ and $\text{NO}_3^-$ in the loads of N provided to a natural system. When $\text{NH}_4^+$ is the dominant form, and when waters are warmer, flagellates, cyanobacteria, and chlorophytes among other classes may proliferate, leading to overall productivity dominated by the small size class of algae (e.g., $<5\ \mu\text{m}$ ). In contrast, when $\text{NO}_3^-$ is the dominant form provided, especially under cooler water conditions, diatoms more likely dominate, and their overall production will be more likely dominated by cells of a larger size class (e.g., $>5\ \mu\text{m}$ ). Moreover, chlorophyll a yield and total production may be higher than under the $\text{NH}_4^+$ enrichment condition. _____	10-43
10.3.4		Diversity of Bacteria, Archaea, and Microzooplankton _____	10-44
10.3.5		Benthic Diversity _____	10-45
10.3.6		Fish Diversity _____	10-46
10.3.7		Trophic Interactions _____	10-46
10.3.8		Models Linking Indicators to Nitrogen Enrichment _____	10-47
	Figure 10-8	Forecasting curves for effects on total nitrogen loadings on (A) chlorophyll and (B) dissolved oxygen (mean and 95% confidence interval) for selected estuaries demonstrating the full range of sensitivity to relative total nitrogen loading. _____	10-49
10.4		Animal Behavior and Disease _____	10-50
10.4.1		Behavior _____	10-50

## **APPENDIX 12 NONACIDIFYING SULFUR ENRICHMENT EFFECTS** 12-1

12.1	Introduction	12-2
	Figure 12-1 Effects of sulfur oxide deposition on chemical (blue boxes), biological (green boxes), and atmospheric (yellow boxes) indicators of ecosystem change, as documented by the previous Integrated Science Assessment and more recent research.	12-4
12.2	Ecosystem Effects of Altered Sulfur Cycling	12-4
12.2.1	The Sulfur Cycle	12-4
	Figure 12-2 Sulfur cycle in terrestrial, forested ecosystems.	12-5
12.2.2	Deposition and Sulfur Stores	12-9
	Table 12-1 New study on sulfur (S) deposition effects on sulfur (S) cycling.	12-10
12.2.3	Sulfide Toxicity	12-10
	Table 12-2 Quantitative effects of sulfide on wetland and aquatic plant species.	12-11
	Figure 12-3 Schematic from Minnesota Pollution Control Agency that illustrates the mitigating effect of iron on the toxicity of sulfide and the stimulatory effect that organic carbon has on sulfide production.	12-15
12.2.4	Internal Eutrophication	12-16
	Figure 12-4 Mechanisms of linked sulfur, iron, and phosphorus cycling in wetland waters and soils.	12-17
12.2.5	Sulfur Effects on Methane Emissions	12-18
	Table 12-3 New studies on nonacidifying sulfur effects on methane emissions.	12-20
12.3	Interactions between Sulfur Deposition and Mercury	12-22

	Figure 12-5.	Sulfate, dissolved organic carbon, and inorganic mercury are all important determinants of the rate and amount of methyl mercury produced by sulfate-reducing prokaryotes. _____	12-23
12.3.1	Mercury Cycle and the Importance of Methylation _____		12-24
	Figure 12-6	Cycling of mercury (Hg) and methylmercury (MeHg) in ecosystems. _____	12-24
12.3.2	Biology of Sulfate-Reducing Prokaryotes _____		12-26
	Table 12-4	New studies on the biology of sulfate-reducing prokaryotes. _____	12-27
	Figure 12-7	The effect of different environmental factors on the relationship between sulfate and mercury methylation. Methylmercury (MeHg) accumulation is minimal at low and high sulfate concentrations, with an optimum near 100 $\mu$ M sulfate (blue line). High dissolved organic matter (DOM) will increase the magnitude of MeHg production across the range of sulfate concentrations (red line). Sulfide produced by methylators will inhibit further methylation if it accumulates in the aqueous environment where methylation occurs, shifting the MeHg optimum left (purple line). However if ecosystem chemistry (iron [Fe], reoxidation of sulfide, organic matter [OM]) allows for rapid sequestration of sulfide to large particles and sediments, the relaxation of the negative feedback of sulfide to sulfur-reducing prokaryotes (SRPs) will shift the MeHg optimum right (green line). _____	12-35
12.3.3	Environmental Drivers of Mercury Methylation Potential _____		12-36
	Table 12-5	Environmental factors that affect mercury (Hg) methylation. _____	12-36
	Figure 12-8	The relationship between surface water sulfate and total mercury or methylmercury fraction in river/leaf litter mesocosms. _	12-40

16.1.4	Long-Term Ecological Monitoring _____		16-33
	Table 16-11	Summary table of observed terrestrial and aquatic acidification long-term trends in Hubbard Brook Experimental Forest and Bear Brook Watershed. _____	16-34
	Table 16-12	Example surface water acidification chemistry studies in the Northeast case study region. _____	16-37
	Table 16-13	Summary of observed terrestrial and aquatic nutrient enrichment long-term responses in Acadia National Park, Hubbard Brook Experimental Forest, Bear Brook Watershed, and other northeastern regions. _____	16-40
16.1.5	Recovery _____		16-45
16.2	Adirondack Case Study: Adirondack Region of New York _____		16-46
	16.2.1 Background _____		16-46
	Figure 16-9	Map of Adirondack park land cover. _____	16-48
	16.2.2 Deposition _____		16-49
	Figure 16-10	Total nitrogen deposition (A) and percentage of oxidized nitrogen deposition (B) for the Adirondack case study area estimated by the National Atmospheric Deposition Program Total Deposition Science committee. _____	16-50
	Figure 16-11	Total sulfur deposition (A) for the Adirondack case study area estimated by the National Atmospheric Deposition Program Total Deposition Science committee. Time series of wet deposition (B) from the National Atmospheric Deposition Program/National Trends Network Whiteface Mountain, NY. _____	16-51
16.2.3	Critical Loads and Other Dose-Response Relationships _____		16-52
	Table 16-14	Terrestrial empirical and modeling research on the response of nitrogen and sulfur deposition for the Adirondack Mountains. _____	16-52
	Figure 16-12	Number of fish species per lake and acidity status, expressed as acid neutralizing capacity, for Adirondack lakes. _____	16-56
	Figure 16-13	Total macroinvertebrate species (community) richness as a function of median pH in 36 streams sampled in the western Adirondack Mountains of New York, 2003–2005; the four standard (New York State) impact categories for species richness are defined. _____	16-58
	Figure 16-14	Species richness of biotic groups in 30 Adirondack study lakes relative to midsummer epilimnetic pH during sample years. _____	16-59
	Table 16-15	Aquatic empirical research on the response of nitrogen and sulfur deposition for the Adirondacks. _____	16-60
	Table 16-16	Critical and target load and exceedance modeling studies in Adirondack Mountains. _____	16-62

16.2.4	Long-Term Monitoring		16-63
	Figure 16-15	(A) Midsummer sulfate concentration in the epilimnion of Brooktrout Lake (○) and in annual wet deposition (●) at local National Atmospheric Deposition Program/National Trends Network Station NY52 from 1984–2012. (B) Midsummer epilimnetic concentrations of inorganic monomeric aluminum (□) and hydrogen ion (■) in Brooktrout Lake from 1984–2012. (C) Midsummer phytoplankton (Δ) and total plankton (phytoplankton, rotifers, crustaceans) (▲) species richness in Brooktrout Lake from 1984–2012.	16-68
16.3	Southeastern Appalachia Case Study		16-69
16.3.1	Background		16-69
	Table 16-17	Species in the Southeast case study region that are listed as threatened or endangered or as a species of concern.	16-72
	Figure 16-16	Great Smoky Mountains National Park and nearby Class I wilderness areas, with emphasis on water sampling locations within GSMNP and critical loads for watersheds described in Appendix 16.2.3.2.	16-77
	Figure 16-17	Land cover in the southern Appalachian Mountains case study region.	16-78
16.3.2	Deposition		16-78
	Figure 16-18	Deposition over Great Smoky Mountain National Park.	16-79
	Figure 16-19	Trends in wet deposition of nitrogen and sulfur in Great Smoky Mountain National Park, 1990–2014.	16-80
	Figure 16-20	Total nitrogen deposition on left, total sulfur deposition on right, for the 3-year average, 2011–2013 in Great Smoky Mountain National Park.	16-81
	Figure 16-21	Modeled sulfur and nitrogen deposition to the Great Smoky Mountain National Park for the year 2000.	16-82
	Figure 16-22.	Annual-averaged monthly footprint of reactive N deposition in Great Smoky Mountain National Park (10.4 kg N/ha/yr), and pie chart of fractional contribution from emission sectors, as estimated by GEOS-Chem adjoint model.	16-83
16.3.3	Critical Loads and Other Dose-Response Relationships		16-83
16.3.4	Characterization and Long-Term Monitoring		16-86
	Table 16-18	Example soil, terrestrial biota, and surface water acidification characterization and long-term monitoring studies in the southern Appalachian Mountains region.	16-87
16.4	Tampa Bay Case Study		16-90
16.4.1	Background		16-90
	Figure 16-23	Tampa Bay mainstem segments and watershed. Also shown are the National Atmospheric Deposition (NADP) National Trends Network wet deposition monitoring site FL41 at Verna wellfield in Sarasota County and the NADP Atmospheric Integrated Research Monitoring Network site FL18 in Hillsborough County.	16-92
	Figure 16-24	Tampa Bay overview map highlighting watershed development and land use.	16-95
16.4.2	Deposition		16-96
	Figure 16-25	Annual wet deposition of ammonium, nitrate, sulfate, and acidity at the National Atmospheric Deposition National Trends Network monitoring site closest to the Tampa Bay case study area.	16-96
	Figure 16-26	Estimated annual loads of total nitrogen from various sources to Tampa Bay summarized from 1976 to 2011.	16-97
	Figure 16-27	(A) Wet and dry nitrogen deposition in Tampa Bay and the surrounding area. (B) Percentage of oxidized nitrogen deposition in Tampa Bay and the surrounding area.	16-99

16.4.3	Long-Term Ecological Monitoring	16-99
	Figure 16-28 Submerged aquatic vegetation cover loss in Tampa Bay.	16-101
	Figure 16-29 Comparison of observed chlorophyll <i>a</i> and that predicted from the total nitrogen load—chlorophyll <i>a</i> relationships for all four mainstem Tampa Bay segments, for 1986–1998 and 1999–2007.	16-102
	Figure 16-30 Total seagrass coverage in Tampa Bay circa 1950 through 2014.	16-104
	Figure 16-31 Trend in hydrologically normalized total nitrogen load to Tampa Bay relative to population increases in the Tampa Bay metropolitan area.	16-105
16.4.4	Nitrogen Management	16-106
	Table 16-19 Numeric nutrient criteria for chlorophyll <i>a</i> for the four mainstem segments of Tampa Bay adopted by the Florida Department of Environmental Protection.	16-106
	Table 16-20 Numeric nutrient criteria for total nitrogen for the four mainstem segments of Tampa Bay.	16-107
16.5	Rocky Mountain National Park Case Study	16-109
16.5.1	Background	16-109
	Figure 16-32 Rocky Mountain National Park ecosystems.	16-110
	Figure 16-33 Rocky Mountain National Park land coverage using the land cover classifications as mapped by the National Land Cover Dataset. Percentage of cover is shown for the four dominant cover types.	16-113
	Figure 16-34 Rocky Mountain National Park hydrologic unit code 12 watersheds.	16-114
16.5.2	Deposition	16-115
	Figure 16-35 Total atmospheric nitrogen and sulfur deposition in the Rocky Mountain National Park region based on TDEP calculations averaged from 2011–2013 (see Appendix 2) and long-term trends in wet atmospheric deposition from the Beaver Meadows National Atmospheric Deposition Program Monitoring site within Rocky Mountain National Park.	16-116
	Figure 16-36 Percentage of atmospheric nitrogen deposited in oxidized forms and through wet deposition in the Rocky Mountain National Park region based on TDEP calculations averaged from 2011–2013 (see Appendix 2).	16-117
	Figure 16-37 Rocky Mountain National Park nitrogen cycle.	16-118
	Figure 16-38 National Park from November 2008 to November 2009, including organic nitrogen and particulate organic nitrogen.	16-119
	Figure 16-39 Annual-averaged monthly footprint of reactive N deposition in Rocky Mountain National Park (4.0 kg N/ha/yr), and pie chart of fractional contribution from emission sectors, as estimated by GEOS-Chem adjoint model.	16-120
16.5.3	Critical Loads and Other Dose-Response Relationships	16-120
	Table 16-21 Terrestrial empirical critical loads of nutrient nitrogen for the Northwestern Forested Mountains ecoregion.	16-121
	Table 16-22 Montane forest and alpine ecosystem critical loads for nitrogen deposition research published since the critical load assessment by Pardo et al. (2011c).	16-124
	Table 16-23 Hindcast absolute and percentage changes in species abundance between 1900 and 2010 in response to historical reconstructions of nitrogen deposition (Sullivan et al., 2005) and historical climate change (IPCC, 2007b).	16-127
	Table 16-24 Critical loads for nitrogen for eutrophication for surface water (high-elevation lakes) in the Rocky Mountains.	16-129

	Table 16-25	Lake water nitrate concentrations in nitrogen deposition studies observing phytoplankton responses. _____	16-130
	Table 16-26	Paleolimnological biological responses in Rocky Mountain lakes exposed to anthropogenic nitrogen deposition. _____	16-131
	Table 16-27	Critical loads of nitrogen or sulfur for surface water acidification Rocky Mountain National Park and other high-elevation lakes in the Rocky Mountains. _____	16-133
	Figure 16-40	The continuum of ecological sensitivity to nitrogen deposition. ____	16-135
	Figure 16-41	Critical load thresholds for current and possible future biogeochemical and biological effects of nitrogen deposition. ____	16-136
16.5.4	Highlights of Additional Research Literature and Federal Reports since January 2008 _____		16-136
	Table 16-28	Summary of freshwater eutrophication studies in the Rocky Mountains since 2008. _____	16-138
16.5.5	Rocky Mountain National Park Initiative _____		16-139
	Figure 16-42	Rocky Mountain National Park Initiative glidepath and current wet nitrogen deposition at Loch Vale in Rocky Mountain National Park. _____	16-141
	Figure 16-43	Rocky Mountain National Park Initiative accomplishment timeline. _____	16-142
16.5.6	Interactions between Nitrogen Deposition, Precipitation, and Large-Scale Ecological Disturbances _____		16-142
16.6	Southern and Central California _____		16-144
	16.6.1 Background _____		16-144
	Figure 16-44	Map of the distribution of vegetation types and land cover in California. _____	16-145
	Table 16-29	Land coverages of Sequoia, Kings Canyons, and Joshua Tree national parks. _____	16-148
	Figure 16-45	Southern and central California case study region showing locations of human population centers. _____	16-149
	16.6.2 Deposition _____		16-150
	Figure 16-46	Patterns and temporal trends of nitrogen and sulfur deposition in Joshua Tree National Park and surrounding region in California. A and B show the 3-year average total deposition of nitrogen and sulfur for 2011–2013 _____	16-151
	Figure 16-47	Patterns and temporal trends of nitrogen and sulfur deposition in Joshua Tree National Park and surrounding region in California. A shows the partitioning between oxidized and reduced nitrogen; B and C show the 3-year average total percentage of wet deposition of nitrogen and sulfur for 2011–2013. _____	16-152
	Figure 16-48	Patterns and temporal trends of nitrogen and sulfur deposition in Joshua Tree National Park and surrounding region in California. The 25-year time series for wet deposition of nitrate, ammonium, sulfate, and hydrogen ion obtained from the National Atmospheric Deposition Program/National Trends Network monitoring site CA67. _____	16-153
	Figure 16-49	Patterns and temporal trends of nitrogen and sulfur deposition of Sequoia and Kings Canyons national parks and surrounding region in California. A and B show the 3-year average total deposition of nitrogen and sulfur for 2011–2013. _____	16-154
	Figure 16-50	Patterns and temporal trends of nitrogen and sulfur deposition of Sequoia and Kings Canyons national parks and surrounding region in California. A shows the partitioning between oxidized and reduced nitrogen, indicated as the fraction of total nitrogen which is oxidized; B and C show the 3-year average total percentage of wet deposition of nitrogen and sulfur for 2011–2013. _____	16-155

Figure 16-51	Patterns and temporal trends of nitrogen and sulfur deposition of Sequoia and Kings Canyons and in Yosemite national parks and surrounding regions in California. A and B show the 25-year time series for wet deposition of nitrate, ammonium, sulfate, and hydrogen obtained from the National Atmospheric Deposition Program/National Trends Network monitoring sites CA99 and CA75. _____	16-156
Figure 16-52	Annual-averaged monthly footprint of reactive N deposition in Joshua Tree National Park (3.2 kg N/ha/yr) and Sequoia National Park (5.7 kg N/ha/yr). Also shown for each park is a pie chart of fractional contribution from emission sectors, as estimated by GEOS-Chem adjoint model. _____	16-158
16.6.3	Critical Loads and Other Dose-Response Relationships _____	16-158
Figure 16-53	Composite critical load exceedance maps for all seven vegetation types included in the study of Fenn et al. (2010) showing the combined exceedance areas and the level of exceedance (kg N/ha/yr). _____	16-161
Table 16-30	Summary of recent empirical dose-response and critical load studies focused on the southern/central California case study area and published since Pardo et al. (2011c). _____	16-162
Table 16-31	Terrestrial critical and target load and exceedance modeling studies in southern/central California. _____	16-165
Table 16-32	Example surface water acidification studies in Sequoia and Kings Canyons National Parks and other Sequoia and Kings Canyons National Parks—relevant areas in the southern/central California case study region. _____	16-168
16.6.4	Highlights of Additional Research Literature and Federal Reports since January 2008 _____	16-173
Table 16-33	Key recent research literature focused on the case study region. _____	16-173
16.6.5	Summary _____	16-175
Figure 16-54	Continuum of critical loads in southern/central California case study area and relevant surrounding region. _____	16-176

---

## Chair of the Charter Clean Air Scientific Advisory Committee

Dr. Louis Anthony (Tony) Cox, Jr.—Cox Associates, Denver, CO

---

## Charter Clean Air Scientific Advisory Committee Members

Dr. James Boylan—Georgia Department of Natural Resources, Atlanta, GA

Dr. Mark W. Frampton—University of Rochester Medical Center, Rochester, NY

Dr. Ronald J. Kendall—Texas Tech University, Lubbock, TX

Dr. Sabine Lange—Texas Commission on Environmental Quality, Austin, TX

Dr. Corey M. Masuca—Jefferson County Department of Health, Birmingham, AL

Dr. Steven C. Packham—Utah Department of Environmental Quality, Salt Lake City, UT

---

## Chair, Oxides of Nitrogen, Oxides of Sulfur and Particulate Matter—Ecological Criteria Review Panel

Dr. Ivan J. Fernandez\*\*—Distinguished Maine Professor, School of Forest Resources and Climate

Dr. Ronald J. Kendall\*\*\*—Head of the Wildlife Toxicology Laboratory and Professor of Environmental Toxicology, Texas Tech University

---

## Oxides of Nitrogen, Oxides of Sulfur and Particulate Matter—Ecological Criteria Review Panel Members

Dr. Edith Allen—Professor of Plant Ecology, Department of Botany and Plant Sciences, University of California Riverside, Riverside, CA

Dr. Praveen Amar—Independent Consultant, Environment, Energy, and Climate Strategies, Lexington, MA

Dr. James Boyd—Senior Fellow and Director, Center for the Management of Ecological Wealth, Resources for the Future, Washington, DC

Dr. Elizabeth W. Boyer—Associate Professor of Water Resources, Department of Ecosystem Science and Management, Pennsylvania State University, University Park, PA

Dr. Douglas Burns—Research Hydrologist, New York Water Science Center, U.S. Geological Survey, Troy, NY

Ms. Lauraine Chestnut—Managing Economist, Stratus Consulting Inc., Boulder, CO

Dr. Charles T. Driscoll, Jr.—Distinguished Professor and University Professor of Environmental Systems Engineering, Department of Civil and Environmental Engineering, College of Engineering and Computer Science, Syracuse University, Syracuse, NY

- Dr. Mark Fenn—Research Plant Pathologist, Pacific Southwest Research Station, USDA Forest Service, Riverside, CA
- Dr. James Galloway—Sidman P. Poole Professor of Environmental Sciences, Department of Environmental Sciences, University of Virginia, Charlottesville, VA
- Dr. Frank Gilliam, Professor—Department of Biological Sciences, Marshall University, Huntington, WV
- Dr. Robert A. Goldstein—Senior Technical Executive for Water and Ecosystems, Electric Power Research Institute, Palo Alto, CA
- Dr. Daven Henze—Assistant Professor and Charles C. Gates Faculty Fellow, Department of Mechanical Engineering, University of Colorado, Boulder, CO
- Dr. Robert W. Howarth—David R. Atkinson Professor of Ecology & Environmental Biology, Department of Ecology and Evolutionary Biology, Cornell University, Ithaca, NY
- Dr. Donna Kenski—Data Analysis Director, Lake Michigan Air Directors Consortium, Rosemont, IL
- Dr. William McDowell—Professor of Environmental Science, Department of Natural Resources and the Environment, University of New Hampshire, Durham, NH
- Dr. Erik Nelson—Assistant Professor, Department of Economics, Bowdoin College, Brunswick, ME
- Dr. Hans Paerl—Kenan Professor of Marine and Environmental Sciences, Institute of Marine Sciences, University of North Carolina—Chapel Hill, Morehead City, NC
- Mr. Richard L. Poirot—Air Quality Planning Chief, Air Quality and Climate Division, Vermont Department of Environmental Conservation, Montpelier, VT
- Dr. Armistead (Ted) Russell—Howard T. Tellepsen Chair and Regents Professor of Civil and Environmental Engineering, Department of Civil and Environmental Engineering, Georgia Institute of Technology, Atlanta, GA
- Dr. Stephen E. Schwartz—Senior Scientist, Environmental and Climate Sciences Department, Brookhaven National Laboratory, Upton, NY
- Dr. Kathleen Weathers—Senior Scientist, Cary Institute of Ecosystem Studies, Millbrook, NY

## Legislative Requirements for the Review of the National Ambient Air Quality Standards

Two sections of the Clean Air Act (CAA) govern the establishment, review, and revision of the National Ambient Air Quality Standards (NAAQS). Section 108 [42 U.S. Code (U.S.C.) 7408] directs the Administrator to identify and list certain air pollutants and then to issue air quality criteria for those pollutants. The Administrator is to list those air pollutants that in their “judgment, cause or contribute to air pollution which may reasonably be anticipated to endanger public health or welfare,” “the presence of which in the ambient air results from numerous or diverse mobile or stationary sources,” and “for which ... [the Administrator] plans to issue air quality criteria ...” [42 U.S.C. 7408(a)(1); ]. Air quality criteria are intended to “accurately reflect the latest scientific knowledge useful in indicating the kind and extent of all identifiable effects on public health or welfare, which may be expected from the presence of [a] pollutant in the ambient air ...” [42 U.S.C. 7408(b)]. Section 109 [42 U.S.C. 7409; [CAA, 1990b](#)] directs the Administrator to propose and promulgate “primary” and “secondary” NAAQS for pollutants for which air quality criteria are issued. Section 109(b)(1) defines a primary standard as one “the attainment and maintenance of which in the judgment of the Administrator, based on such criteria and allowing an adequate margin of safety, are requisite to protect the public health.”<sup>1</sup> A secondary standard, as defined in Section 109(b)(2), must “specify a level of air quality the attainment and maintenance of which, in the judgment of the Administrator, based on such criteria, is requisite to protect the public welfare from any known or anticipated adverse effects associated with the presence of [the] air pollutant in the ambient air.”<sup>2</sup>

In setting standards that are “requisite” to protect public health and welfare as provided in Section 109(b), the U.S. EPA’s task is to establish standards that are neither more nor less stringent than necessary for these purposes. In so doing, the U.S. EPA may not consider the costs of implementing the standards.<sup>3</sup> Likewise, “[a]ttainability and technological

---

<sup>1</sup> The legislative history of Section 109 indicates that a primary standard is to be set at “... the maximum permissible ambient air level ... which will protect the health of any [sensitive] group of the population,” and that for this purpose “reference should be made to a representative sample of persons comprising the sensitive group rather than to a single person in such a group” S. Rep. No. 91:1196, 91st Cong., 2d Sess. 10 (1970).

<sup>2</sup> Section 302(h) of the Act [42 U.S.C. 7602(h)] provides that all language referring to effects on welfare includes, but is not limited to, “effects on soils, water, crops, vegetation, man-made materials, animals, wildlife, weather, visibility and climate, damage to and deterioration of property, and hazards to transportation, as well as effects on economic values and on personal comfort and well-being ...” ([CAA, 2005](#)).

<sup>3</sup> See generally, *Whitman v. American Trucking Associations*, 531 U.S. 457, 465–472, 475–476 (2001).

feasibility are not relevant considerations in the promulgation of national ambient air quality standards.”<sup>1</sup>

Section 109(d)(1) requires that “not later than December 31, 1980, and at 5-year intervals thereafter, the Administrator shall complete a thorough review of the criteria published under Section 108 and the national ambient air quality standards ... and shall make such revisions in such criteria and standards and promulgate such new standards as may be appropriate ....” Section 109(d)(2) requires that an independent scientific review committee “shall complete a review of the criteria ... and the national primary and secondary ambient air quality standards ... and shall recommend to the Administrator any new ... standards and revisions of existing criteria and standards as may be appropriate ....” Since the early 1980s, this independent review function has been performed by the Clean Air Scientific Advisory Committee (CASAC).<sup>2</sup>

---

## **Overview and History of the Reviews of the Secondary National Ambient Air Quality Standards for Nitrogen Dioxide, Sulfur Dioxide, and Particulate Matter**

NAAQS are defined by four basic elements: indicator, averaging time, level, and form. The indicator defines the pollutant to be measured in the ambient air for the purpose of determining compliance with the standard. The averaging time defines the time period over which air quality measurements are to be obtained and averaged or cumulated, considering evidence of effects associated with various time periods of exposure. The level of a standard defines the air quality concentration used (i.e., an ambient concentration of the indicator pollutant) in determining whether the standard is achieved. The form of the standard defines the air quality statistic that is compared to the level of the standard in determining whether an area attains the standard. The Administrator considers these four elements collectively in evaluating the protection to public health provided by the primary NAAQS.

---

### **Nitrogen Dioxide Secondary National Ambient Air Quality Standards**

The first air quality criteria and standards for oxides of nitrogen were issued in 1971 [[U.S. EPA, 1971](#)], 36 FR 8186]. Both the primary and secondary standards were set at 0.053 parts per million (ppm), as an annual arithmetic mean (36 FR 8186). In 1982, the U.S. EPA published Air Quality Criteria for Oxides of Nitrogen ([U.S. EPA, 1982a](#)),

---

<sup>1</sup> See *American Petroleum Institute v. Costle*, 665 F. 2d at 1185.

<sup>2</sup> Lists of chartered CASAC members and of members of the CASAC Panels are available at: <http://yosemite.epa.gov/sab/sabproduct.nsf/WebCASAC/CommitteesandMembership?OpenDocument>.

which updated the scientific criteria upon which the initial standards were based. On February 23, 1984, the U.S. EPA proposed to retain these standards (49 FR 6866). After taking into account public comments, the U.S. EPA published the final decision to retain the existing standards on June 19, 1985 (50 FR 25532).

In November 1991, the U.S. EPA initiated another review and released an updated draft air quality criteria document (AQCD) for review and comment by CASAC and the public (56 FR 59285). The final AQCD was released later in 1993 ([U.S. EPA, 1993](#)). Staff of the Office of Air Quality Planning and Standards (OAQPS) prepared a draft Staff Paper that summarized and integrated the key studies and scientific evidence contained in the revised air quality criteria document and identified the critical elements to be considered in the review of the NO<sub>2</sub> NAAQS. The Staff Paper was reviewed by the CASAC and the public in December 1994, and in September 1995, the U.S. EPA finalized the Staff Paper ([U.S. EPA, 1995b](#)). On October 2, 1995, the Administrator announced her proposed decision not to revise either the primary or secondary NAAQS for NO<sub>2</sub> based on the information available in this review (60 FR 52874; October 11, 1995). After consideration of public comments, the Administrator made a final determination that revisions to neither the primary nor the secondary NAAQS for NO<sub>2</sub> were appropriate at that time (61 FR 52852; October 8, 1996).

The most recent review of the secondary NAAQS standards for oxides of nitrogen was performed jointly with a review of the secondary NAAQS for oxides of sulfur beginning in 2005 (described below).

---

## **Sulfur Dioxide Secondary National Ambient Air Quality Standards**

Based on the 1969 sulfur oxides criteria document ([HEW, 1969](#)), the U.S. EPA promulgated the initial primary and secondary NAAQS for SO<sub>2</sub> on April 30, 1971 (36 FR 8186). The secondary standards were 0.02 ppm as an annual arithmetic mean and 0.5 ppm as a maximum 3-hour, not to be exceeded more than once per year. These secondary standards were established on the basis of vegetation effects evidence described in the 1970 criteria document. Based on additional data available in 1973, revisions were made to Chapter 5 “Effects of Sulfur Oxide in the Atmosphere on Vegetation” of the *Air Quality Criteria for Sulfur Oxides* ([U.S. EPA, 1973](#)), which led the U.S. EPA to propose (38 FR 11355) and then finalize a revocation of the annual mean secondary standard (38 FR 25678). At that time, the U.S. EPA additionally considered welfare effects related to effects on materials, visibility, soils, and water. However, the U.S. EPA concluded that either protection from such effects was afforded by the primary

standard or that sufficient data were not then available to develop criteria for standards based on these effects (38 FR 25680).

In 1980, the U.S. EPA released a combined AQCD for sulfur oxides and particulate matter for CASAC review. Following its review of a draft revised criteria document in August 1980, the CASAC concluded that acidic deposition was a topic of extreme scientific complexity, noting that a fundamental problem of addressing acid deposition in a criteria document is that acidic deposition is produced by several pollutants, including oxides of sulfur, oxides of nitrogen, and the fine particulate fraction of suspended particles [(U.S. EPA, 1982b), pp. 125–126]. Following CASAC closure on the criteria document in December 1981, the U.S. EPA released a final AQCD (U.S. EPA, 1982b), and the OAQPS prepared a Staff Paper that was released in November 1982 (U.S. EPA, 1982c). The issue of acidic deposition was not, however, assessed directly in the OAQPS Staff Paper because the U.S. EPA followed the guidance given by CASAC.

In response to CASAC recommendations for a separate comprehensive discussion of acidic deposition as part of the criteria documents, the U.S. EPA subsequently prepared the following documents: *The Acidic Deposition Phenomenon and Its Effects: Critical Assessment Review Papers, Volumes I and II* (U.S. EPA, 1984a, b) and *The Acidic Deposition Phenomenon and Its Effects: Critical Assessment Document* [(Bennett et al., 1985); 53 FR 14935–14936]. Although these documents were not considered criteria documents and had not undergone CASAC review, they represented the most comprehensive summary of relevant scientific information completed by the U.S. EPA at that point (58 FR 21355).

At about the same time in 1980 as the CASAC recommendation for a comprehensive assessment of acidic deposition, Congress created the National Acid Precipitation Assessment Program (NAPAP). During the 10-year course of this program, a series of reports were issued and a final report was issued in 1990 (NAPAP, 1991).

On April 26, 1988, the U.S. EPA proposed not to revise the existing primary and secondary standards. This proposal regarding the secondary SO<sub>2</sub> NAAQS was due to the Administrator's conclusions that (1) based upon the then-current scientific understanding of the acidic deposition problem, it would be premature and unwise to prescribe any regulatory control program at that time and (2) when the fundamental scientific uncertainties had been reduced through ongoing research efforts, the U.S. EPA would draft and support an appropriate set of control measures (53 FR 14926). Subsequent to proposal, Congress took up consideration of acidic deposition.

On November 15, 1990, Amendments to the CAA were passed by Congress and signed into law by the President. In Title IV of these Amendments, Congress included a

statement of findings that had led them to take this action, including that: “(1) the presence of acidic compounds and their precursors in the atmosphere and in deposition from the atmosphere represents a threat to natural resources, ecosystems, materials, visibility, and public health; (2) the problem of acid deposition is of national and international significance; and that (3) current and future generations of Americans will be adversely affected by delaying measures to remedy the problem...” The goal of Title IV was to reduce emissions of SO<sub>2</sub> by 10 million tons and oxides of nitrogen emissions by 2 million tons from 1980 emission levels in order to achieve reductions over broad geographic regions/areas. In envisioning that further action might be necessary in the long term, Congress included Section 404 of the 1990 Amendments. This section requires the U.S. EPA to conduct a study on the feasibility and effectiveness of an acid deposition standard or standards to protect “sensitive and critically sensitive aquatic and terrestrial resources” and at the conclusion of the study, submit a report to Congress. Five years later, the U.S. EPA submitted to Congress its report titled *Acid Deposition Standard Feasibility Study: Report to Congress* ([U.S. EPA, 1995a](#)) in fulfillment of this requirement. The Report to Congress concluded that establishing acid deposition standards for sulfur and nitrogen deposition might at some point in the future be technically feasible although appropriate deposition loads for these acidifying chemicals could not be defined with reasonable certainty at that time.

The 1990 Amendments also added new language to sections of the CAA that pertain to the scope or application of the secondary NAAQS designed to protect the public welfare. Section 108 (g) specified that “the Administrator may assess the risks to ecosystems from exposure to criteria air pollutants (as identified by the Administrator in the Administrator’s sole discretion).” The definition of public welfare in Section 302 (h) was expanded to state that the welfare effects identified should be protected from adverse effects associated with criteria air pollutants “...whether caused by transformation, conversion, or combination with other air pollutants.”

In response to these legislative initiatives, the U.S. EPA and other federal agencies continued research on the causes and effects of acidic deposition and related welfare effects of SO<sub>2</sub> and implemented an enhanced monitoring program to track progress (58 FR 21357). In 1993, the U.S. EPA announced a decision not to revise the secondary standard, concluding that revision to address acidic deposition and related SO<sub>2</sub> welfare effects was not appropriate at that time (58 FR 21351). In reaching this decision, the U.S. EPA took into account the significant reductions in SO<sub>2</sub> emissions, ambient SO<sub>2</sub> concentrations and ultimately deposition expected to result from implementation of the Title IV program, which was expected to significantly decrease the acidification of water bodies and damage to forest ecosystems and to permit much of the existing damage to be reversed with time (58 FR 21357). While recognizing that further action might be needed

to address acidic deposition in the longer term, the U.S. EPA judged it prudent to await the results of the studies and research programs then underway, including those assessing the comparative merits of secondary standards, acidic deposition standards, and other approaches to control of acidic deposition and related effects, and then to determine whether additional control measures should be adopted or recommended to Congress (58 FR 21358).

In 2000, the U.S. EPA announced receipt of two items related to acidic deposition and the NAAQS (65 FR 48699). The first was a petition submitted to the U.S. EPA in 1999 by representatives of seven northeastern states for the promulgation of revised secondary NAAQS for the criteria pollutants associated with the formation of acid rain (including NO<sub>2</sub>, SO<sub>2</sub>, and fine particulate matter [PM<sub>2.5</sub>]). The petition states that the language in Section 302(h) of the CAA “clearly references the transformation of pollutants resulting in the inevitable formation of sulfate and nitrate aerosols and/or their ultimate environmental impacts as wet and dry deposition, clearly signaling Congressional intent that the welfare damage occasioned by sulfur and nitrogen oxides be addressed through the secondary standard provisions of Section 109 of the Act.” The petition further stated that “recent federal studies, including the NAPAP Biennial Report to Congress: An Integrated Assessment, document the continued—and increasing—damage being inflicted by acid deposition to the lakes and forests of New York, New England, and other parts of our nation, demonstrating that the Title IV program had proven insufficient.” The petition also listed other adverse welfare effects associated with the transformation of these criteria pollutants, including visibility impairment, eutrophication of coastal estuaries, global warming, tropospheric ozone, and stratospheric ozone depletion.

The second item was a related request from the U.S. Department of Interior (DOI) that the U.S. EPA address many of the same adverse environmental effects associated with the same types of air pollutants and with ozone that the DOI asserted were occurring in national parks and wilderness areas (65 FR 48699). Included among the effects of concern identified in the request were acidification of streams, surface waters and/or soils, eutrophication of coastal waters, visibility impairment, and foliar injury from ozone (65 FR 48701). The U.S. EPA requested comment on the issues raised by these requests, stating that it would consider any relevant comments and information submitted, along with the information provided by the petitioners and DOI, before making any decision concerning a response to these requests for rulemaking, which if commenced would include opportunity for public review and comment (65 FR 48701).

---

## Particulate Matter Secondary National Ambient Air Quality Standards

The U.S. EPA first established NAAQS for particulate matter (PM) in 1971 (36 FR 8186, April 30, 1971) based on the original AQCD ([NAPCA, 1969](#)). The AQCD assessed the evidence for a variety of PM-associated welfare effects, including visibility impairment and materials damage (e.g., soiling, corrosion). Based on evidence for such effects, the secondary standards were set at 150  $\mu\text{g}/\text{m}^3$  for the 24-hour average not to be exceeded more than once per year and 60  $\mu\text{g}/\text{m}^3$  for the annual geometric mean. The federal reference method (FRM) specified for determining attainment of the original standards was the high-volume sampler, which collects PM up to a nominal size of 25 to 45 micrometers ( $\mu\text{m}$ ; referred to as total suspended particulates or TSP).

In October 1979 (44 FR 56730; October 2, 1979), the U.S. EPA announced the first periodic review of the air quality criteria and NAAQS for PM. Revised primary and secondary standards were promulgated in 1987 (52 FR 24634; July 1, 1987). In the 1987 decision, the U.S. EPA changed the indicator for particles from TSP to  $\text{PM}_{10}$  to focus on the subset of inhalable particles small enough to penetrate to the thoracic region of the respiratory tract (including the tracheobronchial and alveolar regions) referred to as thoracic particles.<sup>1</sup> The level of the 24-hour standards (primary and secondary) was set at 150  $\mu\text{g}/\text{m}^3$ , and the form was one expected exceedance per year, on average, over 3 years. The level of the annual standards (primary and secondary) was set at 50  $\mu\text{g}/\text{m}^3$ , and the form was annual arithmetic mean averaged over 3 years.

In April 1994, the U.S. EPA announced its plans for the second periodic review of the air quality criteria and NAAQS for PM, and in 1997, the U.S. EPA promulgated revisions to the NAAQS (62 FR 38652, July 18, 1997). In the 1997 decision, the U.S. EPA determined that the fine and coarse fractions of  $\text{PM}_{10}$  should be considered separately. This determination was based on evidence that serious health effects were associated with short- and long-term exposures to fine particles in areas that met the existing  $\text{PM}_{10}$  standards. The U.S. EPA added new standards using  $\text{PM}_{2.5}$  as the indicator for fine particles (with  $\text{PM}_{2.5}$  referring to particles with a nominal mean aerodynamic diameter less than or equal to 2.5  $\mu\text{m}$ ). These new standards were as follows: (1) an annual standard with a level of 15.0  $\mu\text{g}/\text{m}^3$  based on the 3-year average of annual arithmetic mean  $\text{PM}_{2.5}$  concentrations from single or multiple community-oriented monitors and (2) a 24-hour standard with a level of 65  $\mu\text{g}/\text{m}^3$  based on the 3-year average of the 98th percentile of 24-hour  $\text{PM}_{2.5}$  concentrations at each monitor within an area. Also, the

---

<sup>1</sup>  $\text{PM}_{10}$  refers to particles with a nominal mean aerodynamic diameter less than or equal to 10  $\mu\text{m}$ . More specifically, 10  $\mu\text{m}$  is the aerodynamic diameter for which the efficiency of particle collection is 50%. Larger particles are not excluded altogether but are collected with substantially decreasing efficiency while smaller particles are collected with increasing efficiency.

U.S. EPA established a new reference method for the measurement of PM<sub>2.5</sub> in the ambient air and adopted rules for determining attainment of the new standards. To continue to address the coarse fraction of PM<sub>10</sub> (referred to as thoracic coarse particles or PM<sub>10-2.5</sub>; generally including particles with a nominal mean aerodynamic diameter greater than 2.5 µm and less than or equal to 10 µm), the U.S. EPA retained the annual PM<sub>10</sub> standard and revised the form of the 24-hour PM<sub>10</sub> standard to be based on the 99th percentile of 24-hour PM<sub>10</sub> concentrations at each monitor in an area. The U.S. EPA revised the secondary standards by setting them equal in all respects to the primary standards.

Following promulgation of the 1997 PM NAAQS, petitions for review were filed by a large number of parties, addressing a broad range of issues. In May 1999, the U.S. Court of Appeals for the District of Columbia Circuit (D.C. Circuit) upheld the U.S. EPA's decision to establish fine particle standards, holding that "the growing empirical evidence demonstrating a relationship between fine particle pollution and adverse health effects amply justifies establishment of new fine particle standards." *American Trucking Associations v. EPA*, 175 F. 3d 1027, 1055–56 (D.C. Cir., 1999). The D.C. Circuit also found "ample support" for the U.S. EPA's decision to regulate coarse particle pollution, but vacated the 1997 PM<sub>10</sub> standards, concluding that the U.S. EPA had not provided a reasonable explanation justifying use of PM<sub>10</sub> as an indicator for coarse particles (175 F. 3d at 1054–55). Pursuant to the D.C. Circuit's decision, the U.S. EPA removed the vacated 1997 PM<sub>10</sub> standards, and the pre-existing 1987 PM<sub>10</sub> standards remained in place (65 FR 80776, December 22, 2000). The D.C. Circuit also upheld the U.S. EPA's determination not to establish more stringent secondary standards for fine particles to address effects on visibility (175 F. 3d at 1027).

The D.C. Circuit also addressed more general issues related to the NAAQS, including issues related to the consideration of costs in setting NAAQS and the U.S. EPA's approach to establishing the levels of NAAQS. Regarding the cost issue, the court reaffirmed prior rulings holding that in setting NAAQS the U.S. EPA is "not permitted to consider the cost of implementing those standards" (Id. at 1040–41). Regarding the levels of NAAQS, the court held that the U.S. EPA's approach to establishing the level of the standards in 1997 (i.e., both for PM and for the ozone NAAQS promulgated on the same day) effected "an unconstitutional delegation of legislative authority" (Id. at 1034–40). Although the court stated that "the factors U.S. EPA uses in determining the degree of public health concern associated with different levels of ozone and PM are reasonable," it remanded the rule to the U.S. EPA, stating that when the U.S. EPA considers these factors for potential nonthreshold pollutants "what U.S. EPA lacks is any determinate criterion for drawing lines" to determine where the standards should be set.

The D.C. Circuit's holding on the cost and constitutional issues were appealed to the U.S. Supreme Court. In February 2001, the Supreme Court issued a unanimous decision upholding the U.S. EPA's position on both the cost and constitutional issues. *Whitman v. American Trucking Associations*, 531 U.S. 457, 464, 475–76. On the constitutional issue, the Court held that the statutory requirement that NAAQS be “requisite” to protect public health with an adequate margin of safety sufficiently guided the U.S. EPA's discretion, affirming the U.S. EPA's approach of setting standards that are neither more nor less stringent than necessary.<sup>1</sup>

In October 1997, the U.S. EPA published its plans for the third periodic review of the air quality criteria and NAAQS for PM (62 FR 55201; October 23, 1997). On September 21, 2006, the U.S. EPA announced its final decisions to revise the primary and secondary NAAQS for PM to provide increased protection of public health and welfare, respectively (71 FR 61144; October 17, 2006). With regard to the primary and secondary standards for fine particles, the U.S. EPA revised the level of the 24-hour PM<sub>2.5</sub> standards to 35 µg/m<sup>3</sup>, retained the level of the annual PM<sub>2.5</sub> standards at 15.0 µg/m<sup>3</sup>, and revised the form of the annual PM<sub>2.5</sub> standards by narrowing the constraints on the optional use of spatial averaging. With regard to the primary and secondary standards for PM<sub>10</sub>, the U.S. EPA retained the 24-hour standards, with levels at 150 µg/m<sup>3</sup>, and revoked the annual standards.<sup>2</sup> The Administrator judged that the available evidence generally did not suggest a link between long-term exposure to existing ambient levels of coarse particles and health or welfare effects. In addition, a new reference method was added for the measurement of PM<sub>10-2.5</sub> in the ambient air, in order to provide a basis for approving federal equivalent methods (FEMs) and to promote the gathering of scientific data to support future reviews of the PM NAAQS.

Several parties filed petitions for review following promulgation of the revised PM NAAQS in 2006. These petitions addressed the following issues: (1) selecting the level of the primary annual PM<sub>2.5</sub> standard; (2) retaining PM<sub>10</sub> as the indicator of a standard for

---

<sup>1</sup> The Supreme Court remanded the case to the Court of Appeals for resolution of any remaining issues that had not been addressed in that court's earlier rulings (Id. at 475–76). In a March 2002 decision, the Court of Appeals rejected all remaining challenges to the standards, holding that the U.S. EPA's PM<sub>2.5</sub> standards were reasonably supported by the administrative record and were not “arbitrary and capricious” *American Trucking Associations v. EPA*, 283 F. 3d 355, 369–72 (D.C. Cir. 2002).

<sup>2</sup> In the 2006 proposal, the U.S. EPA proposed to revise the 24-hour PM<sub>10</sub> standard in part by establishing a new PM<sub>10-2.5</sub> indicator for thoracic coarse particles (i.e., particles generally between 2.5 and 10 µm in diameter). The U.S. EPA proposed to include any ambient mix of PM<sub>10-2.5</sub> that was dominated by resuspended dust from high density traffic on paved roads and by PM from industrial and construction sources. The U.S. EPA proposed to exclude any ambient mix of PM<sub>10-2.5</sub> that was dominated by rural windblown dust and soils and by PM generated from agricultural and mining sources. In the final decision, the existing PM<sub>10</sub> standard was retained, in part due to an “inability...to effectively and precisely identify which ambient mixes are included in the [PM<sub>10-2.5</sub>] indicator and which are not” (71 FR 61197; October 17, 2006).

thoracic coarse particles, retaining the level and form of the 24-hour PM<sub>10</sub> standard, and revoking the PM<sub>10</sub> annual standard; and (3) setting the secondary PM<sub>2.5</sub> standards identical to the primary standards. On February 24, 2009, the U.S. Court of Appeals for the District of Columbia Circuit issued its opinion in the case *American Farm Bureau Federation v. EPA*, 559 F. 3d 512 (D.C. Cir. 2009). The court remanded the primary annual PM<sub>2.5</sub> NAAQS to the U.S. EPA because the U.S. EPA failed to adequately explain why the standards provided the requisite protection from both short- and long-term exposures to fine particles, including protection for at-risk populations (*American Farm Bureau Federation v. EPA*, 559 F. 3d 512, 520–27; D.C. Cir. 2009). With regard to the standards for PM<sub>10</sub>, the court upheld the U.S. EPA’s decisions to retain the 24-hour PM<sub>10</sub> standard to provide protection from thoracic coarse particle exposures and to revoke the annual PM<sub>10</sub> standard (*American Farm Bureau Federation*, 559 F. 2d at 533–38). With regard to the secondary PM<sub>2.5</sub> standards, the court remanded the standards to the U.S. EPA because the Agency failed to adequately explain why setting the secondary PM standards identical to the primary standards provided the required protection for public welfare, including protection from visibility impairment (*American Farm Bureau Federation*, 559 F. 2d at 528–32). The U.S. EPA responded to the court’s remands as part of the next review of the PM NAAQS, which was initiated in 2007.

In June 2007, the U.S. EPA initiated the fourth periodic review of the air quality criteria and the PM NAAQS by issuing a call for information in the *Federal Register* (72 FR 35462; June 28, 2007). In December 2012, the U.S. EPA announced its final decisions with regard to the secondary PM standards, the U.S. EPA retained the 24-hour and annual PM<sub>2.5</sub> standards and the 24-hour PM<sub>10</sub> standard to address visibility and nonvisibility welfare effects. On judicial review, the revised standards were upheld in all respects (*NAM v EPA*, 750 F.3d 921; D.C. Cir. 2014).

---

### **Combined Review of the Oxides of Nitrogen and Oxides of Sulfur National Ambient Air Quality Standards**

In 2005, the U.S. EPA initiated a joint review of the air quality criteria for oxides of nitrogen and sulfur and the secondary NAAQS for NO<sub>2</sub> and SO<sub>2</sub>. In so doing, the U.S. EPA assessed the scientific information, associated risks, and standards relevant to protecting the public welfare from adverse effects associated jointly with oxides of nitrogen and sulfur. Although the U.S. EPA has historically adopted separate secondary standards for oxides of nitrogen and oxides of sulfur, the U.S. EPA conducted a joint review of these standards because oxides of nitrogen and sulfur and their associated transformation products are linked from an atmospheric chemistry perspective, as well as from an environmental effects perspective. The joint review was also responsive to the

National Research Council (NRC) recommendation for the U.S. EPA to consider multiple pollutants, as appropriate, in forming the scientific basis for the NAAQS ([NRC, 2004](#)).

The review was initiated on December 13, 2005 with a call for information (70 FR 73236) for the development of a revised ISA. A draft Integrated Review Plan (IRP) was released in October 2007, reviewed by CASAC; the final IRP was released in December 2007 ([U.S. EPA, 2007](#)). The first and second drafts of the ISA were released in December 2007 and August 2008 (73 FR 10243), respectively, for CASAC and public review. The final ISA ([U.S. EPA, 2008a](#)) was released in December 2008 (73 FR 75716).

Based on the scientific information in the ISA, the U.S. EPA developed a Risk and Exposure Assessment (REA) to further assess the national impact of the effects documented in the ISA. The Draft Scope and Methods Plan for Risk/Exposure Assessment: Secondary NAAQS Review for Oxides of Nitrogen and Oxides of Sulfur outlining the scope and design of the future REA was released in March 2008 (73 FR 10243). A first and second draft of the REA were released (August 2008 and June 2009) for CASAC review and public comment. The final REA ([U.S. EPA, 2009c](#)) was released in September 2009. Drawing on the information in the final REA and ISA, a first draft, second draft, and final Policy Assessment (PA) were released in March 2010, September 2010, and January 2011, respectively ([U.S. EPA, 2011a](#)).

On August 1, 2011, based on consideration of the scientific information and quantitative assessments, the U.S. EPA published a proposal to (1) retain the existing NO<sub>2</sub> and SO<sub>2</sub> secondary standards, (2) add secondary standards identical to the NO<sub>2</sub> and SO<sub>2</sub> primary 1-hour standards, and (3) not set a new multipollutant secondary standard in this review. After consideration of public comments on the proposed standards and on design of a new field pilot program to gather and analyze additional relevant data, the Administrator signed a final decision in this rulemaking on March 20, 2012. The Administrator's decision was that, while the current secondary standards were inadequate to protect against adverse effects from deposition of oxides of nitrogen and sulfur, it was not appropriate under Section 109(b) to set any new secondary standards at this time due to the limitations in the available data and uncertainty as to the amount of protection the metric developed in the review would provide against acidification effects across the country (77 FR 20281). In addition, the Administrator decided that it was appropriate to retain the current NO<sub>2</sub> and SO<sub>2</sub> secondary standards to address direct effects of gaseous NO<sub>2</sub> and SO<sub>2</sub> on vegetation. Thus, taken together, the Administrator decided to retain and not revise the current NO<sub>2</sub> and SO<sub>2</sub> secondary standards: an NO<sub>2</sub> standard set at a level of 0.053 ppm as an annual arithmetic average, and an SO<sub>2</sub> standard set at a level of 0.5 ppm as a 3-hour average, not to be exceeded more than once per year (77 FR 20281).

The U.S. EPA's decision to not set a secondary NAAQS for oxides of nitrogen and sulfur even though the Administrator had concluded that the existing standards are not adequate to protect against the adverse impacts of aquatic acidification on sensitive ecosystems was challenged by the Center for Biological Diversity and other environmental groups. The petitioners argued that having decided that the existing standards were not adequate to protect against adverse public welfare effects such as damage to sensitive ecosystems, the Administrator was required to identify the requisite level of protection for the public welfare and to issue a NAAQS to achieve and maintain that level of protection. The D.C. Circuit disagreed, finding that the U.S. EPA acted appropriately in not setting a secondary standard given the U.S. EPA's conclusions that "the available information was insufficient to permit a reasoned judgment about whether any proposed standard would be 'requisite to protect the public welfare ...'" (*Center for Biological Diversity, et al. v. EPA*, 749 F.3d 1079, 1087; 2014). In reaching this decision, the court noted that the U.S. EPA had "explained in great detail" the profound uncertainties associated with setting a secondary NAAQS to protect against aquatic acidification.

---

# EXECUTIVE SUMMARY

---

## ES.1 Purpose and Scope of the Integrated Science Assessment

This *Integrated Science Assessment (ISA) for Oxides of Nitrogen, Oxides of Sulfur, and Particulate Matter—Ecological Criteria* is a comprehensive evaluation and synthesis of the most policy-relevant science aimed at characterizing the ecological effects caused by these criteria pollutants.<sup>1</sup> These criteria pollutants are reviewed here together because they all contribute to nitrogen (N) and sulfur (S) deposition, which causes substantial ecological effects. In this document, the term “oxides of nitrogen” refers to total oxidized N ( $\text{NO}_Y$ ), including nitric oxide (NO) and nitrogen dioxide ( $\text{NO}_2$ ) and all other gaseous and particulate oxidized N containing compounds formed from NO and  $\text{NO}_2$ .<sup>2</sup> Total sulfur oxides ( $\text{SO}_X$ ) includes gaseous chemical species (e.g., sulfur dioxide [ $\text{SO}_2$ ], sulfur monoxide [SO], disulfur monoxide [ $\text{S}_2\text{O}$ ], and sulfur trioxide [ $\text{SO}_3$ ]) as well as particulate species, such as ammonium sulfate [ $(\text{NH}_4)_2\text{SO}_4$ ] ([U.S. EPA, 2011a](#)). Particulate species include  $\text{SO}_X$  species like sulfites ( $\text{SO}_3^{2-}$ ) and sulfates ( $\text{SO}_4^{2-}$ ), but among these two species usually only  $\text{SO}_4^{2-}$  make a major contribution to particulate mass. Throughout this document  $\text{SO}_X$  is defined as the sum of  $\text{SO}_2$  and particulate sulfate ( $\text{SO}_4^{2-}$ ), which together represent virtually all of the  $\text{SO}_X$  mass in the atmosphere.<sup>3</sup> Particulate matter (PM) is composed of some or all of the following components: nitrate ( $\text{NO}_3^-$ ),  $\text{SO}_4^{2-}$ , ammonium ( $\text{NH}_4^+$ ), metals, minerals (dust), and organic and elemental carbon.

This ISA serves as the scientific foundation for the review of the ecological effects associated with the secondary (welfare-based) National Ambient Air Quality Standards (NAAQS) for  $\text{NO}_Y$ ,  $\text{SO}_X$ , and PM. The health effects of these criteria pollutants are considered in separate assessments for  $\text{NO}_Y$  ([U.S. EPA, 2016f](#)),  $\text{SO}_X$  ([U.S. EPA, 2016e](#)), and PM ([U.S. EPA, 2019](#)).<sup>4</sup> The Clean Air Act definition of welfare effects includes, but is not limited to, effects on soils, water, wildlife, vegetation, visibility, weather, and

---

<sup>1</sup> The general process for developing an ISA, including the framework for evaluating weight of evidence and drawing scientific conclusions and causal judgments, is described in a companion document, *Preamble to the Integrated Science Assessments* ([U.S. EPA, 2015e](#)), [www.epa.gov/isa](http://www.epa.gov/isa).

<sup>2</sup> This ISA reserves the abbreviation  $\text{NO}_X$  strictly as the sum of NO and  $\text{NO}_2$ —consistent with its use in the atmospheric science community—and uses the term “oxides of nitrogen” to refer to the broader list of oxidized nitrogen species. Oxides of nitrogen refers to  $\text{NO}_Y$  as the total oxidized nitrogen in both gaseous and particulate forms. The major gaseous and particulate constituents of  $\text{NO}_Y$  include nitric oxide (NO), nitrogen dioxide ( $\text{NO}_2$ ), nitric acid ( $\text{HNO}_3$ ), peroxyacetyl nitrate (PAN), nitrous acid (HONO), organic nitrates, and particulate nitrate ( $\text{NO}_3^-$ ). This ISA uses the definitions adopted by the atmospheric sciences community.

<sup>3</sup> The same definition of  $\text{SO}_X$  used in the 2011  $\text{NO}_X\text{SO}_X$  Policy Assessment ([U.S. EPA, 2011a](#)).

<sup>4</sup> In this ISA, the blue electronic links can be used to navigate to cited materials as well as appendices, sections, tables, figures, and studies from this ISA.

climate, as well as effects on man-made materials, economic values, and personal comfort and well-being.

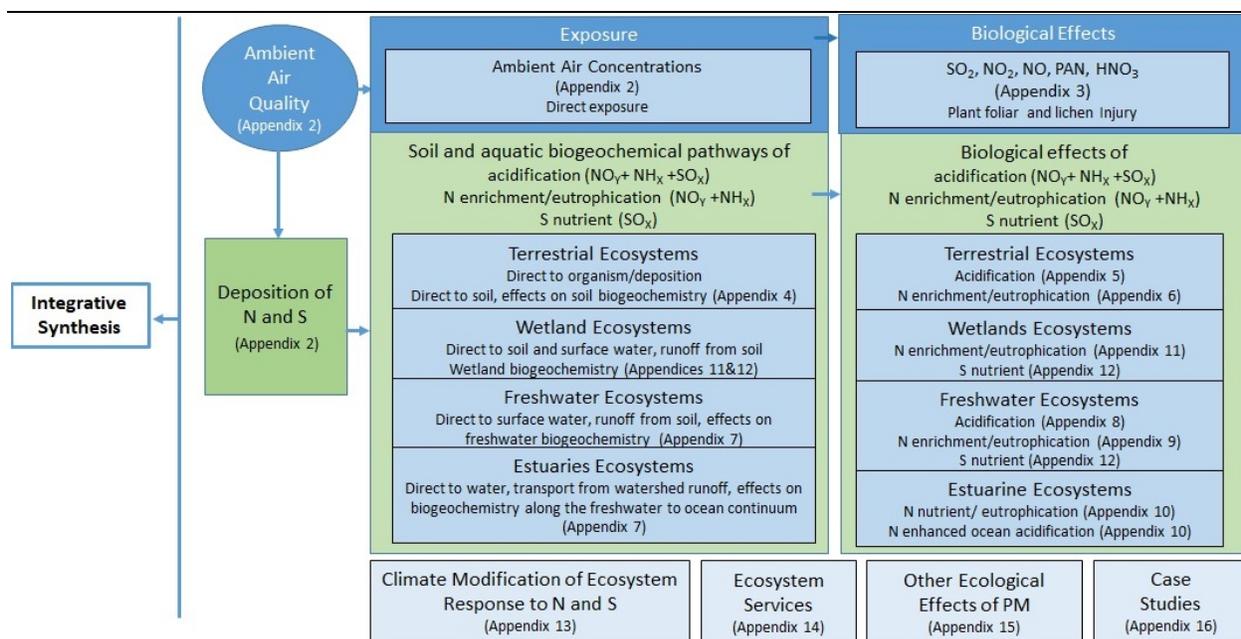

The current secondary NAAQS for NO<sub>Y</sub> and SO<sub>X</sub> were set to protect against direct damage to vegetation by NO<sub>2</sub> or SO<sub>2</sub>. The secondary NAAQS for NO<sub>2</sub> is identical to the primary standard set in 1971: an annual average not to exceed 0.053 ppm N dioxide. The secondary NAAQS for SO<sub>2</sub>, set in 1973, is a 3-hour average of 0.5 ppm SO<sub>2</sub>, not to be exceeded more than once per year. The current secondary standards for PM are intended to address PM-related visibility and nonvisibility welfare effects. These standards are a 3-year annual mean PM<sub>2.5</sub> concentration of 15 µg/m<sup>3</sup>, with the 24-hour average PM<sub>2.5</sub> and PM<sub>10</sub> set at concentrations of 35 µg/m<sup>3</sup> and 150 µg/m<sup>3</sup>, respectively.

This ISA updates the 2008 *ISA for Oxides of Nitrogen and Oxides of Sulfur—Ecological Criteria* [hereafter referred to as 2008 ISA ([U.S. EPA, 2008a](#))], as well as the ecological portion of the 2009 *ISA for Particulate Matter* ([U.S. EPA, 2009a](#)) with studies and reports published from January 2008 through May 2017. There are some studies included that were published more recently than the May 2017 literature cutoff date; these studies were added based on recommendations from the Clean Air Scientific Advisory Committee (CASAC). The U.S. EPA conducted in-depth searches to identify peer-reviewed literature on relevant topics. Subject-matter experts and the public were also able to recommend studies and reports during a kick-off workshop held by the U.S. EPA in March 2014 for NO<sub>Y</sub> and SO<sub>X</sub> and in June 2016 for PM. CASAC recommended the inclusion of additional studies during the review of the first draft. To fully describe the state of available science, the U.S. EPA also carried over the most relevant studies from previous assessments to include in this ISA.

This ISA determines whether NO<sub>Y</sub>, SO<sub>X</sub>, and PM concentrations in the air or deposition from the air cause ecological effects. The ecological effects of deposition are grouped into three main categories: (1) acidification (caused by gaseous NO<sub>Y</sub>, SO<sub>X</sub>, and particulate NH<sub>4</sub><sup>+</sup>, NO<sub>3</sub><sup>-</sup>, SO<sub>4</sub><sup>2-</sup>), (2) N enrichment/N driven eutrophication (caused by gaseous NO<sub>Y</sub> and particulate NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup>), and (3) S enrichment (caused by SO<sub>X</sub> and particulate forms of SO<sub>4</sub><sup>2-</sup>). Ecological effects are further subdivided into terrestrial, wetland, freshwater, and estuarine/near-coastal ecosystems. These ecosystems and effects are linked by the connectivity of terrestrial and aquatic habitats through biogeochemical pathways of N and S.

A schematic of the document organization is given by [Figure ES-1](#). The [Integrated Synthesis](#) (IS) brings together key information on specific subject matter found in the appendices. [Appendix 1](#) is an introduction to the purpose and organization of the material covered in [Appendix 2–Appendix 16](#). [Appendix 2](#) characterizes the sources and atmospheric processes involving NO<sub>Y</sub>, SO<sub>X</sub>, and PM, as well as trends in ambient

concentrations and deposition. [Appendix 3](#) describes direct effects of gas-phase NO<sub>y</sub> and SO<sub>x</sub> on plants and lichens. [Appendix 4](#) describes N and S deposition effects on terrestrial biogeochemistry, and [Appendix 5](#) and [Appendix 6](#) describe the biological effects of terrestrial acidification and terrestrial N enrichment, respectively. [Appendix 7](#) describes N and S deposition effects on aquatic biogeochemistry. [Appendix 8](#) through [Appendix 10](#) characterize the biological effects of freshwater acidification, freshwater N enrichment, and marine eutrophication, respectively. [Appendix 11](#) describes the effects of N deposition on wetlands. [Appendix 12](#) describes the wetland and freshwater effects of S enrichment. [Appendix 13](#) discusses the climate modification of ecosystem response to N and S deposition, and [Appendix 14](#) presents information on N and S deposition effects on ecosystem services. Information on the ecological effects of forms of PM beyond those related to N or S deposition is presented in [Appendix 15](#) (the nonecological welfare effects associated with PM, such as visibility, climate, and material effects, are considered as part of a separate review of PM [81 FR 87933, December 6, 2016]). [Appendix 16](#) includes six locations in the U.S. selected as case study areas that are candidates for additional analysis of risk and exposure. These candidate sites were selected because they have abundant data on ecological effects.

HNO<sub>3</sub> = nitric acid; N = nitrogen; NH<sub>x</sub> = reduced nitrogen; NO = nitric oxide; NO<sub>2</sub> = nitrogen dioxide; NO<sub>y</sub> = nitrogen oxides; PAN = peroxyacetyl nitrate; PM = particulate matter; S = sulfur; SO<sub>2</sub> = sulfur dioxide; SO<sub>x</sub> = sulfur oxides.

**Figure ES-1 Roadmap of the Integrated Science Assessment (ISA) linking atmospheric concentrations and deposition, soil and aquatic biogeochemistry, and biological effects.**

## ES.2 Emissions, Ambient Air Concentrations, and Deposition

The atmospheric chemistry from emission to deposition discussed in this ISA<sup>1</sup> is for the criteria pollutants NO<sub>y</sub>, SO<sub>x</sub>, and PM. NO<sub>y</sub> and SO<sub>x</sub> cause ecological effects in the gas phase and/or after N and S deposition to surfaces. Particulate matter (PM) effects discussed in this document focus on N and S containing species, which together usually make up a large fraction of the PM<sub>2.5</sub> mass in most areas of the U.S. NH<sub>x</sub> (NH<sub>x</sub> = NH<sub>3</sub> + NH<sub>4</sub><sup>+</sup>) includes both gas-phase NH<sub>3</sub> and the PM component NH<sub>4</sub><sup>+</sup>. NH<sub>3</sub> is estimated to account for 19–63% of total observed inorganic N deposition, depending on region ([Appendix 2.1](#)). Therefore, NH<sub>3</sub> is discussed in this ISA along with NO<sub>y</sub> and relevant PM components to better understand and compare their contributions to both wet and dry N deposition.

<sup>1</sup> The term concentration is used throughout the ISA to denote either a mass per unit volume or a volume per unit volume (mixing ratio). The use of concentration to denote abundance expressed as mixing ratio is firmly entrenched in the literature; therefore, it is retained here.

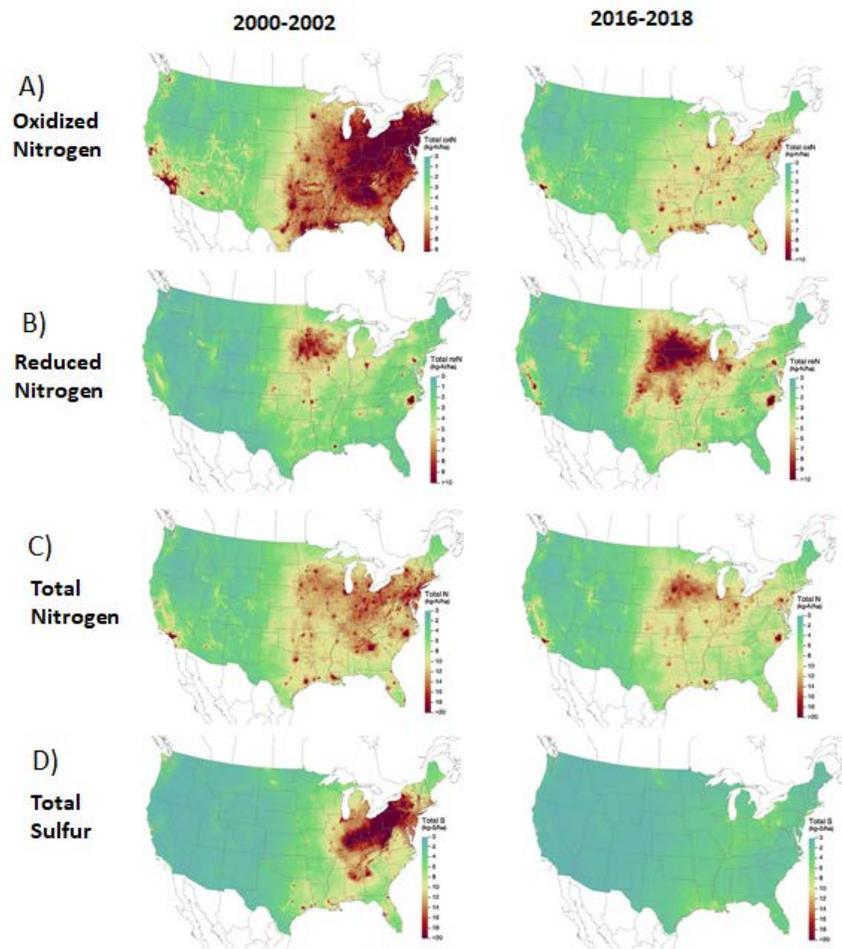

Both gaseous and particulate forms of  $\text{NO}_y$ ,  $\text{SO}_x$ , and  $\text{NH}_x$  contribute to atmospheric wet and dry deposition. The major components of PM in the U.S. are  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{NH}_4^+$ , organic matter, elemental C, crustal material, and sea salt. Of these,  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ , and  $\text{NH}_4^+$  usually have a strong influence on acid deposition, and  $\text{NO}_3^-$  and  $\text{NH}_4^+$ , and in some cases organic N (organic nitrates and reduced organic N), contribute substantially to N deposition and eutrophication.

The sources and precursors to gaseous and particulate forms of  $\text{NO}_y$ ,  $\text{SO}_x$ , and  $\text{NH}_x$  vary. The main contributors to acidifying precipitation are formed from precursor emissions of the gases  $\text{SO}_2$ ,  $\text{NO}_x$ , and  $\text{NH}_3$  ([Appendix 2.2](#)). Electricity-generating units (EGUs) are the source of about half of national gaseous emissions of  $\text{SO}_2$ , mainly from coal-fired power plants. Notably,  $\text{SO}_2$  emissions from EGUs have been decreasing.  $\text{NO}_x$  emissions have a wider distribution of sources, with substantial contributions from highway and off-highway vehicles, lightning, and EGUs. Fertilizer application and animal waste are the main national-scale sources of  $\text{NH}_3$ , with animal waste contributing the most. Primary  $\text{PM}_{2.5}$  and  $\text{PM}_{10}$  emissions are dominated by dust and combustion products of fires, but much of the  $\text{PM}_{2.5}$  mass in the U.S. is produced by reaction of gas-phase precursors to form secondary  $\text{PM}_{2.5}$ . In this process, particulate  $\text{NH}_4^+$ ,  $\text{NO}_3^-$ , and  $\text{SO}_4^{2-}$  are primarily derived from the gaseous precursors  $\text{NH}_3$ ,  $\text{NO}_x$ , and  $\text{SO}_2$  ([Appendix 2.3](#)). Formation of particulate N and S is described in the 2019 *ISA for Particulate Matter* ([U.S. EPA, 2019](#)). An understanding of the sources, chemistry, and atmospheric processes for these gas-phase and PM species is necessary to understand acidifying and N deposition.

Since the passage of the Clean Air Act Amendments in 1990, the emissions of  $\text{NO}_x$  and  $\text{SO}_2$  have declined dramatically. Total emissions of  $\text{SO}_2$  decreased by 89% from 1990 to 2017, resulting in a decrease in  $\text{SO}_2$  concentrations of 89% in the eastern U.S. and 45% in the western U.S. Emissions of  $\text{NO}_x$  in the U.S. declined by 61% between 1990 and 2017, while nationwide annual average 98th percentile  $\text{NO}_2$  concentrations decreased by 53% from 1990 to 2017. These reductions have in turn led to decreases in  $\text{PM}_{2.5}$  concentrations because of declines in the amount of  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  produced, and a decrease in the fraction of  $\text{PM}_{2.5}$  accounted for by  $\text{SO}_4^{2-}$ . Between 1989 and 2017, average particulate  $\text{SO}_4^{2-}$  concentration decreased by 75% in the eastern U.S. and 35% in the western U.S., and average particulate  $\text{NO}_3^-$  concentration decreased by 51% in the eastern U.S. and 37% in the western U.S.

Averaged across the contiguous U.S., deposition of total N (oxidized + reduced N, in kg N/ha/yr) has changed only slightly since 2000 ([Appendix 2.6.2](#)). [Figure ES-2](#) shows that between 2000 and 2018 large decreases in oxidized nitrogen ([Figure ES-2A](#)) have combined with large increases in reduced nitrogen deposition ([Figure ES-2B](#)) to produce a small decrease in total nitrogen deposition ([Figure ES-2C](#)). There is large spatial

variability in N deposition over the contiguous U.S. (Figure ES-2C). According to National Atmospheric Deposition Program Total Deposition Committee's (TDEP's) estimates for 2016–2018 (Appendix 2.6.2), much of the eastern U.S. is estimated to receive at least 10 kg N/ha/yr dry + wet deposition, with some areas receiving more than 15 kg N/ha/yr. Figure ES-2 A through C shows that between 2000 and 2018, large decreases in oxidized nitrogen deposition occurred.

Ha = hectare; kg = kilogram; N = nitrogen; OxN = oxidized nitrogen; ReN = reduced nitrogen; S = sulfur.

Source: We acknowledge the Total Deposition (TDep) Science Committee of the National Atmospheric Deposition Program (NADP) for their role in making the TDep data and maps available.

**Figure ES-2** Wet plus dry deposition of (A) oxidized nitrogen, (B) reduced nitrogen, (C) total nitrogen, and (D) total sulfur over the 3-year periods 2000–2002 and 2016–2018.

For S, wet deposition tends to dominate over dry deposition in large areas of the contiguous U.S. However, in some regions, mostly in the west, dry deposition of mainly SO<sub>2</sub> is greater than wet deposition. Anthropogenic emissions of S and subsequent deposition have declined markedly since the 1990s, with the most pronounced declines in the eastern U.S., as shown in [Figure ES-2D](#). Currently, the highest values of total (wet + dry) SO<sub>x</sub> deposition in the U.S. are in parts of the Ohio Valley region where they range between 15 and 20 kg S/ha/yr.

Both N and S deposition contribute to acidification of ecosystems. The acidity of rainwater has decreased, as indicated by the increase of rainwater pH across the U.S. since 1990, coincident with decreases in the wet deposition of nitrate and sulfate. However, widespread areas are still affected by acidifying precipitation, mainly in the eastern U.S. (see [Appendix 2.6.1](#)). Total acidifying deposition (wet + dry N + S, expressed as H<sup>+</sup> equivalents) fluxes for 2016 to 2018 ranged from a few tenths of H<sup>+</sup> keq/ha/yr over much of the western U.S. to over 1.5 H<sup>+</sup> keq/ha/yr in parts of the Midwest and the Mid-Atlantic regions, and in other isolated hotspots surrounding areas of concentrated industrial or agricultural activity ([Figure IS-6](#)). Estimated deposition fluxes greater than 1.5 keq/ha/yr covered a much smaller portion of the U.S. in 2016–2018 than in 2000–2002.

---

### **ES.3 Ecological Effects**

In this ISA, information on ecological effects from controlled exposure, field addition, ambient deposition, and toxicological studies, among others, are integrated to form conclusions about the causal nature of relationships between NO<sub>y</sub>, SO<sub>x</sub>, and PM and ecological effects. Studies on the ecological effects are considered in relation to a range of ambient concentration and deposition loads that are within two orders of magnitude from current conditions [Preamble ([U.S. EPA, 2015e](#)), Section 5c]. A consistent and transparent framework [Preamble ([U.S. EPA, 2015e](#)), Table II] is applied to classify the ecological effect evidence according to a five-level hierarchy:

1. Causal relationship
2. Likely to be a causal relationship
3. Suggestive of, but not sufficient to infer, a causal relationship
4. Inadequate to infer a causal relationship
5. Not likely to be a causal relationship

The conclusions presented in [Table ES-1](#) are based on recent findings integrated with information from the 2008 ISA ([U.S. EPA, 2008a](#)). The conclusions of [Table ES-1](#) are based on careful consideration of errors and uncertainty in the supporting studies. We

also consider the coherence of findings integrated across studies of underlying geochemical and biological mechanisms. There are 18 causality statements in this ISA ([Table ES-1](#)). Fourteen are causal relationships repeated from the 2008 ISA or modified from the 2008 ISA to include specific endpoints. For these causality statements, new research strengthens the evidence base and is consistent with the 2008 ISA. There is one likely causal relationship repeated from the 2009 *ISA for Particulate Matter*. Three causal relationships are new endpoint categories not evaluated in the 2008 ISA. Although NO<sub>y</sub> and SO<sub>x</sub> can cause phytotoxic injury, current monitored concentrations of gas-phase NO<sub>y</sub> and SO<sub>x</sub> are not high enough to injure vegetation. For all other identified causal relationships identified in this ISA, the evidence indicates a causal association from current levels of S and/or N deposition.

C = carbon; Hg = mercury; HNO<sub>3</sub> = nitric acid; ISA = Integrated Science Assessment; N = nitrogen; NO = nitric oxide; NO<sub>2</sub> = nitrogen dioxide; PAN = peroxyacetyl nitrate; S = sulfur; SO<sub>2</sub> = sulfur dioxide.

<sup>a</sup>The 2008 ISA causality statements for gas-phase HNO<sub>3</sub> was phrased as “changes in vegetation.”

<sup>b</sup>The 2008 ISA included two causality statements for terrestrial biogeochemistry phrased as “relationship between acidifying deposition and changes in biogeochemistry” and “relationship between N deposition and the alteration of biogeochemical cycling of N.”

<sup>c</sup>The 2008 ISA causality statement for biological effects of N enrichment in terrestrial ecosystems was phrased as “relationship between N deposition and the alteration of species richness, species composition, and biodiversity.”

<sup>d</sup>The 2008 ISA causality statement for biological effects of acidifying deposition in terrestrial ecosystems was phrased as “relationship between acidifying deposition and changes in terrestrial biota.”

<sup>e</sup>The 2008 ISA included three causality statements for freshwater biogeochemistry phrased as “relationship between acidifying deposition and changes in biogeochemistry related to aquatic ecosystems,” “relationship between N deposition and the alteration of biogeochemical cycling of N,” and “relationship between N deposition and the alteration of biogeochemical cycling of C.”

<sup>f</sup>The 2008 ISA causality statement for biological effects of acidifying deposition in freshwater ecosystems was phrased as “relationship between acidifying deposition and changes in aquatic biota.”

<sup>g</sup>The 2008 ISA causality statement for biological effects of N deposition in freshwater ecosystems was phrased as “relationship between N deposition and the alteration of species richness, species composition, and biodiversity in freshwater aquatic ecosystems.”

<sup>h</sup>The 2008 ISA causality statement for biological effects of N deposition to estuaries was phrased as “relationship between N deposition and the alteration of species richness, species composition, and biodiversity in estuarine ecosystems.”

<sup>i</sup>The 2008 ISA causality statement for biological effects of S deposition effects on ecosystems was phrased as “relationship between S deposition and increased methylation of Hg, in aquatic environments where the value of other factors is within adequate range for methylation.”

[Figure ES-3](#) presents a visualization of the causality statements integrated into a single diagram. There is not a one-to-one correspondence between the number of causality statements, of which there are 18, and the cells indicated to have causal relationships in the diagram because some causal statements include effects across more than one level of biological organization. The main findings are that gaseous  $\text{NO}_y$  and  $\text{SO}_x$  cause phytotoxic effects, while N and S deposition cause alteration in (1) biogeochemical components of soil and water chemistry and (2) multiple levels of biological organization ranging from physiological processes to shifts in biodiversity and ecological function.

## **ES.4 Direct Phytotoxic Effects of Gas-Phase Oxides of Nitrogen (NO<sub>Y</sub>) and Oxides of Sulfur (SO<sub>X</sub>)**

The current NO<sub>2</sub> and SO<sub>2</sub> secondary NAAQS are set to protect against direct damage to vegetation by exposure to gas-phase oxides of NO<sub>Y</sub> and SO<sub>X</sub>. NH<sub>3</sub> can also have direct phytotoxic effects, but reduced N gases such as NH<sub>3</sub> are not criteria air pollutants. Research continues to support causal relationships between SO<sub>2</sub>, NO<sub>2</sub>, NO, peroxyacetyl nitrate (PAN), HNO<sub>3</sub>, and injury to vegetation (e.g., visible foliar injury, damage to photosynthesis, decline of growth and abundance; ([Table IS-1](#), [Section IS.4](#), [Appendix 3](#)), but research that tests plant response to the lower exposure levels representative of current atmospheric NO<sub>Y</sub> and SO<sub>X</sub> concentrations is limited. Consequently, few studies are available to help determine whether current monitored concentrations of gas-phase NO<sub>Y</sub> and SO<sub>X</sub> are high enough to injure vegetation. It is also known that these can be gases taken up by plants and alter the N cycle in some ecosystems.

---

## **ES.5 Ecological Effects of Nitrogen and Sulfur Deposition**

It is clear from the body of evidence that NO<sub>Y</sub>, SO<sub>X</sub>, and PM contribute to total N and S deposition. In turn, N and S deposition cause alteration of the biogeochemistry and the physiology of organisms, resulting in harmful declines in biodiversity in terrestrial, freshwater, wetland, and estuarine ecosystems in the U.S. Decreases in biodiversity mean that some species become relatively less abundant and may be locally extirpated. In addition to the loss of unique living species, the decline in total biodiversity can be harmful because biodiversity is an important determinant of the stability of ecosystems and their ability to provide socially valuable ecosystem services (see more on biodiversity in [Section IS.2.2.4](#)).

---

### **ES.5.1 Acidification of Terrestrial and Freshwater Ecosystems**

Several decades of research have documented that N and S deposition cause freshwater and terrestrial ecosystem acidification in the U.S. New evidence strengthens the causal relationships for ecosystem acidification determined in the 2008 ISA ([Table IS-1](#)).

Many of the terrestrial and freshwater ecosystems most sensitive to acidification in the U.S. are found in the Northeast and Southeast. In the West, freshwater and terrestrial ecosystems acidified from deposition are now limited in extent and occur mostly in high-elevation sites. Watershed sensitivity to acid inputs depends on characteristics such as underlying geology ([Appendix 4](#) and [Appendix 7](#)) and the sensitivity of species in the local biological community ([Appendix 5](#) and [Appendix 8](#)). Regional heterogeneity of deposition levels that cause ecological effects are in part due to historic exposure and

climate. In the East, especially the southern Appalachian Mountains, and the Northeast, the effects of acidifying deposition have been studied for several decades.

Acidified aquatic habitats have a lower number of species (species richness) of fishes, macroinvertebrates, and phytoplankton. The effects of acidifying deposition on aquatic ecosystems also include physiological impairment or mortality of sensitive species and shifts in biodiversity of both flora and fauna. Organisms at all trophic levels are affected by acidification, with clear linkages to chemical indicators for effects on algae, zooplankton, benthic invertebrates, and fish. Acid-neutralizing capacity (ANC) is a measure of the buffering capacity of natural waters against acidification. Even though ANC does not directly alter the health of biota, it is a key metric of acidification that relates to pH and aluminum levels. Biological effects are primarily attributable to low pH and high inorganic aluminum concentration. Characterization of ANC and its levels of concern have not changed appreciably with the newly available information since the 2008 ISA. Few or no fish species are found in lakes and streams that have very low ANC (near zero) and low pH (near 5.0), and the number of fish species generally increases with higher ANC and pH ([Appendix 8.3](#)). The fish lost to acidification include culturally and recreationally important species.

Acidified terrestrial habitats are characterized by the detrimental physiological effects seen on vegetation, including inhibited growth and decreased plant health. Acidifying deposition can decrease membrane stability and freezing tolerance in young red spruce needles. For many species, calcium (Ca) depletion from the soil and aluminum mobilization cause decreased root uptake of Ca and disrupt fine root physiological functions. Reduced availability of (base) cations in the soil can also make trees more vulnerable to other stresses, such as damage from insects and other pathogens. Within the eastern U.S., the physiological effects of acidifying deposition have been well documented for the several culturally and commercially important tree species with known ecosystem services, particularly sugar maple (*Acer saccharum*) and red spruce (*Picea rubens*). Consistent and coherent evidence available before and since the 2008 ISA suggests acidifying deposition among these species can decrease foliar cold tolerance, increase rates of crown dieback, decrease tree growth, suppress seedling regeneration, and increase mortality rates. ([Section IS.5.3](#); [Appendix 5](#)). Since the 2008 ISA, studies from the northeastern U.S. have shown that Ca addition can alleviate many of these effects, demonstrating that acidification effects can be ameliorated in the short term by soil amendments, suggesting the potential for recovery. However, Ca additions have been studied in only a few areas. Acidifying deposition has also been linked to changes in forest understory plant community composition in the northeastern U.S., grass and forb biodiversity in eight ecoregions across the U.S., and decreased grassland plant species richness in Europe.

Examples of improvement in acidification have been documented in some aquatic ecosystems in the regions most affected. Along with those improvements in acidification, chemical recovery has been observed in the Northeast, as seen by trends in water quality indicators ( $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ , pH, ANC, inorganic monomeric Al, MeHg) towards inferred preindustrial values or, in the case of inorganic Al and MeHg, below water quality threshold values protective of biota and human health. Chemical recovery has not been observed in studies of the southern Appalachians. In a few examples in the Northeast, chemical recovery co-occurs with the movement of biological indicators toward recovery. However, biological recovery has been highly variable among ecosystems and taxonomic groups. Biological recovery lags behind, sometimes by decades, chemical recovery. In addition, the biological recovery trajectory may exhibit hysteresis, in which a system does not follow the same path from acidification to recovery. Most biological communities studied to date where signs of reversal are found have not returned to preacidification conditions and are unlikely to do so, given the extirpation of some species, fundamental alterations in function and structure, decade-long depletion of base cations, and changes in other interacting influences such as climate and land use.

---

## **ES.5.2 Nitrogen Enrichment/Eutrophication of Terrestrial, Wetland, and Aquatic Ecosystems**

Terrestrial, wetland, freshwater, and estuarine ecosystems in the U.S. are affected by N enrichment/eutrophication caused by N deposition. N enrichment/eutrophication refers to N nutrient-driven changes in growth, physiology, and biodiversity. These effects have been consistently documented across the U.S. for hundreds of species. New evidence strengthens the causal relationships for ecosystem N enrichment/eutrophication determined in the 2008 ISA ([Table IS-1](#)).

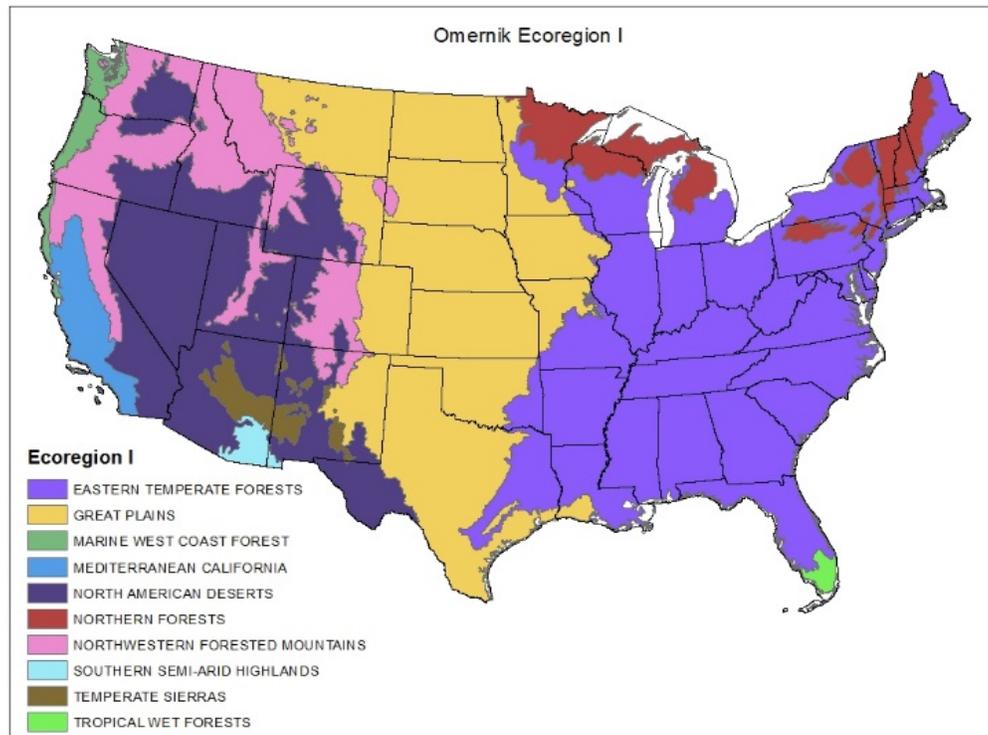

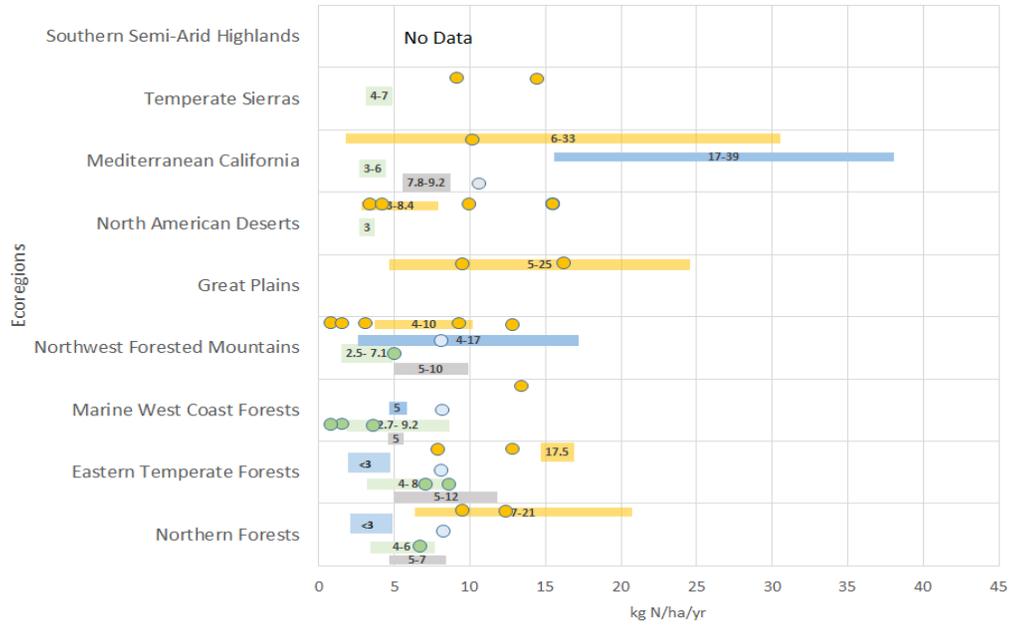

The 2008 ISA documented that the N enrichment effect in sensitive terrestrial and wetland ecosystems starts with the accumulation of N in the soil. This increases the availability of N, a nutrient that increases the growth of some species of soil microbes and vascular plants at the expense of other species, which may decrease biodiversity. Since the 2008 ISA, the largest increase in ecological evidence is for terrestrial N driven enrichment/eutrophication effects ([Section IS.5.1](#), [Section IS.5.2](#); [Appendix 4](#), and [Appendix 6](#)).

This new research confirms the causal relationship between N deposition and ecological effects documented in the 2008 ISA and improves our understanding of the mechanistic links that inform causal determinations between N deposition, biogeochemistry, and biota in terrestrial ecosystems ([Table IS-1](#)). A new causal determination has been added to reflect more specific categories of effects to include physiology, growth, and ecosystem productivity. Further, there is now stronger empirical evidence from across most regions

of the U.S. to quantify critical loads (CLs) for N deposition. The figure below provides estimates of CLs across broad ecoregions and shows the ranges for different functional groups within these systems ([Figure ES-4](#)). Under the CLs, significant harmful effects from N deposition do not occur according to present knowledge, while at or above CLs, N deposition can cause a myriad of ecological effects, including decreased tree growth and increased mortality, and declines in grasses/forbs, lichens, and mycorrhizal fungi.

Since the 2008 ISA, studies have strengthened evidence of species-specific effects of N deposition on tree growth and mortality in the U.S. Although overall tree growth has generally been enhanced by N deposition over the last several decades, there is wide variation among species in growth and mortality responses. Moreover, within some individual species, N deposition can increase growth and/or survival at low levels, while decrease growth and/or survival at higher levels. Species with varying responses have also been shown to co-occur in places in the U.S., suggesting overstory tree community composition shifts with N deposition.

Since the 2008 ISA, studies have also strengthened the findings of N effects on decreasing lichen and mycorrhizal fungi biodiversity and provided additional CL estimates. In terrestrial ecosystems, new evidence provides support that epiphytic lichens (an algal- and/or cyanobacteria-fungal symbiont) and mycorrhizae (a plant-fungal symbiosis at the tips of plant roots) are the organisms most sensitive to atmospheric N deposition and acidifying deposition. Although lichens typically are only a small portion of terrestrial biomass, these changes in lichen communities are meaningful because lichens provide food and habitat for insects, birds, and mammals; contribute to nutrient and hydrologic cycling; have many traditional human uses; and have considerable potential for pharmaceutical use. Changes in the community composition of mycorrhizal fungi and declines in mycorrhizal abundance have been observed in the U.S. These fungi are important for supplying nutrients and water to plants, influencing soil C sequestration, and producing fruiting bodies (mushrooms) used by humans and wildlife.

CL = critical load; ha = hectare; kg = kilogram; N = nitrogen; yr = year.

The rectangles indicate the range of CLs designated by [Pardo et al. \(2011a\)](#); the circles indicate new papers that have specified CLs; data from [Table 6-28](#).

**Figure ES-4 Summary of critical loads for nitrogen in the U.S. for shrubs and herbaceous plants (yellow), trees (blue), lichens (green), and mycorrhizae (gray). Values expressed by major U.S. ecoregions.**

For wetland ecosystems, the 2008 ISA documented that wetlands receiving a larger fraction of their total water budget in the form of precipitation are more sensitive to the effects of N deposition. For example, bogs and fens (55–100% of hydrological input from rainfall) are more sensitive to N deposition than coastal wetlands (10–20% as rainfall). Since the 2008 ISA, CLs for U.S. coastal and freshwater wetlands have been established. The CL for freshwater wetlands is based on C cycling, as well as biodiversity represented by the morphology and population dynamics of the purple pitcher plant (*Sarracenia purpurea*). The CL for coastal wetlands is based on several different ecological endpoints, including plant community composition, microbial activity, and biogeochemistry.

The 2008 ISA documented that the process of N eutrophication is similar in freshwater and estuarine ecosystems and typically begins with a nutrient-stimulated algal bloom that is followed by anoxic conditions. The lack of oxygen in the water due to the respiration and decomposition of the algae affects higher trophic species. The contribution of N deposition to total N loading varies among freshwater lakes and stream ecosystems. Atmospheric deposition is the main source of new N inputs to most headwater stream, high-elevation lake, and low-order stream watersheds far from the influence of other N sources like agricultural runoff and wastewater effluent. N deposition was known at the time of the 2008 ISA to alter biogeochemical processes, nutrient ratios, and concentrations in recipient freshwater ecosystems. New CLs published since the 2008 ISA support previous observations of increased productivity of phytoplankton and algae, species changes, and reductions in diversity in atmospherically N enriched lakes and streams. The productivity of many freshwater ecosystems is N limited. Thus, even small amounts of N can shift nutrient ratios and affect the trophic status of lakes and streams. As reported in the 2008 ISA and newer studies, a shift from N limitation to either colimitation by N and P or limitation by P has been observed in some alpine lakes in the U.S. and other countries, with these shifts correlated with elevated N deposition.

Estuaries support a large biodiversity of flora and fauna and play a role in nutrient cycling. At the time of the 2008 ISA, N was recognized as the major cause of harm to the majority of estuaries in the U.S. Elevated N inputs to coastal areas can alter key processes that influence N and C cycling in near-coastal environments. Data evaluating sources of N to estuaries, from the 2008 ISA and newer studies reviewed in this ISA, indicate that N from atmospheric sources ranges from <10% to approximately 70% of total estuary N inputs; the atmospheric input for most estuaries is between 15 to 40% of total N inputs. N from atmospheric and other sources contributes to increased primary productivity, leading to eutrophication. In some coastal areas eutrophication from N loading may affect carbonate chemistry under certain circumstances, potentially contributing to acidifying conditions along with atmospheric anthropogenic CO<sub>2</sub> inputs and other factors. Since

2008, new paleontological studies, observational studies, and experiments have further characterized the effects of N on phytoplankton growth and community dynamics, macroinvertebrate response, and other indices of biodiversity in streams, rivers, lakes and estuaries. For this ISA, new information is consistent with the 2008 ISA, and the causal determinations for N enrichment in aquatic systems have been updated to reflect more specific categories of effects, including measures of productivity and altered growth of biota ([Table ES-1](#)).

---

### **ES.5.3 Sulfur (S) Enrichment of Wetland and Freshwater Ecosystems**

SO<sub>x</sub> deposition increases SO<sub>4</sub><sup>2-</sup> concentration in surface waters. New evidence supports links between aqueous S concentrations in freshwater ecosystems and both mercury (Hg) methylation and sulfide toxicity ([Table ES-1](#)); however, quantitatively linking these outcomes to atmospheric deposition remains a challenge.

Increasing SO<sub>4</sub><sup>2-</sup> concentration in surface waters can stimulate the microbial transformation of inorganic Hg into methylmercury (MeHg; [Appendix 12](#)). MeHg is the most persistent and toxic form of Hg affecting animals in the natural environment. Indicators of S deposition effects upon Hg methylation include increases in MeHg concentrations or fraction of total Hg in water, sediments, and peat, as well as increases in MeHg concentrations in periphyton, submerged aquatic plants, invertebrates, and fish. New evidence confirms the relationship between aqueous concentrations of SO<sub>4</sub><sup>2-</sup> and MeHg and broadens our understanding of where methylation occurs from the wetlands and lakes reported in the 2008 ISA to include rivers, reservoirs, streams, and saturated forest soils. Hg methylation occurs at anoxic-oxic boundaries in peat moss and periphyton, as well as in wetland, lake, estuarine, and marine sediments. There are published quantitative relationships between surface water SO<sub>4</sub><sup>2-</sup> concentrations and MeHg concentrations, MeHg and total Hg in water, and Hg load in larval mosquitoes and fish. There is also evidence that decreasing S deposition loads over time (observational studies of SO<sub>x</sub> deposition, experimental studies of simulated SO<sub>x</sub> wet deposition) result in lower concentrations of MeHg in water, invertebrates, and fish.

There is new evidence since the 2008 ISA to infer a causal relationship between S deposition and sulfide phytotoxicity, which alters growth and productivity, species physiology, species richness, community composition, and biodiversity in wetland and freshwater ecosystems ([Appendix 12](#)). This new causal statement reflects new research on sulfide phytotoxicity in North American wetlands, as the 2008 ISA described sulfide phytotoxicity only in European ecosystems. Current levels of S deposition cause sulfide toxicity in wetland and aquatic plants. Indicators of sulfide phytotoxicity caused by S deposition include increases in water or sediment sulfide concentrations. Sulfide

negatively effects growth, competitive ability, and persistence in several wetland species, including the economically important species of wild rice and the keystone sawgrass species in the Everglades marshes. To date, no published studies have established regional sensitivities to sulfide phytotoxicity, although studies have observed its effects in New York, Minnesota, and Florida freshwater marshes. There are no S deposition-based critical loads for Hg methylation or sulfide phytotoxicity, although researchers have proposed water quality values to protect biota against these effects in several ecosystems ([Appendix 12](#)).

---

#### **ES.5.4 Ecological Effects of Particulate Matter Other Than Those Associated with Nitrogen and Sulfur Deposition**

There is a likely causal relationship between PM and ecological effects on biota other than those associated with N and S deposition ([Table ES-1](#); [Appendix 15](#)). Since publication of the 2009 PM ISA, new literature has built upon the existing knowledge of ecological effects associated with PM components, especially metals and organics. In some instances, new techniques have enabled further characterization of the mechanisms of PM on soil processes, vegetation, and effects on fauna. New studies provide additional evidence for community-level responses to PM deposition, especially in soil microbial communities. However, uncertainties remain due to the difficulty in quantifying relationships between ambient concentrations of PM and ecosystem response.

---

#### **ES.6 Ecosystem Services**

“Ecosystem services” refers to the concept that ecosystems provide benefits to people, directly or indirectly ([Costanza et al., 2017](#)) and produce socially valuable goods and services deserving of protection, restoration, and enhancement.

The ecosystem services literature has expanded since the 2008 ISA to include studies that better characterize ecosystem service valuation and quantification related to acidification and N enrichment/eutrophication.

Several new studies have paired biogeochemical modeling and benefit transfer equations informed by willingness-to-pay surveys to estimate the monetary damage done to ecosystems and the services they provide in the Adirondacks and Shenandoah regions due to ecosystem acidification ([Appendix 14](#)). Despite this progress, for many regions and specific services, poorly quantified relationships between deposition, ecological effects, and services are the greatest challenge in developing specific data on the economic benefits of emission reductions.

In the 2008 ISA, there were no publications that had specifically evaluated the effects of N deposition on ecosystem services associated with N driven enrichment/eutrophication. Since the 2008 ISA, several comprehensive studies have been published on the ecosystem services related to excessive N in U.S. water bodies. These include an evaluation of services affected by multiple N inputs (including N deposition) to the Chesapeake Bay, a synthesis of the cost-benefits on N loading across the nation, an estimation of the social cost of nitrogen when applied as fertilizer, and an analysis of how N lost from its intended area of application (e.g., agricultural fields) affects ecosystem services of adjacent ecosystems. Most notably, new work identifies over 1,000 links between N deposition and human beneficiaries.

Considering the full body of literature on ecosystem services related to N and S, the following conclusions are offered: (1) there is evidence that N and S emissions/deposition have a range of effects on U.S. ecosystem services and their social value; (2) some economic studies demonstrate such effects in broad terms, but it remains methodologically difficult to derive economic costs and benefits associated with specific regulatory decisions/standards; and (3) numerous, but still inadequately quantified, relationships are now documented between N and S air pollution and changes in final ecosystem goods and services.

---

## **ES.7 Integrating across Ecosystems**

Overall, new evidence since the 2008 ISA increases the weight of evidence for ecological effects, confirming concepts previously identified and improving quantification of dose-response (or deposition-ecological indicator) relationships, particularly for N and S deposition. The ecological effects are described by the causality determinations in [Figure ES-5](#), which reorganizes the information in [Figure ES-3](#) to show a visualization of the effects of NO<sub>y</sub>, SO<sub>x</sub>, and PM by ecosystem type (e.g., terrestrial, wetland, freshwater, and estuarine). With this organization, the multiple effects occurring in each ecosystem due to various pollution combinations of NO<sub>y</sub>, SO<sub>x</sub>, and PM are emphasized. Between two and four different classes of pollutant effects may occur in each ecosystem type in the U.S. For more information on key messages, see the expanded discussion in the [Integrated Synthesis](#); detailed information on specific ecosystem types and specific classes of pollutant effects included in the ISA may be found in the appendices.

# INTEGRATED SYNTHESIS

---

## IS.1 Introduction to This Integrated Science Assessment (ISA)

---

### IS.1.1 Purpose

The Integrated Science Assessment (ISA) is a comprehensive evaluation and synthesis of the policy-relevant science. Policy-relevant science is that which is “useful in indicating the kind and extent of all identifiable effects on public health or welfare which may be expected from the presence of [a] pollutant in the ambient air,” as described in Section 108 of the Clean Air Act ([CAA, 1990a](#)).<sup>1</sup> This ISA communicates critical science judgments on the ecological criteria for oxides of nitrogen, oxides of sulfur, and particulate matter (PM). Accordingly, this ISA is the scientific foundation for the review of the ecological effects of the current secondary (welfare-based) National Ambient Air Quality Standards (NAAQS) for oxides of nitrogen, oxides of sulfur, and particulate matter. The Clean Air Act definition of welfare effects includes, but is not limited to, effects on soils, water, wildlife, vegetation, visibility, weather, and climate, as well as effects on man-made materials, economic values, and personal comfort and well-being. The nonecological welfare effects associated with particulate matter, such as climate and visibility, are considered part of a separate, ongoing review of PM that is outlined in the *Integrated Review Plan (IRP) for the National Ambient Air Quality Standards for Particulate Matter* ([U.S. EPA, 2016d](#)). The human health effects are evaluated in separate assessments conducted as part of the review of the primary (human health-based) NAAQS for oxides of nitrogen ([U.S. EPA, 2016f](#)), oxides of sulfur ([U.S. EPA, 2016e](#)), and as noted above, particulate matter ([U.S. EPA, 2019](#)).

Oxides of nitrogen, oxides of sulfur, and particulate matter are reviewed here together because they are interrelated through complex chemical and physical atmospheric processes and because they all contribute to nitrogen (N) and sulfur (S) deposition, which in turn contributes to well-documented ecological effects. In this document, the term “oxides of nitrogen” refers to all forms of oxidized nitrogen (NO<sub>y</sub>) compounds, including

---

<sup>1</sup> The general process for developing an ISA, including the framework for evaluating weight of evidence and drawing scientific conclusions and causal judgments, is described in a companion document, *Preamble to the Integrated Science Assessments* ([U.S. EPA, 2015e](#)).

NO, NO<sub>2</sub>, and all other oxidized N containing compounds formed from NO and NO<sub>2</sub>.<sup>1</sup> Oxides of sulfur<sup>2</sup> are defined here to include sulfur monoxide (SO), sulfur dioxide (SO<sub>2</sub>), sulfur trioxide (SO<sub>3</sub>), disulfur monoxide (S<sub>2</sub>O), and sulfate (SO<sub>4</sub><sup>2-</sup>). However, SO, SO<sub>3</sub>, and S<sub>2</sub>O are present at much lower ambient levels than SO<sub>2</sub> and SO<sub>4</sub><sup>2-</sup> and are therefore not discussed further. Particulate matter is composed of some or all of the following components: nitrate (NO<sub>3</sub><sup>-</sup>), SO<sub>4</sub><sup>2-</sup>, ammonium (NH<sub>4</sub><sup>+</sup>), metals, minerals (dust), and organic and elemental carbon (C).

This ISA updates the 2008 *Integrated Science Assessment for Oxides of Nitrogen and Sulfur—Ecological Criteria* [hereafter referred to as the 2008 ISA ([U.S. EPA, 2008a](#))], as well as the ecological portion of the *Integrated Science Assessment for Particulate Matter* ([U.S. EPA, 2009a](#)), with studies and reports published from January 2008 through May 2017. Thus, this ISA updates the state of the science that was available for the 2008 ISA, which informed decisions on the secondary oxides of nitrogen and oxides of sulfur NAAQS in the review completed on March 20, 2012. In the final rulemaking, the Administrator’s decision was that, while the current secondary standards were inadequate to protect against adverse effects from deposition of oxides of nitrogen and oxides of sulfur, it was not appropriate under Section 109(b) to set any new secondary standards at this time due to the limitations in the available data and uncertainty as to the amount of protection the metric (Aquatic Acidification Index—see [Section IS.2.2.6](#)) developed in the Policy Assessment ([U.S. EPA, 2011a](#)) would provide against acidification effects across the country (77 FR 20281). In addition, the Administrator decided that it was appropriate to retain the current nitrogen dioxide (NO<sub>2</sub>) and sulfur dioxide (SO<sub>2</sub>) secondary standards to address direct effects of gaseous NO<sub>2</sub> and SO<sub>2</sub> on vegetation. Thus, taken together, the Administrator decided to retain and not revise the current NO<sub>2</sub> and SO<sub>2</sub> secondary standards: an NO<sub>2</sub> standard set at a level of 0.053 ppm, as an annual arithmetic average, and an SO<sub>2</sub> standard set at a level of 0.5 ppm, as a 3-hour average, not to be exceeded more than once per year (77 FR 20281). The current secondary standards for PM are intended to address PM-related welfare effects, including visibility impairment, ecological effects, and effects on materials and climate. These standards are a 3-year annual mean PM<sub>2.5</sub> concentration of 15 µg/m<sup>3</sup>, with the 24-hour average PM<sub>2.5</sub> and PM<sub>10</sub> set at concentrations of 35 µg/m<sup>3</sup> and 150 µg/m<sup>3</sup>, respectively.

---

<sup>1</sup> This ISA reserves the abbreviation NO<sub>x</sub> strictly as the sum of NO and NO<sub>2</sub>—consistent with that used in the atmospheric science community—and uses the term “oxides of nitrogen” to refer to the broader list of oxidized nitrogen species. Oxides of nitrogen refers to NO<sub>y</sub> as the total oxidized nitrogen in both gaseous and particulate forms. The major gaseous and particulate constituents of NO<sub>y</sub> include nitric oxide (NO), nitrogen dioxide (NO<sub>2</sub>), nitric acid (HNO<sub>3</sub>), peroxyacetyl nitrate (PAN), nitrous acid (HONO), organic nitrates, and particulate nitrate (NO<sub>3</sub>). This ISA uses the definitions adopted by the atmospheric sciences community.

<sup>2</sup> Oxides of sulfur refers to the criteria pollutant category.

This new review of the secondary oxides of nitrogen, oxides of sulfur, and particulate matter NAAQS is guided by several policy-relevant questions that were identified in *The Integrated Review Plan for the Secondary National Ambient Air Quality Standard for Nitrogen Oxides, Sulfur Oxides, and Particulate Matter* [hereafter referred to as the 2017 IRP ([U.S. EPA, 2017c](#))].

To address these questions, this ISA aims to characterize the evidence available in the peer-reviewed literature for ecological effects associated with:

- the major gaseous and particulate constituents of total oxidized N ( $\text{NO}_Y$ ), which include NO,  $\text{NO}_2$ ,  $\text{HNO}_3$ , PAN, HONO, organic nitrates, and  $\text{NO}_3^-$ ;
- the major gaseous and particulate constituents of  $\text{SO}_X$ , which include  $\text{SO}_2$  and  $\text{SO}_4^{2-}$ ; and
- PM composed of some or all of the following components: particulate  $\text{NO}_3^-$ , particulate  $\text{SO}_4^{2-}$ , ammonium ( $\text{NH}_4^+$ ), metals, minerals (dust), and organic and elemental carbon (C).

The assessment activities include:

- Identifying policy-relevant literature.
- Evaluating strength, limitations, and consistency of findings.
- Integrating findings across scientific disciplines and across related ecological outcomes.
- Considering important uncertainties identified in the interpretation of the scientific evidence.
- Assessing policy-relevant issues related to quantifying ecological risks, such as ambient air concentrations, deposition, durations, and patterns associated with ecological effects; the relationship between ambient air concentrations, deposition, and ecological response and the existence of thresholds below which effects do not occur; and species and populations potentially at increased risk of ecological effects.

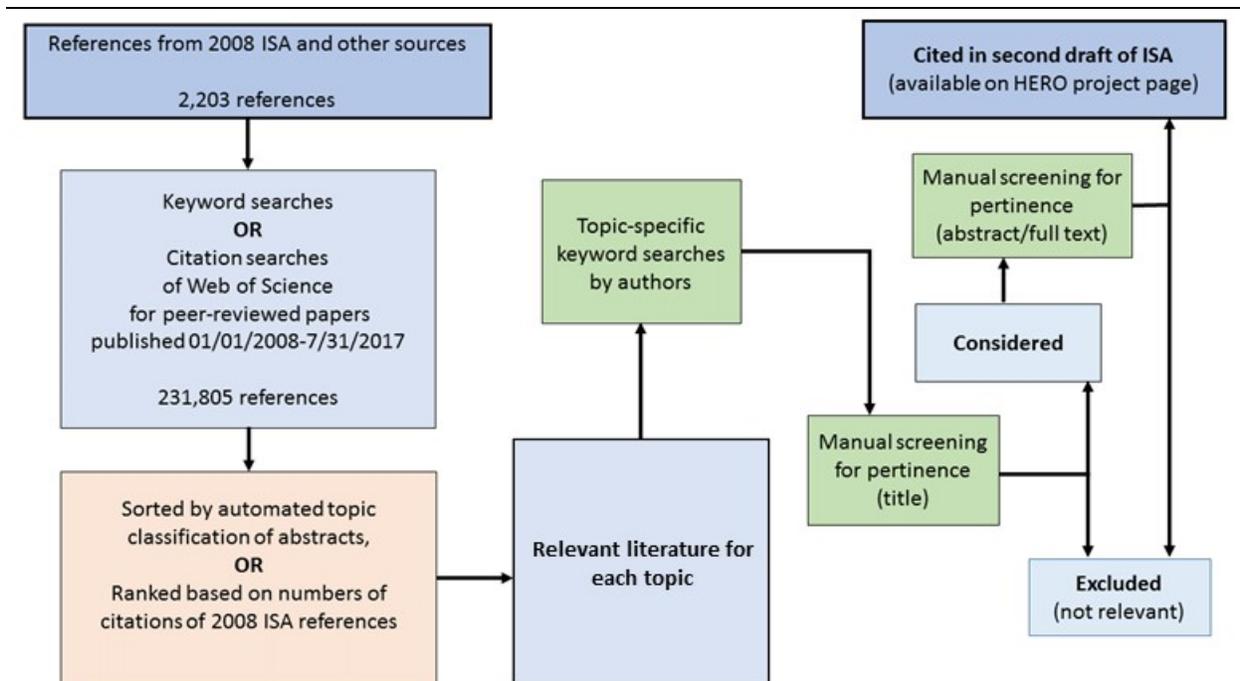

New analyses with the goal of quantifying risk, such as new model runs, Critical Loads (CLs) exceedance maps, and quantified uncertainties regarding modeled scenarios are not conducted in the ISA. These types of analyses, if pursued, require the selection of chemical or biological limits that define CLs and represent adversity. These analyses would also require choosing a time period over which to average deposition. Such scope-of-analysis decisions are more appropriate for the Risk and Exposure Assessment, as described in the 2017 IRP ([U.S. EPA, 2017c](#)). The information summarized in this ISA will serve as the scientific foundation of the Risk and Exposure and Policy Assessments during the current review of the secondary oxides of nitrogen, oxides of sulfur, and particulate matter NAAQS.

---

## IS.1.2 Process and Development

The U.S. EPA uses a structured and transparent process to evaluate scientific information and determine the causality of relationships between air pollution and ecological effects [see Preamble ([U.S. EPA, 2015e](#))]. The ISA development includes approaches for literature searches, criteria for selecting and evaluating relevant studies, and a framework for evaluating the weight of evidence and forming causal determinations. As part of this process, the ISA is reviewed by the public and by the Clean Air Scientific Advisory Committee (CASAC), which is a formal independent panel of scientific experts. This ISA informs the review of the secondary oxides of nitrogen, oxides of sulfur, and particulate matter NAAQS and therefore integrates and synthesizes information characterizing NO<sub>y</sub>, SO<sub>x</sub>, and PM air concentrations. It also examines deposition of these substances and their ecological effects. Relevant studies include those examining atmospheric chemistry, spatial and temporal trends, and deposition, as well as U.S. EPA analyses of air quality and emissions data. Relevant ecological research includes geochemistry, microbiology, physiology, toxicology, population biology, and community ecology. The research includes experimental laboratory and field additions of the pollutants, as well as gradient studies.

The U.S. EPA conducted literature searches to identify relevant peer-reviewed studies published since the previous ISA (i.e., from January 2008 through May 2017; [Figure IS-1](#)).

HERO = Health and Environmental Research Online; ISA = Integrated Science Assessment.

**Figure IS-1 Workflow for collecting relevant literature for the 2017 Integrated Science Assessment for Oxides of Nitrogen, Oxides of Sulfur, and Particulate Matter—Ecological Criteria.**

Multiple search methods were used in the Web of Science database [Preamble ([U.S. EPA, 2015e](#)), [Appendix 2](#)], including searches by keyword and by citations of 2008 ISA references. Subject-matter experts and the public were also permitted to recommend studies and reports during kick-off workshops held by the U.S. EPA in March 2014 for oxides of nitrogen and oxides of sulfur and in February 2015 for particulate matter. The new references were sorted by automated methods into topic areas based on wording in the publication’s abstract or numbers of citations of 2008 ISA references, and the resultant relevant literature was reviewed by the ISA authors. Studies were screened first based on the title and then by the abstract; studies that did not address a relevant research topic based on this screening were excluded. The U.S. EPA also identified studies from previous assessments as definitive works on particular topics to include in this ISA. The HERO project page for this ISA ([https://heronet.epa.gov/heronet/index.cfm/project/page/project\\_id/2965](https://heronet.epa.gov/heronet/index.cfm/project/page/project_id/2965)) contains the references that are cited in the ISA and electronic links to bibliographic information and abstracts.

*The Preamble to the Integrated Science Assessments* ([U.S. EPA, 2015e](#)) describes the general framework for evaluating scientific information, including criteria for assessing study quality and developing scientific conclusions. For ecological studies, emphasis is placed on studies that characterize quantitative relationships between criteria pollutants and ecological effects that occur at concentration and deposition levels relevant to current ambient levels in the U.S. However, experimental studies with higher exposure concentrations are included if they contribute to an understanding of mechanisms.

This ISA draws conclusions about relationships between NO<sub>y</sub>, SO<sub>x</sub>, and PM and ecological effects by integrating information across scientific disciplines and related ecological outcomes and synthesizing evidence from previous and recent studies. Determinations are made about causation, not just association, and are based on judgments of consistency, coherence, and scientific plausibility of observed effects, as well as related uncertainties. The ISA uses a formal causal framework [Table II of the Preamble ([U.S. EPA, 2015e](#))], which is based largely on the aspects for causality proposed by Sir Austin Bradford Hill to classify the weight of evidence according to the five-level hierarchy summarized below.

- Causal relationship
- Likely to be a causal relationship
- Suggestive of, but not sufficient to infer, a causal relationship
- Inadequate to infer the presence or absence of a causal relationship
- Not likely to be a causal relationship

APPENDIX 7 This ISA includes the [Preface](#) (legislative requirements and history of the secondary oxides of nitrogen, oxides of sulfur, and particulate matter NAAQS), an [Executive Summary](#), an [Integrated Synthesis](#), and 16 appendices. The general process for developing an ISA is described in a companion document, *Preamble to the Integrated Science Assessments* ([U.S. EPA, 2015e](#)). The [Integrated Synthesis](#) summarizes the scientific evidence that best informs policy-relevant questions that frame this review. [Appendix 1](#) is an introduction to the appendices. [Appendix 2](#) characterizes the sources, atmospheric processes, and the trends in ambient concentrations and deposition of NO<sub>y</sub>, SO<sub>x</sub>, and PM. [Appendix 3](#) describes direct effects of NO<sub>y</sub> and SO<sub>x</sub> gases on plants and lichens. [Appendix 4–Appendix 6](#) describe N and S deposition effects on terrestrial biogeochemistry and the terrestrial biological effects of terrestrial acidification and N enrichment. [Appendix 7](#) describes the effects of N and S deposition on aquatic biogeochemistry. [Appendix 8–Appendix 10](#) characterize the biological effects of freshwater acidification, freshwater N enrichment, and N enrichment in estuaries and near-coastal systems. [Appendix 11](#) describes the effects of N deposition on wetlands, and [Appendix 12](#) characterizes the ecological effects of S as a nutrient. [Appendix 13](#) presents

information on climate modification of ecosystem response to N and S, and [Appendix 14](#) discusses ecosystem services. [Appendix 15](#) is a review of the ecological effects of forms of PM that are not related to N or S deposition. Finally, [Appendix 16](#) presents case studies for six locations in the U.S. (southern/central California, northeastern U.S., Rocky Mountain National Park, southeastern Appalachia, Tampa Bay, and the Adirondacks) where data are sufficient to well characterize the ecological effects of N and S deposition. These sites would therefore make good candidates for further study to better understand the linkages across various effects and ecosystems and to better assess risk and exposure.

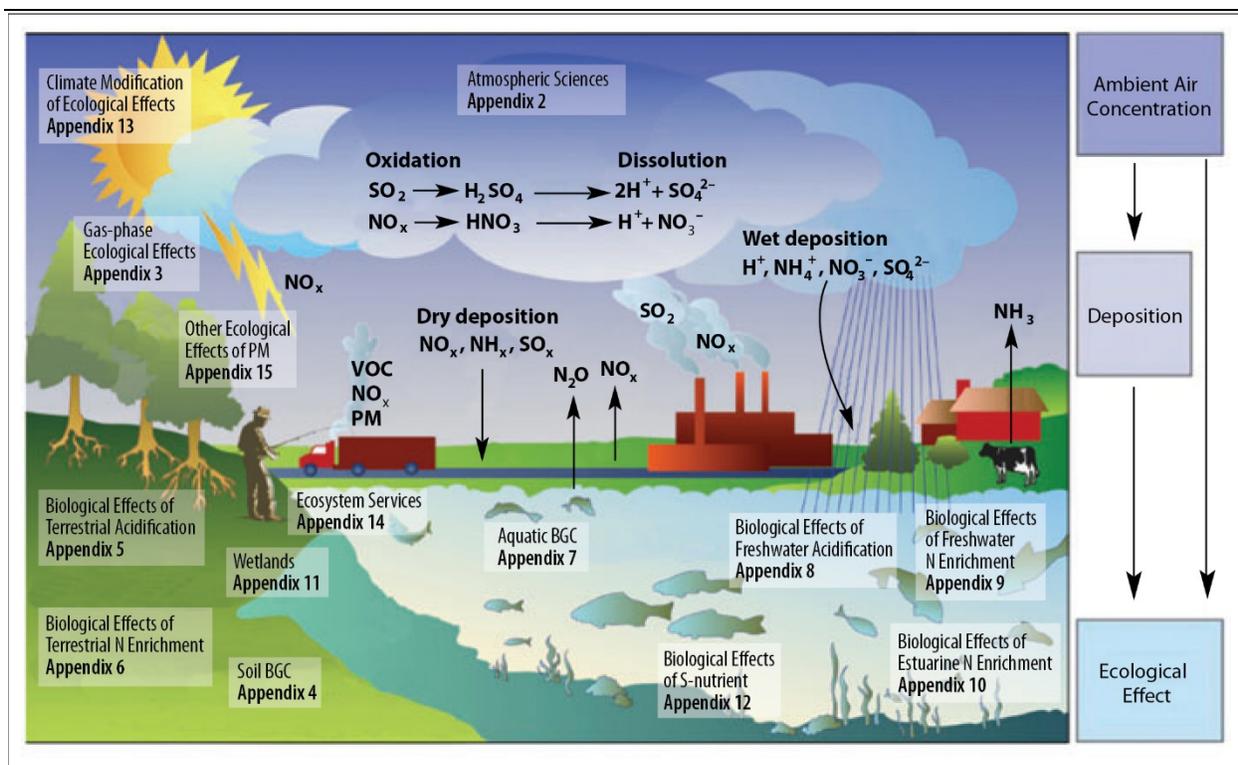

---

## **IS.2 Connections, Concepts, and Changes**

---

### **IS.2.1 Connections**

Although scientific material in this ISA is divided into separate appendices for atmospheric science and the multiple ecological effects, the strong links between the atmosphere and terrestrial and aquatic ecosystems are acknowledged ([Figure IS-2](#)). Emissions of NO<sub>y</sub>, SO<sub>x</sub>, and PM contribute to an accumulation of N and S in the environment that creates a multitude of effects on terrestrial, wetland, and aquatic ecosystems. Nitrogen is a vital component of all biological systems, serving as an essential element to molecules such as amino acids and nucleic acids, which are among the biochemical building blocks of life. As an organizing concept to understand the effects of N within the environment, the sequence of transfers, transformations, and environmental effects has been described as the “N cascade” ([Galloway and Cowling, 2002](#)). The concept of cascading effects also applies to S, which is also an essential macronutrient. Specifics of biogeochemical cycling and biological effects of N are discussed in [Section IS.5](#) and for S are discussed in [Section IS.9](#).

Ca<sup>2+</sup> = calcium ion; GHG = greenhouse gas; H<sup>+</sup> = hydrogen ion; H<sub>2</sub>SO<sub>4</sub> = sulfuric acid; HNO<sub>3</sub> = nitric acid; Mg<sup>2+</sup> = magnesium ion; N<sub>2</sub>O = nitrous oxide; N = nitrogen; NH<sub>3</sub> = ammonia; NH<sub>4</sub><sup>+</sup> = ammonium; NH<sub>x</sub> = NH<sub>3</sub> + NH<sub>4</sub><sup>+</sup> + reduced organic nitrogen compounds; NO = nitric oxide; NO<sub>2</sub> = nitrogen dioxide; NO<sub>3</sub><sup>-</sup> = nitrate; NO<sub>x</sub> = NO + NO<sub>2</sub>; PAN = peroxyacetyl nitrate; PM = particulate matter; SO<sub>2</sub> = sulfur dioxide; SO<sub>4</sub><sup>2-</sup> = sulfate; SO<sub>x</sub> = SO<sub>2</sub> + SO<sub>4</sub><sup>2-</sup>; VOC = volatile organic compounds.

The sum of reactive oxidized nitrogen species is referred to as NO<sub>y</sub> (NO<sub>y</sub> = NO + NO<sub>2</sub> + HNO<sub>3</sub> + 2N<sub>2</sub>O<sub>5</sub> + HONO + NO<sub>3</sub><sup>-</sup> + N<sub>2</sub>O PAN + other organic nitrates).

Although not explicitly indicated, wet and dry deposition of PM components (e.g., metals, minerals, and secondary organic aerosols) also occur and contribute to ecological effects.

Source: Modified from [U.S. EPA \(2008a\)](#).

**Figure IS-2 Overview of atmospheric chemistry, deposition, and ecological effects of emissions of oxides of nitrogen, oxides of sulfur, and reduced nitrogen.**

## IS.2.2 Concepts

This ISA draws on many methodological approaches and disciplines within the larger scientific fields of ecology and atmospheric sciences. The studies discussed herein are best understood in the context of some general concepts within these fields, such as ecosystem scale, structure, and function ([Section IS.2.2.1](#)); deposition and source apportionment to ecosystems ([Section IS.2.2.2](#)); critical loads ([Section IS.2.2.3](#)); biodiversity ([Section IS.2.2.4](#)); the effects of reduced versus oxidized forms of N

([Section IS.2.2.5](#)); and the metric developed in the previous secondary NAAQS review, the Aquatic Acidification Index (AAI; [Section IS.2.2.6](#)). The topics discussed in this “Concepts” section do not have separate sections dedicated to them in the [Integrated Synthesis](#). The topics of ecosystem recovery, ecosystem services, and uncertainty, while conceptual in nature, are not discussed here because they are the focus of more detailed discussions in [Section IS.11](#), [Section IS.13](#), and [Section IS.14](#), respectively.

Ecosystem structure comprises both biodiversity and geography. Biodiversity encompasses many quantitative measures of the abundance and distribution of organisms within a defined geographical area (for a more explicit definition, see [Section IS.2.2.1](#) and [Section IS.2.2.4](#)). Ecosystem function refers to processes that control fluxes and pools of matter and energy in the ecosystem ([Section IS.2.2.1](#)). The loss of biodiversity is a key consequence of the air pollutants discussed in this ISA. The importance of preserving biodiversity and ecosystem function contributes to the sustainability of ecosystem services that benefit human welfare and society in general ([Section IS.2.2.4](#) and [Appendix 14](#)).

In human health assessments, dose-response relationships are used to identify quantitative relationships between chemical exposure (dose) and health outcomes (response), with emphasis on identifying thresholds, or the lowest doses at which negative health outcomes are observed. In ecology, CLs provide a similar quantitative relationship between chemical dose (e.g., deposition) and specific, quantitative changes in ecological properties or processes ([Section IS.2.2.3](#)). For CLs to be used in evaluating the effects of deposition upon ecosystems that receive N or S from multiple sources, those other sources must be considered in comparison to deposition level ([Section IS.2.2.2](#)), as well as the heterogeneous sensitivities of organisms and ecosystems to different chemical forms of deposition ([Section IS.2.2.5](#)).

---

### **IS.2.2.1 Ecosystem Scale, Structure, and Function**

For this assessment, an ecosystem is defined as the interactive system formed from all living organisms (biota) and their abiotic (chemical and physical) environment within a given area ([IPCC, 2007a](#)). Ecosystem spatial boundaries are somewhat arbitrary, depending on the focus of interest or study. Thus, the spatial extent of an ecosystem may range from very small, well-circumscribed systems such as a small pond, to biomes at the continental scale, or the entire globe ([U.S. EPA, 2008a](#)). Ecosystem spatial scale does not always correlate with complexity. A small pond may be a complex system with multiple trophic levels ranging from phytoplankton to invertebrates to several feeding guilds of fish. A large lake, on the other hand, may be a very simple ecosystem, such as the Great

Salt Lake in Utah that covers approximately 1,700 square miles but contains only bacteria, algae, diatoms, and two invertebrate species ([U.S. EPA, 2013b](#)). All ecosystems, regardless of size or complexity, have multiple interactions between biota and abiotic factors. Ecosystems include both structural (geography and biodiversity [e.g., soil type and food web trophic levels]) and functional (flow of energy and matter [e.g., decomposition, nitrification]) attributes. Ecosystem changes are often considered undesirable if important structural or functional components of the ecosystems are altered following pollutant exposure ([U.S. EPA, 2013b](#), [1998a](#)).

Biotic or abiotic structure may define an ecosystem. Abiotic structure includes climatic and edaphic components. Biotic structure includes species abundance, richness, distribution, evenness, and composition, measured at the population, species, community, ecosystem, or global scale. A species (for eukaryotic organisms) is defined by a common morphology, genetic history, geographic range of origin, and ability to interbreed and produce fertile offspring. A population consists of interbreeding groups of individuals of the same species that occupy a defined geographic space. Interacting populations of different species occupying a common spatial area form a community ([Barnthouse et al., 2008](#)). Community composition may also define an ecosystem type, such as a pine forest or a tall grass prairie. Pollutants can affect the ecosystem structure at any of these levels of biological organization ([Suter et al., 2005](#)).

Individual plants or animals may exhibit changes in metabolism, enzyme activities, hormone function, or may suffer gross lesions, tumors, deformities, or other pathologies. However, only some organism-level endpoints affected by pollution, such as growth, survival, and reproductive output, have been definitively linked to effects at the population level and above ([U.S. EPA, 2013b](#)). Population-level effects of pollutants include changes over time in abundance or density (number of individuals in a defined area), age or sex structure, and production or sustainable rates of harvest ([Barnthouse et al., 2008](#)). Community-level attributes affected by pollutants include species richness, species abundance, composition, evenness, dominance of one species over another, or size (area) of the community ([U.S. EPA, 2013b](#)). Pollutants may affect communities in ways that are not observable in organisms or populations ([Bartell, 2007](#)), including (1) effects resulting from interactions between species, such as altered predation rates or competitive advantage; (2) indirect effects, such as reducing or removing one species from the assemblage and allowing another to emerge ([Petraitis and Latham, 1999](#)); and (3) alterations in trophic structure.

Alternatively, ecosystems may be defined on a functional basis. “Function” refers to the suite of processes and interactions among the ecosystem components that involve energy or matter. Examples include water dynamics and the flux of trace gases such as rates of

photosynthesis, decomposition, nitrification, or carbon cycling. Pollutants may affect biotic structure indirectly. For example, a pollutant may first alter abiotic conditions (e.g., soil chemistry), which in turn influences biotic structure and function ([Bartell, 2007](#)).

Some ecosystems, and some aspects of particular ecosystems, are less vulnerable to long-term consequences of pollutant exposure. Other ecosystems may be profoundly altered if a single attribute is affected by pollution. Thus, spatial and temporal definitions of ecosystem structure and function become essential factors in defining affected ecosystem services and in determining CLs for certain pollutants, either as single pollutants or in combination with other stressors.

The main causal determinations of this ISA ([Section IS.2.3](#)) are that N and S deposition affect ecosystem structure, with effects ranging from biogeochemical alterations in soil and water chemistry to multiple levels of biological organization, including species-level alterations of physiological processes and shifts in biodiversity and ecological function.

---

#### **IS.2.2.2 Deposition and Source Contribution of Nitrogen (N) and Sulfur (S) to Ecosystems**

Deposition of N and S results from a variety of human activities and atmospheric processes. Emissions from stationary, mobile, and agricultural sources undergo atmospheric transformation ([Section IS.3.1](#)) to form products that are eventually deposited out of the air onto the land or waterscape ([Section IS.3.3](#)). The contribution of atmospheric deposition to total loading for N and S varies within and among terrestrial, wetland, freshwater, and estuarine ecosystems.

In the 2008 ISA, atmospheric deposition was identified as the main source of anthropogenic N to unmanaged terrestrial ecosystems. This conclusion has been confirmed by new studies on N sources to lands and waterways ([Appendix 4.2](#)). Across all watersheds, atmospheric N deposition is the second largest overall human-mediated N source; agriculture is the largest, and the largest N source to 33% of watersheds. Current deposition levels in the U.S. are discussed in [Appendix 2](#) and [Section IS.3.3](#). No new information has been published on nonatmospheric sources of S in terrestrial ecosystems ([Appendix 4.2](#)); S inputs from the atmosphere are discussed in [Appendix 2](#) and [Section IS.3.3](#).

In the 2008 ISA, atmospheric deposition was also identified as the main source of N to some freshwater ecosystems, including headwater streams, high-elevation lakes, lower order streams in undisturbed areas, and freshwater wetlands (e.g., bogs and fens). Evidence for the influence of N deposition on water chemistry has been further supported

by new studies that quantify the contribution of N deposition to total N loading in freshwater lakes and streams, and which quantify atmospheric contributions during storm events ([Table 7-1](#)). As shown in these studies, deposition can represent a substantial portion of total N loading to surface waters. However, other nonpoint and point sources of N dominate N inputs to high-order streams.

In fresh surface waters and wetlands, S that contributes to enrichment induces acidifying effects. Sources of S include weathering of minerals in sediments and rocks, leaching from terrestrial S cycling, internal cycling, and direct atmospheric deposition. The 2008 ISA showed that drought can release S stored in wetlands or lake sediments because bound sulfide ( $S^{2-}$ ) is exposed to atmospheric oxygen and oxidized to  $SO_4^{2-}$ . Increases in waterborne  $SO_4^{2-}$  concentration through various concurrent processes has been observed as a result of drought in whole-lake observational research (93% increase in Little Rock Lake, WI, from 1.5 to 2.9 mg/L), and in response to variation in water levels from climate change-induced droughts in modelling using Model of Acidification of Groundwater in Catchments (MAGIC). New evidence confirms that fluctuating water levels in wetlands increase  $SO_4^{2-}$  concentration in pulses following water level recovery.

The importance of atmospheric deposition as a cause of estuarine eutrophication is determined by the relative contribution of the atmospheric versus nonatmospheric sources of N input. Sources of N in coastal areas may include direct deposition to the water surface, coastal upwelling from oceanic waters, and transport from watersheds. Freshwater inflows to estuaries often transport N from agriculture, urban, wastewater, and atmospheric deposition sources. Atmospheric deposition constitutes less than half of the total N supply in most, but not all, estuaries ([Table 7-9](#)). Both point sources and nonpoint sources (including runoff, as well as atmospheric deposition) have been identified as targets for mitigation of N loading in coastal areas. Seawater contains high concentrations of  $SO_4^{2-}$ , so atmospheric inputs of S are unlikely to contribute substantially to biogeochemical or biological effects in coastal areas.

---

### IS.2.2.3 Critical Loads Concept and General Approaches

The following section provides a discussion of important concepts regarding Critical Loads (CLs). The definition of a CL is, “a quantitative estimate of an exposure to one or more pollutants below which significant harmful effects on specified sensitive elements of the environment do not occur according to present knowledge” ([Nilsson and Grennfelt, 1988](#)). This definition is intended as background material to support a better understanding of the CL calculations presented throughout the ISA. The main concepts presented here include CLs as an organizing principle, CL heterogeneity across the

landscape, more than one CL for a given location, the pros and cons of methods used to calculate CLs (e.g., empirical, steady state, and dynamic), and a comparison of CLs versus target loads. Uncertainty in calculating CLs is discussed in [Section IS.13](#).

Throughout this ISA, the CL concept is used as an organizing principle to relate atmospheric deposition to ecological endpoints that indicate impairment. The development of a quantitative CL estimate requires a number of steps. An illustrative example of the eight general steps is shown in [Figure IS-3](#).

1) Disturbance	Acidification				Eutrophication	
2) Receptor	Forest		Lake		Grassland	Lake
3) Biological indicator	Sugar Maple	Norway Spruce	Brook trout	Fish species richness	Species diversity	Primary productivity
4) Critical biological response	Failure to reproduce	Seedling death	Presence absence	Species loss	Species loss	Excess productivity
5) Chemical indicator	Soil % Base Saturation	Soil Ca/Al ratio	Lakewater ANC	Lakewater ANC	Soil C/N ratio	Lakewater NO <sub>3</sub>
6) Critical chemical limit	10%	1.0	0 µeq/L	50 µeq/L	20	10 µeq/L
7) Atmospheric pollutant	SO <sub>4</sub> , NO <sub>3</sub> , NH <sub>4</sub>	SO <sub>4</sub> , NO <sub>3</sub> , NH <sub>4</sub>	SO <sub>4</sub> , NO <sub>3</sub> , NH <sub>4</sub>	SO <sub>4</sub> , NO <sub>3</sub> , NH <sub>4</sub>	NO <sub>3</sub> , NH <sub>4</sub>	NO <sub>3</sub> , NH <sub>4</sub>
8) Critical pollutant load	???	???	???	???	???	???

Al = aluminum; ANC = acid-neutralizing capacity; C = carbon; Ca = calcium; L = liter; µeq = microequivalents; N = nitrogen; NH<sub>4</sub> = ammonium; NO<sub>3</sub> = nitrate; SO<sub>4</sub> = sulfate.

Source: [U.S. EPA \(2008a\)](#).

**Figure IS-3** An example of the matrix of information considered in defining and calculating critical loads (see discussion in text). Note that multiple alternative biological indicators, critical biological responses, chemical indicators, and critical chemical limits could be used.

It is important to recognize that there is no single “definitive” CL for an ecological effect. CL estimates reflect the current state of knowledge and the selected limits, indicators, and responses. Changes in scientific understanding may include, for example, new dose-response relationships, better resource maps and inventories, larger survey data sets, continuing time-series monitoring, and improved numerical models.

Calculating multiple CLs for a given pollutant at a single location is not uncommon because of the nested sequence of disturbances, receptors, and biological indicators considered for a given pollutant. Multiple CL values may also arise from an inability to agree on a single definition of “harm.” Calculation of CLs for multiple definitions of “harm” may be deemed useful in subsequent discussions of the analysis and in the decision-making steps that may follow CL calculation.

The heterogeneity of natural environments can affect responsiveness of ecosystems to deposition load. For example, the high spatial variability of soils almost guarantees that for any reasonably sized soil-based “receptor” that might be defined in a CL analysis, there will be a continuum of CL values for any indicator chosen. Although the range of this continuum of values might be narrow, there is nevertheless an a priori expectation in any CL analysis that multiple values (or a range of values) will result from the analysis. Given the heterogeneity of ecosystems affected by N and S deposition, published CL values for locations in the U.S. vary depending on both biological and physical factors.

The three approaches to developing CLs (i.e., empirical observation, steady-state modeling, and dynamic modeling) each have strengths and limitations. It is suggested that the combined approach of calculating CLs from biogeochemical simulation models in conjunction with empirical analyses is the most effective way to characterize the effects of deposition to a given environment ([Fenn et al., 2015](#)). For all three types of models, spatial boundaries of where to apply a CL are important. For example, a CL may apply to a watershed, ecoregion, or species range, depending on how the CL is defined.

An important advantage of empirical CLs is that they are based on measured (vs. modeled) changes in ecological variables in response to inputs. Consequently, the links between deposition and the measured response variable are direct; full process-level knowledge is not required. Empirical CLs are important for validating CL values determined with models ([Fenn et al., 2015](#)).

[Fenn et al. \(2015\)](#) discussed that the advantages of models, “are that ecosystem responses to alternative scenarios can be tested. These might include changes in atmospheric deposition, disturbance or climatic conditions, and responses to silvicultural treatments, grazing, fire, and other disturbances. Simulation modeling allows temporal aspects of ecosystem response in relation to CLs and CL exceedances to be evaluated, including evaluation of historical and future conditions.”

Two key ways that steady-state and dynamic models differ in their modeling of CLs is by how they assume ecosystem equilibrium and by the amount of input data they need for parameterization.

Steady-state models assume that the ecosystem is in equilibrium with the CL of deposition; therefore, the long-term sustainable deposition, that is the CL, is indicated. This is the relevant information needed to provide protection from deposition in perpetuity as the system comes into equilibrium with the pollutant CL. In the U.S., few (if any) ecosystems qualify as steady-state systems. Therefore, the assumption of equilibrium in the steady-state model is often false. The steady-state models give no information concerning the time to achieve the equilibrium or what may happen to the receptor along the path to equilibrium. The recovery of an ecosystem based on a CL from a steady-state model may take several hundred years. In other words, the assumption that attainment of a deposition value below the steady-state CL will result in biological recovery within a specified time period may not be valid. Dynamic models calculate time-dependent CLs and, therefore, do not assume an ecosystem that is in equilibrium. The time-dependent calculation is relevant information to provide protection from damage by the pollutant within a specific time frame. Generally, the shorter the time frame selected, the lower the CL.

Data requirements for steady-state models tend to be much lower than for dynamic models. Therefore, the data required to conduct dynamic modeling are not available for as many places as the data required to conduct steady-state modeling. The few national-scale modeling efforts for both terrestrial and aquatic acidification are both done with steady-state models for this reason.

The results of all three CL approaches are difficult to extrapolate across geographic space. Spatially, variation in biological and biogeochemical processes imposed by climate, geology, biota, and other environmental factors may alter the deposition-response relationship. Empirical CLs may only be applied with confidence to sites with highly similar biotic and environmental conditions ([Pardo et al., 2011a](#)). This is particularly problematic in areas where deposition has received sparse research attention—as is sometimes the case for CLs of N deposition related to N driven eutrophication ([Appendix 6.4](#)). Models may be run at different locations, but the data needed to parameterize them is not always available.

CLs are different from target loads. [Fenn et al. \(2011b\)](#) defined the “target load” as follows: “The acceptable pollution load that is agreed upon by policy makers or land managers. The target load is set below the CL to provide a reasonable margin of safety, but could be set higher than the CL at least temporarily.” Target loads are selected based on the level of ecosystem protection desired, economic considerations, and stakeholder input at a given location.

---

#### IS.2.2.4 The Importance of Biodiversity

There are causal relationships between additions of N and/or S to an ecosystem and biodiversity loss in terrestrial, freshwater, wetland, and estuarine ecosystems in the U.S. ([Table IS-1](#)). What does it mean to lose biodiversity? Biodiversity loss not only means the extirpation of unique living species, it represents the potential loss of ecosystem function and ecosystem services, as shown by several decades of research in a wide variety of natural systems ([Hooper et al., 2012](#); [Balvanera et al., 2006](#); [Tilman, 2000](#)). Numerous studies demonstrate that the number and diversity of organisms in a system control the abundance of habitat for other species, the biogeochemical cycling of nutrients and carbon, and the efficiency at which biotic systems are able to transform limited resources into biomass ([Cardinale et al., 2011](#)). Among plant communities, higher biodiversity leads to higher overall plant productivity and greater retention of soil nutrients ([Reich et al., 2012](#); [Tilman, 2000](#)). In multitrophic systems, higher prey diversity leads to both higher predator growth rates and a smaller impact of predation on prey abundance ([Duffy et al., 2007](#)). Positive impacts of biodiversity on ecosystem services have been documented in forests ([Gamfeldt et al., 2013](#); [Zhang et al., 2012b](#)), grasslands ([Tilman et al., 2012](#)), arid and semiarid ecosystems ([Maestre et al., 2012](#)), and marine systems ([Gamfeldt et al., 2015](#); [Worm et al., 2006](#)) and include effects such as greater carbon storage, fruit production, wood production, and nutrient cycling. In marine ecosystems, biodiversity loss has been linked to increased rates of exponential decreases in water quality through metrics such as higher numbers of beach closures and harmful algal blooms [HABs; [Worm et al. \(2006\)](#)]. Notably, HABs are linked to increased disease prevalence among humans, domestic animals/pets, and aquatic organisms ([Johnson et al., 2010](#)). In addition to the relationship between HABs and disease, there is now empirical evidence from many ecosystems of a broader link between declines in biodiversity and increased transmission and severity of disease ([Johnson et al., 2015b](#)) caused by plant, wildlife, and human pathogens. As a whole, these decades of research have produced an overwhelming body of evidence indicating that the loss of biodiversity risks a deterioration of the ecosystem goods and services on which humanity depends on ([Gamfeldt et al., 2015](#); [Cardinale et al., 2012](#)).

One of the most important consensus observations in biodiversity research is that ecosystem processes are more stable (have less temporal variability) at higher levels of diversity ([Cardinale et al., 2012](#); [McCann, 2000](#); [Naeem and Li, 1997](#); [Tilman and Downing, 1994](#)). This stability occurs because species respond differently to environmental variation. In diverse communities, it is more likely that declines in the growth of one species caused by an environmental change will provide more resources for competing species ([Cardinale et al., 2012](#); [Tilman, 2000](#)). This property was predicted by economists and is similar to how more diversified investment portfolios provide

enhanced stability under fluctuating market conditions ([Doak et al., 1998](#); [Tilman et al., 1998](#)). Notably, there is also consensus that the impact of biodiversity on ecosystem processes is nonlinear, wherein declines in ecosystem processes accelerate as the number of species in a system declines ([Cardinale et al., 2012](#)). Accelerating ecosystem service declines in response to species loss may be because different ecosystem functions require the presence of different sets of species ([Isbell et al., 2015](#); [Reich et al., 2012](#); [Zavaleta et al., 2010](#)). The increased stability of diverse ecosystems makes these systems less vulnerable to environmental change or collapse caused by external forces such as drought or human disturbance ([Isbell et al., 2015](#); [Tilman et al., 2012](#); [Isbell et al., 2011](#); [Worm et al., 2006](#)). For example, coastal systems with higher species diversity had lower rates of fishery collapse and extinction for commercially important fish and invertebrate species, and large marine ecosystems with higher fish diversity recovered more quickly from collapse ([Worm et al., 2006](#)). Thus, there is strong evidence that high biodiversity helps sustain ecosystem services and makes these ecosystem services more resilient to environmental change.

---

### IS.2.2.5 Reduced versus Oxidized Nitrogen Effects across Ecosystems

Individual biochemical and geochemical processes involve specific chemical forms of N, suggesting that there may be consequences in many ecosystems from the ongoing trend of decreasing  $\text{NO}_y$  deposition and increasing  $\text{NH}_x$  deposition in many parts of the U.S. ([Section IS.3](#)). The largest body of evidence that the effects of reduced versus oxidized N may have different consequences for ecological structure and function is for estuaries where the form of N delivered to some coastal areas of the U.S. is shifting from primarily  $\text{NO}_3^-$  to an increase in reduced forms of N. Although unlikely to be attributed solely to atmospheric sources due to the large contribution of N from wastewater, agriculture, and other sources, inputs of ammonia ( $\text{NH}_3$ ) and  $\text{NH}_4^+$  selectively favor specific phytoplankton functional groups (e.g., cyanobacteria, dinoflagellates) including harmful species ([Figure 10-7](#)). Shifts in phytoplankton community composition to species that respond strongly to reduced N have been observed in some coastal regions ([Appendix 10.3.2](#)). Growth of some species of phytoplankton ([Appendix 10.2.2](#)) and macroalgae (seaweed; [Appendix 10.2.3](#)) appear to be related to the form of N. There is also increasing evidence in freshwater systems for the importance of N in harmful algal blooms (HABs), and several studies have shown that the form of N influences freshwater algal species composition ([Appendix 9.2.6.1](#)). In terrestrial systems, oxidation-reduction status of inorganic N seems to have little influence on the biological responses to N deposition ([Appendix 4.3.12](#)).

Because some soil biogeochemical processes involve specific chemical forms of N (e.g., denitrification, ammonium toxicity), there is the potential that biological responses to N deposition (or N addition) could depend on whether the dominant form of deposited N is oxidized ( $\text{NO}_y$ ) or reduced ( $\text{NH}_x$ ). Different responses to individual forms of N have been observed for some soil biogeochemical processes ([Table 4-13](#)) and terrestrial biological responses ([Table 6-1](#)). Moreover, a number of individual studies have observed differential effects of  $\text{NH}_4^+$  versus  $\text{NO}_3^-$  additions on plant community diversity [e.g., [Kleijn et al. \(2008\)](#); [Dias et al. \(2014\)](#)]. In general, however, meta-analyses in the literature have tended to find no difference in the effects of individual forms of N on terrestrial biological endpoints like plant productivity or microbial biomass ([Table 6-1](#)). This result suggests that terrestrial community diversity is also generally not differentially affected by the form of N, possibly because plant uptake of N is mediated by soil biogeochemical cycles that often rapidly transform N between oxidized and reduced forms.

Evidence of wetland responses to different chemical forms of N come primarily from N addition experiments conducted outside of the U.S. In European bogs and fens, both forms of N addition decreased ecosystem N retention, but oxidized N addition caused dissolved organic nitrogen (DON) leaching, while reduced N caused dissolved inorganic nitrogen (DIN) leaching as well as cation leaching ([Appendix 11.3.1.6](#)). Reduced N caused greater physiological stress or injury than equivalent loads of oxidized N in moss species ([Appendix 11.4.5](#) and [Appendix 11.5.5](#)).

---

### IS.2.2.6 Aquatic Acidification Index (AAI)

The 2017 IRP ([U.S. EPA, 2017c](#)) described the Aquatic Acidification Index (AAI) to be a novel approach for a multipollutant standard intended to address deposition-related effects. Scientifically, the AAI represented an advancement in ecological methodology to (1) calculate CLs for aquatic acidification on a national scale, when previously CLs had been calculated on the spatial scale of a watershed and (2) provide a uniform level of ecological protection at the national scale. These advancements were accomplished by first aggregating CLs calculated for the same chemical limit within a defined spatial region. Next, the distribution of the “population” of CL values was evaluated, and the percentage of water bodies to protect was selected as a potential method to evaluate different conservation targets. The AAI also presented novel advancements in atmospheric sciences, including (1) using transference ratios to relate atmospheric concentrations of criteria pollutants to deposition levels and (2) allowing quantification of criteria pollutants ( $\text{NO}_y$  and  $\text{SO}_x$ ) and noncriteria pollutant (e.g.,  $\text{NH}_x$ ) contributions to total acidifying deposition. As a scientific publication, the AAI is documented in [Scheffe](#)

[et al. \(2014\)](#). The AAI was originally developed in the 2011 NO<sub>x</sub>SO<sub>x</sub> Policy Assessment ([U.S. EPA, 2011a](#)), and the equation is described with terms that traditionally define a NAAQS [the indicator,<sup>1</sup> averaging time,<sup>2</sup> form,<sup>3</sup> and level<sup>4</sup>—further described in the 2017 IRP ([U.S. EPA, 2017c](#))].

Key scientific aspects of the AAI equation, as the form of a potential standard, are described in the following excerpt from 2017 IRP ([U.S. EPA, 2017c](#)):

“The AAI, as described in the PA ([U.S. EPA, 2011a](#)), was constructed from steady-state ecosystem modeling, and included atmospheric transference ratios and deposition of reduced forms of nitrogen (ammonia gas and ammonium ion, expressed as NH<sub>x</sub>). These nonoxidized forms of nitrogen were included since ecosystems respond to total nitrogen deposition, whether from oxidized or reduced forms. More specifically, the AAI equation was defined in terms of four ecological and atmospheric factors and the ambient air indicators NO<sub>Y</sub> and SO<sub>X</sub>:

$$AAI = F1 - F2 - F3[NO_Y] - F4[SO_X]$$

**Equation IS-1**

where  $F1^5$  represents the ecosystems natural ability to provide acid-neutralizing capacity (e.g., geology, plant uptake of nitrogen deposition) and other processes;  $F2^6$  represents acidifying deposition associated with reduced forms of nitrogen, NH<sub>x</sub>; and  $F3^7$  and  $F4^8$  are the

---

<sup>1</sup> The “indicator” of a standard defines the chemical species or mixture that is measured in determining whether an area attains the standard.

<sup>2</sup> The “averaging time” defines the time period over which ambient measurements are averaged (e.g., 1-hour, 8-hour, 24-hour, annual).

<sup>3</sup> The “form” of a standard defines the air quality statistic that is compared to the level of the standard in determining whether an area attains the standard.

<sup>4</sup> The “level” defines the allowable concentration of the criteria pollutant in the ambient air.

<sup>5</sup>  $F1$  is defined as:  $ANC_{lim} + CL_r/Q_r$ , with  $ANC_{lim}$  representing a target ANC level. With regard to  $CL_r$ , the PA developed distributions of calculated critical loads for a specific ecoregion; in setting an AAI-based standard, a percentile would need to be specified to reference the value of  $CL_r$  to be used in the AAI equation [[U.S. EPA \(2011a\)](#), p. 7–37]. The PA described the percentile as an aspect of the form for the standard [[U.S. EPA \(2011a\)](#), Section 7.7].

<sup>6</sup>  $F2$  is defined as:  $NH_x/Q_r$ , where  $NH_x$  is the deposition divided by  $Q_r$  [[U.S. EPA \(2011a\)](#), p. 7–37].

<sup>7</sup>  $F3$  is defined as:  $TNO_Y/Q_r$ , where  $TNO_Y$  is the transference ratio that converts deposition of NO<sub>Y</sub> to ambient air concentrations of NO<sub>Y</sub> [[U.S. EPA \(2011a\)](#), p. 7–37].

<sup>8</sup>  $F4$  is defined as:  $TSO_X/Q_r$ , where  $TSO_X$  is the transference ratio that converts deposition of SO<sub>X</sub> to ambient air concentrations of SO<sub>X</sub> [[U.S. EPA, 2011a](#)], p. 7–37].

transference ratios that convert concentrations of  $\text{NO}_Y$  and  $\text{SO}_X$  to related deposition of nitrogen and sulfur [[U.S. EPA \(2011a\)](#), Section 7.7].”

Several other key scientific considerations are included in the AAI that were discussed in the 2011  $\text{NO}_X\text{SO}_X$  Policy Assessment ([U.S. EPA, 2011a](#)).

- Spatial heterogeneity of factors in the AAI equation: The value of factors in the AAI equation vary across the U.S. Factors could be calculated for a spatial boundary based on an ecologically similar landscape (e.g., Omernick ecoregion).
- Temporal heterogeneity: There is a relatively high degree of interannual variability expected in the AAI because it is so strongly influenced by the amount and pattern of precipitation that occurs within a region from year to year; therefore, averaging calculated annual AAI values over 3 to 5 years would provide reasonable stability.
- Level: With regard to a level for the AAI, the 2011  $\text{NO}_X\text{SO}_X$  Policy Assessment ([U.S. EPA, 2011a](#)) concluded that consideration should be given to a level within the range of 20 to 75  $\mu\text{eq/L}$ , noting that a target Acid Neutralizing Capacity (ANC) value of 20  $\mu\text{eq/L}$  would be a reasonable lower end of this range, so as to protect against chronic acidification-related adverse impacts on fish populations which have been characterized as severe at ANC values below this level.

---

### IS.2.3 Changes: New Evidence and Causal Determinations

Since the 2008 ISA, several conceptual changes have occurred in our understanding of the atmospheric sciences and ecological effects of  $\text{NO}_X$ ,  $\text{SO}_X$  and PM. They include our understanding of the sources of N deposition and in the relationship between atmospheric concentration and deposition ([Section IS.3](#) and [Appendix 2](#)). Models of N deposition rely on accurate emissions data. Since the 2008 ISA, deposition of oxidized nitrogen has been decreasing but deposition of reduced nitrogen has been increasing. As a result, the uncertainty in total reactive N emissions ( $\text{NO}_X + \text{NH}_X$ ) has increased because emissions estimates that have the lowest levels of uncertainty are from stationary and mobile sources, which contribute more to  $\text{NO}_X$  than  $\text{NH}_X$  emissions, and higher levels of uncertainty are associated with agricultural emissions, which contribute more to  $\text{NH}_X$  than  $\text{NO}_X$  emissions.

A better understanding of the relationship between atmospheric concentration and deposition has resulted from advances in understanding bidirectional exchange of  $\text{NH}_3$  and  $\text{NO}_Y$  chemistry within canopies. These advances have led to the first efforts to provide a detailed characterization of N and S deposition on a national scale, by using both measured and modeled values to provide estimates of total sulfur and nitrogen deposition across the U.S.

New evidence since the 2008 ISA increases the weight of evidence for ecological effects, confirming concepts previously identified and improving quantification of dose (deposition)–response relationships, particularly for N deposition. The ecological effects are described by the causality determinations. There are 18 causality statements in this ISA ([Table IS-1](#)). Fourteen are causal relationships repeated from the 2008 ISA or modified from the 2008 ISA to include specific endpoints. One is a likely causal relationship repeated from the 2009 PM ISA. Three are new endpoint categories not evaluated in the 2008 ISA. [Table IS-3](#) shows that N and S deposition cause alteration of (1) biogeochemical components of soil and water chemistry and (2) multiple levels of biological organization ranging from physiological processes to shifts in biodiversity and ecological function ([Figure IS-4](#)).

The current NO<sub>2</sub> and SO<sub>2</sub> secondary NAAQS are set to protect against direct damage to vegetation by exposure to gas-phase oxides of nitrogen and oxides of sulfur. Research continues to support causal relationships between SO<sub>2</sub>, NO<sub>2</sub>, NO, peroxyacetyl nitrate (PAN), HNO<sub>3</sub>, and injury to vegetation ([Table IS-1](#)), but research that tests plant response to the lower exposure levels that represent current atmospheric NO<sub>Y</sub> and SO<sub>X</sub> concentrations is limited. Therefore, little evidence is available to help determine whether current monitored concentrations of gas-phase NO<sub>Y</sub> and SO<sub>X</sub> are high enough to injure vegetation.

It is clear that the criteria pollutants NO<sub>Y</sub>, SO<sub>X</sub>, and PM, in addition to the noncriteria pollutant NH<sub>3</sub>, contribute to total N and S deposition, which alters the biogeochemistry and the physiology of organisms, resulting in harmful declines in biodiversity. Decreases in biodiversity mean that some species become relatively less abundant and may be locally extirpated. The current period in Earth's history is the Anthropocene. In addition to a spike in soil radiocarbon from nuclear bomb testing ([Turney et al., 2018](#)), a defining attribute of the Anthropocene is global, human-driven mass extinctions of many species. The biodiversity loss reported in this assessment contributes to the Anthropocene loss of biodiversity ([Rockstrom et al., 2009](#)). In addition to the loss of unique living species, the decline in total biodiversity is harmful because biodiversity is an important determinant of the stability of ecosystems and the ability of ecosystems to provide services to humanity (see more on biodiversity in [Section IS.2.2.4](#)).

**Figure IS-4 Causal relationships between the criteria pollutants and ecological effects.**

Since the 2008 ISA, there is more evidence to support the direct effects of gaseous SO<sub>x</sub> and NO<sub>y</sub> on vegetation. This causality determination is uniquely modified by the observation that there is little or no evidence that such effects are continuing at current, lower levels of exposure now occurring in the U.S.

Since the 2008 ISA, the largest increase in ecological evidence is for terrestrial N driven eutrophication effects ([Section IS.5.1](#), [Section IS.5.2](#), [Appendix 4](#), and [Appendix 6](#)). This new research confirms the causal relationship between N deposition and ecological effects documented in the 2008 ISA. Further, this new research improves our understanding of the mechanistic links that inform causal determinations between N additions via atmospheric deposition, biogeochemistry, and biota in terrestrial ecosystems ([Table IS-1](#)). There is now stronger empirical evidence from across most regions of the U.S. to quantify the levels of N deposition (empirical CLs) that cause biodiversity declines of lichens and grasses/forbs. There is new evidence to quantify empirical CLs across much of the U.S. for nitrate leaching, tree survivorship, and mycorrhizal biodiversity. Many of the N deposition effects are due to historical and continuing N deposition.

New research confirms that N + S deposition causes terrestrial ecosystem acidification, as documented in the 2008 ISA ([Table IS-1](#)). New evidence to characterize terrestrial acidification (soil biogeochemistry changes and biological effects) across large regions of the U.S. is available; in particular, new modeling work has improved calculation of CLs for soil acidification ([Section IS.5.3](#); [Appendix 4](#) and [Appendix 5](#)). Many of the acidification effects are due to historical and continuing N and S deposition ([Section IS.11](#)).

New evidence for freshwater acidification CLs builds on several decades of research documenting freshwater acidification effects on aquatic biota in the U.S. and confirms the causal relationships determined in the 2008 ISA ([Table IS-1](#)). Many of the acidification effects are due to historical and continuing N and S deposition ([Section IS.11](#)).

The sources of N driven eutrophication of fresh waters, estuaries, and wetlands include atmospheric N deposition and N from agricultural and other wastewaters. New research has helped show how these respective sources contribute to total loading. In freshwater ecosystems where atmospheric deposition is the primary source of N, such as in high alpine watersheds, new CLs since the 2008 ISA support previous observations of increased algal productivity, species changes, and reductions in diversity. New evidence also supports clear links between aqueous S concentrations in aquatic systems and both mercury methylation and sulfide toxicity; however, quantitatively linking these outcomes to atmospheric deposition remains a challenge.

---

## IS.3 Emissions and Atmospheric Chemistry

The atmospheric chemistry from emission to deposition discussed in this ISA is for the criteria pollutants  $\text{NO}_Y$ ,  $\text{SO}_X$ , and PM. In addition to gas-phase indicators like  $\text{SO}_2$  and  $\text{NO}_2$  used to monitor criteria pollutant trends, deposition of total N, total S, and total N + S that accounts for a wider range of species is also a main focus.

A wide variety of N containing compounds (oxidized + reduced, and organic + inorganic) contribute to wet and dry N deposition ([Appendix 2.1](#)).  $\text{NH}_X$  ( $\text{NH}_X = \text{NH}_3 + \text{NH}_4^+$ ) includes both the PM component  $\text{NH}_4^+$  and gas-phase  $\text{NH}_3$ . The contribution of  $\text{NH}_3$  to total observed inorganic N deposition may range from 19% in northwestern U.S. locations to 63% in locations in the southwestern U.S. and is generally greater in the summer than in the winter. Therefore,  $\text{NH}_3$  is discussed in the ISA along with  $\text{NO}_Y$  and relevant PM components to better understand and compare their contributions to both wet and dry N deposition. In addition, PM impacts discussed in this document are also mainly focused on N and S containing species, which together usually make up a large fraction of  $\text{PM}_{2.5}$  mass in most areas of the U.S. and have greater and better understood ecological impacts than other PM components.

Gaseous, particulate, and dissolved forms of  $\text{NO}_Y$ ,  $\text{SO}_X$ , and  $\text{NH}_X$  all contribute to atmospheric wet and dry deposition. The major components of particulate matter in the U.S. are  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{NH}_4^+$ , particulate organic matter, elemental carbon, crustal material, and sea salt. While organic matter usually accounts for a large fraction of  $\text{PM}_{2.5}$ , only a small portion can be identified at a molecular level. As a result, there is little information on organic PM impacts, except for individual compounds that make minor contributions to mass. Assessment of ecological impacts of major PM species is largely limited to  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ , and  $\text{NH}_4^+$ . Of these,  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  are also components of total oxides of sulfur and nitrogen, respectively.  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ , and  $\text{NH}_4^+$  usually have a strong influence on acid deposition.  $\text{NO}_3^-$  and  $\text{NH}_4^+$ , and in some cases organic nitrogen (organic nitrates and reduced organic N), make a substantial contribution to N deposition.

Since the 2008 ISA, there have been several new developments including:

- Expansion of ambient monitoring networks to include  $\text{NH}_3$  and  $\text{NO}_Y$  at selected sites, and comparisons of monitoring methods with research grade instruments ([Appendix 2.4](#));
- Adoption of new methods, such as data-model fusion, to integrate deposition information across the U.S. ([Appendix 2.5](#));
- Incorporation of bidirectional exchange into models of dry deposition ([Appendix 2.5.2](#)); and

- Improvements in techniques using satellite-based measurements and chemical transport model simulations to estimate emissions, concentrations, and dry deposition of NO<sub>2</sub>, SO<sub>2</sub>, and NH<sub>3</sub> ([Appendix 2.6](#)).

---

### IS.3.1 Sources and Atmospheric Transformations

Both gaseous and particulate forms of N and S contribute to atmospheric deposition. The main contributors to acidifying precipitation are H<sub>2</sub>SO<sub>4</sub>, HNO<sub>3</sub>, and NH<sub>4</sub><sup>+</sup>, which are formed from precursor emissions of SO<sub>2</sub>, NO<sub>x</sub> (NO + NO<sub>2</sub>), and NH<sub>3</sub> ([Appendix 2.2](#)). Gaseous emissions of NH<sub>3</sub> are dominated by agricultural fertilizer application and animal waste from intensive animal feeding operations, with important local contributions from motor vehicles and episodic contributions from wildland and agricultural fires. Roughly half of SO<sub>2</sub> emissions are from by electricity-generating units (EGUs), mainly coal-fired power plants. Notably, SO<sub>2</sub> emissions from EGUs have been decreasing. NO<sub>x</sub> emissions have a wider distribution of sources, with substantial contributions from highway and off-highway vehicles, lightning, and EGUs. Primary PM<sub>2.5</sub> and PM<sub>10</sub> emissions are dominated by dust and fires, but much of the PM<sub>2.5</sub> mass in the U.S. is produced by reactions that form secondary PM<sub>2.5</sub> from gas phase precursor N and S species. Because of these processes, a sharp decrease in SO<sub>2</sub> emissions and smaller, but substantial decreases in NO<sub>x</sub> emissions have occurred since the passage of the Clean Air Act Amendments in 1990. Emissions of NO<sub>x</sub> in the U.S. declined 61% between 1990 and 2017 ([U.S. EPA, 2020a](#)), while nationwide annual average 98th percentile NO<sub>2</sub> concentrations decreased by 53% from 1990 to 2017 ([U.S. EPA, 2016f](#)). Total emissions of SO<sub>2</sub> decreased by 89% from 1990 to 2017 ([U.S. EPA, 2020a](#)), resulting in a decrease in SO<sub>2</sub> concentrations of 89% in the eastern U.S. and 45% in the western U.S. ([Appendix 2.6.5](#)). National annual NH<sub>3</sub> emissions have fluctuated as a result of changes in both emissions and methods of estimating emissions. However, no clear trend is evident for national NH<sub>3</sub> emissions, with estimates for 1990 and 2017 differing by less than 1% ([U.S. EPA, 2020a](#)). National NH<sub>3</sub> monitoring is too recent for evaluating long-term concentration trends, although more limited studies of NH<sub>3</sub> emissions, concentrations and deposition each suggest slight increases may have occurred ([Appendix 2.6.4](#)).

Major components of particulate N and S include NH<sub>4</sub><sup>+</sup>, NO<sub>3</sub><sup>-</sup>, and SO<sub>4</sub><sup>2-</sup>, which are primarily derived from gaseous precursors NH<sub>3</sub>, NO<sub>x</sub>, and SO<sub>2</sub> ([Appendix 2.3](#)). Together, NO<sub>3</sub><sup>-</sup>, SO<sub>4</sub><sup>2-</sup>, and NH<sub>4</sub><sup>+</sup> make up a large fraction of PM<sub>2.5</sub> mass in most areas of the U.S. Formation of particulate N and S is described in the 2019 *ISA for Particulate Matter* ([U.S. EPA, 2019](#)). An understanding of the sources, chemistry, and atmospheric processes for these gas-phase and PM species provides a background for understanding acidifying and N deposition.

---

### IS.3.2 Measurement and Modeling Techniques

Monitoring networks across the U.S. measure  $\text{NO}_Y$ ,  $\text{SO}_X$ , and  $\text{NH}_X$  species involved in deposition ([Appendix 2.4.1](#)). The National Atmospheric Deposition Program/National Trends Network (NADP/NTN) has monitored precipitation chemistry for several decades at many U.S. sites. The Clean Air Status and Trends Network (CASTNET) has monitored concentrations of inorganic gas and particulate-phase N and S species since 1990. Monitoring of  $\text{NH}_3$  ([Appendix 2.5.3](#)) in the Ammonia Monitoring Network (AMoN), part of the NADP network, was initiated at a subset of CASTNET sites in 2007.  $\text{NH}_3$  was also measured as a part of the Southern Aerosol Characterization (SEARCH) network from 2004 until its termination in 2016. The Interagency Monitoring of Protected Visual Environments (IMPROVE) network and the Chemical Speciation Network (CSN) measure PM and PM components, including  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$ , although these data are not routinely used to estimate deposition rates ([Appendix 2.4.1](#)).

Atmospheric N deposition rates are calculated from measurements and models. Direct measurement of  $\text{NO}_2$  concentration has limited utility for quantifying  $\text{NO}_Y$  deposition rates in areas with less urban influence. Because  $\text{NO}_Y$  is composed of diverse chemical species with a wide range of deposition velocities and physical properties, concentrations of unmeasured component species of  $\text{NO}_Y$  in general and of all  $\text{NO}_Y$  species in data-sparse regions must be provided by regional models. For  $\text{NO}_2$  and  $\text{NH}_3$  this can be done in conjunction with satellite-based remote sensing data ([Appendix 2.4.2](#)).

Estimates of dry deposition ([Appendix 2.5.2](#)) over the contiguous U.S. are inferred by atmospheric models, used with monitoring network data. When combined with accurate estimates of historical trends in emissions and meteorology, these models are able to capture the historical long-term changes in  $\text{PM}_{2.5}$ ,  $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ , and  $\text{NH}_4^+$ , but are subject to uncertainties in their treatment of turbulence, surface interactions, and in particular, seasonal variability in  $\text{NO}_3^-$  deposition, mainly because of uncertainties in  $\text{NH}_3$  emissions. Consequently, dry deposition rates (and ratios of wet-to-dry deposition) continue to be uncertain.

---

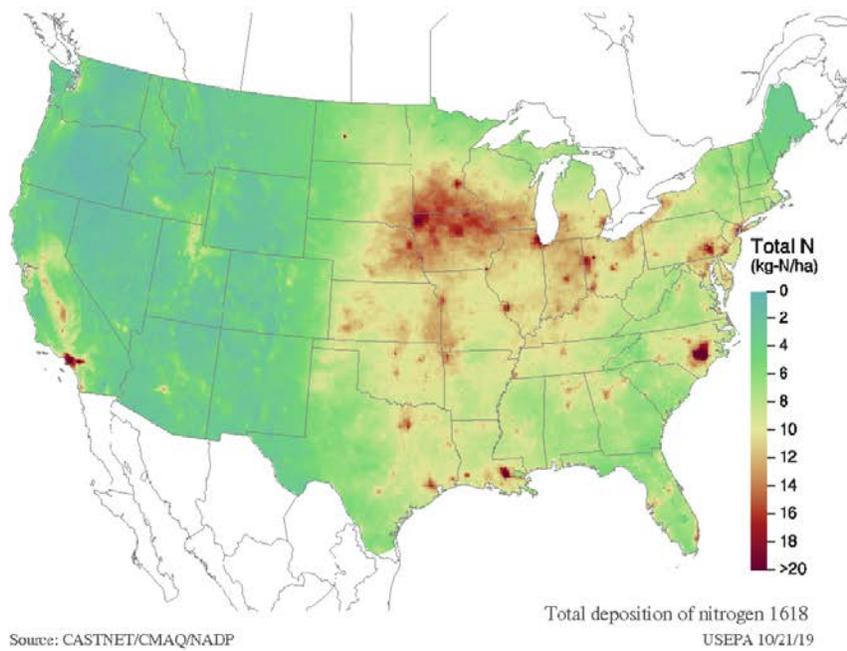

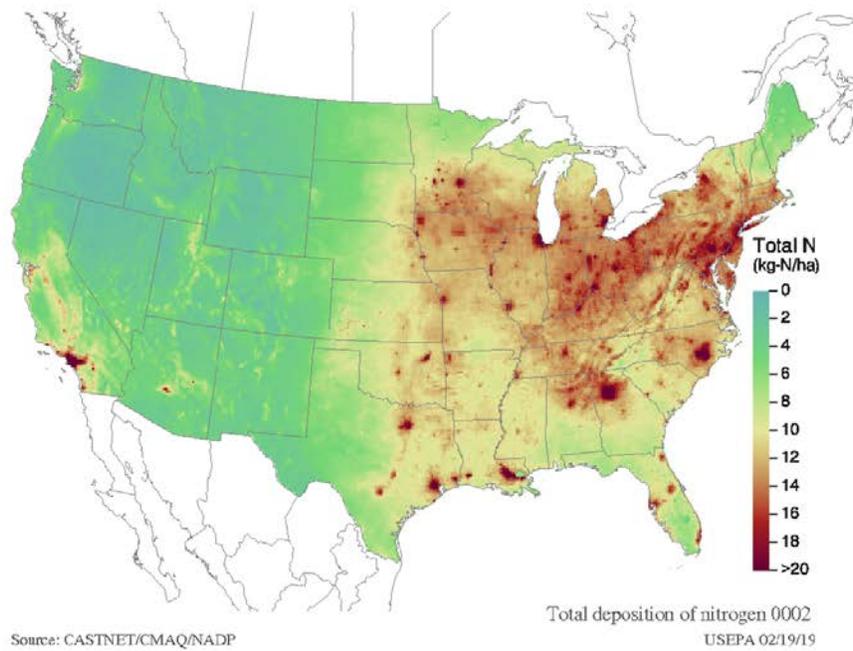

### IS.3.3 Spatial and Temporal Variability in Deposition

Overall deposition of total N (oxidized + reduced N) has decreased slightly over the past since 2000 ([Appendix 2.6.2](#)). This is because although  $\text{NO}_Y$  deposition has declined considerably in the contiguous U.S., deposition of  $\text{NH}_X$  has increased. The large spatial variability in N deposition and changes in geographic distribution of 3-year average N deposition between 2000–2002 and 2016–2018 are evident in the maps ([Figure IS-5](#)) of

3-year average annual dry + wet deposition of  $\text{NO}_Y$  and  $\text{NH}_X$  over the contiguous U.S. estimated using the TDEP (Total Deposition) modeling approach ([Appendix 2.6](#)), which combines output from the Community Multiscale Air Quality (CMAQ) system with wet deposition from the NADP/NTN ([Schwede and Lear, 2014b](#)) and air concentrations from CASTNET.

According to TDEP estimates for 2016–2018 ([Appendix 2.6](#)), much of the eastern contiguous U.S. is estimated to receive at least 10 kg N/ha/yr dry + wet deposition, with some areas receiving more than 15 kg N/ha/yr. Estimates for the spatial extent of the areas receiving at least 10 kg N/ha/yr of deposition and the overall amount of N deposited could be low because reduced organic N species are not routinely monitored.

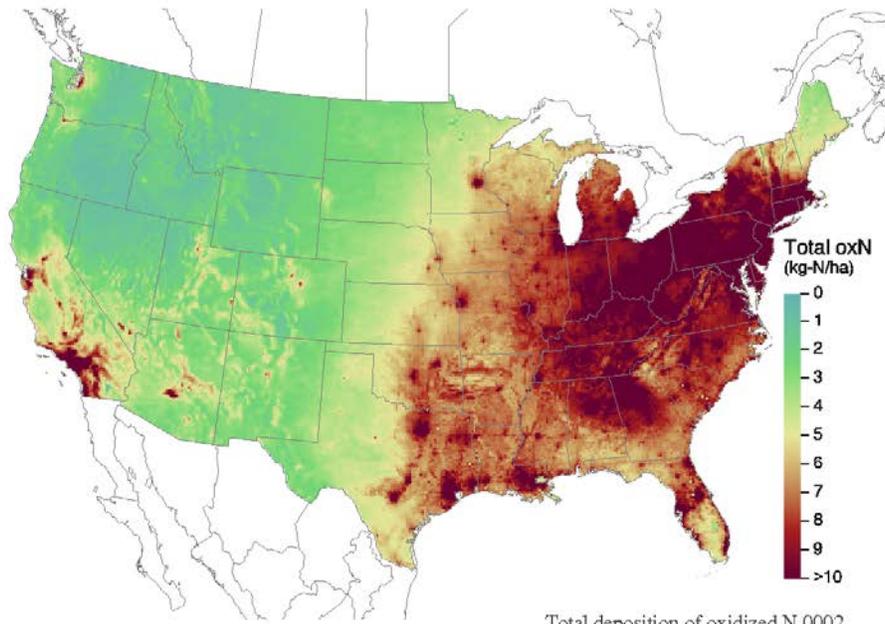

In general, wet deposition of reduced N exceeds that of oxidized N across the contiguous U.S. According to estimates based on CASTNET and NADP data and CMAQ modeling results ([Figure 2-16](#)), deposition of N nationwide occurs mainly by dry deposition of  $\text{HNO}_3$  and  $\text{NH}_3$  (with  $\text{NH}_3$  dominant) and wet deposition of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  (with  $\text{NH}_4^+$  dominant). Hybrid satellite/modeling and CMAQ results indicate that dry deposition of  $\text{NO}_2$  is also a nontrivial source of deposited N in many areas ([Appendix 2.6.6](#)). Over the past 30 years, NADP/NTN data show that wet deposition of inorganic N (oxidized + reduced) decreased in areas such as the Northeast but remained constant or increased in areas such as the central U.S. (see [Figure 2-18](#) in [Appendix 2.6](#)). Wet deposition of total inorganic N has remained fairly constant over the past 30 years, despite declines in  $\text{NO}_X$  emissions, indicating that most of the increases in N wet deposition seen today is of reduced inorganic N. Data for total (wet + dry) deposition are available for a shorter time series than wet deposition, but show a similar increase in the share of reduced N relative to oxidized N. [Figure IS-6](#) shows reductions in TDEP 3-year average oxidized N deposition over the contiguous U.S. between 2000–2002 and 2016–2018, while [Figure IS-8](#) shows the decrease in reduced N deposition compared between the same periods.

**Figure IS-7 Wet plus dry deposition of reduced (inorganic) nitrogen over 3-year periods. Top: 2000–2002; Bottom: 2016–2018.**

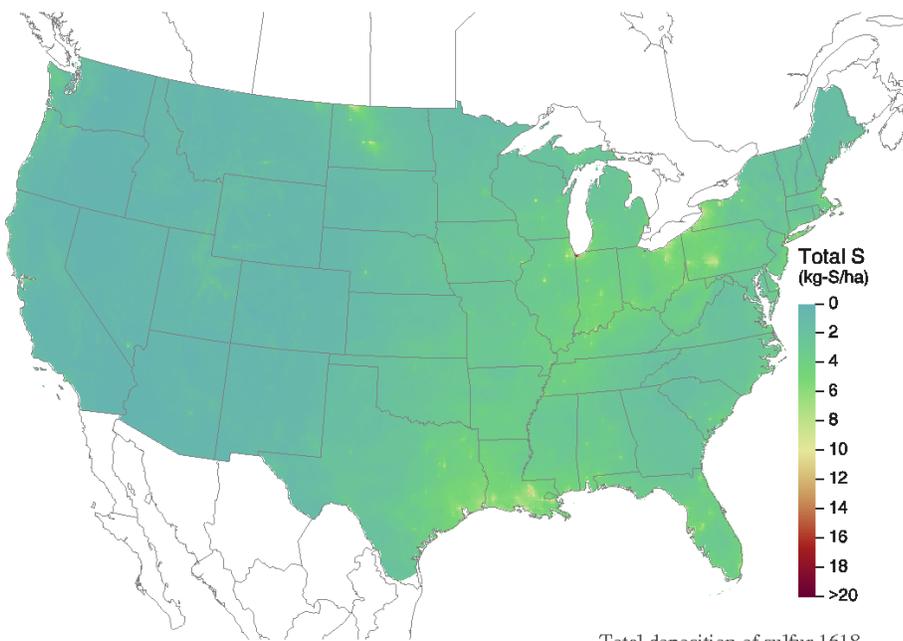

For S deposition, wet deposition tends to dominate over dry deposition in large areas of the contiguous U.S. However, in some regions mainly in the West, dry deposition of mainly SO<sub>2</sub> makes a greater contribution than wet deposition. Anthropogenic emissions of S and subsequent deposition have declined markedly since the 1990s, with the most pronounced declines in the eastern U.S. Currently, some of the highest values of total (wet + dry) SO<sub>x</sub> deposition in the U.S. are in parts of the Ohio Valley region ([Figure 2-41](#)). However, [Figure IS-8](#) shows that TDEP 3-year average total S deposition has decreased substantially between 2000–2002 and 2016–2018, especially in this region.

Both N and S deposition contribute to acidification of ecosystems. The pH of rainwater has increased markedly across the U.S. since 1990, coincident with decreases in the wet deposition of nitrate and SO<sub>4</sub><sup>2-</sup>. However, there are still widespread areas affected by acidifying precipitation, mainly in the eastern U.S. (see [Appendix 2.6](#)). Total acidifying deposition (wet + dry N + S, expressed as H<sup>+</sup> equivalents) fluxes for 2016 to 2018 ranged from a few tenths of H<sup>+</sup> keq/ha/yr over much of the western U.S. to over 1.5 H<sup>+</sup> keq/ha/yr in parts of the Midwest and the Mid-Atlantic regions, and in other isolated hotspots surrounding areas of concentrated industrial or agricultural activity ([Figure IS-9](#)).

**Figure IS-9 Total acidifying deposition of total oxidized nitrogen, reduced nitrogen, and oxidized sulfur expressed as H<sup>+</sup> equivalents per hectare per year over the contiguous U.S. 2016–2018.**

Dry deposition rates are a strong function of surface characteristics, which modify the structure of surface layer turbulence and the resistance to uptake by vegetation ([Appendix 2.5.2](#)). As a result, spatially aggregated estimates of dry deposition fluxes are subject to uncertainty, in addition to uncertainties that are inherent in the measurement of species concentrations and in the inference of dry fluxes (see [Section IS.13](#)). Wet fluxes are not directly influenced by surface characteristics (although orography affects transport and precipitation) but are subject to smaller uncertainties in the measurement of rainfall and chemistry.

## IS.4 Gas-Phase Direct Phytotoxic Effects

New evidence supports the causal determinations made in the 2008 ISA regarding gas-phase effects on vegetation, and there are no new causal statements for gas-phase

effects. As in the 2008 ISA, the current ISA concludes that there are causal relationships between SO<sub>2</sub>, NO<sub>2</sub>, NO, PAN, HNO<sub>3</sub>, and injury to vegetation. This determination is based on consistent, coherent, and biologically plausible evidence ([Appendix 3.2](#), [Appendix 3.3](#), and [Appendix 3.4; Table IS-1](#)). The clearest evidence for these conclusions comes from studies available at the time of the 2008 ISA, but there have been some additional studies since then. Most evidence on the direct effects of gaseous NO<sub>y</sub> and SO<sub>x</sub> comes from controlled exposure studies across many species of vegetation. Most controlled exposure studies over the past several decades have used concentrations of gas-phase NO<sub>y</sub> and SO<sub>x</sub> above current ambient conditions observed in the U.S. Relevant information is lacking on exposures and effects reflecting the more recent lower pollutant conditions. Therefore, there is little evidence available to inform whether current monitored concentrations of gas-phase NO<sub>y</sub> and SO<sub>x</sub> are high enough to injure vegetation.

NH<sub>3</sub> can also have direct phytotoxic effects if the uptake exceeds the ability of a plant to detoxify and assimilate it. However, reduced N gases such as NH<sub>3</sub> are not criteria air pollutants or oxides of N and, therefore, are not the focus of this review of the gas-phase effects. Direct damage from NH<sub>3</sub> to foliage can occur on higher plants and effect bryophytes and lichens. Declines in shrubs and lichens and changes in peat bogs have been reported with NH<sub>3</sub> exposure. Besides being potentially phytotoxic to vegetation, NH<sub>3</sub> exposure can lead to more N inputs into plants and ecosystems through foliage uptake. Ammonia deposition that leads to N enrichment is an important consideration when evaluating total N deposition. These N nutrient effects to vegetation are discussed in [Appendix 6](#).

---

#### IS.4.1 Sulfur Dioxide

In the 2008 ISA, evidence was sufficient to infer a causal relationship between exposure to SO<sub>2</sub> and injury to vegetation. The current secondary standard for SO<sub>2</sub> is a 3-hour average of 0.50 ppm, which is designed to protect against acute foliar injury in vegetation. There has been limited research on acute foliar injury since the 1982 PM-SO<sub>x</sub> Air Quality Criteria Document (AQCD), and there is no clear evidence of acute foliar injury below the level of the current standard. The limited new research since 2008 adds more evidence that SO<sub>2</sub> can have acute negative effects on vegetation but does not change conclusions from the 2008 ISA regarding the causal relationship between SO<sub>2</sub> exposure and vegetation damage or the SO<sub>2</sub> levels producing these effects (see [Appendix 3.1](#)). Consistent with the 2008 ISA, **the body of evidence is sufficient to infer a causal relationship between gas-phase SO<sub>2</sub> and injury to vegetation.**

Increased SO<sub>2</sub> exposure concentrations and longer exposure times are associated with decreases in plant growth and yield. The 1982 PM-SO<sub>x</sub> AQCD concluded that more definitive concentration-response studies were needed before useable exposure metrics could be identified. However, very few studies of the effects of SO<sub>2</sub> on the growth of vegetation in the U.S. have been conducted since 1982. Recent studies from eastern Europe indicate recovery of tree growth in response to decreases in SO<sub>2</sub> concentrations since the 1980s and that annual SO<sub>2</sub> concentrations of 4 ppb decreased silver fir (*Abies alba*) growth. In West Virginia, the growth of eastern red cedar (*Juniperus virginiana*) trees increased with declines in SO<sub>2</sub> emissions since the 1980s.

---

#### IS.4.2 Nitrogen Oxide, Nitrogen Dioxide, and Peroxyacetyl Nitrate

In the 2008 ISA, evidence was sufficient to infer a causal relationship between exposure to NO, NO<sub>2</sub>, and PAN and injury to vegetation. It is well known that in sufficient concentrations, NO, NO<sub>2</sub>, and PAN can have phytotoxic effects on plants by decreasing photosynthesis and inducing visible foliar injury. However, the 1993 Oxides of Nitrogen AQCD concluded that concentrations of NO, NO<sub>2</sub>, and PAN in the atmosphere are rarely high enough to have phytotoxic effects on vegetation ([U.S. EPA, 1993](#)), and very little new research has been performed at concentrations currently observed in the U.S. (see [Appendix 3.3](#)). It is also known that these gases alter the N cycle in some ecosystems, and nutrient effects of N are discussed in [Section IS.5](#). Thus, consistent with the previous 2008 ISA, **the body of evidence is sufficient to infer a causal relationship between gas-phase NO, NO<sub>2</sub>, and PAN and injury to vegetation.**

---

#### IS.4.3 Nitric Acid

In the 2008 ISA, evidence was sufficient to infer a causal relationship between exposure to HNO<sub>3</sub> and changes to vegetation. The 2008 ISA reported experimental exposure to HNO<sub>3</sub> resulted in damage to the leaf cuticle of pine and oak seedlings, which may predispose those plants to other stressors such as drought, pathogens, and other air pollutants. Since the 2008 ISA, [Padgett et al. \(2009b\)](#) investigated dry deposition of HNO<sub>3</sub> on the foliage in a fumigation study and confirmed the earlier research. Nitric acid can also add to N nutrient enrichment of ecosystems and is discussed in [Section IS.5](#). The 2008 ISA also reported several lines of evidence that past and current HNO<sub>3</sub> concentrations may be contributing to the decline in lichen species in the Los Angeles basin. Subsequent studies conducted in the Los Angeles basin since the 2008 ISA provide further evidence of the impacts (see [Appendix 3.4](#)). These new studies continue to

support the causal findings of the 2008 ISA, such that **the body of evidence is sufficient to infer a causal relationship between gas-phase HNO<sub>3</sub> and changes to vegetation.**

---

## IS.5 Terrestrial Ecosystem Nitrogen Enrichment and Acidification

For terrestrial ecosystems, new evidence reinforces causal findings from the 2008 ISA and provides the basis for two new causal statements that reflect a more comprehensive understanding of how N and acidifying deposition alter terrestrial ecosystem biota ([Table IS-1](#)). In general, N deposition may cause soil N enrichment and stimulate the growth of opportunistic species. However, in sensitive soils, deposition of N and/or S can cause soil acidification, which may decrease growth and cause mortality among sensitive plant species. Atmospheric deposition of N and S alter the species composition of terrestrial systems by one of four mechanisms: (1) nutrient enrichment (eutrophication; [Appendix 4](#) and [Appendix 6](#)), (2) acidification ([Appendix 4](#) and [Appendix 5](#)), (3) direct damage ([Appendix 3](#)), and (4) secondary effects (e.g., wildfire; [Appendix 6](#)). Ecosystems and communities may be simultaneously affected by one or more mechanisms depending on the sensitivity of environmental and biological properties to each mechanism.

Despite the abundance of N in the environment, plants are unable to directly access the large pools of N contained in the atmosphere as N<sub>2</sub> gas and in the soil as large organic molecules. Consequently, the limited availability of reactive N often constrains biological activity in terrestrial ecosystems. N deposition is therefore considered nutrient enrichment because N additions generally stimulate plant growth and productivity (cumulative growth of all vegetation within a community), which has been recognized since the second half of the 19th century. In comparison, the biological effects of acidifying deposition are less common and largely constrained to ecosystems with historically high rates of deposition and that are vulnerable because of factors such as geology and climate. While S is also an essential macronutrient, less S is required for growth than N, and areas affected by acidifying deposition typically receive S at rates that greatly exceed biotic demand. Instead, the impact of acidifying deposition stems from the disruptions to biochemical processes caused by decreased pH and shifts in soil physiochemical processes that decrease the supply of other essential nutrients (e.g., Ca, Mg) and from increased mobilization of toxic forms of Al.

Current knowledge of soil biogeochemistry indicates soil N enrichment and soil acidification occur in sensitive ecosystems across the U.S. at present levels of deposition. Newly published work indicates decreasing SO<sub>2</sub> emissions and S deposition have led to early signs of recovery from acidification in some northeastern watersheds, but areas in the Southeast do not show recovery ([Appendix 4](#)). There are many well-defined soil

indicators related to the biological effects of acidifying (N + S) deposition. New evidence uses these indicators to describe the status of ecosystems, either by empirical observation or models. Soil indicators for acidification are more typically modeled than those for eutrophication effects. There is an abundance of new information on biogeochemical pools and processes, including a new conceptual framework for the N saturation of terrestrial ecosystems.

The enrichment of terrestrial ecosystems by N deposition often increases plant productivity and causes changes in physiology and growth rates that vary among species. This has been observed for herbaceous plants and trees across ecoregions. The changing growth rates transform competitive interactions between species, and consequently, lower species diversity is often observed with increasing N deposition within terrestrial communities. The level of N deposition negatively affecting community composition is often expressed as a Critical Load (CL). There are many new CLs available since the 2008 ISA, including those for lichens, herbaceous plants, and mycorrhizae.

The process of terrestrial acidification has been well understood and documented for decades. Recent research, since the 2008 ISA, has confirmed and strengthened this understanding and provided more quantitative information, especially across regional-scale landscapes. Several studies have evaluated the relationships between soil chemical indicators of acidification and ecosystem biological endpoints (see [Table 5-6](#)), and some biogeochemical models are well established. There have been new advances in the parameterization of acidification models to U.S. soils since the 2008 ISA ([Appendix 4.5](#)) resulting in better certainty of CLs. Biological endpoints included in the evaluations include physiological and community responses of trees and other vegetation (such as lichens), soil biota, and fauna.

The following section summarizes the main effects of N and S deposition on terrestrial ecosystems.

---

### **IS.5.1 Soil Biogeochemistry**

In the 2008 ISA, evidence was sufficient to infer causal relationships between (1) acidifying deposition and changes in terrestrial biogeochemistry and (2) between N deposition and terrestrial biogeochemical cycling of N. There is new evidence of how deposition contributes to total loading in ecosystems, as well as new information from addition, gradient, and time-series studies characterizing how deposition affects soil pools and processes. Much of the new work focuses on the effects of N deposition, with relatively little work focusing on S deposition. Soil N enrichment and soil acidification occur in sensitive ecosystems across the U.S. at present levels of deposition. Decreasing

S emissions have led to early signs of recovery from acidification in some northeastern watersheds, but areas in the Southeast do not show recovery (for additional discussion on recovery see [Section IS.11](#)). Deposition rates of total N ( $\text{NO}_Y + \text{NH}_X$ ) are relatively unchanged across much of the contiguous US ([Appendix 2.7](#)). Accordingly, there are no signs of recovery from N enrichment effects. CL determinations have been made at the ecoregion scale for  $\text{NO}_3^-$  leaching. CLs for biological effects are summarized below ([Section IS.5.1.2](#), [Section IS.5.2.2](#), and [Section IS.5.3.3](#)). **The body of evidence is sufficient to infer a causal relationship between N and S deposition and alteration of soil biogeochemistry in terrestrial ecosystems**, which is consistent with the conclusions of the 2008 ISA.

---

### IS.5.1.1 Soil Processes and Indicators

Deposition of N or N + S alters soil chemistry, which can have cascading effects on aquatic ecosystems (for effects on aquatic biology and chemistry see [Appendix 7–Appendix 10](#)). Soil acidification is a natural process that can be accelerated by N or S deposition. Deposition in the forms of  $\text{HNO}_3$  and  $\text{H}_2\text{SO}_4$  can directly acidify soils; however, deposition of reduced forms of N (e.g.,  $\text{NH}_X$ ) can also cause soil acidification by releasing hydrogen ions ( $\text{H}^+$ ) during the microbial oxidation of  $\text{NH}_4^+$  to  $\text{NO}_3^-$ . There are a number of soil biogeochemical processes associated with acidification ([Table IS-2](#)). Base cations can counterbalance acid anions. Base cations are added to the soil by weathering and atmospheric deposition and are removed by leaching and biological uptake. Where acidifying deposition rates are high relative to base cation input, deposition can deplete exchangeable base cation pools in soils. There are several useful indicators of soil acidification ([Table IS-2](#)) that have quantitative relationships to biological responses ([Appendix 5](#)).

---

**Table IS-2 Summary of key soil geochemical processes and indicators associated with eutrophication and acidification.**

Endpoint	N Driven Nutrient Enrichment	Acidification	The Effect of Deposition
<b>Process</b>			
N saturation	X	X	New empirical evidence suggests revising the N saturation concept; specifically, it is now observed that $\text{NO}_3^-$ leaching can occur even if the ecosystem N capacity to retain N has not yet been saturated.

---

**Table IS-2 (Continued): Summary of key soil geochemical processes and indicators associated with eutrophication and acidification.**

Endpoint	N Driven Nutrient Enrichment	Acidification	The Effect of Deposition
Soil N accumulation	X	X	New meta-analyses across ecosystem types confirm inorganic soil NO <sub>3</sub> <sup>-</sup> concentration increases with N addition. A new gradient study confirms that N concentration increases with N deposition. A new addition study confirms increased soil N accumulation. New studies on Soil N accumulation are summarized in <a href="#">Table 4-3</a> .
NO <sub>3</sub> <sup>-</sup> leaching	X	X	New meta-analyses confirm leaching increases with N additions. Regional-scale gradient analyses: <8 kg N/ha/yr onset of leaching; <1 kg N/ha/yr in European forests; in the NE U.S., 90% retention for sites receiving 7 kg N/ha/yr to 60% retention for sites receiving 11 kg N/ha/yr. New USFS CLs for the onset of leaching: 8–10 kg N/ha/yr in eastern and western U.S., 17 kg N/ha/yr in the Sierra Nevada and San Bernardino Mountains. New studies on Soil N accumulation are summarized in <a href="#">Table 4-3</a> .
S accumulation and adsorption		X	Some soils (notably in many watersheds in the SE U.S.) have the capacity to adsorb substantial quantities of S, with essentially no acidification of drainage water. Nevertheless, S adsorption capacity is finite, and under continual high S deposition loading, the adsorptive capacity of soil will eventually be exceeded. New studies of 27 watersheds in the SE indicate most will begin releasing SO <sub>4</sub> <sup>2-</sup> in the next two decades; NE watersheds show a net loss of S from soils now in response to decreased levels of atmospheric S deposition. New studies on soil S accumulation are summarized in <a href="#">Table 4-4</a> .
SO <sub>4</sub> <sup>2-</sup> leaching		X	Atmospheric S deposition generally increases leaching of SO <sub>4</sub> <sup>2-</sup> to surface waters. The amount of deposition that causes the onset of leaching varies across the landscape. New studies on soil SO <sub>4</sub> <sup>2-</sup> leaching are summarized in <a href="#">Table 4-4</a> .
Base cation leaching and exchange		X	Base cation (Ca, Mg, K, Na) release from soil particles to the soil solution occurs in response to the input of acid anions (SO <sub>4</sub> <sup>2-</sup> and NO <sub>3</sub> <sup>-</sup> ) from deposition. New studies confirm base cation depletion continues to occur in the Rocky Mountains (threshold 28 kg N/ha/yr) and in U.K. grasslands, while in a NE forest, 17 yr of N addition did not cause further depletion. A meta-analysis suggests cation depletion soon after increased deposition of acid anions, but this depletion tapers off with time. New studies on base cation leaching and exchange are summarized in <a href="#">Table 4-5</a> .

**Table IS-2 (Continued): Summary of key soil geochemical processes and indicators associated with eutrophication and acidification.**

Endpoint	N Driven Nutrient Enrichment	Acidification	The Effect of Deposition
Al mobilization		X	The threshold for inorganic Al mobilization from soil is <15–20% soil base saturation. This is an extremely important effect of acidifying deposition because inorganic monomeric Al is toxic to biota ( <a href="#">Appendix 5</a> and <a href="#">Appendix 8</a> ). Inorganic Al is minimally soluble at pH 6.0, but solubility increases steeply at pH below 5.5. New studies on Al in soils are summarized in <a href="#">Table 4-6</a> .
Nitrification	X	X	Nitrification releases 2 mol hydrogen ion (H <sup>+</sup> ) per mol NH <sub>4</sub> <sup>+</sup> converted to NO <sub>3</sub> <sup>-</sup> , acidifying soils. As soil inorganic N accumulates, net nitrification rates often increase, and NO <sub>3</sub> <sup>-</sup> can leach from the ecosystem. New N gradient and meta-analysis studies confirm N addition increases nitrification. New studies on nitrification are summarized in <a href="#">Table 4-6</a> .
Denitrification	X		Denitrification is the microbial reduction of NO <sub>3</sub> <sup>-</sup> to NO <sub>2</sub> <sup>-</sup> , NO, the greenhouse gas N <sub>2</sub> O, and N <sub>2</sub> , which occurs under anaerobic conditions. In Europe, soil switched from a source to a sink after two decades of N deposition exclusion. New meta-analysis confirms N addition increases denitrification rates. New studies on denitrification are summarized in <a href="#">Table 4-6</a> .
DOC leaching	X	X	In recent years, the DOC of many lakes and streams has risen, with the source likely from the soils in the adjacent terrestrial watershed. However, the mechanism causing the observed increase is unclear and may be due to a combination of soil recovery from acidification, changes in climate (e.g., temperature and precipitation), and N deposition among other mechanisms. New studies are summarized in <a href="#">Table 4-10</a> .
Decomposition	X	X	The addition of N can stimulate the breakdown of labile compounds that degrade during the initial stages of decomposition, but added N can suppress the decomposition of more recalcitrant material. There are new addition studies and meta-analyses on mechanisms and response trends. New studies are summarized in <a href="#">Table 4-8</a> .
<b>Indicator</b>			
Soil [N]	X	X	Increases in soil [N] indicate soil N accumulation and the size of the soil N pool that may be assimilated by organisms or mobilized via leaching.
Soil C:N ratio	X	X	Decreasing soil C:N linked to changes in decomposition and increases in nitrification and NO <sub>3</sub> <sup>-</sup> leaching. <20–25 causes increased nitrification and elevated risk of NO <sub>3</sub> <sup>-</sup> leaching in the U.S. and <25–30 for increased NO <sub>3</sub> <sup>-</sup> leaching in Europe.

**Table IS-2 (Continued): Summary of key soil geochemical processes and indicators associated with eutrophication and acidification.**

Endpoint	N Driven Nutrient Enrichment	Acidification	The Effect of Deposition
Soil base saturation		X	Increasing N + S deposition decreases the soil pool of exchangeable base cations. <15–20% exchange ion chemistry is dominated by inorganic Al and may cause injury to vegetation (see <a href="#">Appendix 5</a> ).
Soil Bc:Al ratio		X	Increasing N + S deposition decreases the soil pool of exchangeable base cations, often decreasing the Ca:Al ratio. Ca:Al <1.0 causes physiological stress, decreased growth, and mortality of sensitive plant species (see <a href="#">Appendix 5</a> ).
Fungi-to-bacteria ratio	X		New indicator: increasing N deposition decreases the fungi-to-bacteria ratio and causes a transition from N to C limitation among soil food webs.

Al = aluminum; Al<sup>3+</sup> = aluminum(III); Bc = base cations; C = carbon; Ca = calcium; DOC = dissolved organic carbon; H<sup>+</sup> = hydrogen ion; ha = hectare; K = potassium; kg = kilogram; Mg = magnesium; N = nitrogen; N<sub>2</sub> = molecular (atmospheric) nitrogen; N<sub>2</sub>O = nitrous oxide; Na = sodium; NE = northeastern; NH<sub>4</sub><sup>+</sup> = ammonium; NO = nitric oxide; NO<sub>2</sub><sup>-</sup> = nitrite; NO<sub>3</sub><sup>-</sup> = nitrate; S = sulfur; SE = southeastern; SO<sub>4</sub><sup>2-</sup> = sulfate; U.K. = United Kingdom; U.S. = United States; USFS = U.S. Forest Service; yr = year.

Some of the same processes and indicators associated with acidification are also associated with the N enrichment of soils in response to the input of exogenous N ([Appendix 4.3](#)). The 2008 ISA documented that the increase in global reactive N (defined as  $\text{NO}_Y + \text{NH}_X + \text{organic N}$ ) that occurred over the previous century was largely due to three main causes: (1) widespread cultivation of crops that promote conversion of  $\text{N}_2$  gas to organic N through biological N fixation, (2) fossil fuel combustion converting atmospheric  $\text{N}_2$  and fossil N to  $\text{NO}_X$ , and (3) the Haber-Bosch process, which converts nonreactive  $\text{N}_2$  to reactive N to sustain food production and some industrial activities ([Galloway et al., 2003](#); [Galloway and Cowling, 2002](#)).

The 2008 ISA documented that atmospheric deposition of N can increase soil N, the accumulation of which is linked to increased N leaching and decreased retention of N. CLs for the onset of elevated  $\text{NO}_3^-$  leaching are given in [Appendix 4.6.2.2](#).

The 2008 ISA described the conceptual model of N saturation, which occurs when N input rates to terrestrial ecosystems exceed the uptake capacity of the soils and biota and is indicated by the onset of increased soil N leaching. However, more recent work has revised the N saturation model in response to observations in which N leaching resulted from N input rates that are faster than vegetation and soil uptake rates, thus distinguishing capacity N saturation from kinetic N saturation. Budgets from 83 forested watersheds in the northeastern U.S. show that N retention averages 76% of the incoming atmospheric N deposition and decreases from 90% retention at 7 kg N/ha/yr of deposition to 60% retention at 11 kg N/ha/yr of deposition.

The 2008 ISA documented that N enrichment is associated with changes in microbially mediated biogeochemical processes, including nitrification, denitrification, and decomposition ([Appendix 4.3](#)). The addition of N can increase nitrification (the microbial conversion of  $\text{NH}_4^+$  to  $\text{NO}_3^-$ ), which contributes to soil acidification. N deposition to soils can decrease surface soil C:N ratio, which can stimulate nitrification when C:N ratios fall below 20 to 25. The  $\text{NO}_3^-$  created by nitrification may be leached, biologically immobilized, or denitrified. Denitrification is the microbial reduction of  $\text{NO}_3^-$  to  $\text{NO}_2^-$ , NO, the greenhouse gas  $\text{N}_2\text{O}$ , and  $\text{N}_2$ , which occurs under anaerobic conditions. Several syntheses have been published since 2008 evaluating N addition effects on denitrification and nitrification in terrestrial ecosystems. A new meta-analysis shows N addition substantially increases denitrification from many types of ecosystems (e.g., coniferous forest, deciduous forest, tropical forest, wetland, grassland), but not heathlands. Among five chemical forms of N studied,  $\text{NO}_3^-$  addition showed the strongest stimulation of  $\text{N}_2\text{O}$  emission. Using data extracted from 206 peer-reviewed papers, a second meta-analysis observed that the largest changes in the ecosystem N cycle caused by N addition were increased nitrification (+154%),  $\text{N}_2\text{O}$  emissions (+134%), and denitrification (+84%).

---

### IS.5.1.2 National-Scale Sensitivity and Critical Loads

As of the 2008 ISA, the regions of the U.S. with abundant acid-sensitive soils had been well delineated. These acid-sensitive ecosystems are generally located in mountainous terrain in the eastern U.S. and are underlain by bedrock resistant to weathering. However, a similar delineation of the areas sensitive to the eutrophication effects of N had not yet been completed. There is strong evidence demonstrating that biogeochemical sensitivity to deposition-driven eutrophication and acidification is the result of historical loading, geologic/soil conditions (e.g., mineral weathering and S adsorption), and/or natural sources of N and S loading to the system.

Since the 2008 ISA, several new publications have advanced our understanding of soil recovery from acidification and CLs. New publications report the results of field observations and modeling studies on soil recovery from acidification, specifically in the northeastern U.S., and the lack of recovery in the southern Appalachian Mountains ([Table 4-18](#)). New ecoregion-scale terrestrial CLs for  $\text{NO}_3^-$  leaching were published in 2011 and have been updated by more recent published work. Finally, [Clark et al. \(2018\)](#) estimated areas exceeding CLs for terrestrial acidification and  $\text{NO}_3^-$  leaching for the contiguous U.S. for 1800 to 2025. For terrestrial acidification, area exceeding the minimum CL peaked at almost 2.8 million  $\text{km}^2$  by 1975 before declining; whereas, for  $\text{NO}_3^-$  leaching, the area exceeding the minimum CL peaked at roughly 3.4 million  $\text{km}^2$  around 1995.

---

### IS.5.2 Biological Effects of Terrestrial Nitrogen Enrichment

The enrichment of terrestrial ecosystems by N deposition often increases plant productivity and causes changes in physiology and growth rates that vary among species. This combination of effects can alter the composition and decrease diversity of terrestrial communities by transforming competitive interactions between species and changing the availability of other essential resources, including light, water, and nutrients. Because N deposition can cause both eutrophication and acidification and these processes can occur simultaneously, the relationship between N deposition and community composition has often been derived empirically. Many of the effects of N deposition are similar across ecosystems and life forms because N is an essential macronutrient, but the composition and magnitude of how these effects are expressed within an ecosystem can differ as a result of biotic and abiotic influences. Consequently, as with the 2008 ISA, we have grouped the effects of N deposition on physiology and biodiversity by biome (e.g., forest, tundra, grassland, and arid lands), with further framing by life form (e.g., plants, microorganisms) and functional groups (e.g., trees, herbaceous plants). In comparison,

the broadest CLs created by the scientific community are at the ecoregion level, in which spatial boundaries across the landscape are typically defined based on ecological, climatological, and geological differences.

The 2008 ISA documented consistent evidence that N additions increased plant productivity broadly across a wide range of terrestrial ecosystems. Since 2008, a large body of new research on the biological effects of added N in terrestrial ecosystems has been published from investigations of plant and microbial physiology, long-term ecosystem-scale N addition experiments, regional and continental-scale monitoring studies, and syntheses. These studies have been conducted in ecosystems representing biomes in the U.S., including tundra, grasslands, arid and semiarid lands, and tropical, temperate, and boreal forests. Because of the breadth of this research, there is a strong mechanistic and empirical understanding for many of the biological effects of added N. **This body of evidence is sufficient to infer a causal relationship between N deposition and the alteration of the physiology and growth of terrestrial organisms and the productivity of terrestrial ecosystems.**

The varying effects of N deposition on the growth and physiology of individual species have consequence(s) for biodiversity. In the 2008 ISA, evidence was sufficient to infer a causal relationship between N deposition and the alteration of species richness, species composition, and biodiversity in terrestrial ecosystems. The 2008 ISA documented consistent evidence of reduced species richness and altered community composition from N addition studies in the U.S. and N deposition gradient studies in Europe for grassland plant diversity, forest understory plants, and forest mycorrhizal fungi. There was also consistent evidence of altered plant and mycorrhizal community composition from N addition studies in arid and semiarid ecosystems, particularly in southern/central California. There was little evidence of changes in forest overstory tree composition. Since the 2008 ISA, new research techniques have been developed to understand community composition, a larger number of communities have been surveyed, and new regional and continental-scale studies have made it possible to isolate the influence of N deposition from other environmental factors. This new research has provided more extensive and mechanistic evidence, and combined with the findings of the 2008 ISA, **this body of evidence is sufficient to infer a causal relationship between N deposition and the alteration of species richness, community composition, and biodiversity in terrestrial ecosystems.**

---

### IS.5.2.1 Physiology and Biodiversity

At the time of the 2008 ISA, terrestrial ecologists had used meta-analyses to broadly quantify the effects that N deposition can have on the growth of terrestrial plants, concluding that N additions stimulate plant productivity by 20–30% in grasslands, forests, tundra, and wetlands, increase aboveground productivity in herbaceous plant communities, alter plant tissue chemistry, decrease biomass of mycorrhizal fungi, and alter litter decomposition ([Appendix 6.6.1](#)). Recent research has provided further coherent and consistent evidence that N additions stimulate plant growth and productivity, but this research is still dominated by studies of temperate ecosystems and aboveground plant responses ([Figure 6-1](#) and [Figure 6-2](#)).

In the 2008 ISA, the positive plant growth response to N deposition was attributed to higher rates of photosynthesis. However, evidence for this is mixed: increases in photosynthesis following N additions have been observed across a variety of plant functional types, but higher rates of photosynthesis have not been consistently observed in response to chronic N additions meant to simulate atmospheric deposition. There is new support for another mechanism that would increase aboveground growth: decreases in the quantity of C allocated by plants to roots and mycorrhizae. There was evidence in the 2008 ISA that N additions increase aboveground biomass more than belowground biomass, raising the shoot-to-root ratio among plants, but evidence is now more consistent and widespread. Plants also invest substantial amounts of C to support mycorrhizal fungi, but there is evidence this investment declines when N is added to terrestrial ecosystems.

Evidence that biodiversity change can be a consequence of N deposition has accumulated since 2008 and includes new information for major taxonomic groups, including herbaceous plants, overstory trees, and two groups of symbionts (lichens and mycorrhizae). Evidence is now more widespread for decreases in lichen species richness as the result of N deposition in the U.S. There are direct observations that N deposition in the U.S. is changing mycorrhizal community composition and altering herbaceous plant species richness across a broad range of ecosystems, including forests, grasslands, arid and semiarid ecosystems, and alpine tundra. In addition, based on variation in mortality and growth rates of co-occurring tree species, there is also indirect evidence that N deposition is altering overstory tree community composition.

A substantial body of research linking changes in biodiversity to shifts in N availability has been developed. Two hypotheses for species loss are (1) the random-loss hypothesis and (2) the functional trait hypothesis. The random-loss hypothesis suggests rare species are most likely to disappear as increased competition for resources, such as light, eliminates less successful individuals; whereas the functional trait hypothesis predicts

that organisms with disadvantageous traits (e.g., shorter plants) will be outcompeted when N is added. Both hypothesized mechanisms can operate simultaneously, and both tie the changes in physiology, growth, and productivity caused by increased N availability to declines in biodiversity.

As noted in [Appendix 4](#), soil microorganisms have important roles in regulating N and C cycling. There are several mechanisms to alter soil microbial biomass and physiology, including changes in soil pH, increases in inorganic N availability, shifts in soil food webs, and changes in the quantity and quality of available C. There were some observations in the 2008 ISA that added N decreases microbial biomass, but there is now more evidence that added N generally negatively or neutrally affects microbial biomass C and microbial biomass N ([Table 6-4](#)).

#### **IS.5.2.1.1 Forests**

Forests occur within every U.S. state, but are most abundant in the eastern U.S., montane and coastal portions of the western U.S., and Alaska. The distribution of forests is bound by water availability, cold temperatures, and land management. In the 2008 ISA, there was consistent evidence that N additions stimulated forest productivity, but these responses varied widely and included both neutral and negative effects of N additions on tree growth. However, there had been no empirical analyses of how atmospheric N deposition altered forest productivity in the U.S. at broad scales. The 2008 ISA lacked information on whether N deposition had any impact on the diversity and composition of forest overstory trees, but it did present evidence for changes in the composition of herbaceous vegetation, epiphytic lichens, and microbial communities. The addition of new research since the 2008 ISA provides coherent evidence that N deposition alters the physiology and growth of overstory trees and provides indirect evidence that N deposition changes the community composition of overstory trees. Further, new research supports N deposition altering the physiology, growth, and community composition of understory plants, lichens, mycorrhizal fungi, soil microorganisms, and arthropods ([Appendix 6.2.3](#) and [Appendix 6.3.3](#)).

As of the 2008 ISA, most long-term N addition experiments were conducted in temperate forests in the northeastern U.S. or in temperate or boreal forests in Europe. In these studies, conifer species were less likely than broadleaf species to exhibit positive growth responses to added N and more frequently exhibited increased mortality and decreased growth. Since the 2008 ISA, new observations from experiments, forest inventory studies, model simulations, and data synthesis efforts have been published, quantifying increases in forest net primary productivity (NPP), net ecosystem productivity (NEP), and ecosystem C storage ([Figure 6-3](#)). Overall, evidence is consistent that N deposition

broadly increases tree growth and forest productivity, including specific evidence indicating that current rates of N deposition in the contiguous U.S. broadly stimulate aboveground forest productivity ([Appendix 6.2.3.1](#)).

Despite these broad effects, it is also clear that with N addition growth and mortality responses vary by tree species. Many of the observations in the 2008 ISA have been reinforced by more recent research, including long-term forest inventory data collected from across the U.S. and Europe. Recent analyses of U.S. forest inventory data by [Horn et al. \(2018\)](#) found that tree species vary in their growth and mortality responses to N deposition ([Appendix 6.2.3.1](#)). Responses of individual tree species ranged from consistently increasing growth with greater N deposition; to increasing growth at lower N deposition but decreasing growth at higher levels; to consistently decreasing growth with greater N deposition. Mortality responses showed a similar pattern between species. Notably, species with varying responses in growth and mortality co-occurred in places in the U.S. Thus, this indirect evidence suggests that changes in tree community composition are occurring due to N deposition ([Appendix 6.3.3.1](#)). These analyses represent an advancement in our understanding from the time of the 2008 ISA.

In comparison, there is direct evidence that N deposition is altering the composition of forest understory plant communities ([Appendix 6.3.3.2](#)). The evidence for altered forest understory plant communities (also known as herbaceous layer or groundcover vegetation) comes from both the 2008 ISA and from the more recent literature. Changes in understory plant communities have been observed in monitoring plots along atmospheric N deposition gradients in the U.S. and in Europe. In Europe, forest understory plant communities have shifted with increasing N toward more nutrient-demanding and shade-tolerant plant species.

Higher rates of aboveground tree growth in response to N deposition might be due to shifts in C allocation away from belowground processes. Changes in C allocation in response to additional N have been accompanied by decreases in the abundance of mycorrhizal fungi and changes in mycorrhizal community composition ([Table 6-2](#), [Table 6-14](#)). Evidence for composition change is particularly abundant in ectomycorrhizal fungal communities ([Table 6-14](#)); there are fewer observations of how arbuscular mycorrhizal fungal communities change in response to N additions ([Table 6-3](#); [Table 6-16](#)). There are also numerous observations of altered total microbial (including bacterial) biomass and community composition. For microbial biomass, most studies identified since 2008 showed either negative or neutral effects of N additions, consistent with the results of syntheses published before the 2008 ISA ([Table 6-4](#)). Changes in soil microbial community composition were identified along an N deposition gradient in Europe and in all three N addition studies ([Table 6-14](#)). The effects of N additions on

individual microbial taxonomic groups (bacteria, archaea, fungi, etc.) have been less consistent ([Table 6-15](#)). Overall, there is evidence that N additions can decrease total microbial biomass and alter microbial communities in forest soils.

Within soil food webs, soil microorganisms have both direct and indirect links to arthropods. Because arthropods feed upon both microorganisms and litter, they can be important regulators of decomposition, nutrient cycling, and forest productivity. Several studies have examined the response of forest arthropod communities to added N, including a group of studies on insect herbivores conducted in southern California ([Table 6-17](#)). There is coherent evidence that N additions can alter forest arthropod communities.

Epiphytic lichens have long been recognized as sensitive to air pollution. Although these organisms often make up a small portion of forest biomass, they have important roles in hydrologic cycling, nutrient cycling, and as sources of food and habitat for other species. New research on lichen community composition identified since the 2008 ISA has further added to the consistent and coherent evidence that lichen communities in the U.S. and Europe are sensitive to current levels of atmospheric N deposition ([Appendix 6.2.6](#); [Table 6-23](#)). In particular, the U.S. Forest Service's Forest Inventory and Analysis Program has ample data on the abundance of lichens throughout the U.S., and shifts in lichen community composition clearly attributable to atmospheric N pollution have been observed in forests throughout the West Coast, in the Rocky Mountains, and in southeastern Alaska. Shifts in epiphytic lichen growth or physiology have been observed along atmospheric N deposition gradients in the highly impacted area of southern California, but also in more remote locations such as Wyoming and southeastern Alaska ([Table 6-5](#)). Experimental N studies have also created more detailed insight into changes in lichen physiology processes.

Overall, there is widespread evidence from forests that N deposition alters the growth and physiology of trees, and indirectly suggests N deposition affects tree community composition. Nitrogen deposition in forests also alter the growth, physiology, and biodiversity of herbaceous plants, lichens, soil microorganisms, and arthropods.

#### **IS.5.2.1.2 Tundra**

Within the U.S., tundra ecosystems are limited to Arctic ecosystems in Alaska and to relatively isolated, high elevation sites. Although these ecosystems tend to be remote, the influence of atmospheric N deposition is distinct and there was evidence in the 2008 ISA indicating that alpine tundra plant communities were sensitive to atmospheric N deposition. Alpine organisms may be more sensitive to N deposition because of the

unique nature of N cycling in these ecosystems, which tend to have limited inorganic N availability. Since the 2008 ISA, numerous studies of tundra physiological, productivity, and community composition responses to added N have been published, providing further evidence that N deposition alters the growth and physiology of alpine plant communities, including vascular plants (herbaceous and woody), bryophytes, and lichens ([Appendix 6.2.4](#)), as well as evidence of altered soil microbial communities ([Table 6-8](#); [Table 6-19](#)).

As in forests, increases in N content in response to additional N are widespread in tundra plant communities ([Table 6-6](#)). Higher tissue N concentrations in response to added N have been observed in multiple studies for vascular plants, bryophytes, and lichens. The 2008 ISA noted that plant growth and biomass responses tended to be species specific. Subsequent studies have confirmed this result ([Table 6-6](#)), showing varying responses to added N among ecosystem types, plant functional groups, and species. Whereas vascular plants tend to show a positive response to added N, both bryophytes and lichens tend to decrease in biomass and cover ([Table 6-5](#); [Table 6-6](#)).

Given the varying effects of N addition on species physiology and growth, the numerous observations of N addition impacts on species richness, species diversity, and community composition among vascular plants, bryophytes, and lichens in alpine and Arctic tundra ecosystems are unsurprising ([Appendix 6.3.4](#); [Table 6-18](#)). Within the U.S., these observations have included effects of N additions on plant community composition in Colorado and Washington. In northern Europe, decreases in plant species richness along atmospheric N deposition gradients have been documented. Overall, this new research has provided further evidence that experimental N additions can alter plant biodiversity in alpine and Arctic tundra ecosystems and has provided new evidence that current rates of atmospheric N deposition in Europe are associated with a loss of plant species richness in these ecosystems.

There are relatively few observations regarding the effect of N additions on total microbial biomass or the biomass response of individual microbial taxonomic groups in tundra ecosystems, and these results have also been largely inconsistent. However, new research has provided evidence that N additions can alter microbial community composition in alpine tundra ecosystems ([Table 6-8](#); [Table 6-19](#)).

### **IS.5.2.1.3 Grasslands**

Grasslands are most prevalent in the central U.S., yet also are widely distributed across the U.S. in areas where woody vegetation is excluded by environmental factors or management. There was widespread evidence at the time of the 2008 ISA that the

growth, physiology, and productivity of grassland plants could be altered by N deposition. In addition, there were multiple lines of evidence in the 2008 ISA that grassland plant, mycorrhizal, and microbial communities were sensitive to N inputs. Combined with subsequent research, the evidence is clear that physiology, growth, and community composition of plants, mycorrhizae, soil microorganisms, and arthropods are sensitive to N inputs in grasslands.

Although NPP can be limited by multiple factors (e.g., water, herbivores, other nutrients) in all ecosystems, limitations other than N tend to be more marked in grasslands than forests, making it harder to understand and predict the effects of increased N availability. However, the general response is similar ([Appendix 6.2.5](#)): N additions stimulate NPP, increase foliar N, and increase allocation to aboveground biomass (increased ratio of shoot:root mass).

Evidence from the U.S. of grassland plant community composition change in the 2008 ISA was based on N addition studies in Mediterranean grasslands in California and northern prairie ecosystems. However, large-scale assessments of biodiversity across observed atmospheric N deposition gradients were restricted to Europe. Recent research provides further evidence that N deposition reduces grassland biodiversity in the U.S. and Europe ([Appendix 6.3.5](#)). Since 2008, there have been direct observations of reduced species richness along atmospheric N deposition gradients for grasslands in the U.S. and Europe. These gradient studies have documented an interaction with soil pH, noting that N deposition causes a greater loss of species richness and a shift in community composition at sites with lower pH. Together, these findings from deposition gradients in the U.S. and Europe provide coherent evidence that N deposition causes shifts in plant community composition and the loss of plant species richness through mechanisms of both acidification and eutrophication. Experimental studies published since 2008 have provided more insight into the mechanisms linking changes in plant and microbial community composition to increased N availability, providing evidence that declines in species richness increase with time and that competition for resources such as water may exacerbate the effects of N addition on diversity.

Overall, the additional studies in grassland ecosystems have confirmed that many of the responses observed in the older N addition studies also occur at present rates of atmospheric N deposition. These changes include losses in forb species richness (which make up the majority of grassland biodiversity), greater growth of grass species (which make up the majority of grassland biomass), changes in reproductive rates, as well as shifts in mycorrhizal ([Table 6-16](#)), soil microbial ([Table 6-20](#)), and arthropod populations. In total, because of the prevalence of N limitation in grasslands and the dominance by fast-growing species that can shift in abundance rapidly (in contrast to

forest trees), grasslands appear especially sensitive to N input rates comparable to N deposition across much of the contiguous U.S.

#### **IS.5.2.1.4 Arid and Semiarid**

Arid and semiarid ecosystems are abundant in areas of the western U.S. where climate or orography create annually or seasonally dry conditions. At the time of the 2008 ISA, a large amount of information was available on how N deposition affected the growth and physiology of plants and microorganisms in arid and semiarid ecosystems, and there was coherent evidence that plant communities in these ecosystems could be altered by the added N. Evidence for these effects was particularly strong in coastal sage scrub (CSS), chaparral, and Mojave Desert ecosystems in southern California. Within the CSS ecosystems, N deposition has been linked to increased mortality in native shrubs, decreased abundance of arbuscular mycorrhizal fungi, higher cover of invasive annual plants, and increased wildfire activity. Similar increases in invasive annual plant cover and fire frequency have also been attributed to N deposition in areas of the Mojave Desert downwind of urban centers in southern California. Research since 2008 has further documented these effects, with consistent evidence that N deposition can affect the physiology, growth, and community composition of plants and soil microorganisms in arid and semiarid systems.

The effects of N deposition on physiological and biogeochemical processes in arid and semiarid ecosystems are even more clearly dependent on moisture availability than in grasslands ([Appendix 6.2.6](#)). In these ecosystems, inorganic N often accumulates in the soil during dry periods, and growth and physiological responses to additional N are only observed when and where sufficient moisture is available. Two additional important effects of aridity include (1) higher soil base saturation and pH that buffer these systems from the acidification effects of N deposition and (2) spatially patchy nutrient availability that develops beneath isolated shrub canopies. One important effect of N deposition on arid and semiarid ecosystems is to decrease the patchiness of nutrient availability, which promotes the growth of invasive annual plants in the spaces between the isolated shrubs. The growth of these annual plants creates a more continuous fuel bed for wildfires, increasing the prevalence of fire, and shifting plant community composition toward more fire-adapted plant species.

Since 2008, increases in aboveground plant biomass or plant cover have been observed in the U.S. in the Mojave and Sonoran Deserts, and in southern California chaparral, and internationally in China and Spain ([Appendix 6.2.6](#)). Given the linkage to fire, it is notable that there have been multiple observations of increased annual plant growth in the Mojave Desert in response to added N.

New research has also provided further evidence that N deposition alters plant communities in arid and semiarid ecosystems, particularly in southern California, but also in other locations ([Appendix 6.3.6](#)). Many of these studies documented changes in plant community composition, with fewer observations of plant species loss or changes in plant diversity. Overall, this body of research has provided consistent and coherent evidence that N deposition is altering the growth, physiology, and community composition of plants in arid and semiarid ecosystems. Relative to plants, there are fewer studies of microbial communities ([Table 6-12](#); [Table 6-22](#)), but these studies provided evidence that N additions can alter the abundance, physiology, and community composition of soil microorganisms in arid and semiarid ecosystems.

---

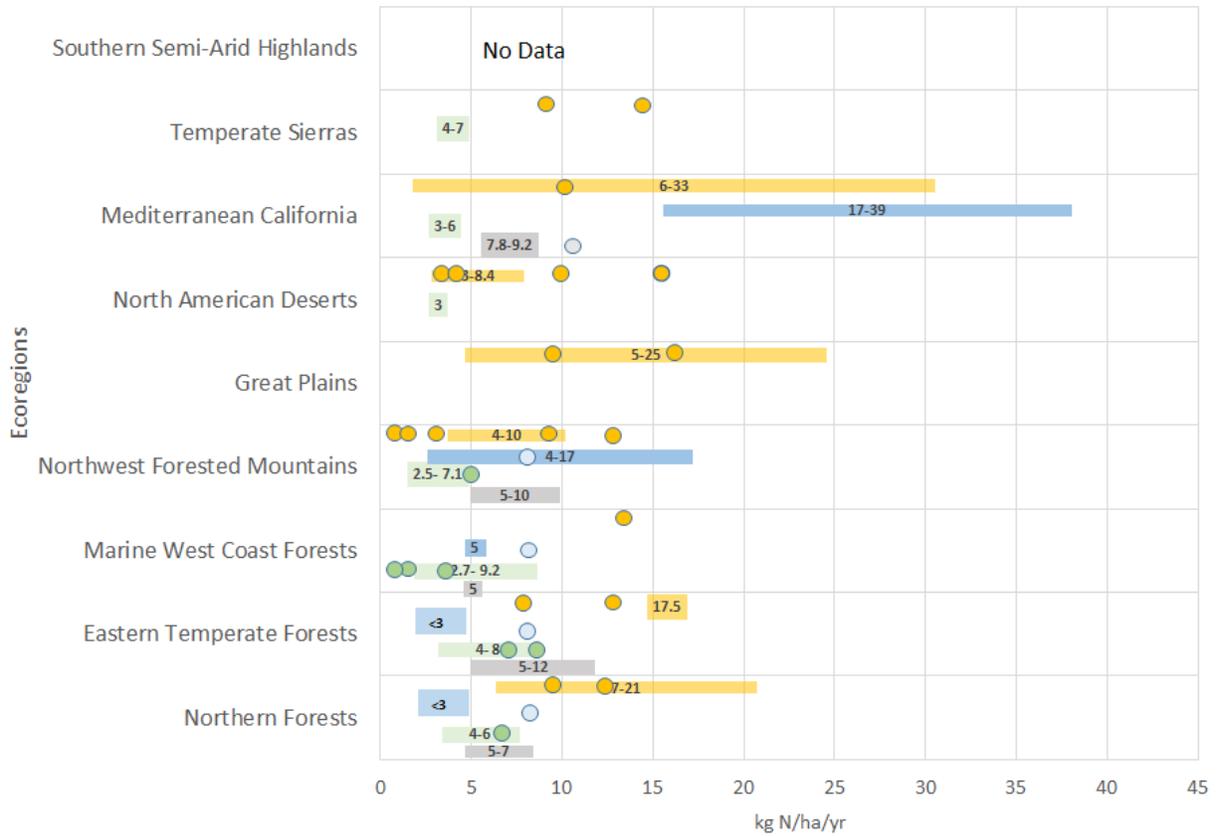

### IS.5.2.2 National-Scale Sensitivity and Critical Loads

At the time of the 2008 ISA, there had been little quantification of the extent and distribution of N sensitivity in terrestrial ecosystems in the U.S. In the 2008 ISA, there was no published U.S. national CL assessment. Since then, substantial work has been done on quantifying N CLs for U.S. ecoregions. The most notable new work is the U.S. Department of Agriculture—Forest Service (USDA-FS) *Assessment of Nitrogen Deposition Effects and Empirical Critical Loads* ([Pardo et al., 2011a](#)). That assessment was organized by Level 1 ecoregions, and where data were available, CL calculations were made for individual ecosystem types (e.g., forests within the Mediterranean California ecoregion) and life forms (i.e., lichens, mycorrhizal fungi). This ISA largely follows that structure, reporting terrestrial N CLs for life forms (e.g., herbaceous plants) within each ecoregion, which is a geographically defined area within a broader biome (e.g., forests) based on distinct physical and biological features (e.g., Northwest Forested Mountains, Eastern Temperate Forests, etc.).

Newer CL studies are presented in tandem with the CLs reported by [Pardo et al. \(2011a\)](#) in [Table 6-28](#) and [Figure IS-10](#). The majority of values for new CLs are within the range of CLs identified by [Pardo et al. \(2011a\)](#). Notably, however, [Simkin et al. \(2016\)](#) identified a new average CL for herbaceous plants in open canopy (7.9 kg N/ha/yr) forests in the Eastern Temperate Forest ecoregion, and new lower CLs were derived for alpine ecosystems in the Northwest Forested Mountains ecoregion. There are also new CLs for herbaceous species in two ecoregions previously lacking a CL for herbaceous plants [[Table 6-28](#), [Simkin et al. \(2016\)](#)].

Recently, [Clark et al. \(2018\)](#) estimated CL exceedance areas for the contiguous U.S. over a more than 200 year period. Overall, this analysis showed that terrestrial N CLs have been exceeded for many decades in areas across the U.S. Exceedance areas peaked in

1995 for changes in lichen communities and plant community composition at 3.47 and 2.87 million km<sup>2</sup>, respectively, before declining marginally by 2006. The minimum forest tree health CL was exceeded in 2.41 million km<sup>2</sup> by 1855 and did not change much over time, primarily because the relatively low CL compared to deposition values in the Eastern Temperate and Northern forest ecoregions.

CL = critical load; ha = hectare; kg = kilogram; N = nitrogen; yr = year.

The rectangles indicate the range of CLs designated by [Pardo et al. \(2011a\)](#); the circles indicate new papers that have specified CLs; data from [Table 6-28](#).

**Figure IS-10 Summary of critical loads for nitrogen in the U.S. for shrubs and herbaceous plants (yellow), trees (blue), lichens (green), and mycorrhizae (gray).**

---

### IS.5.3 Biological Effects of Acidification

Since publication of the 2008 ISA, the overarching understanding of terrestrial acidification has not appreciably changed. Recent research has confirmed and strengthened this understanding that acidification can be caused by acidifying deposition (N + S) and provided more quantitative information, especially across regional-scale landscapes. Several studies have evaluated the relationships between soil chemistry indicators of acidification and ecosystem biological endpoints (see [Table 5-6](#)). Soil chemistry indicators examined in recent literature include exchangeable base cations (Bc), soil pH, exchangeable acidity (H<sup>+</sup> and Al), exchangeable Bc:Al ratio, base saturation, and Al concentrations. The most common indicator used in determining CLs is the soil solution Bc:Al ratio. [Appendix 5.2.1](#) discusses the uncertainty considerations when using this indicator. Biological endpoints included in the evaluations consisted of physiological and community responses of trees and other vegetation, lichens, soil biota, and fauna.

---

#### IS.5.3.1 Physiology and Growth

In the 2008 ISA, evidence was sufficient to infer a causal relationship between acidifying deposition and changes in terrestrial biota; the evidence included changes in plant physiology, plant growth, and terrestrial biodiversity. The physiological effects of acidification on terrestrial ecosystems in the U.S. were well characterized at the time of the 2008 ISA and included slower growth and increased mortality among sensitive plant species. Consistent and coherent evidence from multiple species and studies in 2008 showed that the biological effects of acidification on terrestrial ecosystems were generally attributable to physiological impairment caused by Al toxicity and decreased ability of plant roots to take up base cations (Appendix 3.2.2.3 of the 2008 ISA). Much of the new evidence for the negative effects of acidifying deposition comes from Ca addition experiments, in which the addition of Ca has alleviated many of the negative plant physiological and growth effects. Consistent with the findings of the 2008 ISA, **the body of evidence is sufficient to infer a causal relationship between acidifying N and S deposition and the alteration of the physiology and growth of terrestrial organisms and the productivity of terrestrial ecosystems.**

In the 2008 ISA, acidifying deposition, in combination with other stressors, was found to be a likely contributor to physiological effects that led to the decline of sugar maple (*Acer saccharum*) trees occurring in portions of the eastern U.S. with base-poor soils. Studies since the 2008 ISA support these findings (see [Appendix 5.2.1.1](#)). For example, recent field studies have shown relationships between soil chemical indicator threshold values

and tree responses. Substantial declines in sugar maple regeneration have been found at soil base saturation levels <20%, which is consistent with the range reported in the 2008 ISA.

In new studies, sugar maple grew more rapidly and showed increased regeneration responses with increasing exchangeable base cations, base saturation, and soil pH, however, growth was stunted and regeneration reduced with increasing exchangeable Al. In other studies, the growth, regeneration, and physiological responses of sugar maple to the soil conditions created by acidifying deposition were reversed or ameliorated by Ca additions. Similarly, the 2008 ISA reported that processes associated with soil acidification contributed to physiological stress, high mortality rates, and decreasing growth trends of red spruce (*Picea rubens*) trees. New evidence from Ca addition studies provides further support for these mechanisms (see [Appendix 5.2.1.2](#)). Added Ca reversed or ameliorated many of the physiological responses to acidification.

In the 2008 ISA, there was limited information on the effects of acidification on other tree species. Since the 2008 ISA, research has observed varying physiological sensitivity to soil acidification among eight eastern U.S. tree species. New studies since the 2008 ISA have also added new information about the effects of acidifying deposition on forest understory vegetation, grasslands, lichens, and higher trophic level organisms (snails and salamanders) that support the terrestrial acidification conclusions of the 2008 ISA.

---

### IS.5.3.2 Biodiversity

The 2008 ISA noted strong evidence that acidifying deposition could alter terrestrial community composition and cause a loss of terrestrial biodiversity. The physiological and growth effects of acidifying deposition are not uniform across species, resulting in altered species composition and decreased biodiversity whereby sensitive species are replaced by more tolerant species. For example, increasing soil base cation availability was tied to greater sugar maple growth and seedling colonization, whereas American beech (*Fagus grandifolia*) was relatively more dominant on soils with lower base cation availability (see [Appendix 5.2.1.3.1](#)). Measurements of soil acid-base chemistry have been used as a predictor of understory species composition, with 50 understory species associated with high soil base cation status. In another set of studies, soil acid-base chemistry was correlated with soil biodiversity and community composition. For example, addition of Ca resulted in changes in soil bacterial community composition and bacterial community structure that were correlated with soil exchangeable Ca, pH, and P (see [Appendix 5.2.4](#)). Based on research included in the 2008 ISA and these new studies, **the body of evidence is sufficient to infer a causal relationship between acidifying N and S deposition and**

## **the alteration of species richness, community composition, and biodiversity in terrestrial ecosystems.**

---

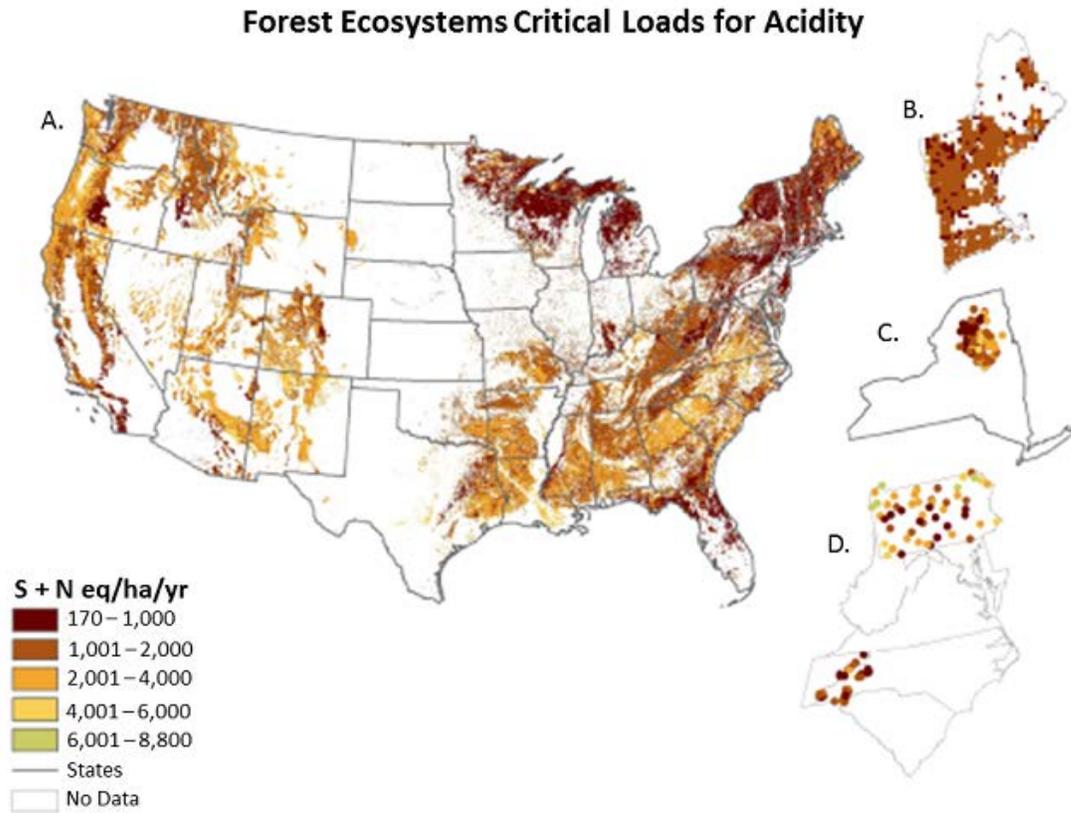

### **IS.5.3.3 National-Scale Sensitivity and Critical Loads**

The sensitivity of soils to acidifying deposition is discussed in detail in [Appendix 4](#). In general, surficial geology is the principal factor governing the sensitivity of terrestrial ecosystems soil to acidification from S and N deposition. Other factors that contribute to the sensitivity of soils to acidifying deposition include topography, soil chemistry, and land use. Several widely accepted models are currently used in the U.S. to assess the terrestrial effects of S and N deposition ([Appendix 4.5](#)). These models are typically used to evaluate acidification effects on biota by assigning a value of a soil parameter that relates to the onset of a harmful biological effect. Since the 2008 ISA, estimates of base cation weathering (BCw), which are input to soil acidification models have improved and are being applied for deriving new CLs in the U.S. Forests of the Adirondack Mountains of New York, Green Mountains of Vermont, White Mountains of New Hampshire, the Allegheny Plateau of Pennsylvania, and mountain tops and ridges forest ecosystems in the southern Appalachians are the regions that are most sensitive to terrestrial acidification from atmospheric deposition (Appendix 3.2.4.2 of the 2008 ISA).

Models used to determine CLs of acidifying deposition included SMB, STA, MAGIC, ForSAFE-VEG, and empirical models. Several models and extrapolation methods to estimate BCw rates were also investigated. The PROFILE model was evaluated as a model to estimate soil BCw rates to support estimates of SMB CLs in the U.S. (see [Appendix 4.5](#)). In general, recently published models used soil solution Bc:Al ranging from 1.0 to 10.0 as an indicator to estimate CLs in North America.

Ecosystem sensitivities to ambient N and S deposition were also characterized by developing CLs and exceedances (see [Appendix 4.6](#); [Figure IS-11](#), and [Appendix 5.5](#)). Calculated CLs for forest plots based on the soil solution Bc:Al of 10.0 in the northeastern U.S. ranged from 11 to 6,540 eq/ha/yr (eq quantifies the supply of available H<sup>+</sup> ions, combining the acidifying effects of N and S deposition), and 15–98% (calculated using maximum and minimum weathering rates) of these plot-level CLs were exceeded by N and S deposition. In this region, correlation analyses showed that the growth of 17 tree species were negatively correlated with CL exceedance. In Pennsylvania, CLs based on the soil solution Bc:Al of 10.0 for hardwood forests ranged from 4 to 10,503 eq/ha/yr and were exceeded by estimated N and S deposition in the year 2002 in 53% of the plots. Several studies found that CL and exceedance determinations could be influenced by BCw rates, soil chemical indicators, N retention, tree species-specific base

cation uptake, and the type and accuracy of deposition estimates (i.e., wet, bulk, total, measured or modeled).

eq = equivalent; ha = hectare; yr = year.

(A) [McNulty et al. \(2007\)](#); CLs are mapped at 1-km<sup>2</sup> grids (center map). For uncertainty, see [Li and McNulty \(2007\)](#). (B) [Duarte et al. \(2013\)](#); CLs are mapped at 4-km<sup>2</sup> grids. (C and D) [Phelan et al. \(2014\)](#); CLs are mapped for each sampling site (Pennsylvania). [McDonnell et al. \(2014b\)](#); [Sullivan et al. \(2011b\)](#); [Sullivan et al. \(2011a\)](#); CLs are mapped as a single point at the center point of the watershed (New York and North Carolina).

---

## IS.6 Freshwater Ecosystem Nitrogen Enrichment and Acidification

For freshwater systems, new evidence reinforces causal findings from the 2008 ISA ([Table IS-1](#)). It also expands the scope of existing causal findings to include additional biota affected by N enrichment and acidifying deposition and supports quantification of these effects with new CLs (see [Section IS.6.3.2](#)). Freshwater systems include lakes (lentic systems) and rivers and streams (lotic systems). In freshwater ecosystems, N may cause N enrichment/eutrophication. Aquatic eutrophication results in increased productivity of algae and aquatic plants, altered nutrient ratios, and sometimes decreased oxygen levels. Deposition of N, S, or N + S can cause acidification, which affects watershed biogeochemical processes and surface water chemistry. Freshwater N enrichment and acidification take place in sensitive ecosystems across the U.S. at present levels of deposition and may occur simultaneously in some water bodies.

New studies have added to the body of evidence in the 2008 ISA that N nutrient enrichment and acidifying deposition alter freshwater biogeochemistry with subsequent biological effects. There is new information on biogeochemical processes including cycling of N and S. Both N enrichment/eutrophication and acidification can impact physiology, survival, and biodiversity of sensitive aquatic biota. The 2008 ISA and new studies provide examples of lakes and streams that show signs of eutrophication, especially increased algal growth and shifts in algal biodiversity, in response to N addition. The current causal statement for nutrient enrichment effects of N deposition now includes altered algal growth and productivity as well as the endpoints of species richness, community composition, and biodiversity reported in the 2008 ISA ([Table IS-1](#)). For biological effects of aquatic acidification, the current causal statement has been expanded from the 2008 ISA to include the specific endpoints of physiological impairment, alteration of species richness, community composition, and biodiversity ([Table IS-1](#)). New studies also show that despite reductions in acidifying deposition, many aquatic ecosystems across the U.S. are still experiencing changes in ecological structure and functioning at multiple trophic levels. Although there is evidence for chemical recovery in many previously acidified ecosystems, biological recovery has been limited ([Appendix 8.4](#)).

A number of freshwater monitoring efforts have facilitated the analysis of long-term trends in surface water chemistry and ecological response in areas affected by acidifying (N + S) deposition ([Appendix 7.1.3](#)). Many of these studies have been conducted in the U.S., especially in the Northeast and the Appalachian Mountains. Although many of these monitoring programs were in existence at the time of the 2008 ISA and were considered in that analysis, more recent publications reflect the longer period of

monitoring and strengthen previous conclusions. Surface water chemistry data from long-term monitoring by federal, state, and local agencies, as well as university research groups and nonprofits has been combined into several publicly available metadatabases ([Appendix 7.1.3.2](#)) enabling further regional trend analysis. Since the early 2000s, U.S. EPA, together with the states, tribes, and other entities and individuals, have collaborated on a series of statistically representative surveys (National Aquatic Resource Surveys [NARS]) of the nation's waters, including surveys of lakes ([U.S. EPA, 2016h, 2009b](#)), streams ([U.S. EPA, 2016i](#)), wetlands ([U.S. EPA, 2016j](#)), and coastal waters ([U.S. EPA, 2016g](#)). These periodic surveys, which are based on standard sampling and analysis protocols and consistent quality assurance, include chemical and biological indicators of nutrient enrichment and acidification ([Appendix 7.1.3](#)).

---

## IS.6.1 Freshwater Biogeochemistry

In the 2008 ISA, evidence was sufficient to infer a causal relationship between N and S deposition and the alteration of biogeochemical cycling of N and C in freshwater ecosystems, and between acidifying deposition and changes in biogeochemistry of fresh waters. As documented in the 2008 ISA and by newer studies, biogeochemical processes and surface water chemistry are influenced by characteristics of the catchment and the receiving waters. A number of studies since 2008 have focused on improving understanding of aquatic acidification and eutrophication processes mediated by N. Many of these studies have focused on pathways of pollutant and other constituent movement within ecosystems, including monitoring studies of various kinds. Chemical indicators of N deposition identified by the 2008 ISA were  $\text{NO}_3^-$  and DIN concentrations in surface waters. Increased N deposition to freshwater systems via runoff or direct atmospheric deposition, especially to N limited and N and phosphorus (P) colimited systems, can alter N cycling ([Appendix 7](#)) and stimulate primary production ([Appendix 9](#)). Data from long-term monitoring, experimental manipulations, and modeling studies provide consistent and coherent evidence for biogeochemical changes associated with acidifying N and S deposition. The strongest evidence for a causal relationship between acidifying deposition and aquatic biogeochemistry comes from studies of changes in surface water chemistry. Surface water chemistry indicators of acidic conditions and acidification effects include concentrations of  $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ , inorganic aluminum (Al), calcium (Ca), sum and surplus of base cations, acid-neutralizing capacity (ANC), and surface water pH. New information on biogeochemical cycling of N and S, acidifying deposition effects on biogeochemical processes and changes to chemical indicators of surface water chemistry associated with acidification and N nutrient enrichment is consistent with the conclusions

of the 2008 ISA, and **the body of evidence is sufficient to infer a causal relationship between N and S deposition and the alteration of freshwater biogeochemistry.**

---

### IS.6.1.1 Freshwater Processes and Indicators

Key processes and geochemical indicators of freshwater acidification and N enrichment ([Table IS-3](#)) link to biological effects ([Appendix 8](#) and [Appendix 9](#)). Surface water chemistry integrates the sum of soil and water processes that occur upstream within a watershed. Several key biogeochemical processes cause or contribute to surface water eutrophication and acidification, and these processes have been the focus of substantial research over the last three decades. Since the 2008 ISA, experimental studies, isotopic analyses, and monitoring and observational studies have further investigated the cycling of S, N, C, and base cations; these studies substantiate and further quantify earlier findings.

Spatial and temporal patterns of  $\text{NO}_3^-$  in lakes and streams have typically been used as indicators that a freshwater system is receiving excess N which will cause acidification or eutrophication. Qualitatively, northeastern U.S. spatial patterns in surface water  $\text{NO}_3^-$  concentrations suggest an influence by atmospheric N deposition. However, considerable variation in the relationship between stream chemistry and deposition was associated with land use and watershed attributes. It was well known at the time of the 2008 ISA that key processes such as nitrification and denitrification are quantitatively important portions of the N cycle and that they can be influenced by atmospheric inputs. More recent research has further substantiated these earlier findings and provided additional quantitative context ([Appendix 7.1.2.3](#)).

Deposition is a source of S to watersheds that, along with geologic sources of S such as sulfide minerals, contribute  $\text{SO}_4^{2-}$  to surface waters ([Appendix 4](#)). The 2008 ISA found that S deposition alters soil and drainage water chemistry through sustained leaching of  $\text{SO}_4^{2-}$ , associated changes in soil chemistry, and accumulation of S in the soil through adsorption and biological assimilation. Declines in lake  $\text{SO}_4^{2-}$  concentrations have been observed in locations where S deposition has decreased significantly such as in the Adirondack Mountains ([Appendix 7.1.5.1](#)). In addition, internal watershed sources of S, which were earlier believed to be relatively minor in the northeastern U.S., have and will likely continue to become proportionately more important as S deposition continues to decline. Reductions in  $\text{SO}_x$  deposition have not consistently resulted in increases of ANC in surface water.

**Table IS-3 Summary of key aquatic geochemical processes and indicators associated with eutrophication and acidification.**

Endpoint	N Driven Nutrient Enrichment	Acidification	The Effect of Deposition
<b>Process</b>			
NO <sub>3</sub> <sup>-</sup> leaching into water bodies	X	X	Leaching from terrestrial ecosystems is an important source of NO <sub>3</sub> <sup>-</sup> in freshwater ecosystems. See NO <sub>3</sub> <sup>-</sup> leaching in <a href="#">Table IS-2</a> .
SO <sub>4</sub> <sup>2-</sup> leaching into water bodies		X	Leaching from terrestrial ecosystems is an important source of SO <sub>4</sub> <sup>2-</sup> in freshwater ecosystems. See SO <sub>4</sub> <sup>2-</sup> leaching in <a href="#">Table IS-2</a> .
Nitrification	X	X	Nitrification is an acidifying process, releasing 2 mol hydrogen ion (H <sup>+</sup> ) per mol NH <sub>4</sub> <sup>+</sup> converted to NO <sub>3</sub> <sup>-</sup> . As the N cycle becomes enriched through cumulative N addition, net nitrification rates often increase, and NO <sub>3</sub> <sup>-</sup> concentrations increase.
Denitrification	X		Denitrification is the microbial process that transforms NO <sub>3</sub> <sup>-</sup> by anaerobically reducing it to NO <sub>2</sub> <sup>-</sup> , NO, N <sub>2</sub> O, and N <sub>2</sub> .
DOC leaching into water bodies	X	X	DOC contributes to acidity of freshwater ecosystems. See DOC leaching in <a href="#">Table IS-2</a> .
<b>Indicator</b>			
Surface water [NO <sub>3</sub> <sup>-</sup> ]	X	X	Increased N deposition (to surface waters or to terrestrial watershed; see <a href="#">Table IS-2</a> ) increases the water NO <sub>3</sub> <sup>-</sup> concentration. High concentrations of NO <sub>3</sub> <sup>-</sup> in lakes and streams, indicative of terrestrial ecosystem N saturation, have been found at a variety of locations throughout the U.S. ( <a href="#">U.S. EPA, 2006c</a> ; <a href="#">Stoddard, 1994</a> ). Comparison of preindustrial estimates to modern measurements suggested elevated concentrations in water bodies as a result of N deposition ( <a href="#">Fenn et al., 2011b</a> ).
Surface water DIN	X		Increased N deposition increases DIN in most freshwater aquatic environments, largely as NO <sub>3</sub> <sup>-</sup> .
Surface water N:P ratios	X		Increased N deposition can alter the ratio of N to P in freshwater systems. Freshwater biota have different nutrient requirements and changes in nutrient ratios may alter species richness, community structure, and biodiversity, especially primary producers.
Surface water [SO <sub>4</sub> <sup>2-</sup> ]		X	Increased S deposition (to surface waters or to terrestrial watershed, see <a href="#">Table IS-2</a> ) increases the water SO <sub>4</sub> <sup>2-</sup> concentration. Comparison of preindustrial estimates to modern measurements suggested elevated concentrations in water bodies are a result of S deposition.

**Table IS-3 (Continued): Summary of key aquatic geochemical processes and indicators associated with eutrophication and acidification.**

Endpoint	N Driven Nutrient Enrichment	Acidification	The Effect of Deposition
Surface water (base cation)		X	Several studies in the eastern U.S. suggested that base cation concentrations in surface waters increased during the initial phases of acidification into the 1970s. This trend reversed, and base cations have decreased primarily in response to decreasing $\text{SO}_4^{2-}$ and $\text{NO}_3^-$ concentrations. Many base cations (especially $\text{Ca}^{2+}$ ) are important nutrients for aquatic biota.
Surface water ANC		X	Increased N and S deposition decrease ANC. Surface water ANC correlates with other biologically influential chemical metrics, including pH, inorganic Al concentration, Ca concentration, and organic acidity. ANC <50–100 $\mu\text{eq/L}$ typically poses a risk for species survival, species richness, and biodiversity.
Surface water pH		X	Surface water pH is a common alternative to ANC as an indicator of acidification, but ANC is a better indicator at pH >6.0 and is less sensitive to dissolved $\text{CO}_2$ . N and S deposition are associated with decreasing pH in surface waters.
Surface water Inorganic Al		X	Acidifying N and S deposition increase mobilization of inorganic Al from terrestrial ecosystems into surface water, increasing surface water concentrations. Inorganic Al in surface waters is (1) widely toxic and (2) leaches from terrestrial ecosystems only in response to acidic conditions. Earlier studies demonstrated reduced growth and survival of various species of fish at inorganic Al concentrations between approximately 2 and 7.5 $\mu\text{mol/L}$ . Most recently, 20% mortality of young-of-the-year brook trout was documented in situ during a 30-day period with a median inorganic Al concentration of 2 $\mu\text{mol/L}$ .

Al = aluminum; ANC = acid-neutralizing capacity; Ca = calcium;  $\text{CO}_2$  = carbon dioxide; DIN = dissolved inorganic nitrogen; DOC = dissolved organic carbon;  $\text{H}^+$  = hydrogen ion; ha = hectare; kg = kilogram; L = liter;  $\mu\text{eq}$  = microequivalents;  $\mu\text{mol}$  = micromole; N = nitrogen;  $\text{N}_2$  = molecular (atmospheric) nitrogen;  $\text{N}_2\text{O}$  = nitrous oxide; NE = northeast;  $\text{NH}_4^+$  = ammonium; NO = nitric oxide;  $\text{NO}_2$  = nitrogen oxide;  $\text{NO}_3^-$  = nitrate; P = phosphorus; S = sulfur;  $\text{SO}_4^{2-}$  = sulfate; U.S. = United States; USFS = U.S. Forest Service; yr = year.

#### IS.6.1.1.1 Acidification

The acidifying effects of N and S deposition in U.S. waters have been well characterized for several decades. Traditionally, acidification involves both chronic and episodic processes. [Driscoll et al. \(2001b\)](#) characterized chronically acidic lakes and streams as having ANC of <0  $\mu\text{eq/L}$  throughout the year, while episodic acidification occurs when ANC falls below 0  $\mu\text{eq/L}$  only for hours to weeks. Chronic acidification refers to average conditions and is often measured as summer and fall chemistry for lakes and as spring baseflow chemistry for streams. Chronic acidification is no longer prevalent in regions of the U.S. affected by acidic deposition ([Fakhraei et al., 2016](#); [Fakhraei et al., 2014](#)). Episodic acidification is associated with precipitation or snowmelt events when high

volumes of water flow through watersheds. Episodes generally cause changes in the following chemical parameters: ANC, pH, base cations,  $\text{SO}_4^{2-}$  concentration,  $\text{NO}_3^-$  concentration, inorganic Al concentration, organic acid anions, or DOC. New studies show that both N and S contributed to episodic acidification over a 20-year period at Bear Brook, ME (see [Appendix 7.1.5.1.2](#)). It is known that the biota in many streams/lakes are impacted when the ANC is consistently below 50  $\mu\text{eq/L}$ . For example, the U.S. EPA National Lakes Assessment used an ANC threshold of  $>50 \mu\text{eq/L}$  as indicative of nonacidified water bodies ([U.S. EPA, 2009b](#)).

The most widely used measure of surface-water acidification is ANC. As reported in the 2008 ISA and newer studies, ANC is the primary chemical indicator of historic acidification and for predicting the recovery expected from decreasing atmospheric deposition. ANC correlates with the surface water constituents (pH,  $\text{Ca}^{2+}$ , and inorganic Al concentration) that contribute to or ameliorate acidity effects in biota. As reported in the 2008 ISA, lake and stream ANC values decreased throughout much of the 20th century in a large number of acid-sensitive lakes and streams throughout the eastern U.S. This effect has been well documented in monitoring programs, paleolimnological studies, and model simulations ([Appendix 7.1.5.1](#)). Biological indicators of acidification, such as decreased fish species richness, are discussed in [Appendix 8.3](#).

Surface water pH is another indicator of acidification. It also correlates with surface water chemical constituents that have biotic effects (inorganic Al,  $\text{Ca}^{2+}$ , and organic acids). The 2008 ISA included the scientific consensus that low pH can have direct toxic effects on aquatic species ([U.S. EPA, 2008a](#); [Driscoll et al., 2001b](#)). A pH value of 6.0 is the level below which biota are at increased risk from acidification ([Appendix 8.3](#)). The 2008 ISA noted that increasing trends in pH (decreasing acidification) were common in surface waters in the northeastern U.S. through the 1990s and up to 2004. This trend has continued in more recent times at many locations ([Appendix 7.1.2.5](#)). Rates of change have generally been relatively small.

As stated in the 2008 ISA, the concentration of dissolved inorganic monomeric Al in surface waters is an especially useful indicator of acidifying deposition because (1) it is toxic to many aquatic species and (2) it leaches from soils only under acidic conditions including acidifying deposition, acid mine drainage, or from rare geologic deposits. Inorganic Al has well-documented effects on aquatic biota at specific thresholds ([Appendix 8.3](#)) and is often the greatest threat to aquatic biota below pH 5.5. The 2008 ISA noted that concentrations of inorganic Al decreased slightly in some surface waters in the northeastern U.S. in response to decreased levels of acidifying deposition, suggesting chemical recovery in some of these surface waters ([U.S. EPA, 2008a](#)), and

this trend has generally continued ([Appendix 7.1.5](#); see discussion on recovery [Section IS.11](#)).

Assessments of acidifying deposition effects dating from the 1980s and reported in the 2008 ISA showed  $\text{SO}_4^{2-}$  to be the primary acidifying ion in most acid-sensitive waters in the U.S. The 2008 ISA presented temporal data that showed a trend of increasing concentrations of  $\text{SO}_4^{2-}$  in surface waters before the period of peak S emissions in the early 1970s. After the peak,  $\text{SO}_4^{2-}$  surface water concentrations decreased in a widespread trend. The rate of recovery varied by ecosystem, and new studies indicate that as atmospheric S deposition has declined, soils with large stores of historically deposited S (e.g., the Blue Ridge Mountain region) have begun releasing this adsorbed S to drainage water ([Appendix 4](#)), preventing or slowing aquatic recovery.

As stated in the 2008 ISA, the quantitatively most important component of the overall surface water acidification and chemical recovery responses has been the change in base cation supply. Decreases in base cation concentrations in surface waters in the eastern U.S. have been ubiquitous over the past two to three decades and closely tied to trends in  $\text{SO}_4^{2-}$  concentrations in surface waters. Change in base cation supply with surface water acidification was highlighted in [Charles and Christie \(1991\)](#) and in the 2008 ISA. Base cations are added to watershed soils by weathering of minerals and atmospheric deposition, and are removed by uptake into growing vegetation or by leaching. Acidic deposition increased leaching of base cations, because  $\text{SO}_4^{2-}$  anions percolating through the soil tend to carry base cations along with them to maintain the charge balance. In watersheds that received high levels of historical acidic deposition, current exchangeable concentrations of  $\text{Ca}^{2+}$  and other base cations are substantially reduced from likely preindustrial levels, having been depleted by many years of acidic deposition. This base cation depletion in watersheds constrains ANC and pH recovery of surface waters, as described in the 2008 ISA. New studies of base cations, which include experiments, modeling, and gradient studies, have further corroborated these earlier findings.

Changes in DOC concentration or properties can affect the acid-base chemistry of surface waters and perhaps the composition of aquatic biota. In soils and water, DOC constitutes only a portion of dissolved organic matter (DOM), which also includes other constituents such as organic nitrogen, phosphorus, and sulfur. However, the very large majority of studies that include DOC do not explicitly include all of DOM. It has been recognized that surface water DOC concentrations decreased to some extent as a result of acidification, and that these concentrations would likely increase with recovery. However, the strength of this response and the magnitude of DOC changes have exceeded scientific predictions. Recent research on this topic has been diverse and has included experiments, observation, isotope studies, and synthesis and integration work.

Overall, these studies illustrate large increases in DOC with acidification recovery in some aquatic systems. Increases in DOC constrain the extent of ANC and pH recovery, but decrease the toxicity of dissolved Al by converting some of it from inorganic to organic forms ([Lawrence et al., 2013](#)). However, DOC is not an indicator of recovery everywhere; some recovering sites have not shown increasing trends in DOC.

#### **IS.6.1.1.2 Nitrogen Enrichment/Eutrophication**

In aquatic systems, N is a nutrient that stimulates growth of primary producers (algae and/or aquatic plants). Atmospheric deposition of N to freshwater systems can increase the absolute supply of nutrients and alter N and P ratios. The freshwater ecosystems in the U.S. most likely to be sensitive to nutrient enrichment from N deposition are headwater streams, lower order streams, and alpine lakes, which have very low nutrients and productivity and are far from local pollution sources ([U.S. EPA \(2008a\); Appendix 9.1.1.4](#)). These nutrient shifts alter stoichiometric composition of water chemistry, thereby shifting the nutrient status of lakes. Even small inputs of N in low nutrient water bodies can affect biogeochemical processing of N and increase the productivity of photosynthesizing organisms, resulting in a larger pool of fixed carbon (C). Nutrient enrichment leads to changes in aquatic assemblages and biodiversity in freshwater ([Appendix 9](#)) and coastal regions ([Appendix 10](#)).

Indicators of altered N cycling include changes in the concentrations of  $\text{NO}_3^-$  in surface waters. The concentration of  $\text{NO}_3^-$  in water provides an index of the balance between removal and addition of N to terrestrial ecosystems. Studies of several types have been conducted in recent years to elucidate these processes and include experimental studies, isotopic analyses, and monitoring and observational studies. Both water column and sediment N transformations have been further characterized ([Appendix 7.1.2.3](#)). New research suggests that denitrification may, in some situations, play a larger role than was previously recognized in the 2008 ISA in removing oxidized N from the watershed.

As reported in the 2008 ISA and in newer studies, atmospheric N has been positively correlated to total N in lakes along gradients of atmospheric deposition. N deposition in some high-deposition lakes has changed the nutrient status of these lakes from a more-or-less balanced (mainly N deficient) state to more consistently P limited conditions ([Appendix 9.2.4](#)). Since the 2008 ISA, several studies have reported increases in P deposition to water bodies in the U.S., possibly affecting shifts in lake trophic status from P to N limitation or colimitation, as well as prolonging N limitation ([Appendix 9.1.1.2](#)). In higher order streams, N deposition typically mixes with N derived from other nonatmospheric sources, including urban/suburban point and nonpoint

sources, industrial sources, and agricultural sources, with atmospheric sources typically being most pronounced during high flow conditions ([Table 7-2](#)).

---

### **IS.6.1.2 Models**

Models used to assess the effects of N and S deposition on U.S. ecosystems were reviewed in the 2008 ISA (Annex A). Several of the models used for terrestrial ecosystems (see [Section IS.5.3.3](#)) such as MAGIC and PnET/BGC are also applicable to aquatic systems. Both models have been widely applied, mainly to relatively small, upland watersheds. Three other models, Spatially Referenced Regressions on Watershed Attributes (SPARROW), Watershed Assessment Tool for Evaluating Reduction Scenarios for Nitrogen (WATERS-N), and Surface Water Assessment Tool (SWAT) have been used to evaluate N loading to mixed-use watersheds in larger river systems. Another model that has been applied to the analysis of nutrient enrichment in aquatic systems is AQUATOX, which simulates nutrient dynamics and effects on aquatic biota. Few new freshwater acidification or eutrophication models have been developed and published since 2008. A new national water quality modeling system (Hydrologic and Water Quality System, HAWQS) is under development by Texas A&M University and the USDA for the U.S. EPA's Office of Water (<https://epahawqs.tamu.edu/>). The model is intended to assist resource managers and policy makers in evaluating the effectiveness of water pollution control efforts. Freshwater eutrophication and acidification models are described in greater detail in [Appendix 7.1.4.2](#).

---

### **IS.6.1.3 National-Scale Sensitivity**

Sensitivity of lakes, streams, and rivers to biogeochemical changes associated with N and S deposition varies across the U.S. The biogeochemical sensitivity to acidifying deposition will be discussed together with biological sensitivity in [Section IS.6.2.2](#). Sensitivity to N enrichment will be discussed with biological sensitivity in [Section IS.6.3.2](#).

---

## **IS.6.2 Biological Effects of Freshwater Nitrogen Enrichment**

In the 2008 ISA, evidence was sufficient to infer a causal relationship between N deposition and the alteration of species richness, community composition, and biodiversity in freshwater ecosystems. The freshwater systems most affected by nutrient enrichment due to atmospheric deposition of N were remote oligotrophic high-elevation

lakes with low N retention capacity. In these ecosystems, N changes the biota, especially by increasing algal growth and shifting algal communities. Freshwater organism responses to N enrichment can be assessed through biological indicators, including chlorophyll *a*, phytoplankton and periphyton (algae attached to a substrate) biomass, diatoms, and trophic status. The current causal statement has been expanded to include effects on algal growth and productivity ([Table IS-1](#)). New evidence since 2008 of N enrichment includes paleolimnology, phytoplankton community dynamics, macroinvertebrate response, and indices of biodiversity. This new evidence is consistent with the conclusions and strengthens the evidence base of the 2008 ISA, and together, **the body of evidence is sufficient to infer a causal relationship between N deposition and changes in biota, including altered growth and productivity, species richness, community composition, and biodiversity due to N enrichment in freshwater ecosystems.**

---

### **IS.6.2.1 Physiology and Biodiversity Effects**

Inputs of N to freshwater systems stimulate algal growth, which leads to a cascade of effects on algal community composition and biodiversity. Algal species have differential responses to N loading and shifts in nutrient ratios, so dominant species may change in response to N enrichment. As reported in the 2008 ISA and in newer studies, shifts in nutrient limitation from N limitation to colimitation by N and P, or to P limitation, have been observed in some alpine lakes. New biodiversity studies are summarized in [Table 9-3](#). Since the 2008 ISA, several meta-analyses have reported an increase in P atmospheric deposition to water bodies, highlighting the need to account for how sustained P deposition can modify the effects of anthropogenically emitted N deposition on productivity ([Appendix 9.1.1.4](#)). P addition delays the shift to P limitation (prolonged N limitation) for phytoplankton.

#### **IS.6.2.1.1 Primary Producers**

The body of evidence for biological effects of N enrichment in remote freshwater systems (where atmospheric deposition is the predominant source of N) is greatest for phytoplankton, the base of the freshwater food web. Most studies focused on phytoplankton, although several new studies indicate that both benthic and pelagic primary producers respond to N inputs, and at least some studies have shown that periphyton outcompeted phytoplankton for limiting nutrients ([Appendix 9.3.3](#)). The 2008 ISA and new studies include lake surveys, fertilization experiments, and nutrient bioassays that show a relationship between increased N concentrations in the water

column and increased pelagic and benthic algal productivity (measured by chlorophyll *a* concentration). An increase in lake phytoplankton biomass with increasing N deposition was reported in the Snowy Range in Wyoming and in Europe. New studies in the Colorado Rocky Mountains, where atmospheric deposition ranged from 2 to 7 kg N/ha/yr, found correlations between higher chlorophyll *a* and higher rates of deposition ([Appendix 9.2.1](#)).

The 2008 ISA and newer studies ([Table 9-1](#) and [Appendix 9.3.2](#)) show a general shift in algal dominance from chrysophytes that dominate low N lakes to cyanophytes and chlorophytes in higher N lakes. Two nitrophilous species of diatom, *Asterionella formosa* and *Fragilaria crotonensis*, serve as indicators of N enrichment in lakes; however, increased relative abundance of *A. formosa* has also been attributed to lake warming in some regions where N deposition is decreasing ([Appendix 9.3.2](#)). New studies show that glacial meltwater has higher NO<sub>3</sub><sup>-</sup> relative to snow meltwater with different influences on algal community composition in some regions of the U.S. ([Appendix 9.3.2](#)). In a comparison of lakes in the Rockies with different meltwater sources, fossil diatom richness in snowpack-fed lakes was at least double the richness of lakes with both glacial and snow meltwater inputs; however, alterations in phytoplankton community structure were not observed in lakes in the northern Cascade Mountains, WA. Some shifts in algal biodiversity observed in high-elevation waters are attributed to climate change or nutrient effects and climate as costressors ([Appendix 13](#)).

The role of N in freshwater harmful algal bloom formation has been further researched since the 2008 ISA. Additional evidence continues to show that availability and form of N influences algal bloom composition and toxicity, and inputs of inorganic N selectively favor some HAB species, including those that produce microcystin. Microcystin is prevalent in U.S. waters as reported in recent regional and national surveys. The risk of HAB formation is low in high-elevation oligotrophic water bodies where N deposition is the dominant source of N, but transport of atmospheric inputs can exacerbate eutrophic conditions in downstream water bodies. Increased understanding of the role of N as a limiting nutrient in many freshwater systems has led to recommendations to consider both N and P in nutrient-reduction strategies.

Few studies in the U.S. have considered the effects of atmospheric deposition on aquatic macrophytes, although declines in macrophyte occurrence were noted in a new survey of Lake Tahoe that compared the lake's biota with that from a survey conducted in the 1960s ([Caires et al., 2013](#)). Atmospheric N contributions are a substantial portion (approximately 57%) of the total N loading to Lake Tahoe.

### **IS.6.2.1.2 Zooplankton**

Compared to changes in primary producers, biological responses to N deposition at higher trophic levels are not well characterized, but atmospheric N can alter food web interactions (see [Appendix 9.3.4](#)). A few studies in the 2008 ISA and newer studies showed zooplankton responses to N related shifts in phytoplankton biomass potentially altering food web interactions.

### **IS.6.2.1.3 Macroinvertebrates**

Few studies published since the 2008 ISA have linked atmospheric N deposition to taxonomic shifts and declines in invertebrates ([Appendix 9.3.5](#)). These studies do not attribute shifts in the abundance of higher invertebrates to N deposition alone, because their abundance is also determined by additional factors such as climate and the presence of invasive species. New studies provide additional evidence that trophic interactions may moderate algal growth following nutrient loading. In Lake Tahoe, which receives 57% of N inputs from atmospheric sources, endemic invertebrate taxa have declined 80 to 100% since the 1960s due to nutrient inputs and invasive species.

---

## **IS.6.2.2 National-Scale Sensitivity and Critical Loads**

New data have not appreciably changed the identification of sensitive lakes and streams in the U.S. since the 2008 ISA. Nutrient enrichment effects from N most likely occur in undisturbed, low-nutrient headwater and lower order streams and lakes at higher elevations in the western U.S. ([Appendix 9.1](#)), including the Snowy Range in Wyoming, the Sierra Nevada, and the Colorado Front Range. A portion of these lakes and streams where effects are observed are in Class I wilderness areas which are afforded special Clean Air Act protections. The responses of high-elevation lakes vary with catchment characteristics ([Appendix 9.1](#)) and N deposition estimates at these high elevation sites are associated with considerable uncertainty, especially dry deposition ([Appendix 2](#)). In these systems, even low inputs of atmospheric N can shift N limitation to colimitation by N and P, or to P limitation ([Appendix 9.2.4](#)), altering algal species composition and productivity.

In the 2008 ISA, diatom assemblage shifts were reported at N deposition rates as low as 1.5 kg N/ha/yr. Additionally, a hindcasting exercise in remote alpine Rocky Mountain National Park lakes associated algal changes between 1850 and 1964 with an increase in wet N deposition of 1.5 kg N/ha/yr. Since the 2008 ISA, empirical and modeled CLs for the U.S. have been estimated based on surface water  $\text{NO}_3^-$  concentration, diatom

community shifts, and phytoplankton biomass nutrient limitation shifts indicative of a shift from N limitation to P limitation. A CL ranging from 3.5 to 6.0 kg N/ha/yr was identified for high-elevation lakes in the eastern U.S. based on the nutrient enrichment inflection point [where  $\text{NO}_3^-$  concentrations increase in response to increasing N deposition; [Baron et al. \(2011b\)](#)]. Another CL of 8.0 kg N/ha/yr for eastern lakes based on the value of N deposition at which significant increases in surface water  $\text{NO}_3^-$  concentrations occur was estimated by [Pardo et al. \(2011c\)](#). In both Grand Teton and Yellowstone National Parks, CLs for total N deposition ranged from  $<1.5 \pm 1.0$  kg N/ha/yr to  $>4.0 \pm 1.0$  kg N/ha/yr ([Nanus et al., 2017](#)). Exceedance estimates were as high as 48% of the Greater Yellowstone area study region, depending on the threshold value of  $\text{NO}_3^-$  concentration in lake water selected as indicative of biological harm. An empirical CL of 4.1 kg N/ha/yr above which phytoplankton biomass P limitation is more likely than N limitation was identified by [Williams et al. \(2017b\)](#) for the western U.S. Modeled CLs ranged from 2.8 to 5.2 kg N/ha/yr.

---

### IS.6.3 Biological Effects of Freshwater Acidification

The 2008 ISA found evidence sufficient to infer a causal relationship between acidifying deposition and changes in aquatic biota, including strong evidence that acidified aquatic habitats had lower species richness of fishes, macroinvertebrates, and phytoplankton. The effects of acidifying deposition on aquatic ecosystems also include physiological impairment or mortality of sensitive species and shifts in biodiversity of both flora and fauna. Organisms at all trophic levels are affected by acidification, with clear linkages to chemical indicators for effects on algae, benthic invertebrates, and fish ([Table 8-9](#)). Biological effects are primarily attributable to low pH and high inorganic Al concentration. ANC integrates chemical components of acidification ([Table IS-2](#)) but does not directly alter the health of biota.

Effects of acidification on fish species are especially well characterized and many species are harmed. Both in situ and lifestage experiments in fish support thresholds of chemical indicators for biological effects. Most of these effects were documented in a rigorous review of acidification effects on aquatic biota that was included in the 2008 ISA. Overall, the updated research synthesized in this ISA reflects incremental improvements in scientific knowledge of aquatic biological effects and indicators of acidification as compared with knowledge summarized in the 2008 ISA. The fundamental understanding of mechanisms has not changed, and the causal relationships between acidifying deposition and biological effects on aquatic ecosystems are now, and were in 2008, well supported. New studies also show that despite reductions in acidifying deposition, alterations in aquatic biodiversity and ecosystem functioning caused by acidification

persist. Although there is evidence for chemical recovery in many ecosystems, biological recovery has been limited ([Section IS.6.2.2](#)). New research is consistent with the causal determination in the 2008 ISA and has strengthened the evidence base for these effects. The current causal statement has been expanded to include specific endpoints of physiological impairment, as well as effects at higher levels of biological organization ([Table IS-1](#)). **The body of evidence is sufficient to infer a causal relationship between acidifying deposition and changes in biota, including physiological impairment and alteration of species richness, community composition, and biodiversity in freshwater ecosystems.**

---

### IS.6.3.1 Physiology and Biodiversity Effects

The deterioration in water quality caused by acidification affects the physiology, survivorship, and biodiversity of many species from several taxonomic groups and at multiple trophic levels. As stated in the 2008 ISA, biological effects are primarily attributable to low pH (or ANC) and high inorganic Al concentrations under chronic or episodic acidic conditions. During acidification episodes, water chemistry may exceed the acid tolerance of resident aquatic biota, with effects that include fish mortalities, changes in species composition, and declines in species richness across multiple taxa. Studies reviewed in the 2008 ISA showed that the earlier aquatic lifestages were particularly sensitive to acidification. New effects thresholds have been identified for aquatic organisms consistent with observations in the 2008 ISA ([Table 8-10](#)). New evidence is congruent with findings in the 2008 ISA that high levels of acidification (to pH values below 5 and ANC lower than the range of 50 to 100 µeq/L) eliminate sensitive species from freshwater streams. This information is reviewed below.

#### IS.6.3.1.1 Primary Producers

Phytoplankton are primary producers at the base of the aquatic food web. These photosynthetic organisms vary in tolerance of acidic conditions and include diatoms, cyanobacteria, dinoflagellates, and other algal groups. The 2008 ISA reported reduced species richness of freshwater plankton in response to acidification-related decreases in pH and increases in inorganic Al. Effects were most prevalent when pH decreased to the 5 to 6 range. Effects on productivity are uncertain. Since the 2008 ISA, several paleolimnological and field studies have further linked phytoplankton community shifts to chemical indicators of acidification ([Appendix 8.3](#)). For example, [Lacoul et al. \(2011\)](#) reviewed information on the effects of acidification and observed that the largest declines in phytoplankton species richness occur over a pH range of 4.7 to 5.6 in Atlantic Canada.

#### **IS.6.3.1.2 Zooplankton**

Zooplankton comprise many groups of freshwater unicellular and multicellular organisms including protozoans, rotifers, cladocerans, and copepods. Zooplankton feed on phytoplankton or other zooplankton. Decreases in ANC and pH and increases in inorganic Al concentration have been shown to contribute to the loss of zooplankton species or abundance in lakes. In the 2008 ISA, thresholds for zooplankton community alteration were between pH 5 and 6. In the Adirondacks, a decrease in pH from 6 to 5 decreased zooplankton richness in lakes, and at ANC <0, zooplankton richness was only 45% of the richness in unacidified lakes. Newer studies support effects in a similar pH range (see [Appendix 8.3.1.2](#)). Zooplankton have also been used as indicators of biological recovery ([Appendix 8.4.2](#)).

#### **IS.6.3.1.3 Benthic Invertebrates**

Acidification has strong impacts on aquatic invertebrates because H<sup>+</sup> and Al are directly toxic to sediment-associated invertebrates like bivalves, worms, gastropods, and insect larvae. In the 2008 ISA and in new studies in [Appendix 8.3.3](#), decreases in ANC and pH and increases in inorganic Al concentration contribute to declines in abundance or extirpation of benthic invertebrate species in streams. Acidification to pH values below 5 eliminates mayflies (Ephemeroptera), a taxa indicative of stream water quality, along with other aquatic organisms. Since the 2008 ISA, a survey of benthic macroinvertebrates by [Baldigo et al. \(2009\)](#) in the Adirondack Mountains indicated that macroinvertebrate communities were intact at a pH above 6.4, with moderate acidification effects at pH 5.1 to 5.7, and severe acidification effects at a pH less than 5.1. Similarly, thresholds of pH 5.2 to 6.1 were identified for sensitive invertebrates from Atlantic Canada ([Appendix 8.3.3](#)).

#### **IS.6.3.1.4 Fish**

The effects of low pH and ANC and of high inorganic Al concentrations have been well characterized in fish for many decades ([Appendix 8.3.6](#)). The 2008 ISA reported that acidification impairs gill function and can cause respiratory and circulatory failure in fish. Sensitivity to pH and inorganic Al varies among fish species, and among lifestages within species, with early lifestages more sensitive to acidification. The most commonly studied species were brown trout (*Salmo trutta*), brook trout (*Salvelinus fontinalis*), and Atlantic salmon (*Salmo salar*). Studies published since the 2008 ISA, especially in Atlantic salmon, add to the existing information on sublethal effects and confirm variation in

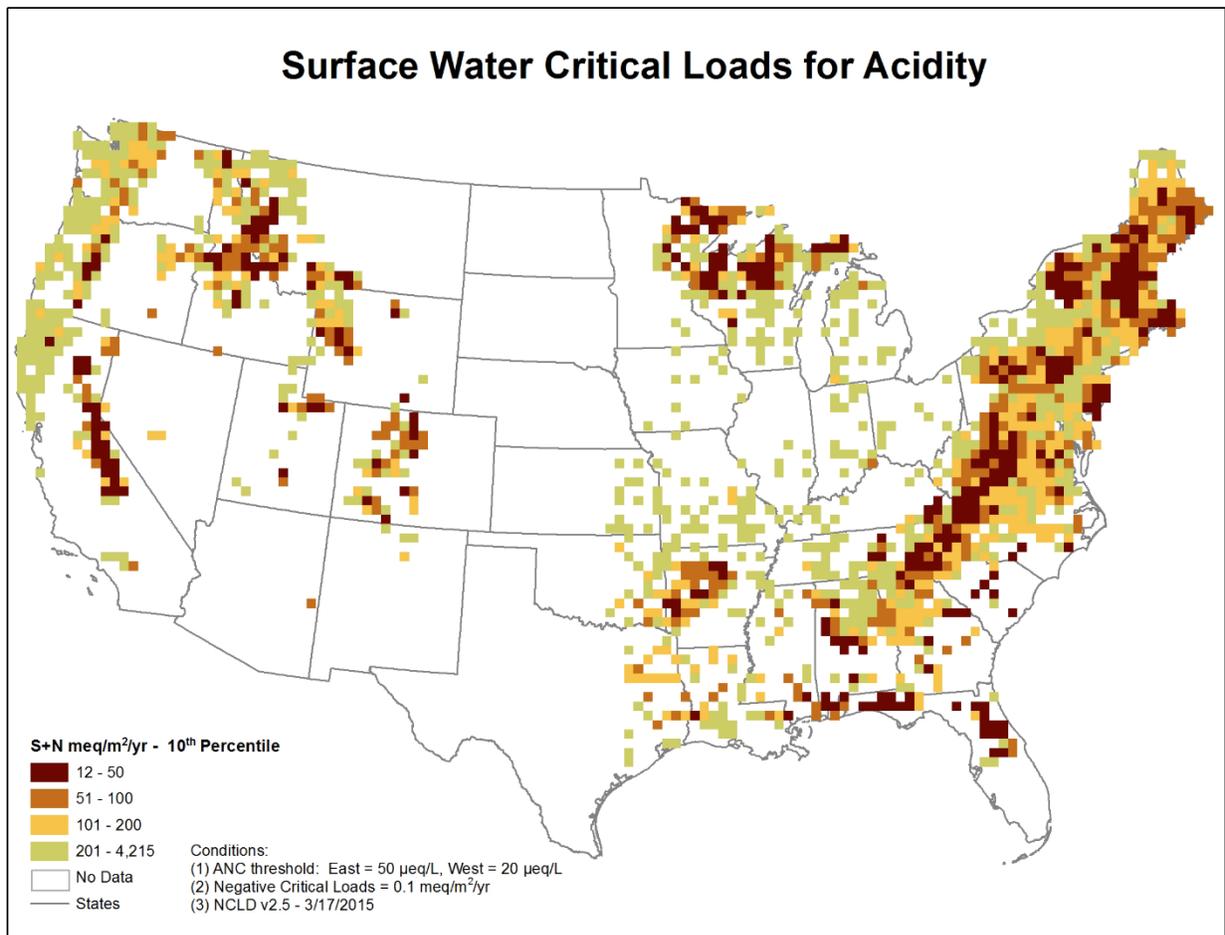

sensitivity among lifestages ([Appendix 8.3.6.1](#)). Since 2008, new studies include acidification effects on migratory activities and behavior. New studies on fish show behavioral effects at pH <6.6 ([Appendix 8.3.6.5](#)).

As summarized in [Baker et al. \(1990a\)](#) and the 2008 ISA, fish populations in acidified streams and lakes of Europe and North America have declined, and some have been eliminated as a result of atmospheric deposition of N and S and the resulting changes in pH, ANC, and inorganic Al concentrations in surface waters. There is often a positive relationship between pH and the number of fish species, particularly between pH 5.0 and 6.5. Additional pH thresholds published since the 2008 ISA ([Table 8-2](#)) support this range, and several new studies consider the role of DOC in controlling pH and subsequent effects on biota. In the 2008 ISA and in new research, few or no fish species are found in lakes and streams that have very low ANC (near zero; [Figure 8-4](#) and [Table 8-3](#)) and low pH (near 5.0). The number of fish species generally increases at higher ANC and pH values. Al is very toxic to fish, and thresholds to elevated concentrations of this metal in acidified waters are summarized in [Table 8-4](#).

---

### **IS.6.3.2 National-Scale Sensitivity, Biological Recovery, and Critical Loads**

The extent and distribution of acid-sensitive freshwater ecosystems and sensitive regions in the U.S. were well known at the time of the 2008 ISA. Measured data on lake and stream ANC across the U.S. exhibit clear spatial patterns ([Figure 8-11](#)). Surface waters in the U.S. that are most sensitive to acidification are largely found in the Northeast, southern Appalachian Mountains, Florida, the upper Midwest, and the mountainous West ([Figure IS-12](#)). Levels of acidifying deposition in the West are low in most areas and rare in acidic surface waters, and the extent of chronic surface water acidification to date has been very limited. However, episodic acidification occurs in both the East and West at sensitive locations, and this is partly natural and partly caused by humans. Geographic patterns in acidification sensitivity vary in response to spatial differences in geology, hydrologic flow paths, presence and depth of glacial till, climate, and other factors ([Appendix 8.5.1](#)). In the eastern U.S., acid-sensitive ecosystems are generally located in upland, mountainous terrain underlain by weathering-resistant bedrock. Some of the most in-depth studies of the effects of acid stress on fish were conducted in streams in Shenandoah National Park in Virginia and in lakes in the Adirondack Mountains of New York. Effects on fish have also been documented in acid-sensitive streams of the Catskill Mountains of southeastern New York, and the Appalachian Mountains from Pennsylvania to Tennessee and South Carolina.

ANC = acid-neutralizing capacity; meq = milliequivalent; yr = year.

Source: <http://nadp.slh.wisc.edu/committees/clad>.

**Figure IS-12** Surface water critical loads for acidity in the U.S. 10th percentile aggregation for 36-km<sup>2</sup> grids with sulfur (S) and nitrogen (N).

Biological recovery in acid-affected areas is discussed in [Section IS.11](#). Typically, biological recovery occurs only if chemical recovery ([Appendix 7.1.5.1](#)) is sufficient to allow growth, survival, and reproduction of acid-sensitive plants and animals. Surface water chemistry recovery varies by region, with the strongest evidence for improvement in the Northeast and little or no recovery in central Appalachian streams. Acidification and recovery of fresh waters will also be affected by the physical, chemical, and biological modifications to acid inputs projected to occur with changes in annual mean temperature and magnitude of precipitation ([Appendix 8.5.3](#)). As reported in the 2008 ISA and in new studies, biological recovery is slower than chemical recovery in many

systems (see [Appendix 8.4](#)). The time required for biological recovery is unknown and only partial biological recovery may be possible.

Since the 2008 ISA, considerable CL research has focused on aquatic acidification in the U.S. The CLs for deposition for aquatic acidification are expressed in eq/ha/yr of S, N, or S + N because one or both pollutants can contribute to the observed effects. New empirical CLs include 571 eq N/ha/yr in the Northeast and 286 eq N/ha/yr in the West to prevent episodic acidification in high-elevation lakes ([Table 8-7](#)). Steady-state CLs have been derived at many locations since the 2008 ISA ([Table 8-8](#)). Steady-state CLs of acidifying deposition for lakes in the Adirondack Mountains (1,620 eq/ha/yr) and for the central Appalachian streams (3,700 eq/ha/yr) were calculated to maintain a surface water ANC of 50  $\mu\text{eq/L}$  on an annual basis ([NAPAP, 2011](#)). CL values of less than 500 eq/ha/yr were calculated for one-third of streams in the Blue Ridge ecoregion, to maintain stream ANC at 50  $\mu\text{eq/L}$ . For lakes in Class I and II wilderness areas in the Sierra Nevada, CLs for acidifying deposition in 2008 were estimated at ANC values of 0, 5, 10, and 20  $\mu\text{eq/L}$ , which span the range of minimum ANC values observed in Sierra Nevada lakes. The median CL for granitic watersheds based on a critical ANC limit of 10  $\mu\text{eq/L}$  was 149 eq/ha/yr. Slightly more than one-third of these lakes had estimated rates of acidifying deposition higher than their CL.

In addition to the steady-state and empirical loads described above, CL estimates have been derived from dynamic modeling ([Appendix 8.5.4](#)). For example, there is new work on simulated past and future effects of N and S on stream chemistry in the Appalachians and Adirondack Mountain lakes. In 12 watersheds in the Great Smoky Mountain National Park, target levels of ANC to protect aquatic life were used and ranged from minimal (0  $\mu\text{eq/L}$ ) to considerable protection (50  $\mu\text{eq/L}$ ). For the 12 study streams, target levels of  $\text{NO}_3^- + \text{SO}_4^{2-}$  deposition ranged from 270 to 3,370 eq/ha/yr to reach an ANC of 0  $\mu\text{eq/L}$  by 2050 and 0 to 1,400 eq/ha/yr to reach an ANC of 50  $\mu\text{eq/L}$  by 2050. However, the majority of streams could not achieve the ANC target of 50  $\mu\text{eq/L}$ . Modeling also suggests that complete recovery from acidification may not be possible by the year 2100 at all sites in the southern Blue Ridge region ([Sullivan et al., 2011b](#)) even if S emissions cease entirely. In Shenandoah National Park, MAGIC modeling based on simulations of 14 streams identified a target load of about 188 eq S/ha/yr to achieve an ANC = 50  $\mu\text{eq/L}$  (preindustrial level based on hindcast simulations) in 2100 in sensitive streams. In a dynamic modeling simulation in the Adirondack Mountains, about 30% of the lakes in the region had a target load <500 eq/ha/yr to protect lake ANC to 50  $\mu\text{eq/L}$  ([Sullivan et al., 2012a](#)). Future decreases in  $\text{SO}_4^{2-}$  deposition are suggested to be more effective in that region in increasing Adirondack lake water ANC than equivalent decreases in  $\text{NO}_3^-$  deposition. In another modeling study of 20 Adirondack watersheds, estimates of

preindustrial ANC for the study lakes ranged from 18 to 190  $\mu\text{eq/L}$ , and simulations estimate that lake ANC has decreased by 26 to 100  $\mu\text{eq/L}$  as a legacy of acidification.

---

## **IS.7 Estuarine and Near-Coastal Ecosystem Nitrogen Enrichment**

For estuaries (areas where fresh water from rivers meets the salt water of oceans) and near-coastal systems, causality determinations from the 2008 ISA are further supported and strengthened by additional studies ([Table IS-1](#)). Estuaries support a large biodiversity of flora and fauna and play a role in nutrient cycling. N from the atmosphere and other sources contributes to increased primary productivity, leading to eutrophication ([Table 10-1](#)), and N pollution is the major cause of harm to most estuaries in the U.S. ([Appendix 10](#)). Source apportionment data in the 2008 ISA and newer studies indicate that atmospheric contributions to estuarine N are heterogeneous across the U.S., ranging from <10% to approximately 70% of total estuary N inputs ([Table 7-9](#)). In estuaries, increasing nutrient over-enrichment leading to eutrophication is indicated by water quality deterioration, resulting in numerous harmful effects, including areas of low dissolved oxygen (DO) concentration (hypoxic zones), species mortality, and HABs. New studies support the 2008 ISA's causal findings that increased N loading to coastal areas can alter biogeochemical processes and lead to shifts in community composition, reduced biodiversity, and mortality of biota. The current causal statement of biological effects of N enrichment in estuarine ecosystems has been expanded to include total primary production, altered growth, and total algal community biomass ([Table IS-1](#)).

---

### **IS.7.1 Estuary and Near-Coastal Biogeochemistry**

In the 2008 ISA, the evidence was sufficient to infer a causal relationship between reactive N deposition and biogeochemical cycling of N and C in estuarine and near-coastal marine systems. Evidence reviewed in the 2008 ISA, along with new studies, indicates elevated N inputs to coastal areas can alter key processes that influence N and C cycling in near-coastal environments. As external organic matter loading to coastal areas has increased in recent decades in many parts of the U.S., the varying rates of different N cycling processes within estuaries themselves can also affect the magnitude of eutrophication experienced as a result of external N enrichment. Nitrogen additions not only cause the total pool of N to be larger but may also perturb N cycling in such a way that the system may exacerbate eutrophication to a greater extent than expected based on N additions alone. Research conducted since the 2008 ISA has shown that many of these N cycling processes are more important in the estuarine environment than previously understood. The removal of N through denitrification is a valuable ecosystem service in

terms of constraining the extent and magnitude of eutrophication. Additional research has established dissimilatory  $\text{NO}_3^-$  reduction to  $\text{NH}_4^+$  (DNRA) as a more important N reduction pathway in some estuaries. Ammonium produced via DNRA can lead to enhanced productivity and respiration, which may exacerbate hypoxia. Recent studies indicate that DNRA rates are higher in warmer months and can also take up a larger percentage of total N reduction activity when temperatures are higher. The roles of sedimentary microbial processes of denitrification and  $\text{N}_2$  production via anaerobic ammonium oxidation (anammox) have been further characterized. New research has shown that the community of N fixing microorganisms is more diverse in estuarine and coastal waters than previously thought, and that N fixation occurs more widely than previously assumed. Influence of benthic macrofauna on N cycling has received increased research attention in part due to the potential for these organisms to mitigate external N enrichment. Along with atmospheric anthropogenic  $\text{CO}_2$  inputs and other factors, eutrophication from N loading may affect carbonate chemistry in coastal areas, contributing to acidifying conditions in some circumstances such as where there is spatial or temporal decoupling of production and respiration processes. Monitoring of coastal areas shows that excess nutrient inputs continues to be a widespread problem in many parts of the U.S. New research further supports conclusions of the 2008 ISA, and **the body of evidence is sufficient to infer a causal relationship between N deposition and the alteration of biogeochemistry in estuarine and near-coastal marine systems.**

---

### IS.7.1.1 Nitrogen Enrichment

Estuarine biogeochemistry is complicated because it directly controls more than just the N cycle; the response to N loading resulting in eutrophication affects the chemical cycling of metals and DO ([Appendix 7.2.3](#)), redox conditions, pH ([Appendix 7.2.4](#)), and ultimately energy transfer (e.g., food webs from microbes to humans). The response to N loading is also tightly controlled by the availability of organic matter (i.e., C) and its lability and reactivity. External organic matter loading to estuarine and coastal waters appears to be increasing and these excess nutrient inputs are occurring within the context of other stressors such as climate change ([Appendix 7.2.6.12](#)) and rising atmospheric  $\text{CO}_2$ , which further modify coastal biogeochemistry ([Doney, 2010](#)). As reported in the 2008 ISA, estuaries are generally N limited, and have received sufficiently high levels of N input from human activities (including deposition, agricultural runoff, and wastewater) to cause eutrophication. Highly variable environments within estuaries are characterized by a gradient of increasing salinity toward the ocean. As N moves downstream, some fraction is taken up by phytoplankton or removed by microbial denitrification. Key processes that influence N cycling include hypoxia, nitrification, denitrification, and

decomposition. Until recently, it was generally believed that  $\text{NH}_3$  oxidation was accomplished only by Proteobacteria in marine environments. New research has discovered that some archaea can also oxidize  $\text{NH}_3$ . These ammonia-oxidizing archaea are dominant in some estuaries, while ammonia-oxidizing bacteria are more important in others.

In the complex environment of the freshwater-to-ocean continuum, there are many chemical and biological indicators of eutrophic condition. One approach is to measure total nutrient loading and concentrations; however, these data need to be interpreted in the context of the physical and hydrological characteristics that determine ecosystem response. Water quality measures such as pH and DO, along with key biological indicators such as chlorophyll *a*, phytoplankton abundance, HABs, macroalgal abundance, and submerged aquatic vegetation (SAV; rooted vascular plants that do not emerge above the water), can all be used to assess responses to nutrient loading ([Table 10-1](#)). Nitrogen removal from the estuary is also influenced by faunal as well as microbial communities.

Organic particles in coastal regions sink to the sediment-water interface where they accumulate and decompose. Decomposition of these organic particles transforms nutrients and depletes  $\text{O}_2$  in the water. Decreasing DO can create hypoxic (<2 mg/L of dissolved  $\text{O}_2$ ) or anoxic zones inimical to fish and other aerobic life forms. Oxygen depletion largely occurs only in bottom waters under stratified conditions, not throughout the entire water column. This can result in seasonal hypoxia in shallow coastal regions, particularly those that are receiving high inputs of nutrients from coastal rivers. Development of hypoxia is increasingly a concern in estuaries across the U.S. ([Appendix 10.2.4](#)).

Since the 2008 ISA, a number of papers have identified links between nutrient enrichment and effects on estuarine carbonate chemistry, resulting in coastal acidification or basification ([Appendix 7.2.4](#)). Eutrophication and acidification/basification are complex biogeochemical processes that are driven by the same hydrological (stratification) and biological (production/respiration) processes that can result in hypoxia and enhanced organic matter loading. Acidification can occur by direct atmospheric anthropogenic  $\text{CO}_2$  dissolution into the ocean. But under certain conditions N enrichment can contribute to acidifying/basifying conditions, such as in systems with strong thermal stratification or with spatial or temporal decoupling of production and respiration processes. With increasing N inputs to coastal waters,  $\text{CO}_2$  in the water column is produced from degradation of excess organic matter from changing land use, as well as respiration of living algae and seagrasses, which in turn can make the water more acidic.

Estuarine carbonate chemistry is complex, responding to a wide variety of natural, anthropogenic, physical (mixing), chemical and biological drivers.

---

### IS.7.1.2 Models

Since the 2008 ISA, several new applications of existing models have quantified eutrophication processes in estuaries and near-coastal marine ecosystems. These have included studies that focused primarily on N cycling or hypoxia. Other models of estuarine eutrophication focus on N load apportionment, or on relationships between N loads and ecological endpoints. Since the 2008 ISA, SPARROW has been used to estimate total N loads within watersheds to determine sources of N to streams and rivers; it has also been applied at regional and national scales. Additional models and tools that include the contribution of N directly from the atmosphere have been applied to U.S. estuaries, including the Watershed N Loading Model (NLM) and the Watershed Deposition Tool (WDT). The latter was developed by the U.S. EPA to map atmospheric deposition estimates to watersheds using wet and dry deposition data from CMAQ ([Schwede et al., 2009](#)). This tool links air and water quality modeling data for use in total maximum daily load (TMDL) determinations and analysis of nonpoint-source impacts. New model applications include studies that focused primarily on endpoints of N cycling, hypoxia, and HABs. Models of coastal eutrophication are described in greater detail in [Appendix 7.2.8](#).

---

### IS.7.1.3 National-Scale Sensitivity

Sensitivity of estuaries to biogeochemical changes associated with N enrichment varies across the U.S. The biogeochemical sensitivity of estuaries and near coastal areas will be discussed together with national-scale biological sensitivity to N enrichment in [Section IS.7.3](#).

---

## IS.7.2 Biological Effects of Nitrogen Enrichment

In the 2008 ISA, evidence was sufficient to infer a causal relationship between N deposition and the alteration of species richness, community composition, and biodiversity in estuarine ecosystems. The strongest evidence for a causal relationship was from changes in biological indicators of nutrient enrichment (chlorophyll *a*, macroalgal [seaweed] abundance, HABs, DO, and changes in SAV; [Table 10-1](#)). Some indicators, such as chlorophyll *a*, are directly linked to nutrient enrichment and provide evidence of

early ecosystem response; other indicators, such as low DO and decreases in SAV, indicate more advanced eutrophication. Phytoplankton are the base of the coastal food web and increases in primary producer biomass and altered community composition associated with increased N can lead to a cascade of direct and indirect effects at higher trophic levels. At the time of the 2008 ISA, N was recognized as the major cause of harm to the most estuaries in the U.S. Since 2008, new paleontological studies, observational studies, and experiments have further characterized the effects of N on phytoplankton growth and community dynamics, macroinvertebrate response, and other indices of biodiversity. For this ISA, new information is consistent with the 2008 ISA and the causal determination has been updated to reflect more specific categories of effects to include total primary production, altered growth, and total algal community biomass. This new research strengthens the evidence base and is consistent with the 2008 ISA ([Table IS-1](#)) that **the body of evidence is sufficient to infer a causal relationship between N deposition and changes in biota including total primary production, altered growth, total algal community biomass, species richness, community composition, and biodiversity due to N enrichment in estuarine environments.**

Since the 2008 ISA, additional evidence has shown that reduced forms of atmospheric N play an increasingly important role in estuarine and coastal eutrophication and HAB dynamics. New studies emphasize that N inputs interact with physical and hydrologic factors to increase primary productivity and eutrophication in coastal areas. Climate-related changes in temperature, precipitation, and wind patterns, as well as extreme weather events, stronger estuary stratification, increased metabolism and organic production, and rising sea-levels are all expected to modify coastal habitats ([Appendix 10.1.4.1](#)).

---

### IS.7.2.1 Primary Producers

Algae are the base of the coastal food web, and the 2008 ISA showed that changes in chemical composition of N inputs can shift the algal community and cascade up the food web. Chlorophyll *a* is a broadly recognized indicator of phytoplankton biomass and is used as a proxy for assessing effects of estuarine nutrient enrichment. It can signal an early stage of water quality degradation related to nutrient loading and is incorporated into water quality monitoring programs and national-scale assessments including U.S. EPA's National Coastal Condition Assessment ([Appendix 7.2.7](#)). Phytoplankton sampling, microcosms studies, and sediment core analysis have shown changes in phytoplankton community structure in estuaries with elevated N inputs ([Appendix 10.3](#)). These shifts at the base of the food web to species that are not as readily grazed (e.g., cyanobacteria, dinoflagellates) have a cascade of effects including poor trophic

transfer and an increase in unconsumed algal biomass, which could stimulate decomposition and O<sub>2</sub> consumption, and thus increase the potential for hypoxia.

There is consistent and coherent evidence that the incidence of HAB outbreaks is increasing in both freshwater and coastal areas, a problem that has been recognized for several decades ([Appendix 10.2.2](#)). Of the 81 estuary systems for which data were available for the National Estuarine Eutrophication Assessment (NEEA), 26 exhibited a moderate or high symptom expression for nuisance or toxic algae ([Bricker et al., 2007](#)). Since the 2008 ISA, HAB conditions and effects of HAB toxins on wildlife have been further characterized ([Appendix 10.2.2](#)). Toxins released during HABs can be harmful to fish and shellfish and may be transferred to higher trophic levels. The form of N affects phytoplankton growth and toxin production of some HAB species. Increasing loads of NH<sub>3</sub><sup>+</sup>/NH<sub>4</sub><sup>+</sup> have been linked to the expansion of HABs and altered phytoplankton community dynamics ([Appendix 10.3.3](#)). Cyanobacteria, and many chlorophytes and dinoflagellates, may be better adapted to NH<sub>4</sub><sup>+</sup>, while diatoms generally thrive in the presence of oxidized forms of N such as NO<sub>3</sub><sup>-</sup> ([Figure 10-7](#)).

Macroalgal (seaweed) growth is also stimulated by increased N inputs, which increase the dominance of faster growing benthic or pelagic macroalgae to the exclusion of other species ([Appendix 10.2.3](#)). Studies published since the 2008 ISA provide further evidence that macroalgae respond to the form of N, with some species showing greater assimilation and growth rates with NH<sub>4</sub><sup>+</sup> than with NO<sub>3</sub><sup>-</sup>. Increased abundance of macroalgae, which block light, and increased epiphyte loads on the surface of SAV may reduce the growth and biomass of SAV. SAV, including the eelgrass *Zostera marina*, are important ecological communities found within some coastal bays and estuaries that are sensitive to elevated nutrient loading, and the loss of this habitat can lead to a cascade of ecological effects because many organisms are dependent upon seagrasses for cover, breeding, and as nursery grounds. Recently, the presence of seagrass beds was linked to decreased bacterial pathogens of humans, fishes, and invertebrates in the water column and lower incidence of disease in adjacent coral reefs ([Appendix 10.2.5](#)). The 2008 ISA reported correlations between increased N loading and declines in SAV abundance, and newer studies have further characterized this relationship. In a survey of southern New England estuaries, reduced eelgrass extent was observed at increased watershed N loading. New studies have characterized the role of invertebrate mesograzers, such as small crustaceans and gastropods, in controlling algal growth, potentially buffering eutrophication effects on seagrass communities ([Appendix 10.3.7](#)). Macroalgae may not be a good indicator of eutrophication in some upwelling-influenced estuaries in the Pacific Northwest because an increase in macroalgal biomass in these systems does not appear to be associated with temporal declines in eelgrass ([Appendix 10.2.3](#)).

---

### IS.7.2.2 Bacteria and Archaea

Ammonia-oxidizing prokaryotes carry out nitrification in estuarine waters.

Ammonia-oxidizing archaea have been described relatively recently, and several studies since the 2008 ISA have considered community responses of ammonia-oxidizing bacteria and archaea. Community structure of ammonia-oxidizers is related to nutrient inputs and affected by the form of available N ([Appendix 10.3.4](#)).

---

### IS.7.2.3 Invertebrates

In coastal areas with severe seasonal hypoxia, the community of benthic organisms shifts toward shorter life spans and smaller body size ([Appendix 10.2.4](#)). Reduced species density and diversity in the northern Gulf of Mexico are linked to persistent hypoxic events. The form of N present has been shown to affect molluscan taxonomic assemblages ([Appendix 10.3.5](#)). Shifts in algal composition and productivity can affect growth of shellfish that feed on phytoplankton. Shellfish contribute to N and C cycling and can improve water quality, and recent research has explored the use of these organisms for coastal N remediation ([Appendix 7.2.6.11](#)). Harvest of shellfish for human consumption removes nutrients from estuaries.

N enrichment is one of several factors linked to increased disease susceptibility, bleaching, and reduced calcification rate in corals ([Appendix 10.4.2](#)). Several studies have isolated effects of N, which affects corals via pathways that are distinct from P. The threatened status of staghorn coral (*Acropora cervicornis*) and elkhorn coral (*Acropora palmata*) under the U.S. Endangered Species Act has been linked to indirect N pollution effects, specifically low DO, algal blooms that alter habitat, and other non-nutrient stressors ([Hernández et al., 2016](#)). Increasing acidification of coastal waters, which may be exacerbated by elevated N inputs under certain circumstances ([Appendix 7.2.4](#)), is projected to alter marine habitat, have a wide range of effects at the population and community level and affect food web processes. Although the interactions between elevated CO<sub>2</sub>, decreasing pH, and nutrient inputs are complex, calcareous plankton, oysters, clams, sea urchins, and coral that produce calcium carbonate shells may be affected by long-term decreases in pH ([Appendix 10.5](#)).

---

### IS.7.2.4 Fish

Fish biodiversity is altered by increased N inputs and resulting changes in biological and chemical indicators ([Appendix 10.3.6](#)). Many fish are unable to persist at DO levels

below 2 mg/L ([Figure 10-4](#)). Recent studies in the southern Gulf of Saint Lawrence have linked SAV loss to declines in fish biodiversity, although organisms did not change positions within food webs. In laboratory conditions, turbidity associated with eutrophication alters fish reproductive behaviors. Hypoxia has also recently been shown to affect reproduction in fish. For example, hypoxia acts as an endocrine disruptor in Atlantic croaker (*Micropogonias undulatus*; [Appendix 10.2.4](#)).

---

### IS.7.3 National-Scale Sensitivity and Critical Loads

The NEEA, the most recent comprehensive survey of eutrophic conditions in U.S. estuaries conducted by the National Oceanic and Atmospheric Administration, defined eutrophication susceptibility as the natural tendency of an estuary to retain or flush nutrients ([Bricker et al., 2007](#)). In estuaries that have longer water residence times, nutrients are more likely to lead to eutrophic conditions ([Appendix 10.1.4](#)). As reported in the 2008 ISA and newer studies, nutrient loading accelerates hypoxia, which is more likely in marine waters with limited water exchange, water column stratification, and high production and settling of C to bottom waters. Other factors identified in the 2008 ISA that increase estuary sensitivity to eutrophication include human population, agricultural production, and the size of the estuary relative to its drainage basin. The NEEA reported that the most eutrophic estuaries in the U.S. occur in the mid-Atlantic region, and the estuaries with the lowest degree of eutrophication are in the North Atlantic ([Figure 10-2](#)). Estuaries identified in the 2008 ISA as susceptible to eutrophication include the Chesapeake Bay, Pamlico Estuary in North Carolina, Long Island Sound, as well as along the continental shelf adjacent to the Mississippi and the Atchafalaya River discharges to the Gulf of Mexico. New research at the regional scale includes long-term studies of several coastal systems that are looking at trends in coastal water quality and chemistry. A 23-year study of the Chesapeake Bay concluded that water quality has decreased and chlorophyll *a* levels have increased since 1986, in part due to long-term climate trends (see [Appendix 10.2.5](#)).

Since the 2008 ISA, there is additional information on the extent and severity of eutrophication and hypoxia in sensitive regions. Areas of eutrophication-related hypoxia are found on the U.S. eastern and western coasts and the Gulf of Mexico ([Figure 10-5](#)). The 2008 ISA reported that the largest zone of hypoxic coastal water in the U.S. was the northern Gulf of Mexico on the Louisiana-Texas continental shelf. In the summer of 2017, the hypoxic zone in the Gulf was the largest ever measured at 14,123 km<sup>2</sup> [8,776 mi<sup>2</sup>; [U.S. EPA \(2017f\)](#)]. Atmospheric deposition to watersheds in the Mississippi/Atchafalaya River Basin contributes approximately 16 to 26% of the total N load to the Gulf of Mexico ([Appendix 10.2.4](#)). Long Island Sound also experiences

periods of anoxia. In other U.S. coastal systems, hypoxia incidence is increasing, but DO impacts are relatively limited temporally and spatially. In the Pacific Northwest, coastal upwelling not related to anthropogenic sources can be a large source of nutrient loads, and the advection of this upwelled water can introduce hypoxic water into estuaries.

The NEEA suggested that only a small fraction of the estuary systems evaluated showed moderate to high SAV loss ([Bricker et al., 2007](#)), mostly in the mid-Atlantic region.

While seagrass coverage is improving in some estuaries, such as Tampa Bay (Tampa Bay Case Study, [Appendix 16](#)), many estuaries continue to see declines in seagrass extent. SAV is often at a competitive disadvantage under N enriched conditions because of the fast growth of opportunistic macroalgae that preferentially take up  $\text{NH}_4^+$  and can block light from seagrass beds.

There are thresholds of response identified for some biological and chemical indicators of N enrichment in estuaries ([Appendix 10](#)). The amount of chlorophyll *a* is an indicator of phytoplankton biomass, and thus, a proxy for assessing estuarine nutrient enrichment. In general, 0–5  $\mu\text{g/L}$  chlorophyll *a* is considered a good condition, concentrations between 5 and 20  $\mu\text{g/L}$  are classified as fair condition, and concentrations of >20  $\mu\text{g/L}$  indicate poor conditions ([Table 10-2](#)). A new response threshold of tidal-averaged total N concentration of <0.34 mg/L has been identified for healthy eelgrass in Massachusetts waters. Markedly decreased eelgrass coverage is observed at N loading rates  $\geq 100$  kg N/ha/yr, and levels above 50 kg N/ha/yr are likely to impact SAV habitat extent in shallow New England estuaries ([Table 10-4](#)). [Greaver et al. \(2011\)](#) identified the range of 50–100 kg N/ha/yr total N loading as the empirical CL for loss of eelgrass based on [Latimer and Rego \(2010\)](#). In terms of DO, concentrations of 0 mg/L are anoxic, 0–2 are indicative of hypoxic conditions, and 2–5 mg/L are biologically stressful conditions ([Figure 10-4](#)). Oxygen depletion largely occurs only in bottom waters under stratified conditions, not throughout the entire water column.

The indicators of nutrient enrichment in coastal areas (chlorophyll *a*, HABs, macroalgal abundance, DO, SAV, and benthic diversity) have been incorporated into indices of coastal eutrophication. In the 2008 ISA, the Assessment of Estuarine Tropic Status (ASSETS) categorical Eutrophication Condition index (ECI) developed for the NEEA was used as an assessment framework for coastal U.S. estuaries ([Bricker et al., 2007](#)). Additional indices of estuarine functioning that incorporate biological indicators have since been developed both in the U.S. and internationally ([Appendix 10.2.6](#)).

Comparisons of these frameworks have identified robust methods to measure estuarine response, such as incorporation of annual data, frequency of occurrence, spatial coverage, secondary biological indicators, and a multicategory rating scale.

Since the 2008 ISA, N enrichment has been linked to coral bleaching and reduced calcification rates ([Appendix 10.4.2](#)). Near-coastal coral reefs in the U.S. occur off south Florida, Texas, Hawaii, and U.S. territories in the Caribbean and Pacific.

---

## IS.8 Wetland Ecosystem Nitrogen Enrichment and Acidification

New evidence, including new CLs, supports and strengthens the causal findings from the 2008 ISA regarding N enrichment effects in wetlands ([Table IS-1](#)). In freshwater wetlands and coastal wetland ecosystems, deposition of N and S does not tend to cause acidification-related effects at levels currently common in the U.S. However, the 2008 ISA documented that wetlands can be sensitive to N enrichment and eutrophication effects. Newer studies have characterized N effects on biogeochemistry, physiology, biodiversity, national sensitivity, and CLs for freshwater and coastal wetlands; coastal wetlands are typically tolerant of higher N loading than freshwater wetlands.

---

### IS.8.1 Wetland Biogeochemistry

In the 2008 ISA, evidence was sufficient to infer a causal relationship between N deposition and the alteration of wetland biogeochemical cycling. Although sources and rates of N inputs vary widely among wetlands, N deposition contributes substantially to total loading in many wetlands. This additional N alters C cycling, N cycling, and the release of nutrients to hydrologically connected surface waters. New research together with the information included in the 2008 ISA shows that **the body of evidence is sufficient to infer a causal relationship between N deposition and the alteration of biogeochemical cycling in wetlands.**

The 2008 ISA reported that N enrichment altered N cycling in wetland ecosystems. Chemical indicators of N deposition in wetlands include  $\text{NO}_3^-$  and  $\text{NH}_4^+$  leaching, DON leaching, N mineralization, denitrification rates, and  $\text{N}_2\text{O}$  emissions. A wetland can act as a source, sink, or transformer of atmospherically deposited N, and these functions vary with season and hydrological conditions. Vegetation type, physiography, local hydrology, and climate all influence source/sink N dynamics in wetlands. A new synthesis of global wetland data showed that a wetland's reactive N removal and water quality improvement is proportional to its reactive N load, and removal efficiency is 26% higher in nontidal than tidal wetlands. Further, a new meta-analysis showed that N enrichment increases wetland  $\text{N}_2\text{O}$  emissions by 207%. New studies have also evaluated the effects of N loading/N addition on other endpoints related to N cycling in peat bog, riparian, mangrove, and salt marsh wetlands (see [Appendix 11.3.1](#)). The endpoints evaluated

include ecosystem N retention, wetland export of N to surface waters, N fixation, N mineralization, denitrification, emission of N<sub>2</sub>O, and bacterial abundance, activity, and composition in wetland soils. The results of North American studies are summarized in [Figure 11-2](#). Across studies, N enrichment decreases the ability of wetlands to retain and store N, which may diminish the wetland ecosystem service of improving water quality.

In the 2008 ISA, evidence from Canadian and European peatlands showed that N deposition had negative effects on *Sphagnum* (moss) bulk density and mixed effects on *Sphagnum* productivity depending on the history of deposition. There is new information on how N deposition alters biogeochemical cycling of C in wetlands. Chemical indicators of N deposition in wetlands include soil organic matter, total soil C or peat C, CO<sub>2</sub> emissions, and CH<sub>4</sub> emissions. Long-term C storage is an important ecosystem service of wetlands for which measures of physical marsh stability can serve as a proxy, and physical indicators of N deposition can include temperature, bulk density, physical resistance, and soil water content. In addition, changes to plant growth rates and productivity indicate altered C cycling in wetlands, and are summarized in [Section IS.8.2](#).

The literature evaluates the effects of N deposition, N loading, or experimental N addition on C cycling in bogs, fens, riparian or intermittent marshes, freshwater tidal marshes, mangroves, and salt marshes (see [Appendix 11.3.2](#)). Significant effects of N loading upon biogeochemical cycling of C in North American wetlands (in which the N addition was 500 kg N/ha/yr or lower) are summarized in [Figure 11-3](#). N enrichment decreases wetland retention of C, as indicated by new studies and a new meta-analysis that show that N enrichment increases methane production in salt marshes. New studies of marshes along the Gulf Coast and East Coast find that N enrichment also decreases the bulk density of salt marshes, making marshes less resilient to physical stresses from tidal or storm flooding, and may accelerate coastal marsh loss.

---

## IS.8.2 Biological Effects of Wetland Nitrogen Enrichment/Eutrophication

In the 2008 ISA, evidence was sufficient to infer a causal relationship between N deposition and the alteration of species richness, species composition, and biodiversity in wetlands. New evidence is presented in the following sections regarding the effects of N upon wetland plant physiology, architecture, demography, and biodiversity. **The body of evidence is sufficient to infer a causal relationship between N deposition and the alteration of growth and productivity, species physiology, species richness, community composition, and biodiversity in wetlands.**

---

### IS.8.2.1 Growth, Productivity, and Physiology

In the 2008 ISA, evidence from Canadian and European bogs and fens showed that N deposition had negative or mixed effects on *Sphagnum* (moss) productivity, depending on history of deposition. In Canadian ombrotrophic peatlands experiencing deposition of 2.7–8.1 kg N/ha/yr, peat accumulation increased with N deposition, but accumulation rates had slowed by 2004, indicating a degree of N saturation. Coastal wetlands responded to N enrichment with increased primary production, which shifted microbial and plant communities and altered pore water chemistry, although many of the studies in coastal wetlands used N enrichment levels more like those of wastewater than atmospheric deposition. New research on N enrichment effects on growth and productivity was conducted in ombrotrophic bogs, intermittent wetlands, freshwater tidal marsh, mangroves, and coastal salt marshes (see [Appendix 11.4](#)). Ecological endpoints evaluated to assess N loading effects on growth and productivity include plant aboveground biomass and productivity, plant belowground biomass of roots and rhizomes, and growth rates, and are summarized along with N effects on C cycling in [Figure 11-3](#). The effects of N additions on plant physiology were not addressed in the 2008 ISA, but information regarding these effects is available for bogs and fens, riparian wetlands, freshwater tidal marshes, mangroves, and salt marshes (see [Appendix 11.5](#)). Ecological endpoints evaluated to assess N loading effects on plant physiology include stoichiometry (i.e., nutrient concentrations and ratios of multiple nutrients in plant tissue), nutrient acquisition efficiency (including insectivory rates in carnivorous plants), nutrient use efficiency, and nutrient reabsorption efficiency. These endpoints are summarized in [Figure 11-4](#).

In general, across types of wetlands, nitrogen loading increases aboveground growth and productivity while decreasing or not affecting belowground growth and productivity. In bogs and fens, N deposition decreases growth of state-listed *Sarracenia purpurea* (purple pitcher plant), and N enrichment increases aboveground productivity of emergent sedges more than of peat-building moss species. These changes cascade up to affect biodiversity in bogs and fens (see below, [Section IS.8.2.2](#)). In freshwater and tidal marshes, N enrichment increases aboveground productivity while decreasing belowground productivity, and this shift from belowground to aboveground plant productivity may account for changes in wetland C storage (see [Section IS.8.1](#)).

Changes to plant physiology and stoichiometry vary by species tolerance to N and N acquisition strategies. In bogs, N enrichment typically causes increased plant tissue N concentrations, decreased N use efficiency, and decreased N resorption efficiency during senescence. After several years of exposure to high rates of N loading, bog plants may experience leaf N saturation and limitation by other nutrients (e.g., P, K, and Ca,

indicated by increasing reabsorption efficiencies), resulting in leaf damage in sensitive species. *S. purpurea* (purple pitcher plant) decreases its dependence upon insectivory for nutrition at N deposition rates of 4.4 kg N/ha/yr. In freshwater marshes, N enrichment also increases plant tissue N concentrations while increasing P limitation and altering resorption efficiencies.

Plant architecture was not addressed in the 2008 ISA, and demography was addressed only for bogs and fens. Aboveground, plant architecture includes branching patterns, as well as the size, shape, and position of leaves and flower organs. New studies find N enrichment affects plant architecture in a salt marsh, in mangroves, in freshwater tidal marshes, and in a riparian wetland ([Appendix 11.6](#)). In terms of plant demography, the 2008 ISA found positive population growth rates for *S. purpurea* at 0 or 1.4 kg N/ha/yr, but population losses at 14 kg N/ha/yr. N deposition above 6.8 kg N/ha/yr increases population extinction risk of *S. purpurea*. New studies show that N addition has species-specific effects on reproduction of West Coast salt marsh plant species and that it increases mortality across the global distribution of mangrove species ([Appendix 11.7](#)).

---

### IS.8.2.2 Biodiversity

In the 2008 ISA, evidence was sufficient to infer a causal relationship between N deposition and the alteration of species richness, species composition, and biodiversity in wetlands. Notably, the 2008 ISA cited 4,200 native plant species in U.S. wetlands, 121 of which are federally endangered. Given their relative area, wetlands provide habitat to a disproportionately high number of rare plants. Many wetland species have adapted to N limited conditions, including endangered species in the genera *Isoetes* (3 endangered species) and *Sphagnum* (15 endangered species), as well as insectivorous plants such as pitcher plants (*Sarracenia* spp.) and sundews (*Drosera rotundifolia*).

Coastal wetlands responded to N enrichment with increased primary production, changing microbial and plant communities, and altered pore water chemistry, although many of the studies available in 2008 used high N enrichment levels more similar to N loading from wastewater than from atmospheric deposition. New research since 2008 across environmentally relevant N levels including N deposition gradient studies, experimental N addition studies, and observational studies show that N enrichment altered biodiversity in bogs and fens, intermittent wetlands, freshwater wetlands, freshwater tidal wetlands, and coastal salt marshes (see [Appendix 11.8](#)).

New research from wetland ecosystems strengthens the 2008 causal statement. New research confirms that, as in terrestrial systems, N addition can decrease the abundance and richness of sensitive species while increasing the abundance and richness of tolerant

species. In bogs and fens, N enrichment decreases the survival of insectivorous plants and the cover of mosses, while increasing the cover of shrub species. In freshwater marshes, N enrichment changes plant community composition, increases the abundance of and stresses caused by invasive plant species, promotes the harmful algal species that produce the toxin microcystin, and increases mosquito larvae that are vectors for zoonotic diseases (see [Figure 11-1](#)). In freshwater tidal and coastal marshes, N enrichment changes plant community composition, increases cover of invasive plant species, increases herbivory by invertebrates, and increases herbivory by the invasive mammal *Myocastor coypus* (nutria).

---

### IS.8.2.3 National Sensitivity and Critical Loads for Wetlands.

Freshwater and coastal wetlands tend to have different sensitivity to added N. Broadly, wetlands that receive a larger fraction of their total water budget in the form of precipitation are more sensitive to the effects of N deposition. For example, bogs (70–100% of hydrological input from rainfall) are more sensitive to N deposition than fens (55–83% as rainfall), which are more sensitive than coastal wetlands (10–20% as rainfall).

Since the 2008 ISA, an N CL for U.S. coastal wetlands has been established. The CL is based on several different ecological endpoints, including plant community composition, microbial activity, and biogeochemistry (63–400 kg N/ha/yr) and that this CL includes total N loading values not just N deposition. [Figure 11-6](#) shows a comparison of the N CL for coastal wetlands with recent studies of ecological impacts of N (at N levels of 100–250 kg N/ha/yr).

Since the 2008 ISA, two N CLs for U.S. freshwater wetlands have been established. The CL for wetland C cycling, quantified as altered peat accumulation and NPP, is between 2.7 and 13 kg N/ha/yr. The upper end of this CL range is based on measurements of wet deposition only (10 to 13 kg N/ha/yr), and therefore, does not reflect total N loading. There is also a CL to protect biodiversity based on morphology and population dynamics of the purple pitcher plant (*Sarracenia purpurea*) between 6.8–14 kg N/ha/yr. A more recent study across an N deposition gradient suggests that purple pitcher plant populations experience negative effects of N deposition at rates lower than this CL, but the more recent research has not yet been incorporated into the CL framework. A comparison of freshwater wetland CLs to observed ecological impacts of N from recent studies (4.4–500 kg N/ha/yr) is given in [Figure 11-7](#).

---

## IS.9 Freshwater and Wetland Ecosystem Sulfur Enrichment

New evidence from wetland and freshwater aquatic ecosystems strengthens and extends the causal findings of the 2008 ISA regarding nonacidifying sulfur effects and provides the basis for a new causal determination ([Table IS-1](#)). New research together with the information included in the 2008 ISA shows that the evidence is sufficient to infer a causal relationship between S deposition and the alteration of Hg methylation in surface water, sediment, and soils in wetland and freshwater ecosystems. **New evidence is sufficient to infer a new causal relationship between S deposition and changes in biota due to sulfide phytotoxicity, including alteration of growth and productivity, species physiology, species richness, community composition, and biodiversity in wetland and freshwater ecosystems.**

SO<sub>x</sub> deposition can have chemical and biological effects other than acidification, particularly in flooded wetland soils and aquatic ecosystems. The 2008 ISA described qualitative relationships between SO<sub>4</sub><sup>2-</sup> deposition and a number of ecological endpoints, including altered S cycling, sulfide phytotoxicity, internal eutrophication of aquatic systems, altered methane emissions, increased mercury (Hg) methylation, and increased Hg loading in animals, particularly fish. [Table 12-11](#) summarizes the chemical concentrations that alter ecological endpoints and the quantitative relationships describing the effects of SO<sub>4</sub><sup>2-</sup> deposition. Recent research supports these relationships between S deposition and ecological endpoints and provides the basis for SO<sub>x</sub> deposition levels, water column SO<sub>4</sub><sup>2-</sup> concentrations, and water column sulfide concentrations protective of plants and animals.

---

### IS.9.1 Biogeochemistry

SO<sub>x</sub> deposition alters biogeochemical processes via S enrichment. The processes include S cycling (see [Appendix 12.2.1](#)), P cycling (see [Appendix 12.2.4](#)), C cycling (see [Appendix 12.2.5](#)), and Hg cycling (see [Appendix 12.3](#)). The primary chemical indicator for nonacidifying or enrichment effects of S in wetland and aquatic ecosystems is surface water SO<sub>4</sub><sup>2-</sup> concentration, as it is for acidifying effects. The 2008 ISA reported that chemical reduction of SO<sub>4</sub><sup>2-</sup> was an important indicator of SO<sub>x</sub> effects on water chemistry because the process generates ANC. There are no new studies on ANC generation through SO<sub>4</sub><sup>2-</sup> reduction, although microbial SO<sub>4</sub><sup>2-</sup> reduction remains an active area of research. In aquatic ecosystems for which atmospheric and terrestrial S inputs are similar in magnitude to rates of microbial SO<sub>4</sub><sup>2-</sup> reduction, the products of microbial SO<sub>4</sub><sup>2-</sup> transformation may be more reliable indicators of S enrichment effects

than surface water  $\text{SO}_4^{2-}$  concentrations. These chemical indicators include methylmercury (MeHg), sulfide, and phosphate.

MeHg is the most persistent and toxic form of Hg in the natural environment. It is measured in surface water or aquatic sediments (MeHg concentration or the percentage of MeHg in total Hg) to predict its effects on biota. Several new studies demonstrate significant positive relationships between surface water  $\text{SO}_4^{2-}$  concentrations and water or sediment MeHg concentrations (see [Appendix 12.3.5](#)). Another product of  $\text{SO}_4^{2-}$  reduction, sulfide (measured as surface water or sediment pore water  $\text{S}^{2-}$  concentrations), is also a water quality indicator of deposition effects on biota. In freshwater ecosystems with iron-rich sediments, sulfide may react with iron bound to phosphates in the sediment to release phosphate into the water column, increasing primary productivity recent literature refers to this process as internal eutrophication ([Appendix 12.2.4](#)).

In terms of S enrichment effects on carbon cycling, the 2008 ISA documented the suppression of methane emissions in wetland soils by  $\text{SO}_4^{2-}$  addition in several studies and noted that 15 kg S/ha/yr suppressed methane emissions. Recent research has confirmed that S enrichment increases the abundance or metabolic activity of  $\text{SO}_4^{2-}$ -reducing prokaryotes (SRPs), which under some conditions compete with methanogens by suppressing their activity, and in turn, suppressing methane emissions ([Appendix 12.2.4](#)). However, there are no new studies documenting S deposition effects on methane emissions in U.S. ecosystems.

---

## IS.9.2 Biological Effects of Sulfur Enrichment

Nonacidifying S effects upon biota include plant toxicity, changes in plant growth and biodiversity, and increased Hg concentrations in biota. The toxicological effects of Hg accumulation in animals were documented in the 2008 ISA and newer studies.

---

### IS.9.2.1 Sulfur Nutrient and Toxicity to Plants

Plants and other organisms require S as an essential nutrient. The deposition of S can affect plant protein synthesis by affecting S availability for S containing amino acids, which in turn will affect N uptake. The 2008 ISA documented the effects of  $\text{SO}_4^{2-}$  toxicity on plant development and reproduction at very high S loads. There is no new evidence of S deposition effects upon plant S nutrition or  $\text{SO}_4^{2-}$  toxicity. The product of microbial  $\text{SO}_4^{2-}$  reduction, sulfide, is an important plant toxin, and the 2008 ISA documented sulfide phytotoxicity in European systems. Together with new research showing sulfide phytotoxicity in North American wetlands, **the body of evidence is**

**sufficient to infer a causal relationship between S deposition and changes in biota due to sulfide phytotoxicity including alteration of growth and productivity, species physiology, species richness, community composition, and biodiversity in wetland and freshwater ecosystems.**

The 2008 ISA showed that sulfide toxicity decreased the biomass of wetland plants and aquatic macrophytes in mesocosms under aquatic S concentrations higher than current U.S. concentrations. In Europe, research showed that a threshold value of  $<48 \text{ mg SO}_4^{2-}/\text{L}$  in surface water would protect the sensitive aquatic species *Stratiotes aloides* and *Potamogeton acutifolius* (not native to contiguous US), as well as to protect *P. zosteriformis* and *Utricularia vulgaris*, which are both native and widely distributed in contiguous US. New research has demonstrated sulfide phytotoxicity effects at current ambient sulfide concentrations in multiple ecosystems within the U.S. ([Appendix 12.2.3](#)). Sulfide decreased total plant cover and cover of dominant species in a New York fen and decreased the growth rate of *Cladium jamaicense* (sawgrass), a keystone species in the Florida Everglades. *Zizania palustris* (wild rice) is an economically and culturally important species sensitive to sulfide, and the Minnesota Pollution Control Agency has developed a model for this species that calculates protective levels of water  $\text{SO}_4^{2-}$  concentrations, given (specific) iron and DOC concentrations in water bodies. A recent review identifies sulfide thresholds between  $0.3\text{--}29.5 \text{ mg S}^{2-}/\text{L}$  for altered growth, productivity, physiology, or increased mortality of 16 freshwater wetland emergent plant and aquatic submerged macrophyte species native to North America (see [Table 12-2](#)).

---

### IS.9.2.2 Sulfur Effects on Mercury Methylation

In the 2008 ISA, evidence was sufficient to infer a causal relationship between S deposition and increased methylation of Hg in aquatic environments where the value of other factors is within an adequate range for methylation. In the 2008 ISA, sulfur-reducing bacteria (SRB) were identified as the organisms responsible for Hg methylation. New evidence shows the ability to methylate Hg is more broadly distributed phylogenetically, including both bacteria and archaea, which is why this document refers to  $\text{SO}_4^{2-}$ -reducing mercury methylators as sulfur-reducing prokaryotes (SRPs) rather than SRB ([Appendix 12.3.2](#)). In the 2008 ISA, wetland and lake-bottom sediments were identified as habitat for mercury methylating SRPs. Recent research documents microbial mercury methylation in lakes, in wetland sediments and moss, within periphyton, in marine ecosystems, and within disturbed terrestrial forest soils ([Appendix 12.3.2](#) and [Appendix 12.3.3](#)). Microbial mercury methylation responsive to  $\text{SO}_x$  deposition occurs in freshwater lakes, freshwater wetlands, freshwater reservoirs, and freshwater agricultural areas ([Appendix 12.3.4](#)). Between the 2008 ISA and new research, **the body of evidence**

**is sufficient to infer a causal relationship between S deposition and the alteration of Hg methylation in surface water, sediment, and soils in wetland and freshwater ecosystems.**

Hg methylation is determined in part by surface water  $\text{SO}_4^{2-}$ , because many strains of SRPs possess the recently identified gene pair *hgcAB*, and pair their metabolism of C with both dissimilatory  $\text{SO}_4^{2-}$  reduction and mercury methylation (see [Appendix 12.3.2](#) and [Figure 12-5](#)). Microbial methylation rates are determined by other environmental requirements of SRPs, including seasonality and temperature, pH, salinity, amount of organic matter in the water and sediments, and concentrations of iron and nitrate ([Appendix 12.3.3](#)). New research demonstrates that Hg methylation occurs at current ambient  $\text{SO}_4^{2-}$  concentrations within U.S. water bodies. Multiple lines of evidence support a relationship between  $\text{SO}_4^{2-}$  surface water concentrations and MeHg concentration or production in various freshwater systems. Linear relationships between  $\text{SO}_4^{2-}$  concentrations and MeHg concentrations were observed in sediments of the South River, VA, across peat bogs in Minnesota and Ontario, and across prairie pothole lakes in Saskatchewan ([Figure 12-17](#)). In addition to the studies of lake and wetland sediments reviewed in the 2008 ISA, studies employing lab incubations show that  $\text{SO}_4^{2-}$  increases Hg methylation in samples from Adirondack peat bogs, from South River, VA sediments, from periphyton growing in North American lakes and wetlands, and from leaf packs in Minnesota river water ([Appendix 12.3.3.1](#)). Experimental addition of S to field mesocosms or whole ecosystems has shown that S enrichment as wet S deposition increases MeHg in water, sediment, or biota, in Little Rock Lake, WI; Bog Lake Fen, MN; the Experimental Lakes Area, Ontario; and the bog experiment at Degerö Stormyr, Sweden ([Appendix 12.3.4.1](#)). In observational studies of S and Hg deposition, fish Hg concentrations decline with temporal declines in  $\text{SO}_x$  deposition in Isle Royale (a Class I area). Fish Hg concentrations correlate positively with Hg and S deposition across Texas ecoregions, and a 12-year study found that fish Hg in Voyageurs National Park (a Class I area) declined in lakes with decreasing S deposition only when lake DOC remained constant ([Appendix 12.3.5.1](#)). New research is consistent and coherent with the research presented in the 2008 ISA in demonstrating that sulfur enrichment from  $\text{SO}_x$  deposition stimulates mercury methylation in North American ecosystems. Current research suggests that mercury methylation generally peaks between 10 and 100 mg  $\text{SO}_4^{2-}$ /L in surface water, and quantitative relationships between S and Hg, such as target values or thresholds, are reported in [Table 12-12](#).

---

### IS.9.2.3 Sulfur, Mercury, and Animal Species

Mercury is a developmental, neurological, endocrine, and reproductive toxin across animal species. The 2008 ISA documented Hg accumulation in fish, songbirds, four turtle species, insectivorous passerine birds, and the common loon (*Gavia immer*). Recent research also documented Hg accumulation in insectivore songbirds, bats, and fish in agricultural wetlands. The 2008 ISA reported that 23 states had issued fish advisories by 2007 in response to the U.S. EPA's fish tissue criterion of 0.3 µg MeHg/g fish (0.3 ppm), set to protect human health. The 2008 ISA reported on the negative impacts of Hg on the development, morphology, survival, or reproduction in the following fish species: walleye (*Stizostedion vitreum*), grayling (*Thymallus thymallus*), mummichog (*Fundulus heteroclitus*), rainbow trout (*Oncorhynchus mykiss*), fathead minnows (*Pimephales promelas*), and zebrafish (*Danio rerio*). However, a recent report on Hg in streams of the U.S. by the USGS summarizes current research indicating that birds, fish, and fish-eating wildlife experience negative effects of Hg at lower concentrations than the 0.3 ppm criterion set to protect human health on the basis of fish consumption.

The 2008 ISA documented a link between decreased S deposition and decreased fish MeHg concentrations. Recent research in Voyageurs National Park (a Class I Area) supports this finding, and there is supporting evidence from fish surveys of Texas reservoirs across regions with different S deposition loads. There is also supporting evidence from an S addition experiment in a peat bog in the Marcell Experimental Forest in northern Minnesota, where increased S loading increased Hg concentrations in larval *Culex* spp. (mosquitoes), which are an important food source for both aquatic and terrestrial species ([Appendix 12.4](#) and [Figure 12-18](#)). In addition to the studies that consider S deposition, there are recent studies that consider  $\text{SO}_4^{2-}$  concentrations in water in relation to fish Hg concentrations in six lakes in South Dakota, and in the marshes of the Everglades ([Appendix 12.4](#)). In the freshwater marshes of the Everglades, recent work indicates a concentration of 1 mg/L  $\text{SO}_4^{2-}$  to keep water MeHg low ([Appendix 12.3.4.3](#)) and protect fish from elevated Hg burdens in that system ([Figure 12-14](#)).

---

### IS.9.3 National-Scale Sensitivity and Critical Loads

The 2008 ISA identified ecosystems in the Northeast as particularly sensitive to Hg methylation in response to S deposition because many watersheds in this region have abundant wetlands and freshwater water bodies with high DOC and low pH. The U.S. EPA national stream surveys found that MeHg in predator fish exceeded the Hg criterion in a quarter of stream miles and half the lakes surveyed. Fish MeHg levels were highest

in streams in watersheds with considerable wetland area, and surveys showed highest fish MeHg concentrations in the southeastern U.S., suggesting that ecosystems sensitive to SO<sub>x</sub> deposition effects on Hg methylation extend beyond the Northeast ([Figure 12-15](#)). Recent studies confirm that Hg methylation is more widespread than was documented at the time of the 2008 ISA. New research conducted in agricultural wetlands in California suggests Hg methylation in these systems may provide a route to animal and human Hg exposure through food, specifically MeHg concentrations in rice seeds.

There are no CLs for S to prevent sulfide phytotoxicity or Hg methylation, although there are SO<sub>4</sub><sup>2-</sup> and sulfide water quality values that represent protective levels against toxic effects of sulfide and Hg to biota (see [Table 12-12](#)). There are European CLs for Hg concentrations in soil and fish tissue targeted to protect human health, drinking water quality, and terrestrial soils, but these CLs are not framed in terms of SO<sub>x</sub>, Hg, or PM deposition (see [Appendix 12.6](#)).

---

## IS.10 Ecological Effects of Particulate Matter Other Than Nitrogen (N) and Sulfur (S) Deposition

Since publication of the 2009 PM ISA, new literature builds upon the existing knowledge of ecological effects associated with PM components other than those associated with N and S deposition, especially metals and organics. In some instances, new techniques have enabled further characterization of the mechanisms of PM on soil processes, vegetation, and effects on fauna. New studies provide additional evidence for community-level responses to PM deposition, especially in soil microbial communities. However, uncertainties remain due to the difficulty in quantifying relationships between ambient concentrations of PM and ecosystem response. Overall, **the body of evidence is sufficient to infer a likely causal relationship between deposition of PM and a variety of effects on individual organisms and ecosystems**, based on information from the previous review and new findings in this review. However, the new findings are limited in scope.

PM deposition comprises a heterogeneous mixture of particles differing in origin, size, and chemical composition. Exposure to a given concentration of PM may, depending on the mix of deposited particles, lead to a variety of toxic responses and ecosystem effects. Effects of PM on ecological receptors can be both chemical and physical ([U.S. EPA, 2009a, 2004](#)). As described in the 2009 *Integrated Science Assessment for Particulate Matter* (2009 PM ISA), particulates that elicit direct and indirect effects on ecological receptors vary by size, origin, and chemical composition. Ecological outcomes are attributed more to particle composition than to particle size ([Grantz et al., 2003](#)).

PM-associated metals and organics are linked to responses in biota; however, the heterogeneous nature of PM composition and distribution coupled with the variability inherent in natural environments confound assessment of the ecological effects of particulates. Although most effects are from chemical composition of PM, there are some effects of particle size such as changes to flux of solar radiation and soiling of leaves by large coarse particles in areas near industrial facilities and unpaved roads. Atmospheric deposition of PM from crustal material may be a source of base cations (especially  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ , and  $\text{K}^+$ ) that can partially ameliorate the effects of acidifying deposition. Base cations are important plant nutrients that in some locations are in short supply ([U.S. EPA, 2009a](#)).

In general, new studies on PM deposition to vegetation support findings in previous PM reviews on altered photosynthesis, transpiration, and reduced growth. Since the 2009 PM ISA, additional characterization of PM effects at the leaf surface has led to a greater understanding of PM foliar uptake. Alterations in leaf fatty acid composition are associated with metals transferred to plant tissues from PM deposition on foliar surfaces ([Appendix 15.4.2](#)).

An important characteristic of fine particles (0.1 to 1.0  $\mu\text{m}$ ) is their ability to affect the flux of solar radiation increases in the diffuse component. A newly available research method links changes in expression of proteins involved in photosynthesis to increases in the diffuse component due to aerosols and PM. Although this method has not been widely applied, it may represent an important way to study mechanistic changes to photosynthesis in response to more diffuse radiation resulting from PM in the air column ([Appendix 15.2](#)).

Several studies published since the 2009 PM ISA show PM chemical constituent effects on soil physical properties and nutrient cycling. Previous findings in the PM ISA of changes to microbial respiration and biomass are further supported by new studies. Microbial communities respond to PM in various ways depending on their tolerance to heavy metals and organics ([Appendix 15.5.3](#)).

In fauna, results from ecotoxicity assays with PM extracts using bacteria, rotifers, nematodes, zebrafish, and earthworms support findings in the 2009 PM ISA that toxicity is not related to the total mass of PM in the extract, but to the chemical components of the PM. In nematodes exposed to PM from air filters, the insulin-signaling pathway was identified as a possible molecular target. Use of wildlife as PM biomonitors has been expanded to new taxa since the last PM review. Several studies in invertebrates and birds report physiological responses to air pollutants, including PM ([Appendix 15.6](#)).

For ecosystem-level effects, a gradient of response with increasing distance from PM source was reported in the 2009 PM ISA. Newly available studies from long-term ecological monitoring sites provide limited evidence for recovery in areas such as those around former smelters due to the continued presence of metals in soils after operations ceased. A novel experimental microecosystem using microbial communities living in terrestrial mosses indicates that PM deposition alters responses of primary producers, decomposers, and predators ([Appendix 15.3](#)).

---

## **IS.11 Recovery of Ecosystems from Nitrogen (N) and Sulfur (S) Deposition in the U.S.**

Evidence from across the U.S. of ecosystem recovery from N nutrient enrichment and acidification corresponding to long-term trends in N and S emissions varies. Most studies of recovery focus on ecosystem acidification recovery due to decreases in S emissions and deposition. Overall N emissions and deposition have been increasing or relatively steady, although a few areas have seen some decrease ([Appendix 2.7](#)). Consequently, the amount of new information available and reported here on N enrichment recovery is small.

---

### **IS.11.1 Overarching Concepts of Ecological Recovery from Acidification**

Both chemical and biological indicators are used to assess the degree of ecological degradation associated with environmental stressors and document responses in ecosystems where improved conditions allow for recovery. Recovery can be documented by measurement of indicators and projected/modeled recovery trajectories.

Chemical recovery of aquatic and terrestrial ecosystems is characterized by trends in water quality indicators ( $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ , pH, ANC, inorganic monomeric Al, MeHg) towards inferred preindustrial values or, in the case of inorganic Al and MeHg, below water quality threshold values protective of biota and human health. Preindustrial conditions varied across the U.S. depending on climate, geology, and biological communities, and preindustrial chemical indicator values are currently inferred from models, paleolimnology samples, or historical samples. When evaluating ecosystem recovery from acidification, it is important to note that different chemical pools within the soil or water column may recover at different rates with the same decreases in atmospheric deposition. For example, the soil solution Ca:Al ratio,  $\text{SO}_4^{2-}$ , or  $\text{NO}_3^-$  respond more quickly than will total N. Indicators of slowly recovering pools (such as the percentage of base saturation in the soil or soil C to N ratio) will have long response

times with regard to changes in atmospheric deposition. An indicator such as acid-neutralizing capacity (ANC), which is influenced by both fast and slow pools, has an intermediate response time. Chemical indicators such as ANC or pH may not necessarily follow a recovery path that mirrors the reverse of the acidification path due to dynamic relationships among ANC, pH, DOC, and inorganic Al; depletion of soil base cation pools; and/or pH-dependent S adsorption on soils. In addition, the ANC level that reflects recovery of pH or Al<sub>i</sub> may differ between the acidification and recovery phases ([Hesthagen et al., 2008](#)).

Biological recovery may follow chemical recovery of such water and soil quality constituents; however, there may be a lag of decades between the onset of chemical recovery and biological recovery [[U.S. EPA \(2008a\)](#); [Appendix 8](#)]. As observed in some of the early studies on formerly acidified systems, the biological recovery trajectory may exhibit hysteresis, where a system does not follow the same path from acidification to recovery ([Frost et al., 2006](#)). Complete biological recovery would entail a return to the same species make-up, richness, and abundance as existed in the ecosystem in question prior to the advent of human-caused acidic deposition (around the year 1860 in North American ecosystems). In a practical sense, complete biological recovery is probably not attainable at most acidified locations within a reasonable management time frame (perhaps 100 years) because soil reserves of base cations at many locations have been depleted in response to many decades of acidic deposition and because other stressors, in addition to acidic deposition, have also altered ecosystem structure and/or function or will do so in the coming decades. Such stressors include changes in climate, land use, and other perturbations. More commonly, partial biological recovery may be possible. Ecosystems deemed to be on a recovery trajectory are those found to be moving towards a mix of species presence and abundance that approximates the undisturbed state. There is substantial evidence that recovery rates from acidification differ between taxonomic groups [e.g., rotifers vs. crustaceans; [Frost et al. \(2006\)](#); [Malley and Chang \(1994\)](#)]. In general, recovery in freshwater ecosystems is characterized by populations of plankton and benthic invertebrates prior to the recovery of fish populations, although most biological communities studied to date have not returned to preacidification conditions, even after recovery of chemical parameters.

---

## IS.11.2 Acidification Recovery in the U.S.

Long-term monitoring has been very important in tracking the ecological response to N and acidifying deposition ([Appendix 7](#) and [Appendix 4.4](#)). Experimental liming studies have also provided some evidence for biological recovery, although these types of studies are limited in the U.S. ([Appendix 4.3.4](#) and [Appendix 8.4.6](#)). The historical focus on

aquatic acidification has resulted in more data to evaluate recovery in aquatic than terrestrial ecosystems ([Appendix 7.1.3](#)). Fewer studies have tracked the potential recovery of terrestrial ecosystems; however, since the early 1990s, increasing evidence indicates that soils in some areas are beginning to recover, yet most sensitive regions continue to acidify in response to deposition ([Appendix 4.6.1](#)). In areas where N and S deposition has decreased, chemical recovery must first create physical and chemical conditions favorable for growth, survival, and reproduction of the pre-1860 assemblage for biological recovery to occur.

The northeastern U.S. and southern Appalachians are two regions of the U.S. where a large body of research has evaluated recovery. In the Northeast, evidence for chemical recovery is primarily from soils ([Appendix 4.6.1](#)) and freshwater lakes and streams ([Appendix 7.1.5.1](#)). In regard to biological recovery ([Appendix 8.4](#)), newer studies have documented some evidence for zooplankton recovery and the successful reintroduction of brook trout in previously acidified Adirondack water bodies or recolonization of previously acidic lakes from refugia ([Appendix 8.6.6](#)). In addition to decreased acidification, a few studies report declines in methylmercury concentrations in biota or water in response to decreasing S, which is suggestive of ecosystem recovery ([Appendix 12.5](#)).

In contrast to the northeastern U.S., there is little evidence for recovery in the southern Appalachian Mountain region ([Appendix 4.6.1](#) and [Appendix 16.3](#)). This area is characterized by an abundance of low-ANC streams situated on acidic, highly weathered soils. Streams in this region are strongly affected by  $\text{SO}_4^{2-}$  adsorption on soils, and long-term monitoring studies suggest that soil base cation depletion has prevented chemical recovery ([Appendix 7.1.5.1.4](#)). Biogeochemistry modeling scenarios suggest that even with large decreases in  $\text{SO}_4^{2-}$  deposition, it may take decades for soil base cation levels to recover in this region.

New studies continue to support findings in the 2008 ISA that biological response to water chemistry recovery varies among taxa and water bodies, and that most biological communities studied have not returned to preacidification conditions, even after recovery of chemical parameters ([Appendix 8.4](#)). Since the 2008 ISA, research has demonstrated that the DOC of many lakes and streams has risen, with the source of the DOM and associated DOC likely to be the soils in the terrestrial watershed ([Table IS-2](#); [Appendix 4.3.9](#) and [Appendix 7.1.2.9](#)). The mechanism causing the observed increase in DOC is unclear; it may be a combination of soil recovery from acidification, changes in climate (e.g., temperature and precipitation), and N deposition, among other mechanisms. DOC interacts like a weak acid; therefore, DOC concentration may affect pH and ANC levels and constrain the extent of recovery from acidification. At the same time, the

acidic properties of DOC make it a host for binding trace metals such as toxic inorganic Al (for additional discussion on inorganic Al and DOM see [Appendix 4.3.5](#)) and decreases the toxicity of dissolved Al to aquatic organisms. Overall, current research indicates DOC increases are inconsistent across surface waters in the U.S., with large increases in DOC with acidification recovery in some locations and no increases in other recovering sites.

---

### **IS.11.3 Nitrogen (N) Driven Nutrient Enrichment Recovery in the U.S.**

Most freshwater systems sensitive to nutrient effects of atmospheric deposition of N have shown no evidence for biological recovery, although decreases in  $\text{NO}_3^-$  concentrations consistent with declines in N deposition have been reported in some regions of the U.S., notably the Appalachian, Adirondack, and Rocky Mountains ([Appendix 7.1.5](#)). Some estuaries have shown improvements in biological indicators, such as increases in the extent of SAV, in response to decreases in N inputs from atmospheric deposition and in wastewater and agricultural runoff. For an example, see the Tampa Bay case study ([Appendix 16](#)). In other coastal areas of the U.S., biological indicators of nutrient enrichment have remained relatively unchanged or declined. In the well-studied Chesapeake Bay watershed where extensive restoration efforts have been implemented, water quality and measures of ecological condition have shown little improvement during a 23-year period ([Williams et al., 2010](#)). The one exception to the pattern of no improvement in water quality was an observed increase in the amount of SAV ([Appendix 10.2.5](#)).

---

## **IS.12 Climate Modification of Ecosystem Response to Nitrogen (N) and Sulfur (S) Deposition**

Nitrogen and S deposition occur in many ecosystems concurrently experiencing multiple stressors, including human-driven climate change. Climate change effects on U.S. ecosystems were recently summarized in the U.S. National Climate Assessment ([Galloway et al., 2014](#); [Groffman et al., 2014](#)). Each appendix of the ISA evaluating N enrichment or acidification includes a section on how climate modifies the ecosystem response. In the context of this section of the ISA, climate refers to meteorological factors over a 5-year horizon (because NAAQS are reviewed every 5 years) in contrast to long-term climate change, or associated changes to  $\text{CO}_2$  concentrations. Additionally, to serve as a foundation for the discussion, text in [Appendix 13](#) is excerpted from [Greaver et al. \(2016\)](#), a current review of how climate (e.g., temperature and precipitation) modifies ecosystem response to N that focuses on empirical observations.

Anthropogenic emissions of greenhouse gases are likely to cause a global-average temperature increase of 1.5 to 4.0°C and a significant shift in the amount and distribution of precipitation by the end of the 21st century ([Collins et al., 2013](#)). Recent work has focused on the effects of anthropogenic N on the Earth’s radiative forcing ([Pinder et al., 2012](#)) and how temperature and precipitation alter ecological responses to N exposure ([Greaver et al., 2016](#)). Most work is conducted on the effects of climate interactions with N or acidifying deposition (N + S); relatively little work is conducted on how climate modifies ecosystem response to S nutrient-related effects.

Understanding climate effects on ecosystems is a rapidly expanding field with many new empirical studies, meta-analyses, and modeling work published since the 2008 ISA. General patterns of how climate affects some biogeochemical processes are known and how climate alters growth rates and biodiversity of some species have been identified, [Figure 13-1](#) is an example of how processes relevant to N enrichment and acidification may be altered with either wetter or drier conditions. In addition to the excerpt from [Greaver et al. \(2016\)](#), additional studies are summarized for effects of climate on N transport and transformation ([Table 13-1](#)), N and C cycling ([Table 13-2](#)), acidification ([Table 13-3](#)), and biodiversity ([Table 13-4](#)). Our understanding of the effects of climate on ecosystem response to N and S deposition varies; for many ecological endpoints, data are insufficient to quantify either the direction or magnitude of how climate may alter ecosystem response with certainty.

---

## IS.13 Ecosystem Services

“Ecosystem services” refers to the concept that ecosystems provide benefits to people, directly or indirectly ([Costanza et al., 2017](#)), and that ecosystems produce socially valuable goods and services deserving of protection, restoration, and enhancement ([Boyd and Banzhaf, 2007](#)). The concept of ecosystem services recognizes that human well-being and survival are not independent of the rest of nature, and that humans are an integral and interdependent part of the biosphere ([Costanza et al., 2017](#)). In some cases, and in line with more conventional economic thinking, ecosystem services analysis can result in attaching monetary values to ecosystem outcomes. However, because ecosystem services are often public goods their benefits can be difficult to monetize. We emphasize that this practical difficulty in no way implies that ecosystem service benefits are small or without value. At a minimum, ecosystem services analysis involves discussion and, ideally, quantification of ecological outcomes understood by households, communities, and businesses. Explicitly linking ecosystem services to social and economic welfare measures has proven difficult because of the broad definition of ecosystem services and the numerous types of services that could be affected. An analysis of ecosystem services

specifically altered by NO<sub>x</sub>, SO<sub>x</sub>, and PM would translate the effects of ambient concentrations and deposition into biological, physical, or monetary metrics that give insight to public welfare effects.

For acidification, the ecosystem service literature since the 2008 ISA includes studies that better characterize ecosystem service valuation by pairing biogeochemical modeling and benefit transfer equations informed by willingness-to-pay surveys, especially for the Adirondacks and Shenandoah regions ([Appendix 14](#)). Aside from valuation studies, there is an improved understanding of the numerous causal pathways by which N and S deposition may affect ecosystem services, supported by studies that relate deposition to final ecosystem services under the FEG-CS ([Bell et al., 2017](#); [Clark et al., 2017](#); [Irvine et al., 2017](#); [O'Dea et al., 2017](#); [Rhodes et al., 2017b](#)). However, for many regions and specific services, poorly characterized dose-response between deposition, ecological effect, and services are the greatest challenge in developing specific data on the economic benefits of emission reductions ([NAPAP, 2011](#)).

In the 2008 ISA there were no publications that specifically evaluated the effects of N deposition on ecosystem services associated with N driven eutrophication. Since then several comprehensive studies have been published on the ecosystem services related to N pollution in the U.S. ([Appendix 14](#)). These include an evaluation of services affected by multiple N inputs (including N deposition) to the Chesapeake, a synthesis of the cost-benefits on N loading across the nation, and analysis of the amount of N that leaked out of its intended application area causing effects on adjacent ecosystems and ecosystem services, two calculations of the social cost of nitrogen (Minnesota and the Mississippi Alluvial Valley), and an estimate of the cost to remove N from the White River Basin in Indiana (this work specifically identified the costs of the atmospheric portion of total N loading). The estimate of the total number of ecosystem services affected by N is better quantified by the new studies that use FEG-CS ([Bell et al., 2017](#); [Clark et al., 2017](#); [Irvine et al., 2017](#); [O'Dea et al., 2017](#); [Rhodes et al., 2017b](#)). In these analyses, CL exceedances for N related air pollution were used as a model stressor from which a total of 1,104 unique chains linking stressor to beneficiary were identified.

The conclusions considering the full body of literature are that (1) there is evidence that N and S emissions/deposition have a range of effects on U.S. ecosystem services and their social value; (2) there are some economic studies that demonstrate such effects in broad terms; however, it remains methodologically difficult to derive economic costs and benefits associated with specific regulatory decisions/standards; and (3) there is an improved understanding of the numerous causal pathways by which N and S deposition may affect ecosystem services, though most of these causal relationships remain to be quantified.

---

## IS.14 Key Scientific Uncertainties

Evaluation of uncertainty is an important part of ecosystem assessment. Uncertainty refers to the absence of information and is a way to describe how certain we are in scientific knowledge. As described by [Curry and Webster \(2011\)](#), the nature of uncertainty can be expressed by the distinction between ontic uncertainty and epistemic uncertainty. Ontic uncertainty is associated with inherent variability or randomness and is an irreducible form of uncertainty. Epistemic uncertainty is associated with imperfections of knowledge, which may be reduced by further research and empirical investigation. [Walker et al. \(2003\)](#) [as summarized in [Curry and Webster \(2011\)](#)] characterized uncertainty as a progression from deterministic understanding to total ignorance:

**“Statistical uncertainty** is the aspect of uncertainty that is described in statistical terms. An example of statistical uncertainty is measurement uncertainty, which can be due to sampling error or inaccuracy or imprecision in measurements.

**“Scenario uncertainty** implies that it is not possible to formulate the probability of occurrence of one particular outcome. A scenario is a plausible but unverifiable description of how the system and/or its driving forces may develop over time. Scenarios may be regarded as a range of discrete possibilities with no a priori allocation of likelihood.

**“Recognized ignorance** refers to fundamental uncertainty in the mechanisms being studied and a weak scientific basis for developing scenarios. Reducible ignorance may be resolved by conducting further research, whereas irreducible ignorance implies that research cannot improve knowledge.”

The understanding and reporting of uncertainty is not consistent across scientific disciplines, and uncertainty may be quantified by various methods. [Csavina et al. \(2017\)](#) provided an overview of terminology and definitions of 41 different terms used to describe uncertainty. Here we provide a summary of some of the key methods that may be used to evaluate the uncertainty of the relationships between NO<sub>x</sub>, SO<sub>x</sub>, and PM pollutants and ecological effects. This summary presents uncertainties associated with several specific concepts, including source emissions measurements, atmospheric deposition estimates, empirical measurements of CLs, models used to estimate CLs, and uncertainties in the aquatic acidification index. Quantified estimates of uncertainty vary according to the number of decision points ([Section IS.14.2.3](#)), including the method used and the input parameters under consideration; therefore, the analyses and discussion of

quantified uncertainty values will occur in the Risk and Exposure Assessment as scoped in the 2017 IRP ([U.S. EPA, 2017c](#)).

---

## IS.14.1 Atmospheric Science

Estimating atmospheric deposition involves quantification of emissions, atmospheric concentrations, and deposition fluxes of the various species that make up atmospheric SO<sub>x</sub>, NO<sub>y</sub>, and NH<sub>x</sub>. This is accomplished with environmental measurements, model predictions, or hybrid approaches that combine measurements and modeling methods. There are a wide range of uncertainties across the environmental measurements and model parameters used to estimate atmospheric deposition fluxes. The largest uncertainties are those for dry deposition and ammonia emissions, whether measured or modeled. The smallest uncertainties are associated with ambient concentration measurements and continuously monitored stationary emissions like electric power plants.

---

### IS.14.1.1 Emissions Uncertainty

Quantitative uncertainty estimates are not documented in the National Emissions Inventory (NEI), but uncertainties are often evaluated through separate efforts by comparing inventory predictions with measured long-term trends, statistical source apportionment methods, inverse chemical transport modeling, and comparison with satellite data ([Appendix 2.2.2](#)). SO<sub>2</sub> and NO<sub>x</sub> emission uncertainties for electricity-generating units, the major source of SO<sub>2</sub> and an important source of NO<sub>x</sub>, are in the 10–15% range because emissions are usually continuously monitored ([Appendix 2.2.3](#)). NO<sub>x</sub> emission uncertainties for mobile sources, the largest source of NO<sub>x</sub>, arise from differences in engine type, size, age, and maintenance, as well as fuel composition and emission control equipment. Overestimation of NO<sub>x</sub> emissions from mobile sources was proposed as an explanation for modeled NO<sub>x</sub> concentration bias in several studies. However, mixed results have been observed across several studies when modeled concentrations were compared with measurements. Estimates of NO<sub>x</sub> emissions uncertainties are in the 10–20% range for on-road gasoline and diesel vehicles, and up to 30% for off-road vehicles like ships, airplanes, and locomotives ([Appendix 2.2.3](#)). Spatial and temporal variability in soil NO<sub>x</sub> emissions can lead to uncertainty in emissions estimates. Soil emissions occur mainly during summer and across the U.S., but some areas, such as the central Corn Belt of the U.S., release more NO<sub>x</sub> emissions than others ([Appendix 2.2.3](#)).

In contrast, total NH<sub>3</sub> emissions uncertainties appear to be greater, underestimated by as much as a factor of two or more according to several recent studies ([Appendix 2.2.3](#)). The predominant sources, livestock operations and fertilizer application, exhibit large temporal and regional variability due to differences in climate conditions and farming practices. As a result, detailed models are required for estimating NH<sub>3</sub> emissions ([Appendix 2.2.2](#)), but data on local environmental conditions and farming practices necessary for good model performance are often not available. Large discrepancies between modeled and measured N concentrations and deposition rates have been attributed to uncertainties in NH<sub>3</sub> emissions ([Appendix 2.2.3](#)). Activity rates, including those for mobile source emissions, are also difficult to quantify, contributing to uncertainty in NH<sub>3</sub> emission estimates ([Appendix 2.2.3](#)).

---

### IS.14.1.2 Atmospheric Measurement Uncertainty

Uncertainties in concentration and deposition measurements from network-based measurements are generally under 20%, and surface concentration uncertainties from satellite-based measurements typically somewhat higher. Concentration and deposition data are derived from several specialized national monitoring networks, including the national SO<sub>2</sub> monitoring network, the NCore network for multipollutant concentration monitoring including NO<sub>y</sub>, the Ammonia Monitoring Network, CASTNet for estimating dry deposition, and the National Trends Network for wet deposition ([Appendix 2.4.1](#)). Uncertainties are estimated from reports of precision in data quality reports where available, and otherwise from network data quality objectives.

For air concentration measurements used to estimate dry deposition, CASTNet measured precision was 2–5% for SO<sub>4</sub><sup>2-</sup>, 5–13% for NO<sub>3</sub><sup>-</sup>, and 2–6% for NH<sub>3</sub> in 2016 ([Appendix 2.4.5](#)). Additional uncertainty is associated with estimating dry deposition from NTN concentration data. Uncertainties of 30% for SO<sub>2</sub> and 40% for HNO<sub>3</sub> have been reported using a simple inferential approach ([Clarke et al., 1997](#)). However, single site determinations are of limited use because dry deposition fluxes are determined by several factors and can vary considerably over small spatial scales. In most recent efforts, dry and total deposition on a regional or national scale is usually modeled with CTMs ([Section IS.14.1.3](#)).

Precipitation concentration measurement precision and estimated wet deposition precision in the National Trends Network were less than 7% for SO<sub>4</sub><sup>2-</sup> and NO<sub>3</sub><sup>-</sup> and less than 20% for NH<sub>3</sub>. PRISM (Parameter-elevation Regression on Independent Slopes Model) enhances spatial resolution using National Trends Network data to improve the creation of wet deposition maps ([Appendix 2.6](#)). Uncertainty for PRISM data sets has

been evaluated in the literature using cross validation and a 70% prediction interval for different data sets. NH<sub>3</sub> air concentration measurement methods used in AMoN were evaluated and found to have a precision of 10% ([Appendix 2.4.3](#)). Minimum performance specifications for SO<sub>2</sub> monitoring from the national SO<sub>2</sub> monitoring network include a precision of 2.0% ([Appendix 2.4.4](#)). Data quality objectives for NO<sub>y</sub> in the NCore network include a precision of 15% ([Appendix 2.4.2](#)). Uncertainty in satellite-based measurements depend on vertical profile, cloud fraction, cloud-top pressure, surface reflectivity, and extent of aerosol scattering. Estimates of 20% for NO<sub>2</sub> ([Appendix 2.4.2](#)) and 10–45% for SO<sub>2</sub> ([Appendix 2.4.4](#)) have been reported for cloud-free conditions.

---

### IS.14.1.3 Atmospheric Modeling Uncertainty

The Community Multiscale Air Quality modeling system is probably the most widely used model in the U.S. for estimating atmospheric deposition. CMAQ accurately modeled total SO<sub>x</sub>, but partitioning resulted in overpredicting SO<sub>2</sub> and underpredicting SO<sub>4</sub><sup>2-</sup>. In a recent CMAQ evaluation, SO<sub>2</sub> concentrations were overestimated by 39 to 47%, and SO<sub>4</sub><sup>2-</sup> concentrations were underestimated by 9 to 17%, as annual averages over a range of 4 years compared to surface-based measurements. In addition, atmospheric NO<sub>3</sub><sup>-</sup> concentrations were overestimated by 22 to 26%, as annual averages over a range of 4 years compared to surface-based measurements ([Appendix 2.5.3](#)). Mixed results have been observed in several recent comparisons of CMAQ wet deposition estimates to network-based measurements, with average differences in modeled results and measurements ranging from ≤15 to 99% for NO<sub>3</sub><sup>-</sup>, SO<sub>4</sub><sup>2-</sup>, and ≤15 to 60% for NH<sub>3</sub> ([Appendix 2.5.3](#)). Modeling methods for estimating dry and total deposition are still under development, and uncertainties have not been extensively evaluated or quantified. Recent sensitivity analysis results found less than 5% differences in total deposition estimates because of compensation of competing model processes, but extensive comparison of model results and measurements are not available ([Appendix 2.5.3](#)).

[Horn et al. \(2018\)](#) used deposition and forest inventory data (from 2000 to 2016) to assess the relationship between deposition and growth and survival of 71 tree species across the contiguous U.S. in a correlational analysis. Authors attempted to reduce uncertainty by accounting for other variables, either directly in their model or by quantifying and avoiding instances with high collinearity. The authors isolated the effects of N deposition from S deposition by adding S deposition explicitly into their models. Using variance inflation factors (VIFs), they also quantified the collinearity of N and S deposition against a suite of environmental variables that might have an effect. The analysis focused on the relationships of tree growth and survival to N and S deposition where the VIF was less

than or equal to 3. VIF values of 3–10 have been proposed as thresholds above which there is a potential for high collinearity ([Horn et al., 2018](#)). To what extent variables not included could have varied with deposition and had an effect, including ozone and drought, remained a key uncertainty.

[Clark et al. \(2018\)](#) analyzed exceedances of multiple types of CLs for the contiguous U.S. since 1800 and projecting out to 2025. The study authors discussed the uncertainty around CMAQ deposition estimates using CMAQ estimates starting in 1980. They noted that CMAQ may underestimate hot spots of deposition in space (e.g., concentrated deposition because of an orographic effect) or in time (e.g., from cloudbursts). CLs are an ecosystem response to deposition, and so any errors associated with deposition estimates would propagate through CLs. [Fenn et al. \(2010\)](#) found that CMAQ estimates and N in throughfall were similar under low throughfall conditions, but CMAQ underestimated N deposition when throughfall was high. [Clark et al. \(2018\)](#) noted that CMAQ is corrected using NADP data, but NADP sites do not provide complete spatial coverage. Remote sites are likely underrepresented.

In addition to measurable uncertainties associated with measurement precision or comparisons between models and measurements, there are also structural uncertainties due to incomplete understanding of the underlying science related to atmospheric deposition that are not possible to quantify. The main structural uncertainties associated with deposition estimates are canopy effects on NO<sub>x</sub> (including both bidirectional gas exchange and canopy reactions), bidirectional exchange of NH<sub>3</sub> with biota and soils, and processes determining transference ratios that relate average concentration to deposition ([Appendix 2.5](#)).

---

## IS.14.2 Ecological Effects

Evaluation of ecological effects caused by acidification or eutrophication involves a suite of parameters and dose-response functions, both empirical and modeled. The quantitative uncertainty of empirically observed variables in ecology is determined by using statistics. A suite of mathematical statistical models is available to describe the variability among empirical observations and the strength of a cause and ecological effect relationship, the appropriate method to apply depends on the experimental design. Statistics for empirical data include calculation of probability, distributions, standard deviation, variance, *t*-tests, ANOVA, linear regression, spatial statistics, Bayesian analysis, and multivariate analysis, among others. In general, ecological endpoints determined by empirical studies to be affected by deposition were reported in the ISA if they were statistically significant; this means the magnitude of effect was larger than the estimated uncertainty.

Models of chemical and ecological processes, including biogeochemistry, provide representations of biological and geochemical interactions through mathematical expressions. The models used to characterize aquatic and terrestrial biogeochemistry response to N and S deposition can be complex, including many interacting variables. Model results are often compared to empirically collected data to confirm the model. Each of the input variables used in a biogeochemical model entails uncertainty. Model uncertainty is governed, in part, by how close the model predictions are to actual observations. Uncertainty in modeled results may arise from limitations in input data or from limitations in model assumptions. Statistical inference methodologies enable uncertainty analysis and determine the strength of the relation between a given uncertain input and the output (i.e., sensitivity analysis). For biogeochemistry models these methods include first-order sensitivity index, Monte Carlo technique, extended Fourier amplitude sensitivity test, Morris one-factor-at-a-time, and Bayesian analysis.

---

#### **IS.14.2.1 Empirical Critical Loads**

Empirical N CLs for terrestrial and aquatic ecosystems reported in this ISA have been estimated using empirical data sets. The exact effects threshold may be determined using expert judgement. For example, if three levels of N addition are applied to a study site (10, 20, and 30 kg N/ha/yr) and an effect is noticed at 20 kg N/ha/yr, then the CL is estimated at <20 kg N/ha/yr. Another approach would be to fit a mathematical function to the observations, and a scientific judgement made to identify the level of deposition and/or N addition, or threshold, at which the ecological effect is considered to occur and which is likely to be biologically adverse.

There are some challenges associated with developing CLs that can result in uncertainty. First, because biological responses are often continuous, there can be a lack of an obvious cutoff between adverse and nonadverse effects. As a result, individual author groups have selected different response thresholds. For example, N CLs for lichens have been calculated for (1) deposition values associated with thallus N concentrations above the 97% distribution quantile observed for clean sites ([Fenn et al., 2008](#)), (2) community composition shifts from oligotroph to eutroph dominance ([Fenn et al., 2008](#)), (3) low probability of detecting regionally distributed sensitive species ([Root et al., 2015](#); [Geiser et al., 2010](#)), or (4) extirpation of oligotrophs ([Fenn et al., 2008](#)). Secondly, clean site data can be lacking in some ecoregions. For instance, few empirical data are available for sites in the eastern U.S. with deposition rates <4 kg N/ha/yr. This makes it difficult to quantify physiological or community compositional conditions that may have occurred in this region at deposition rates of 1–4 kg N/ha/yr.

The [Pardo et al. \(2011a\)](#) study provided a compilation of terrestrial and aquatic N CLs reported since the 2008 ISA. Uncertainty in the derivation of empirical CLs for N input as presented by [Pardo et al. \(2011a\)](#) arises in estimating the ambient (and perhaps historical) deposition loads and in estimating the biological effects caused by those deposition levels. According to [Pardo et al. \(2011a\)](#), sources of uncertainty in N deposition estimates for N CLs at the Ecoregion Level 1 scale include “(1) the difficulty of quantifying dry deposition of nitrogenous gases and particles to complex surfaces; (2) sparse data, particularly for arid, highly heterogeneous terrain (e.g., mountains); and (3) sites with high snowfall or high cloud water/fog deposition, where N deposition tends to be underestimated.” Examples of high uncertainty include high-elevation sites in the Rockies and Sierra Nevada mountains, due in part to highly uncertain estimates of dry deposition ([Appendix 2](#)). For sensitive receptors such as phytoplankton, shifts in high-altitude lakes, N deposition model bias may be close to, or exceed, predicted CL values ([Williams et al., 2017a](#)).

Physical, chemical, and ecological variability across lakes affect their response to N deposition and contribute to uncertainty of CL estimates ([Appendix 9.1.1.2](#)). A review by [Bowman et al. \(2014\)](#) noted that current N CLs for sensitive alpine systems may not be protective under future climate scenarios of warmer summer temperatures and a shorter duration of snow cover.

Between the publication of [Pardo et al. \(2011a\)](#) and the cutoff date for literature in this ISA (May 2017), some additional aquatic and terrestrial N CLs have been published ([Appendix 4](#); [Appendix 6.5](#)). [Simkin et al. \(2016\)](#) was not based on field addition or N gradient of deposition studies; instead, the methods were a spatial analysis of plant diversity using a large data set of over 15,000 forest, shrubland, and herbaceous sites across the U.S. Atmospheric N deposition varied nearly 20-fold across the site gradient. The study authors found that N deposition was negatively correlated with plant species richness at many locations, but positively correlated at others with most of the positive correlations in areas with low N deposition averaging 3 kg N ha/yr or less. [Simkin et al. \(2016\)](#) also estimated the uncertainty surrounding the mean CL estimates. For open canopy ecosystems, for example, they estimated a mean of 8.7 kg N ha/yr and provided 95% confidence intervals, which can be used as estimates of uncertainty, of 6.4 to 11.3 kg N ha/yr. For closed canopy systems, the mean of 13.4 kg N ha/yr was surrounded by a 95% confidence interval of 6.8 to 22.2 kg N ha/yr.

[Clark et al. \(2018\)](#) noted that many of the CLs used are empirically derived. Some of the uncertainties with these CLs are that they are often from one or two studies at a given location or area and extrapolated to a larger area, such as an entire Level 1 ecoregion. Thus, there is uncertainty about how representative these are for larger areas. As noted in

[Horn et al. \(2018\)](#), there also can be covariates unaccounted for that could affect estimates of CLs. CLs also do not generally account for historical effects that already might have affected the ecosystem. There are also uncertainties regarding process-based CLs, such as the terrestrial acidification CL. [Clark et al. \(2018\)](#) specifically pointed towards the existence of poor estimates of soil weathering despite the importance of soil weathering estimates for acidification CLs.

The majority of studies that evaluate terrestrial N CLs for N enrichment effects are based on observed response of a biological receptor to N deposition (or N addition as a proxy for deposition), without a known soil chemistry threshold that causes the biological effect. In contrast, CLs for acidification are typically based on the deposition amount that gives rise to a soil chemical indicator value which is known to cause an adverse biological effect. The link between soil chemical indicator and biological effect is based on empirical evidence ([Appendix 5](#)). The relationship between deposition and the biogeochemistry that causes effects on soil chemistry is typically modeled ([Appendix 4; Section IS.14.2](#)).

---

## **IS.14.2.2 Modeled Critical Loads**

### **IS.14.2.2.1 Terrestrial and Aquatic Acidification: Biogeochemistry**

A variety of process models have been used to estimate past and future resource conditions under scenarios of acidification/recovery responses and critical and target loads, both aquatic and terrestrial. Models include simple approaches such as the simple mass-balance equation (SMBE), and dynamic models, such as PnET-BGC and ForSAFE, MAGIC, VSD, and VSD+ ([Appendix 4.5](#)). CLs for terrestrial and aquatic acidification are calculated by the model to determine the amount of deposition that alters soil or water chemistry to a threshold value known to have detrimental effects on a biological receptor.

Each of the several well-established models of terrestrial biogeochemistry used to evaluate soil acidification ([Appendix 4.5](#)) rely heavily on input or simulated values for base cation weathering (BCw) rate, one of the most influential yet difficult to estimate parameters in the calculation of critical acid loads of N and S deposition for protection against terrestrial acidification ([Appendix 4.5.1.1](#)). Obtaining accurate estimates of weathering rates is difficult because weathering is a process that occurs over very long periods of time, and the estimates on an ecosystem's ability to buffer acid deposition rely on accurate estimates of weathering. Various approaches can be used to estimate BCw, including the empirical soil clay approach, the PROFILE model [e.g., [Phelan et al. \(2014\)](#)], the F-factor approach ([U.S. EPA, 2009c](#)), and calibration of a dynamic model

such as MAGIC [e.g., [Povak et al. \(2014\)](#); [McDonnell et al. \(2014b\)](#)]. There are new studies on estimating BCw, including evaluation of uncertainty ([Whitfield et al., 2018](#); [Futter et al., 2012](#)). When applying PROFILE to upland forests in the U.S., [Whitfield et al. \(2018\)](#) found the greatest uncertainty in BCw estimate was due to the particle size class-based method used to estimate the total specific surface area on which weathering reactions can take place.

The uncertainty of forest soil CLs for acidification in U.S. calculated using simple mass-balance equations (SMBE) was investigated by [Li and McNulty \(2007\)](#). The results included a quantification of how 17 of the model's parameters contributed to the uncertainty and indicated that uncertainty in the CLs came primarily from components of base cation weathering and acid-neutralizing capacity, whereas the most critical parameters were BCw base rate, soil depth, and soil temperature. The study authors concluded that improvements in estimates of these factors are crucial to reducing uncertainty and successfully scaling up SMBE for national assessments (see [Appendix 4.6](#)).

Several dynamic models are commonly used to model terrestrial soil acidification ([Appendix 4.5](#)). [Tominaga et al. \(2009\)](#) conducted a Monte Carlo multiple-model evaluation of the dynamic models MAGIC, SAFE, and VSD and found that given the same deposition scenario, the three models (without calibration) simulate changes in soil and soil solution chemistry differently, but the basic patterns were similar. The study authors also found the greatest differences in model outputs were attributed to the cation exchange submodel. [Bonten et al. \(2015\)](#) compared how well the common types of dynamic models used to evaluate terrestrial soils (VSD, MAGIC, ForSAFE, and SMARTml) quantified several variables including soil S, soil pH, soil ANC, BC, base saturation, and Al ([Appendix 4.5.3](#)).

Uncertainty analysis of a dynamic model (VSD) used for CL based on soil chemistry chemical limits showed that the main drivers of uncertainty were largely dependent on the chemical criterion selected [[Appendix 5.5.3.3](#); [Reinds and de Vries \(2010\)](#)]. For example, base cation weathering, deposition, and the parameters describing the H-Al equilibrium in the soil solution were the main sources of uncertainty in the estimates of maximum CLs for S ( $Cl_{max}[S]$ ) based on the Al:Bc criterion of 1.0, and uncertainty in  $Cl_{max}(S)$  based on ANC was completely determined by base cation inputs. The denitrification fraction was the most important source of uncertainty for the maximum CLs of N ( $Cl_{max}[N]$ ). Calibration of VSD reduced the levels of uncertainty for all CLs and criteria.

[Fakhraei et al. \(2017b\)](#) reviewed sensitivity and uncertainty analysis techniques (e.g., first-order sensitivity index, Monte Carlo technique, extended Fourier amplitude

sensitivity test, Morris one-factor-at-a-time, and Bayesian analysis) in the context of a biogeochemistry model. The study authors applied these techniques to determine the uncertainty and sensitivity of the PnET-BGC model calculation of TMDLs of acidifying deposition that occur in high-elevation, acid-impaired streams in GSMNP ([Fakhraei et al., 2017a](#)). Sensitivity analyses showed that modeled estimates of maximum allowable acidifying deposition loads were most sensitive to uncertainty in model input parameters of air temperature, precipitation quantity, and rate of calcium weathering. Importantly, as more uncertainty was incorporated into model input parameters ( $\pm 5$  to  $\pm 10$  to  $\pm 20\%$  uncertainty), estimates of allowable deposition loads to protect aquatic ecosystem recovery decreased in magnitude ([Fakhraei et al., 2017a](#)).

#### **IS.14.2.2.2 Biogeochemistry and Plant Biodiversity Linked Modeling**

Plant biodiversity models, such as VEG and PROPS, have been coupled to dynamic biogeochemical models, such as ForSAFE and VSD+ ([Mcdonnell et al., 2018b](#); [Mcdonnell et al., 2018a](#); [Phelan et al., 2016](#)). ForSAFE-VEG is an older and more broadly applied model than VSD + PROPS. There are some key differences between VEG and PROPS. Plant species in the VEG component of ForSAFE-VEG are defined by mathematical equations based on expert opinion regarding such parameters as plant needs for moisture, sunlight, and N supply to represent unobservable fundamental niches. In the PROPS, statistical relationships based on empirical data are used to characterize plant species, which are more likely to approximate real-world niches influenced by competition among species. These model chains are subject to the same constraints and uncertainties as the biogeochemical models on their own, plus those of the plant response modules.

#### **IS.14.2.2.3 Aquatic Eutrophication Modeling**

Many of the models that estimate N loads to the coastal zone from land-based inputs (agricultural practices, sewage, atmospheric deposition, natural lands) and freshwater inflow have been compared, and there is a good deal of knowledge about their limitations and uncertainties ([McCrackin et al., 2013](#); [Alexander et al., 2008](#)). A National Research Council review determined that these models are hydrodynamically complex and tend to be site specific. Thus, they are difficult to apply broadly ([NRC, 2000](#)).

The SPARROW model application used only wet N deposition. A large amount of N from nonpoint source urban influences (most likely due primarily to the dry deposition of exhaust N gases) often approximately doubles the importance of N deposition as an N source to higher order river systems ([Howarth, 2008a, b](#)).

---

### IS.14.2.3 Additional Key Considerations for Critical Loads

The choice of model for CL estimation, or for scenario projection, depends largely on the availability of time, data, and resources. Major decisions inherent in the modeling efforts include:

- Empirical observation or application of a model
- Steady-state or dynamic model
- Statistical or process-based model
- Protection against acidification or nutrient N enrichment
- Site-specific, regional, or national spatial scale
- Resources to be protected (i.e., stream, lake, soil, vegetation, aquatic biota)
- Chemical indicator(s) of adverse effects (e.g., water ANC, water  $\text{NO}_3^-$ , soil BS)
- Critical level(s) for selected indicator(s)
- Time frame of evaluation (i.e., ambient, 2050, long-term steady state)

Each of these decision points introduces additional uncertainties, data needs, and potential assessment errors. [U.S. EPA \(2008a\)](#) summarized CL research and monitoring needs identified by [U.S. EPA \(2006b\)](#) at the time of the previous (2009) U.S. EPA Risk and Exposure Assessment.

---

### IS.14.3 Aquatic Acidification Index

Detailed analysis of uncertainty in the AAI equation can be found in Appendix F of the 2011 Policy Assessment for the Review of the Secondary National Ambient Air Quality Standards for Oxides of Nitrogen and Oxides of Sulfur ([U.S. EPA, 2011a](#)). The AAI is made up of components including ecosystem effects; dose-response relationships; underlying ecosystem sensitivity to acid deposition, biogeochemical, atmospheric and deposition processes; and characterization of ecosystem services. Some degree of uncertainty exists in all of the components of the AAI. Overall, the 2011 Policy Assessment found, on balance, low uncertainty in the information and processes associated with linkages from ecological effects to atmospheric conditions through deposition and ecosystem modeling. However, it acknowledged the need to improve certainty of several components including nitrogen and sulfur deposition processes in CMAQ, natural emissions of  $\text{NO}_x$  from lightning processes, and improving the amount of samples of CL estimates at several ecoregions ([U.S. EPA, 2011a](#)).

---

# APPENDIX 1    QUALITY ASSURANCE AND INTRODUCTION TO APPENDICES

---

## 1.1    Quality Assurance Summary

The use of quality assurance (QA) and peer review helps ensure that the U.S. EPA conducts high-quality science assessments that can be used to help policymakers, industry, and the public make informed decisions. Quality assurance activities performed by the U.S. EPA ensure that environmental data are of sufficient quantity and quality to support the Agency's intended use. The ISA for Oxides of Nitrogen, Oxides of Sulfur and Particulate Matter-Ecological Criteria is classified as a Highly Influential Scientific Assessment (HISA), which is defined by the Office of Management and Budget (OMB) as a scientific assessment that is novel, controversial, or precedent-setting, or has significant interagency interest (OMB, 2004). OMB requires a HISA to be peer reviewed before dissemination. To meet this requirement, the U.S. EPA engages the Clean Air Scientific Advisory Committee (CASAC) as an independent federal advisory committee to conduct peer reviews. Both peer-review comments provided by the CASAC panel and public comments submitted to the panel during its deliberations about the external review draft were considered in the development of this ISA.

Agency-wide, the U.S. EPA Quality System provides the framework for planning, implementing, documenting, and assessing work performed by the Agency, and for carrying out required quality assurance and quality control (QA/QC) activities. Additionally, the Quality System covers the implementation of the U.S. EPA Information Quality Guidelines (U.S. EPA, 2002). This ISA follows all Agency guidelines to ensure a high-quality document.

Within the U.S. EPA, Quality Assurance Project Plans (QAPPs) are developed to ensure that all Agency materials meet a high standard for quality. U.S. EPA has developed a Program-level QAPP (PQAPP) for the ISA Program to describe the technical approach and associated QA/QC procedures associated with the ISA Program (PQAPP ID# L-HEEAD-0030253-QP-1-0). All QA objectives and measurement criteria detailed in the PQAPP have been employed in developing this ISA. Quality assurance checks were conducted on numerical entries used in the appendices, and at a minimum, the numbers obtained from every tenth reference cited in the appendices were verified against the original source by an independent scientist for accuracy. Furthermore, publicly available databases (e.g., National Emissions Inventory, Air Quality System database) from which data was used in analyses were verified to have their own QA processes in place. U.S. EPA QA staff are responsible for the review and approval of all quality-related

documentation. Because this is a Highly Influential Scientific Assessment, U.S. EPA QA staff performed a Technical System Audit on the ISA in June 2018 and August 2019. These audits verified that the appropriate QA/QC procedures and reviews were adequately performed and documented.

---

## 1.2 Introduction to the Appendices

The appendices and [Integrated Synthesis](#) serve different purposes in this ISA. The [Integrated Synthesis](#) is meant to summarize the key messages derived from assessment of the policy relevant science of NO<sub>y</sub>, SO<sub>x</sub>, and PM in this review of the secondary National Ambient Air Quality Standards. It provides a general introduction to the purpose, process, development, and organization of the ISA as well as highlights connections, concepts, and changes based on new evidence and causality. In addition, the [Integrated Synthesis](#) provides a discussion of uncertainty and a synthesis of information on the recovery of ecosystems from N and S deposition.

While the purpose of the [Integrated Synthesis](#) is to synthesize, integrate, and provide key messages, the purpose of the appendices is to provide a more detailed description of the state of science for specific topic areas. [Appendix 1](#) is an introduction to the purpose and organization of [Appendix 2–Appendix 16](#). [Appendix 2](#) characterizes the sources, atmospheric processes, and the trends in ambient concentrations and deposition of NO<sub>y</sub>, SO<sub>x</sub>, and PM. [Appendix 3](#) describes the direct effects of NO<sub>y</sub> and SO<sub>x</sub> gases on plants and lichens. [Appendix 4–Appendix 6](#) describe the effects of N and S deposition on biogeochemistry and the biological effects of acidification and N enrichment in terrestrial environments. [Appendix 7](#) describes the effects of N and S deposition on aquatic biogeochemistry. [Appendix 8–Appendix 10](#) characterize the biological effects of freshwater acidification, freshwater N enrichment, and N enrichment in estuaries and near-coastal systems. [Appendix 11](#) describes the effects of N deposition on wetlands, and [Appendix 12](#) characterizes the ecological effects of S as a nutrient. [Appendix 13](#) presents information on climate modification of ecosystem response to N and S, while [Appendix 14](#) discusses ecosystem services. [Appendix 15](#) is a review of the ecological effects of forms of PM, not related to N or S deposition. Finally, [Appendix 16](#) presents case studies for six locations in the U.S. (southern California, northeastern U.S., Rocky Mountain National Park, southeastern Appalachia, Tampa Bay, and the Adirondacks) where data are sufficient to well characterize the ecological effects of N and S deposition. These sites would therefore make good candidates to assess risk and exposure by exploring linkages across various effects and ecosystems-types in a specific location.

---

## APPENDIX 2 SOURCE TO DEPOSITION

---

### 2.1 Introduction

In this appendix, emphasis is placed on those species subject to atmospheric processes relevant for review of the air quality criteria and associated welfare-based secondary National Ambient Air Quality Standards (NAAQS) for oxides of nitrogen, oxides of sulfur, and/or particulate matter (PM). As such, this appendix largely focuses on examining the fundamental and applied science of atmospheric processes relevant to assessing environmental exposures and effects associated with atmospheric deposition of nitrogen (N) and sulfur (S) species, including those present in PM.<sup>1</sup> Together this information serves as a prologue to the detailed descriptions of the evidence of ecological effects from oxidized and reduced N and oxidized S, including those present in PM, that follow in later appendices.

Recent advances in research on N and S emissions sources, atmospheric transformation and transport, measurement and modeling techniques, atmospheric loadings, and deposition processes relevant to this review of the NAAQS are evaluated in this appendix. N and S species of interest are generally classified into three groups: oxidized nitrogen, reduced nitrogen, and oxidized sulfur. While NO<sub>2</sub> and SO<sub>2</sub> are the most well known as air pollutants, research on the entire range of oxides of nitrogen and sulfur is considered for review of the air quality criteria. Reduced nitrogen is also discussed because it strongly influences the atmospheric deposition of NO<sub>Y</sub> and SO<sub>X</sub> as well as the chemistry of PM formation. Oxidized nitrogen, reduced nitrogen, and oxidized sulfur all have particulate forms (NO<sub>3</sub><sup>-</sup>, NH<sub>4</sub><sup>+</sup>, SO<sub>4</sub><sup>2-</sup>), which together account for a large fraction of PM mass ([U.S. EPA, 2019](#)), as well as gas-phase components that act as major precursors to PM. Thus, a consideration of the combined effects of oxides of nitrogen, oxides of sulfur, and PM requires an understanding of the atmospheric processes involving oxidized nitrogen, reduced nitrogen, and oxidized sulfur.

Oxidized nitrogen species considered here range from nitric oxide (NO) and nitrogen dioxide (NO<sub>2</sub>), collectively referred to as NO<sub>X</sub>, to higher order organic and inorganic oxidation products, collectively referred to as NO<sub>Z</sub> (e.g., pNO<sub>3</sub>, HNO<sub>3</sub>, HONO, PAN, other organic nitrates). NO<sub>Z</sub> is especially relevant when considering nutrient addition to ecosystems and the acidification of surface waters. NO<sub>X</sub> and NO<sub>Z</sub> together are referred to

---

<sup>1</sup> Since ecological effects of PM are governed mainly by PM composition, the most relevant PM species (nitrate and sulfate) are also species that are derived from sulfur and nitrogen oxide precursors, and there is a high degree of overlap in the discussion of the impacts of NO<sub>Y</sub> and SO<sub>X</sub>, and the impacts of PM<sub>2.5</sub>. The PM ISA ([U.S. EPA, 2009a](#)) provides more extensive information about the atmospheric processes for total PM mass.

as  $\text{NO}_Y$  (i.e.,  $\text{NO}_X + \text{NO}_Z = \text{NO}_Y$ ). Nitrous oxide ( $\text{N}_2\text{O}$ ) is an oxide of nitrogen, but it is not included as a component of  $\text{NO}_Y$ .  $\text{N}_2\text{O}$  contributes to stratospheric ozone depletion and climate forcing [AR5; [IPCC \(2013\)](#)], but it contributes little to N deposition, and is not included in this appendix.

Reduced nitrogen species are  $\text{NH}_3$  and  $\text{NH}_4^+$  as well as reduced organic nitrogen compounds.  $\text{NH}_3$  and  $\text{NH}_4^+$  together are referred to as  $\text{NH}_X$  (i.e.,  $\text{NH}_3 + \text{NH}_4^+ = \text{NH}_X$ ). Reduced nitrogen contributes to acidification and N enrichment, and it also has a key role in neutralizing acidity in cloud, fog, and rainwater as well as aqueous aerosol particles formed from atmospheric oxidation of  $\text{SO}_2$  and  $\text{NO}_X$ . Additionally,  $\text{NH}_3$  is a precursor for atmospheric particulate matter, reacting with gas-phase nitric acid ( $\text{HNO}_3$ ) to form ammonium nitrate ( $\text{NH}_4\text{NO}_3$ ), a major component of N deposition in many areas of the U.S. For this assessment,  $\text{NO}_Y$  and  $\text{NH}_X$  are grouped together as total reactive nitrogen,  $\text{N}_r$  (i.e.,  $\text{NO}_Y + \text{NH}_X = \text{N}_r$ ).  $\text{N}_r$  does not include nitrous oxide and reduced organic nitrogen compounds. However, to the extent it is available, information on the sources, abundances, and fate of reduced organic nitrogen is included in the sections that follow.

Gaseous oxides of sulfur ( $\text{SO}_X$ ) is defined to include sulfur monoxide ( $\text{SO}$ ), sulfur dioxide ( $\text{SO}_2$ ), sulfur trioxide ( $\text{SO}_3$ ), and disulfur monoxide ( $\text{S}_2\text{O}$ ). Of these only  $\text{SO}_2$  is present in the lower troposphere at concentrations relevant for environmental considerations. However,  $\text{SO}_2$  interacts with particles and cloud drops and is oxidized to sulfate.  $\text{SO}_2$  and sulfate ( $\text{SO}_4^{2-}$ ) account for much of the acidification of surface water in the U.S. and together these make up total oxides of sulfur discussed in this appendix ( $\text{SO}_X$ ).

Particulate matter (PM) impacts discussed in this document are also mainly focused on N and S containing species, which together usually make up a large fraction of the fine PM mass in many areas of the U.S. and have better understood and potentially greater ecological impacts than other PM components. PM is usually classified into two size fractions which differ in their physical and chemical characteristics, atmospheric behavior, and health and environmental effects. These are  $\text{PM}_{2.5}$ , particles smaller than 2.5  $\mu\text{m}$  in diameter, and  $\text{PM}_{10-2.5}$ , particles with diameter between 2.5 and 10  $\mu\text{m}$ . Ecological impacts of PM depend largely on its composition ([U.S. EPA, 2009a, 2004](#)). Together  $\text{PM}_{2.5}$  and  $\text{PM}_{10-2.5}$  make up  $\text{PM}_{10}$ . PM contains numerous individual components representing a wide range of chemical and physical properties. However, in most areas of the U.S.  $\text{PM}_{2.5}$  mass is composed mainly of sulfate, nitrate, and organic materials. In contrast,  $\text{PM}_{10-2.5}$  is composed of crustal material similar in composition to soil in the area where the  $\text{PM}_{10-2.5}$  is found, as well as sea salt in coastal areas. There is little discussion of  $\text{PM}_{10-2.5}$  effects in this document because in most rural and remote areas  $\text{PM}_{10-2.5}$  is largely due to natural sources like soil and sea salt.

There are several other reasons for focusing on the sulfate and nitrate fraction of  $PM_{2.5}$  mass in this document in addition to the observation that they often account for most  $PM_{2.5}$  mass. Together they also usually account for an even greater fraction of  $PM_{2.5}$  in rural and remote areas that make up most of the U.S. land mass over which effects in this document are relevant. While organic matter can also account for a large fraction of  $PM_{2.5}$ , it is composed of a wide variety of individual compounds that cannot be identified at a molecular level, making it difficult to assess ecological impacts. Also, there is little information on organic PM impacts, except for individual compounds that make minor contributions to mass. As a result, the main contributors to  $PM_{2.5}$  mass for which ecological impacts can be readily assessed are limited to sulfate and nitrate, which are also components of total oxides of sulfur and oxides of nitrogen, respectively. Since ecological effects of PM are governed mainly by PM composition, the most relevant PM species (nitrate and sulfate) are also species that are derived from sulfur and nitrogen oxide precursors, and there is a high degree of overlap in the discussion of the impacts of  $NO_y$  and  $SO_x$ , and the impacts of  $PM_{2.5}$ .

In addition to nitrogen (N) and sulfur (S) and their transformation products, other PM components such as trace metals and organics are deposited to ecosystems and may subsequently impact biota. Evidence for effects of PM on ecological receptors include direct effects of airborne PM on radiative flux and both direct and indirect effects of deposited particles. Direct effects include alteration of leaf processes from deposition of PM (“dust”) to vegetative surfaces ([U.S. EPA, 2009a](#)). Indirect effects encompass physiological responses associated with uptake of PM components and alterations to ecosystem structure and function (see [Appendix 15](#)).

Much of the discussion in sections dealing with chemistry, measurement, and deposition (both wet and dry) focus on sulfuric acid ( $H_2SO_4$ ) and  $HNO_3$ , which have been long established as the major species contributing to acid rain. Other N and S species that either hydrolyze to form acids are also included, along with organic acids, to the extent that they contribute substantively to acidification of terrestrial (see [Appendix 5](#)) and aquatic environments (see [Appendix 8](#)) and/or N enrichment (see [Appendix 6](#), [Appendix 7](#), [Appendix 10](#), and [Appendix 11](#)).

Major sources of the precursors ( $NO_x$ ,  $SO_2$ ) to the formation of  $HNO_3$  and  $H_2SO_4$  include on- and off-highway vehicles and electricity-generating units (EGUs).  $SO_2$  is oxidized to  $H_2SO_4$  either in the gas phase or cloud water by several well-known mechanisms.  $NO_2$  is oxidized to  $HNO_3$ , which can either deposit as  $HNO_3$  or interact with  $NH_3$  to form particulate  $NH_4NO_3$ .  $NH_4NO_3$  can exhibit semivolatile behavior that can substantially alter the distance over which  $NH_3$  and  $HNO_3$  can travel. Reduced organic nitrogen species, which could have large agricultural sources, can constitute a substantial fraction

of N delivered to ecosystems by precipitation. In areas where the rainwater pH is greater than about 4.5, pH is not exclusively controlled by N and S species, as organic acids such as formic, acetic, and oxalic acids can be major contributors to the acidity of rainwater.

A wide variety of N containing compounds, consisting of oxidized and reduced organic and inorganic species contribute to wet and dry deposition. In general, deposition of reduced (organic + inorganic) N exceeds that of oxidized N across the contiguous U.S. (CONUS). Nationwide, deposition of N species occurs mainly by dry deposition of  $\text{HNO}_3$  and  $\text{NH}_3$ . The pattern is more complex for S in that for large areas, mainly in the central U.S., wet deposition tends to dominate over dry deposition. However, in some regions mostly in the west, dry deposition of mainly  $\text{SO}_2$  makes a greater contribution than wet deposition.

Precipitation chemistry has been monitored at a large number of sites across the U.S. for several decades as part of the National Atmospheric Deposition Program (NADP). Concentrations of inorganic gas and particulate phase N and S species have been monitored across the U.S. since 1990 by the Clean Air Status and Trends Network (CASTNET). These concentrations are used in atmospheric models to infer dry deposition (i.e., the transfer of gaseous and particulate pollutants from the atmosphere to the surface by impaction through turbulent motions and gravitational settling). Starting in 2007, monitoring of  $\text{NH}_3$  was initiated at a subset of CASTNET sites. Cloud deposition, which can account for the bulk of deposition at high elevations in mountainous areas, is monitored at two locations on a regular basis, but has been the subject of shorter term field studies in various locations in the U.S.

Although the pH of rainwater has increased noticeably across the U.S., coincident with notable decreases in the wet deposition of nitrate and sulfate since 1990, there are still widespread areas, mainly in the eastern U.S., affected by acid precipitation. Deposition of total nitrogen has not reflected the continuing decrease in  $\text{NO}_x$  emissions, largely because deposition of  $\text{NH}_3$  has increased. Large areas, at least one-third of the contiguous U.S. (CONUS), are estimated to receive at least 10 kg/ha/yr wet + dry deposition of reactive nitrogen species. This estimate is likely too low because reduced organic nitrogen species are not measured by the routine monitoring networks or considered in air quality models such as U.S. EPA's Community Multiscale Air Quality (CMAQ) modeling system.

Three of the four major contributors to inorganic N deposition are included in the definitions of either oxides of nitrogen or particulate matter:  $\text{HNO}_3$  is an oxide of nitrogen,  $\text{NH}_4^+$  is a PM component, particulate  $\text{NO}_3^-$  is both a PM component and an oxide of nitrogen. The fourth major contributor,  $\text{NH}_3$ , is neither an oxide of nitrogen nor a component of particulate matter. In a recent comparison, the contribution of  $\text{NH}_3$  to total inorganic N deposition ranged from 19% in locations in the Northwest U.S. to 63% in

locations in the Southwest U.S., and was generally higher in summer than in winter ([Li et al., 2016d](#)). In general, the majority of inorganic N deposition was accounted for by oxides of nitrogen and particulate matter in the Northwest, Northeast, Southeast, and Rocky Mountains, but the contribution of oxides of nitrogen and particulate matter was roughly equivalent to contributions from NH<sub>3</sub> in the Upper Midwest, Florida, and smaller in the Southwest ([Li et al., 2016d](#)). However, because NH<sub>3</sub> is a PM precursor, it can also be definitively stated that inorganic N deposition is entirely accounted for by oxides of nitrogen, PM components, and PM precursors.

Since the *2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur—Ecological Criteria* [hereafter referred to as the 2008 ISA; [U.S. EPA \(2008a\)](#)], there have been a number of new developments. These apply to methods, such as data-model fusion to integrate information for deposition across the U.S.; the use of chemistry-transport models linking deposition to ambient air quality; the expansion of CASTNET monitoring to include NH<sub>3</sub> and NO<sub>y</sub> at selected sites and intercomparisons of monitoring methods with research grade instruments; and advances being made in satellite-based measurements in conjunction with chemistry-transport model simulations of tropospheric NO<sub>2</sub>, SO<sub>2</sub>, and NH<sub>3</sub> that will allow mapping of dry deposition over remote areas with spatial resolution of ~10 km × 10 km. These new developments are described in the following sections of this appendix. [Appendix 2.2](#) considers sources and emissions of N, S, and PM to the atmosphere. [Appendix 2.3](#) summarizes the atmospheric chemical transformations of N and S compounds and formation of PM that occur during transport from sources to deposition to the surface. [Appendix 2.4](#) describes measurement of relevant atmospheric species, including national monitoring networks and methods. [Appendix 2.5](#) discusses the use of chemical transport models to estimate deposition. [Appendix 2.6](#) shows the geographic distributions of atmospheric concentrations and deposition of N, S, and PM.

---

## 2.2 Sources of Nitrogen and Sulfur Compounds and Particulate Matter to the Atmosphere

This section describes advances in our understanding of NO<sub>x</sub>, NH<sub>3</sub>, and SO<sub>2</sub> emissions. [Appendix 2.2.1](#) describes annual national emissions of each species based mainly on the 2014 National Emissions Inventory (NEI). [Appendix 2.2.2](#) describes methods of estimating emissions. Methods for major sources of SO<sub>2</sub> and NO<sub>x</sub> are reliable and have remained largely the same since the last review. The same is true to an extent for direct PM emissions. However, there have been fundamental changes in methods for estimating NH<sub>3</sub> emissions, and these are described in some detail. [Appendix 2.2.3](#) describes emission uncertainties, including recent comparisons between NEI data and alternative

methods of estimating emissions. Geographic distributions of emissions are presented in [Appendix 2.5](#), where they can be more directly compared with concentration and deposition data.

---

## 2.2.1 National Emissions by Source

N and S containing compounds contributing to deposition can be either primary (i.e., directly emitted from sources) or secondary (i.e., produced from atmospheric reactions involving precursor species directly emitted from sources). Major primary species include NO<sub>x</sub>, SO<sub>2</sub>, NH<sub>3</sub>, and reduced organic nitrogen (RON).

[Table 2-1](#) shows nationwide emissions of NO<sub>x</sub>, SO<sub>2</sub>, and NH<sub>3</sub> by source category compiled from the 2014 National Emissions Inventory (NEI) and other sources. Emissions estimates are not available for RON. For the most part, NO<sub>x</sub>, SO<sub>2</sub>, and NH<sub>3</sub> are each emitted by different sources. NO<sub>x</sub> emissions come from several important sources. Highway vehicles are the largest source category of NO<sub>x</sub> emissions nationwide, but off-highway vehicles, EGUs, other stationary fuel combustion, industrial processes, fires, and biogenic emissions from soil are all substantial contributors to total NO<sub>x</sub> emissions. Lightning is not included in the NEI, but it can also contribute substantially to total NO<sub>x</sub> emissions. Although lightning is shown as a relatively modest source of NO<sub>x</sub>, most production by lightning occurs during the summer and is the highest in the south-central and southwestern U.S. ([Zhang et al., 2012a](#)).

NH<sub>3</sub> originates mainly from agricultural sources, which account for ~80% of its emissions nationwide. Major sources are livestock waste, including confined animal feeding operations, and soils, after addition of N containing fertilizers. Fertilizer application occurs mainly during spring and summer. Emissions from livestock waste are roughly three times those from fertilizer application. In addition to NH<sub>3</sub>, reduced organic compounds such as urea and a wide range of proteins and other biological components are also emitted as the result of agricultural activity. [Xing et al. \(2013\)](#) observed that in contrast to SO<sub>2</sub>, NO<sub>x</sub>, and other pollutants, total national emissions of NH<sub>3</sub> increased from 1990 to 2010. The authors attributed this to agricultural emissions, including livestock, which they also identified as the dominant source of NH<sub>3</sub> emissions in the continental U.S. However, regionally the relative importance of agricultural and vehicle emissions is likely to be variable. The deposition of reduced nitrogen can be three times higher near roads ([Bettez et al., 2013](#)), and motor vehicles can be a substantial contributor to total NH<sub>3</sub> emissions in urban areas ([Baum et al., 2001](#)).

**Table 2-1 Emissions of NO<sub>x</sub> (nitric oxide + nitrogen dioxide), sulfur dioxide, and ammonia by source category for 2017 (Teragrams<sup>a</sup> N, S/yr).**

	NO <sub>x</sub>	SO <sub>2</sub>	NH <sub>3</sub>
Highway vehicles	1.0	0	0.1
Off-highway	0.7	0.1	<0.1
Utilities (fuel combustion)	0.3	0.6	<0.1
Other stationary (fuel combustion)	0.3	0.1	<0.1
Industrial and other processes	0.4	0.4	0.2
Livestock waste	0	0	1.9

<sup>b</sup>Not applicable.

<sup>c</sup>[Bouwman et al. \(1997\)](#).

Source: <https://www.epa.gov/air-emissions-inventories/air-pollutant-emissions-trends-data> update except as noted.

SO<sub>2</sub> emissions are dominated by stationary sources burning fossil fuels, particularly EGUs, which contribute about half of total nationwide SO<sub>2</sub> emissions. SO<sub>2</sub> emissions densities in most counties east of the Mississippi River are larger than in most counties in the West (see [Appendix 2.6.5](#)).

Emissions of NO<sub>x</sub> and SO<sub>2</sub> have decreased appreciably in recent years. National emissions of NO<sub>x</sub> have decreased by 61%, and national SO<sub>2</sub> emissions by 89% from 1990 to 2017 ([OAQPS-Emissions Inventory and Analysis Group, 2016](#)). Further details of declining emissions for these species can be found in the ISAs for health effects for NO<sub>x</sub> and SO<sub>2</sub> ([U.S. EPA, 2017d, 2016f](#)). In contrast, nationwide primary PM<sub>2.5</sub> and PM<sub>10</sub> emissions estimates have changed little between the 2002 NEI ([U.S. EPA, 2009a](#)) and the 2017 NEI ([U.S. EPA, 2020a](#)), with national PM<sub>2.5</sub> emissions estimates decreasing from 5.8 to 5.7 MMT, and PM<sub>10</sub> emissions estimates decreasing from 21.6 to 17.1 MMT. National annual NH<sub>3</sub> emissions have fluctuated as a result changes in both emissions and

methods of estimating emissions. However, no clear trend is evident in national NH<sub>3</sub> emissions, with estimates for 1990 and 2017 differing by less than 1%.

Not included in [Table 2-1](#) are primary emissions of PM<sub>2.5</sub> and PM<sub>10</sub>. Nationwide PM<sub>10</sub> emissions according to the 2014 NEI totaled 17.0 MMT. This is somewhat higher than the SO<sub>2</sub>, NO<sub>x</sub>, and NH<sub>3</sub> emissions in [Table 2-1](#), but 85% of these were from dust and fires, dominated by soil and organic matter. By comparison, total nationwide PM<sub>2.5</sub> primary emissions totaled 5.3 MMT based on the 2014 NEI. This is comparable to the totals for NO<sub>x</sub>, SO<sub>2</sub> in [Table 2-1](#) when it is considered that emissions in [Table 2-1](#) are given in terms of mass of N and S and does not include oxygen, while PM<sub>2.5</sub> emissions are based on total mass. However, primary PM<sub>2.5</sub> emissions are also dominated by dust (i.e., agricultural dust and road dust) and fires (i.e., wildfires, prescribed fires, and agricultural fires), which together account for two-thirds of total nationwide PM<sub>2.5</sub> primary emissions. PM<sub>2.5</sub> from these source categories are mainly crustal material (dust) and organic matter (fires).

As described in [Appendix 2.1](#), in rural and remote areas secondary PM<sub>2.5</sub> formed from NO<sub>x</sub> and SO<sub>2</sub> account for a greater fraction of PM<sub>2.5</sub> than primary PM<sub>2.5</sub>. The fraction of PM<sub>2.5</sub> accounted for by NO<sub>3</sub><sup>-</sup> and SO<sub>4</sub><sup>2-</sup> formed from SO<sub>2</sub> and NO<sub>x</sub> in various U.S. locations is discussed in [Appendix 2.3](#). The NO<sub>x</sub>, SO<sub>2</sub>, and NH<sub>x</sub> emissions listed in [Table 2-1](#) cannot be used to quantitatively estimate the amount of secondary PM formed because the precursors are not completely converted to PM. However, they provide not only an estimate of emissions that lead to total NO<sub>y</sub> and SO<sub>x</sub>, but also provide an estimate of the emissions that can be used in conjunction with atmospheric models to estimate PM<sub>2.5</sub> concentrations (see [Appendix 2.5](#)). The emissions estimated in [Table 2-1](#) are ultimately responsible for a large fraction of PM<sub>2.5</sub> in many areas, and it is the fraction of PM mass (i.e., SO<sub>4</sub><sup>2-</sup>, NO<sub>3</sub><sup>-</sup>, NH<sub>4</sub><sup>+</sup>) for which ecosystem impacts are best understood.

---

## 2.2.2 Methods of Estimating Emissions

The source categories used in [Table 2-1](#) represent groups of similar NEI source sectors. Highway Vehicles comprise all on-road vehicles, including light-duty as well as heavy-duty vehicles, both gasoline and diesel powered. Off-highway vehicles and engines include aircraft, commercial marine vessels, locomotives, and nonroad equipment. Utilities (Fuel Combustion), also identified as electric power-generating units (EGUs), are mostly coal burning, but some facilities burn natural gas and other fuels. Other Stationary (Fuel Combustion) includes commercial/institutional, industrial, and residential combustion of biomass, coal, natural gas, oil, and other fuels. Industrial and Other Processes include a variety of different industries, including chemical

manufacturing, cement manufacturing, and oil and gas production. The other processes included in this category include gasoline stations and terminals, commercial cooking, road and construction dust, solvent use, and waste disposal. Agriculture includes both fertilizer application and livestock waste emissions. Fires include wildfires, prescribed fires, and agricultural field burning. The biogenic category includes emissions from vegetation and soil. Both nitrifying and denitrifying organisms in the soil can produce NO<sub>x</sub>, mainly in the form of NO.

Emissions data for each source category listed in [Table 2-1](#) are from the 2014 National Emissions Inventory (NEI), Version 1. The NEI is a national compilation of criteria air pollutant and hazardous air pollutant emissions. The process of estimating emissions is explained for each source in a detailed technical support document for the inventory ([U.S. EPA, 2016b](#)). The NEI is maintained to support the NAAQS, and the Clean Air Act requires states to submit emissions to the U.S. EPA as part of their State Implementation Plans (SIPs). The Air Emissions Reporting Rule (AERR) requires agencies to report all sources of emissions, except fires and biogenic sources. Reporting of open fire sources, such as wildfires, is encouraged, but not required. Data in the NEI come from a variety of sources. The emission values are predominantly from state, local, and tribal agencies and are used wherever they are available, unless there are gaps or problems with submitted data. U.S. EPA quality assures and augments the data provided by states to assist with data completeness using separate augmentation procedures for each source as described in detail in a technical support document to fill in gaps for sources and/or pollutants that are often not reported by state, local, and tribal agencies. The intent is to create the most complete inventory for use in air quality modeling, national rule assessments, international reporting, and other reports. QA procedures and acceptance criteria are detailed in the NEI technical support document ([U.S. EPA, 2016b](#)).

For nonpoint sources, U.S. EPA provides tools that state, local, and tribal agency staff can use to generate emission estimates. For the 2014 NEI, the U.S. EPA developed emission estimates for many nonpoint sectors in collaboration with a consortium of inventory developers from various state agencies regional planning organizations called the Nonpoint Method Advisory (NOMAD) Committee. More detailed NOMAD subcommittees were established to collaborate on methods and emission factors for key nonpoint source categories/sectors, including oil and gas exploration and production, residential wood combustion, agricultural NH<sub>3</sub> sources (including fertilizer and livestock), and industrial and commercial/institutional fuel combustion, among other sources. The U.S. EPA also generates emission estimates as stand-alone data sets covering biogenics, agricultural livestock, fertilizer application, nonroad mobile sources, rail emissions, and commercial marine vessel ports and in-transit (underway) sources. U.S. EPA data sets for sources and pollutants are used only for sources not provided by

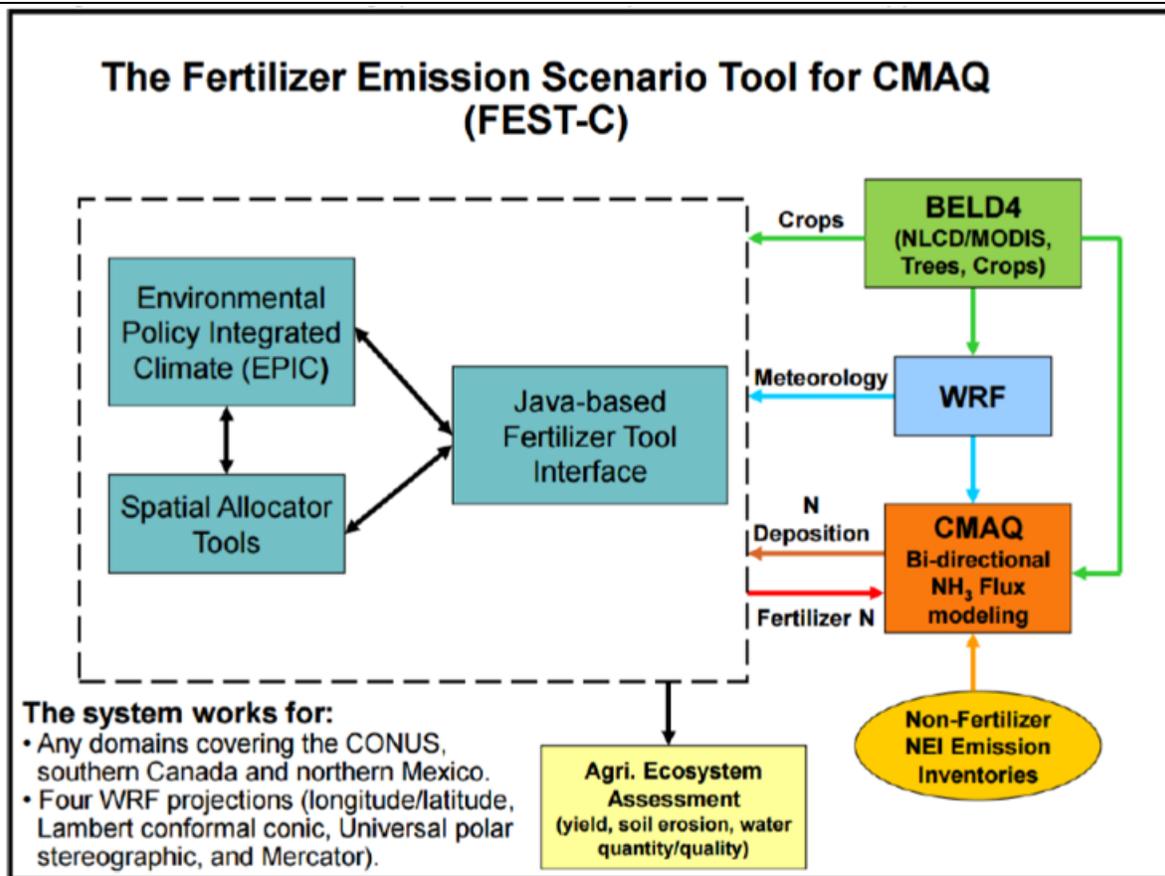

state, local, and tribal data. Tools and methods for estimating emissions from a given source, including EGUs, agricultural livestock, fertilizer application, mobile sources, agricultural and wildland fires (wildfires + prescribed fires), and wood combustion, were described in the 2014 NEI technical support document ([U.S. EPA, 2016b](#)).

The 2014 NEI technical support document provides considerable detail on emission factors and emission estimation methods by source used to generate the data in [Table 2-1 \(U.S. EPA, 2016b\)](#). Methods for estimating PM<sub>2.5</sub> and PM<sub>10</sub> emissions from dust and fire, the two largest national sources, are derived from experimental emission factors along with source specific information (e.g., crop type and tilling frequency for agricultural dust, vehicle weight and miles traveled for unpaved road dust) using source specific equations available in the NEI technical support document. These methods are largely well-established, although they have been updated to accommodate satellite data and emissions modeling improvements, particularly in the case of fire emissions.

Methods for estimating emissions from electric power-generating units and mobile sources, the largest sources of SO<sub>2</sub> and NO<sub>x</sub>, are also well established, and emissions from these sources are decreasing. In contrast, ammonia emissions in the U.S. are increasing ([Butler et al., 2016](#)), and significant uncertainties in the magnitude as well as spatial and temporal variability of NH<sub>3</sub> emissions estimates were reported in the 2008 ISA ([U.S. EPA, 2008a](#)). Two new methods for estimating ammonia emissions from fertilizer applications and livestock waste are highly relevant to understanding NH<sub>x</sub> sources and deposition are provided here as examples, but a similar level of detail is given in the NEI technical support document for other sources of NH<sub>3</sub>, SO<sub>2</sub>, and NO<sub>x</sub>, and a thorough reading of that document is necessary for a full description of emissions estimation methods used to construct [Table 2-1 \(U.S. EPA, 2016b\)](#).

Soil and fertilizer emissions are treated differently in the NEI for NH<sub>3</sub> and NO<sub>x</sub>. For NH<sub>3</sub>, fertilizer application is recognized as a major source for which emissions are specifically estimated, and emissions from fertilizer application are estimated only for NH<sub>3</sub>. The approach to calculating emissions from fertilizer application in the 2014 NEI is a completely new methodology to estimate ammonia (NH<sub>3</sub>) emissions from agricultural soils. The approach to estimate 2014 fertilizer emissions consists of these steps: (1) run the Fertilizer Emissions Scenario Tool for CMAQ FEST-C (v1.2; <https://www.cmascenter.org/fest-c/>) and the bidirectional version of CMAQ (v5.0.2; <https://www.cmascenter.org/>) to produce year 2011 nitrate (NO<sub>3</sub>), ammonium (NH<sub>4</sub><sup>+</sup>, including urea), and organic (manure) nitrogen (N) fertilizer usage estimates, and gaseous ammonia NH<sub>3</sub> emission estimates respectively; (2) calculate county-level emission factors for 2011 as the ratio of bidirectional CMAQ NH<sub>3</sub> fertilizer emissions to FEST-C total N fertilizer application; (3) run FEST-C to produce year 2014 NO<sub>3</sub>, NH<sub>4</sub><sup>+</sup> (including

Urea), and organic (manure) nitrogen fertilizer usage estimates; and (4) multiply county-level 2014 FEST-C total fertilizer estimates by the 2011 emission factors to estimate 2014 NH<sub>3</sub> emissions. FEST-C reads land use data from the Biogenic Emissions Land Use Dataset (BELD) Version 4, meteorological variables from the Weather Research and Forecasting (WRF v3.7.1) model (<https://www.mmm.ucar.edu/weather-research-and-forecasting-model>) and nitrogen deposition data from a previous or historical average CMAQ simulation. The Environmental Policy Integrated Climate (EPIC) modeling system (<http://epicapex.tamu.edu/>) provides information regarding fertilizer timing, composition, application method, and amount. [Figure 2-1](#) provides a comprehensive flowchart of the complete EPIC/FEST-C/WRF modeling system.

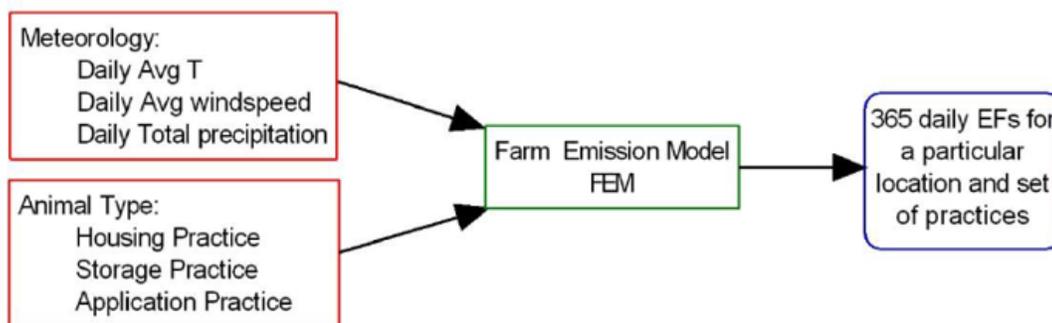

Source: [U.S. EPA \(2016b\)](#).

**Figure 2-1 Modeling system used to compute 2014 Fertilizer Application Emissions.**

Fertilizer application can also lead to NO<sub>x</sub> emissions, but it does not dominate soil emissions of NO. Biogenic emissions of NO are computed based on 2014 meteorology data from the Weather Research and Forecasting (WRF) model version 3.8 (WRF v3.8) and using the Biogenic Emission Inventory System, Version 3.61 (BEIS 3.61) model, based on land use and vegetation data ([U.S. EPA, 2016b](#)). The contribution of fertilizers to soil NO<sub>x</sub> emissions is not estimated in the NEI, but it has been estimated as 10% globally ([Hudman et al., 2012](#)). Biogenic emissions of NH<sub>3</sub> are not estimated in the NEI, but aside from fertilizer application it is a minor contributor, as shown in [Table 2-1](#). Further details on estimating biogenic NO<sub>x</sub> emissions are given in the NEI Technical Support Document ([U.S. EPA, 2016b](#)).

Livestock waste is another important source of ammonia in the U.S. In the 2014 NEI, the U.S. EPA has updated the methodology for ammonia emissions from the housing/grazing, storage and application of manure from beef cattle, dairy cattle, swine, broiler chicken, and layer chicken production. Cows, swine, and chickens account for 95% of national NH<sub>3</sub> emissions from livestock waste in 2014. The approach to estimate 2014 livestock NH<sub>3</sub> emissions from these animals consists of these general steps: (1) estimate 2014 county-level animal populations using 2012 and 2014 USDA agricultural census data; (2) use a model developed by Carnegie-Mellon University ([McQuilling and Adams, 2015](#); [Pinder et al., 2004a](#); [Pinder et al., 2004b](#)) to produce daily resolved, climate-level emission factors for a particular distribution of management practices for each county and animal type, as expressed as emissions/animal; and (3) multiply the county animal populations by the daily emission factor for each county and animal type to estimate emissions per day and sum daily emissions across the entire year for each county and SCC to produce annual emissions for use in the NEI. The model inputs and outputs are shown in [Figure 2-2](#).

Source: [U.S. EPA \(2016b\)](#).

**Figure 2-2 Process to produce specific location and practice specific daily emission factors for livestock waste.**

Similar details are given for estimating emissions for major sources of NO<sub>x</sub> and SO<sub>2</sub> in the NEI technical support document ([U.S. EPA, 2016b](#)), including EGUs, on-road mobile sources, marine vessels, locomotives, other nonroad sources, airports, rail yards, landfills, agricultural and wildland fires, wood combustion, other fuel residential and industrial fuel combustion, charcoal grilling, waste disposal, vegetation and soil, and other sources. Air emissions data from the 2014 Toxic Release Inventory (TRI) were also used in the 2014 NEI to supplement point source NH<sub>3</sub> emissions provided to the U.S. EPA by state, local, and tribal agencies. The TRI is a U.S. EPA database containing data on disposal or other releases including air emissions of over 650 toxic chemicals from approximately 21,000 facilities. Data are submitted annually by U.S. facilities that meet TRI reporting criteria.

### 2.2.3 Evaluation and Uncertainty

As described in the 2008 ISA ([U.S. EPA, 2008a](#)), emissions from different sources in the NEI are estimated with a wide range of methods that include direct measurements, indirect measurements, model predictions, and assumptions. Because there are unknown, incomplete, and variable emission rates, as well as unknown sources that are not represented, the NEI reflects an on-going process of updating increasing or declining emissions, improving estimation methods, and filling data gaps as measurements become available or understanding of emissions changes. Often, steps are taken to reduce errors in estimation as they are discovered, resulting in improved estimates as uncertainties are found. For example, the estimate of [Gilliland et al. \(2003\)](#) that annual NEI NH<sub>3</sub> was 37%

higher than estimates based on modeled  $\text{NH}_4^+$  deposition led to the development of lower emission factors for nondairy cows and swine ([U.S. EPA, 2008a](#)). Because of these unknowns and limitations, quantitative uncertainty estimates based on probability density functions or other statistical methods are not provided with NEI data. Instead, emission factors receive a rating based on the reliability of methods used for determining the emission factor. The rating is based on both the number of representative sources and the characteristics of the data used to determine the emission factor, but it does not imply statistical error bounds or confidence intervals for the emission factor ([U.S. EPA, 1996](#)).

As an alternative, uncertainties are often evaluated through separate efforts using a variety of techniques. These techniques include comparing inventory predictions with measured long-term trends, comparing emission estimates derived from principle component analysis or other statistical methods, comparing emissions estimated by inverse modeling of chemical transport models, and comparison with satellite data ([U.S. EPA, 2008a](#)). The distinction between the inventory compilations like the NEI and alternative satellite- and model-based methods of estimating emissions is generally described in terms of bottom-up and top-down estimates. The entries in emissions inventories are obtained using a bottom-up approach, in which entries are based on emissions factors, activity rates, and control device efficiency for various source types. This contrasts to a top-down approach in which measurements of pollutant concentrations from satellites, aircraft, or surface monitors are used to constrain a priori estimates of emissions using a chemistry-transport model (CTM).

Because of this variety of top-down approaches and the number of separate studies resulting in a wide range of estimated uncertainties, there is no single estimate of uncertainty that applies to either total emissions or emissions from individual sources in [Table 2-1](#). However, reports from numerous publications on emissions inventory evaluation have resulted in a wide range of uncertainty estimates for application to NEI data, and these were summarized in the 2008 ISA ([U.S. EPA, 2008a](#)). Across all sources, total  $\text{NO}_x$  emissions estimates from satellite data ranged from “highly consistent” with NEI estimates ([Martin et al., 2006](#)) to 68% higher than NEI estimates ([Jaegle et al., 2005](#)). Fewer estimates of individual source emissions were evaluated, with  $\text{NO}_x$  emissions both higher and lower than estimates using other methods.

Some recent work has shown summertime over-prediction of model  $\text{NO}_x$  estimates using recent U.S. EPA inventories (e.g., 2008 and 2011) when compared against monitored ambient concentrations ([Canty et al., 2015](#); [Anderson et al., 2014a](#)). [Appel et al. \(2017\)](#) found in their simulations that  $\text{NO}_x$  model over-estimates in summer were greatly diminished or reversed in other seasons. [Anderson et al. \(2014a\)](#) and [Travis et al. \(2016\)](#) concluded that emissions of  $\text{NO}_x$  from mobile sources are being overestimated and are

the source of this bias. Studies over Texas ([Souri et al., 2016](#); [Tang et al., 2015](#)) suggested a smaller or no bias in on road NO<sub>x</sub> emissions compared to [Anderson et al. \(2014a\)](#) and [Travis et al. \(2016\)](#), and suggested that both high and low biases in other NO<sub>x</sub> source categories (e.g., area sources, point sources, soil NO) impact model/measurement discrepancies. [Marr et al. \(2013\)](#) used near-road measurements to also conclude that mobile source NO<sub>x</sub> emissions in U.S. EPA's 2008 NEI agreed well with measurements (i.e., within 3%). The cause of discrepancies between measured and modeled concentrations are difficult to diagnose because the emission modeling process and associated photochemical modeling is complex. Researchers are continuing to investigate this question.

There can be higher uncertainties for specific sources. For example, about 60% of the total NO<sub>x</sub> emitted by soils nationwide is estimated to occur in the central Corn Belt of the U.S. Spatial and temporal variability in soil NO<sub>x</sub> emissions can lead to uncertainty in emissions estimates. Soil emissions occur mainly during summer and across the entire country, including areas where anthropogenic emissions are low. Emission rates depend primarily on fertilization amount, soil temperature, and moisture. Models of NO<sub>x</sub> emissions from soils [e.g., [Hudman et al. \(2012\)](#)] include these dependencies, but most measurements on which they are based are made at temperatures <30°C. However, in agricultural areas subjected to very high temperatures (>40°C) like the Imperial Valley, CA, emissions factors for NO following fertilizer application ranged from 1.8 to 6.6%, as compared to estimates of typically ~1 to 2% ([Oikawa et al., 2015](#)). [Oikawa et al. \(2015\)](#) also suggested that in many areas of the Southwest, the NEI overestimates anthropogenic emissions at the expense of soil emissions and that these soil emissions have a noticeable effect on ozone formation. [Travis et al. \(2016\)](#) estimated that combustion accounts for 68% of NO<sub>x</sub> emissions in the Southeast in summer, with the remainder from soils. These results indicate that soil emissions need to be better understood. Estimating emissions from highway vehicles can also be challenging because there is a wide variation in emissions between different vehicles.

Activity rates and uncertainties for NH<sub>3</sub> are difficult to quantify, and estimates have yet to be made for reduced organic nitrogen. NH<sub>3</sub> emission estimates are generally more uncertain than NO<sub>x</sub> and SO<sub>2</sub> emission estimates because of the variety of agricultural practices used, re-emission after deposition, and the dispersed nature of agricultural processes, as well as the complex influences of meteorology on processes controlling transformation and removal of nitrogen species on spatial and temporal emission patterns. As described in [Appendix 2.5.2](#), NO<sub>2</sub> and NH<sub>3</sub> can be both emitted from and deposited to soils, water, or vegetation depending on their atmospheric concentrations and characteristics of the underlying surface.

Mixed results were reported in evaluating the total NH<sub>3</sub> emissions estimates in the 2008 ISA ([U.S. EPA, 2008a](#)). However, as described above, there have been major changes in estimation methods for the most important ammonia sources since that report, and more recently [Paulot et al. \(2014\)](#) showed that a range of published bottom-up and top-down estimates of annual total U.S. ammonia emissions agreed within 10%. The NEI national estimate of 2.3 Tg NH<sub>3</sub> from [Table 2-1](#) was within 20% of the average across all estimates of  $2.8 \pm 0.2$  Tg NH<sub>3</sub> reported by [Paulot et al. \(2014\)](#). However, in the same comparison there was a divergence in the timing of the seasonal maximum, and agreement varied considerably temporally and spatially ([Paulot et al., 2014](#)).

Most SO<sub>2</sub> emissions originate from point sources having well-known locations and identifiable fuel streams. Uncertainties in annual emissions were estimated to range from 4 to 9% for SO<sub>2</sub> and slightly larger for NO<sub>x</sub> from the same point sources identified in the 1985 NAPAP inventories for the U.S. ([Placet et al., 1990](#)).

---

## 2.3 Atmospheric Chemistry of Nitrogen and Sulfur Species and Particulate Matter (PM)

The atmospheric chemistry of N and S species relevant for the production of ecosystem nutrients and acidic species was extensively reviewed in the 2008 ISA ([U.S. EPA, 2008a](#)). The main findings from that review and key findings from more recent studies and reviews are included here. [Appendix 2.3.1](#) describes atmospheric NO<sub>x</sub> chemistry and the formation of HNO<sub>3</sub>. [Appendix 2.3.2](#) describes atmospheric sulfur oxide chemistry and the formation of H<sub>2</sub>SO<sub>4</sub>. [Appendix 2.3.3](#) reviews the role of ammonia as the most important atmospheric base for neutralizing atmospheric nitric and sulfuric acids and forming PM. The chemistry of all of these species largely controls the extent of acid deposition as well as the fraction of nitrogen in particulate matter, which in turn determines deposition rate and transport distance. The remaining sections review atmospheric organic sulfur and nitrogen compounds ([Appendix 2.3.4](#)), atmospheric organic acids ([Appendix 2.3.5](#)), and formation of PM<sub>2.5</sub> ([Appendix 2.3.6](#)).

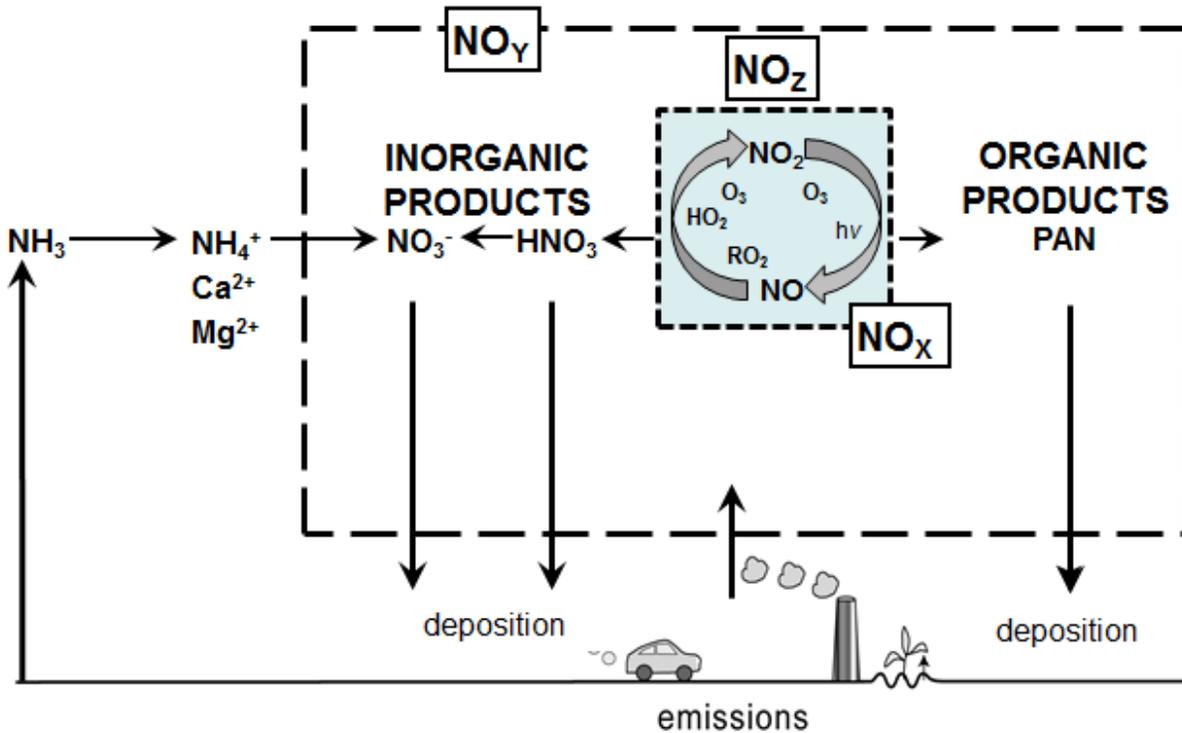

---

### 2.3.1 Nitrogen Oxides

NO<sub>x</sub> (NO + NO<sub>2</sub>) is the precursor for oxidized nitrogen species that contribute to acidic deposition. More specific details on the chemistry and transformation of NO<sub>x</sub> can be found in the *2016 ISA for Oxides of Nitrogen—Health Criteria* ([U.S. EPA, 2016f](#)) and for SO<sub>x</sub> in the *2008 ISA for Sulfur Oxides* ([U.S. EPA, 2017d](#)). Hence, those topics are only briefly recounted here with special reference to the secondary NO<sub>x</sub> and SO<sub>x</sub>

NAAQS. Oxidized nitrogen species ( $\text{NO}_Y$ ) are introduced into the atmosphere as  $\text{NO}_X$ , mainly from fossil fuel combustion as described in [Appendix 2.2](#). [Figure 2-3](#) summarizes the atmospheric reactions of  $\text{NO}_X$ , showing rapid inter-conversion of  $\text{NO}$  and  $\text{NO}_2$  in sunlight, with slower formation of more oxidized organic and inorganic products ( $\text{NO}_Z$ ).

A large number of oxidized nitrogen species in the atmosphere are formed from the oxidation of  $\text{NO}$  and  $\text{NO}_2$  (shown in the inner box). These include nitrate radicals ( $\text{NO}_3$ ), nitrous acid ( $\text{HONO}$ ), nitric acid ( $\text{HNO}_3$ ), dinitrogen pentoxide ( $\text{N}_2\text{O}_5$ ), nitryl chloride ( $\text{ClNO}_2$ ), peroxyntiric acid ( $\text{HNO}_4$ ), peroxyacetyl nitrate (PAN) and its homologues (PANs), other organic nitrates, such as isoprene- and monoterpene-derived nitrates, and particulate nitrate ( $\text{pNO}_3^-$ ). These species (and  $\text{NH}_3$ ) are characterized by large differences in their solubilities ([Table 2-2](#)), which determine their ability to be taken up by cloud droplets, airborne particles, and moist surfaces.

Ca<sup>2+</sup> = calcium ion; HNO<sub>3</sub> = nitric acid; HO<sub>2</sub> = hydroperoxy radicals; hv = energy of solar photon with frequency v;  
Mg<sup>2+</sup> = magnesium; NH<sub>3</sub> = ammonia; NH<sub>4</sub><sup>+</sup> = ammonium; NO = nitric oxide; NO<sub>2</sub> = nitrogen dioxide; NO<sub>3</sub><sup>-</sup> = nitrate ion; NO<sub>x</sub> = the sum of NO and NO<sub>2</sub>; NO<sub>z</sub> = oxidation products of NO<sub>x</sub>; NO<sub>y</sub> = NO<sub>x</sub> + NO<sub>z</sub>; O<sub>3</sub> = ozone; PAN = peroxyacetyl nitrate; RO<sub>2</sub> = organic peroxy radicals.

Note: The inner shaded box contains NO<sub>x</sub> (NO + NO<sub>2</sub>). The outer box contains other species (NO<sub>z</sub>) formed from reactions of NO<sub>x</sub>. All species shown in the outer and inner boxes are collectively referred to as NO<sub>y</sub> by the atmospheric sciences community.

**Table 2-2 Henry's law coefficients for selected reactive nitrogen species at 25°C in water.**

Compound	Coefficient (mol/kg/bar)
HNO <sub>3</sub>	2.6 × 10 <sup>6</sup>
HONO	49
NO	0.0019
NO <sub>2</sub>	0.012
PAN	4.1
NH <sub>3</sub>	61

1 bar = 10<sup>5</sup> Pa; C = Celsius; HNO<sub>3</sub> = nitric acid; HONO = nitrous acid; NH<sub>3</sub> = ammonia; NO = nitric oxide; NO<sub>2</sub> = nitrogen dioxide; PAN = peroxyacetyl nitrate.

Source: adapted from [Sutton et al. \(2011\)](#).

Reactions producing more oxidized forms of nitrogen (NO<sub>z</sub>) involve mainly O<sub>3</sub>, OH, and organic radicals with NO and NO<sub>2</sub>. The reaction of NO<sub>2</sub> with OH leads directly to HNO<sub>3</sub>:

**Equation 2-1**

The reaction of NO<sub>2</sub> with O<sub>3</sub> produces nitrate radical (NO<sub>3</sub>), which reacts further to form dinitrogen pentoxide (N<sub>2</sub>O<sub>5</sub>), and ultimately also produces HNO<sub>3</sub>:

**Equation 2-2**

**Equation 2-3**

**Equation 2-4**

The relative importance of these two paths for producing HNO<sub>3</sub> is strongly location and seasonally dependent, with the first path dominating when OH radicals are abundant (during the day) and the second during the night and under cold conditions. [Warneck \(1999\)](#) estimated that most HNO<sub>3</sub> is formed in the sunlit portions of clouds by the reaction of NO<sub>2</sub> with OH, with much smaller amounts from the pathway involving N<sub>2</sub>O<sub>5</sub> hydrolysis. Because it is highly soluble, HNO<sub>3</sub> is taken up by particles or cloud droplets to form NO<sub>3</sub><sup>-</sup> and is also deposited onto moist surfaces, such as on vegetation. HNO<sub>3</sub> also

recycles back to NO<sub>2</sub> in the gas phase by photolysis and reaction with OH radicals, but on timescales longer than that for uptake by cloud droplets, particles, and the surface.

Whereas photolysis of HNO<sub>3</sub> is slow ( $\tau \sim 10^6$  s) in the gas phase, it can be two orders of magnitude faster on moist surfaces ([Ye et al., 2016](#)), releasing NO<sub>2</sub> and/or HONO back to the atmosphere.

NO<sub>2</sub> reacts with organic peroxy radicals to form organic nitrates such as peroxyacetyl nitrate (PAN) and its homologues as shown on the right side of [Figure 2-3](#); other RO<sub>2</sub>NO<sub>2</sub> compounds are much less stable than PANs. NO and NO<sub>3</sub> radicals also react with organic radicals produced by the oxidation of isoprene and monoterpenes to form a wide range of organic nitrates. Considering the troposphere as a whole, most of the mass of NO<sub>z</sub> shown in [Figure 2-3](#) is in the form of PAN and HNO<sub>3</sub>. However, organic nitrates such as isoprene- and monoterpene-derived nitrates increase in importance in the planetary boundary layer (PBL), and are likely to be dominant in vegetated areas ([Kim et al., 2015a](#); [Min et al., 2014](#)).

In forested areas, the initial step in the production of isoprene nitrates (INs) is most often the reaction of isoprene with OH radicals to produce isoprene peroxy radicals. These can react with HO<sub>2</sub> radicals, other RO<sub>2</sub> radicals, or isomerize to produce a variety of organic compounds. They can also react with NO to produce multifunctional organic nitrates. Lifetimes on the order of one to a few hours can be estimated for these first generation INs based on their reactions with OH radicals and O<sub>3</sub> ([Lockwood et al., 2010](#); [Paulot et al., 2009](#)). The reaction products can further react with NO (after internal rearrangement) to form secondary organic nitrates such as ethanal nitrate, methacrolein nitrate, propanone nitrate, and methyl vinyl ketone nitrate. The second-generation organic nitrates are more stable than the first-generation INs because they lack a double carbon (C = C) bond. Obviously, the relative importance of pathways forming nitrates or other products depends on the ambient concentrations of NO and other oxides of nitrogen for which many key experimental details are still lacking. During the SEAC<sup>4</sup>RS measurement campaign, which took place in the summer of 2013 in the southeastern U.S., [Travis et al. \(2016\)](#) found that these two pathways were of comparable importance.

In addition to oxidation initiated by OH radicals, isoprene is also oxidized by NO<sub>3</sub> radicals. [Rollins et al. \(2009\)](#) determined a yield of first-generation carbonyl nitrates of 70% based on experiments in large reaction chambers. These first-generation nitrates can further react with NO, leading to the production of second-generation organic (alkyl) nitrates. [Mao et al. \(2013\)](#) estimated that the global mean lifetime is ~5 days for these second-generation organic nitrates. [Mao et al. \(2013\)](#) also suggested that the export of INs and other organic nitrates followed by their decomposition is potentially a larger source of NO<sub>x</sub> to the boundary layer of the western North Atlantic Ocean than the export

of PANs. Some INs are low enough in volatility that they can partition to the particle phase [e.g., [Rollins et al. \(2009\)](#)]. Once in the particle phase, the INs hydrolyze to form HNO<sub>3</sub> and an alcohol, with a rate constant that correlates strongly with the acidity of the particles ([Rindelaub et al., 2015](#); [Jacobs et al., 2014](#)).

In addition to considering the chemistry of isoprene-derived nitrates during SEAC<sup>4</sup>RS, [Fisher et al. \(2016\)](#) considered the formation of organic nitrates derived from the oxidation of monoterpenes with either one or two double bonds. Their modeling results suggest that isoprene- and monoterpene-derived nitrates account for 25 to 50% and ~10% of total organic nitrates and that production of isoprene- and monoterpene-derived nitrates account for ~20% of the net loss of NO<sub>x</sub> emitted in the Southeast during summer. [Fisher et al. \(2016\)](#) also noted that production of organic nitrates involving biogenic VOCs is the dominant NO<sub>x</sub> sink only in areas where elevated levels of biogenic VOCs coincide with low NO<sub>x</sub> levels (otherwise the major sink would be formation of HNO<sub>3</sub>). As a result, these processes will represent only a minor pathway for NO<sub>x</sub> loss. In any event, as with isoprene-derived nitrates, monoterpene-derived nitrates are also mainly taken up by particles with formation of HNO<sub>3</sub>. Uptake by particles was estimated by [Fisher et al. \(2016\)](#) to account for ~60% of the removal of gas-phase organic nitrates, with ~20% recycled back to NO<sub>x</sub> and another 15% deposited to the surface.

---

### 2.3.2 Sulfur Oxides

SO<sub>2</sub> is the only gas phase form of SO<sub>x</sub> (SO<sub>2</sub> + SO<sub>4</sub><sup>2-</sup>) emitted in the tropospheric boundary layer at concentrations of concern for environmental exposures ([U.S. EPA, 2008c](#)). It reacts in both the gas phase and in aqueous solution in clouds and particles to form SO<sub>4</sub><sup>2-</sup>. As described in the 2008 ISA ([U.S. EPA, 2008a](#)), the steps involved in aqueous-phase oxidation of SO<sub>2</sub> begins with dissolution of SO<sub>2</sub> following [Jacobson \(2002\)](#):

Equation 2-5

and is followed by formation and dissociation of H<sub>2</sub>SO<sub>3</sub>:

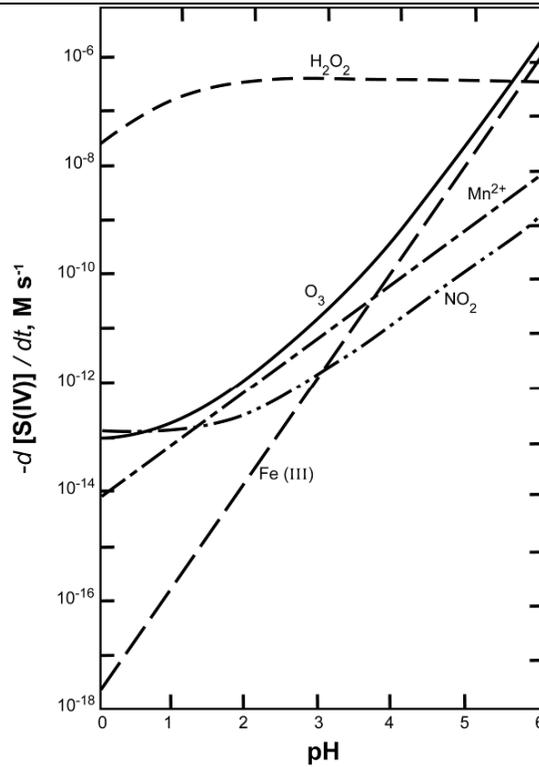

Equation 2-6

Dissolved SO<sub>2</sub> thus rapidly partitions into four forms with the same oxidation state, with their relative concentrations dependent on pH:

Equation 2-7

S(IV) is then oxidized to  $\text{SO}_4^{2-}$  in cloud water primarily by either  $\text{H}_2\text{O}_2$ ,  $\text{O}_3$ , and  $\text{O}_2$  in the presence of dissolved Fe(III). Reaction with  $\text{H}_2\text{O}_2$  is most important at pH less than about 5.3, and reaction with either dissolved  $\text{O}_3$  or with  $\text{O}_2$  catalyzed by Fe(III) becomes most important at pH greater than about 5.3, as shown in [Figure 2-4 \(Seinfeld and Pandis, 1998\)](#).

aq = aqueous; Fe(III) = iron (oxidation number III);  $\text{H}_2\text{O}_2$  = hydrogen peroxide; Mn(II) = manganese (oxidation number II);  $\text{NO}_2$  = nitrogen dioxide;  $\text{O}_3$  = ozone; S(IV) = sulfur (oxidation number IV);  $\text{SO}_2$  = sulfur dioxide.  
 Concentrations assumed are:  $[\text{SO}_2(\text{g})] = 5$  ppb;  $[\text{NO}_2(\text{g})] = 1$  ppb;  $[\text{H}_2\text{O}_2(\text{g})] = 1$  ppb;  $[\text{O}_3(\text{g})] = 50$  ppb;  $[\text{Fe(III)(aq)}] = 0.3$   $\mu\text{M}$ ;  $[\text{Mn(II)(aq)}] = 0.03$   $\mu\text{M}$ .  
 Source: [Seinfeld and Pandis \(1998\)](#).

**Figure 2-4** Rate of conversion of sulfur (IV) to sulfur (VI) by different oxidation paths as a function of pH.

The remaining  $\text{SO}_2$  is oxidized to  $\text{H}_2\text{SO}_4$  in the gas phase with a characteristic timescale of ~10 days [based on  $\text{OH} = 10^6/\text{cm}^3$  and rate coefficient =  $1.3 \times 10^{-12}/\text{cm}^3/\text{molec}/\text{s}$ ; [Sander et al. \(2011\)](#)] following a multistep process:

Equation 2-8

Equation 2-9

and/or by

Equation 2-10

where sCI is a stabilized Criegee intermediate ([Berndt et al., 2012](#); [Mauldin et al., 2012](#); [Welz et al., 2012](#)) and products refer to other organic radicals. Criegee radicals are produced by the reaction of alkenes with  $\text{O}_3$  during both night and day. The relative importance of the OH and sCI pathways depends in large measure on the local concentration of alkenes, in particular biogenic alkenes. [Welz et al. \(2012\)](#) also raised the possibility that Criegee radicals might be important for the oxidation of  $\text{NO}_2$  to form nitrate radicals.  $\text{SO}_3$  produced by either path further reacts to form gas-phase  $\text{H}_2\text{SO}_4$  via

Equation 2-11

Because  $\text{H}_2\text{SO}_4$  is extremely soluble, it is removed rapidly by transfer to the aqueous phase of particles and cloud droplets.

---

### 2.3.3 Acid Neutralization by Ammonia

As the most common soluble base in the atmosphere,  $\text{NH}_3$  plays a key role in neutralizing the acidity in ambient particles and in cloud, fog, and rainwater resulting from dissolution of  $\text{H}_2\text{SO}_4$  and  $\text{HNO}_3$ , and the weak acidity due to organic acids. The atmospheric lifetime of  $\text{NH}_3$  with respect to oxidation by OH radicals is ~2 months [based on  $\text{OH} = 10^6 \text{ molec/cm}^3$  and rate coefficient =  $1.6 \times 10^{-13} \text{ /cm}^3 \text{ /molec/s}$ ; [Sander et al. \(2011\)](#)]. As a result, uptake by cloud droplets, particles, and the surface is favored over reaction with OH radicals. [Xu and Penner \(2012\)](#) estimated a globally averaged lifetime for  $\text{NH}_3$  of ~11 hours as a result of these processes, implying strong spatial and temporal variability of  $\text{NH}_3$  concentrations.

Sulfuric acid can be partly or totally neutralized by  $\text{NH}_3$ . [Seinfeld and Pandis \(1998\)](#) defined two regimes: (1) ammonia poor  $[\text{TA}] < 2 [\text{TS}]$  and (2) ammonia rich  $[\text{TA}] > 2 [\text{TS}]$ , where TA and TS refer to total ammonia, ammonium and sulfate concentrations in gas, aqueous, and solid forms. In the first regime, there is partial neutralization; sulfate is in the form of  $(\text{NH}_4)\text{HSO}_4$ , the vapor pressure of  $\text{NH}_3$  is very low, equilibrium favors

formation of ammonium sulfate over ammonium nitrate, any nitrate is driven to the gas phase, and ammonium nitrate levels are low (or even zero). In the second regime, sulfate is in the form of  $(\text{NH}_4)_2\text{SO}_4$ , and any  $\text{NH}_3$  left over could react with  $\text{HNO}_3$  to form  $\text{NH}_4\text{NO}_3$ . However, this conceptual model neglects interactions with organic compounds. Analysis of data by [Kim et al. \(2015a\)](#) from the SEAC<sup>4</sup>RS field study and the Chemical Speciation Network (CSN) during August–September of 2013 indicates that the extent of neutralization of sulfuric acid and acidic sulfate by ammonium was incomplete in the Southeast despite an excess of atmospheric  $\text{NH}_3$ . [Kim et al. \(2015a\)](#) suggested that uptake of  $\text{NH}_3$  is inhibited by organic compounds in particles. This suggestion is in accord with laboratory studies of [Liggio et al. \(2011\)](#) who found that organic compounds, especially terpenes and *n*-alkanes on particle surfaces are effective in inhibiting  $\text{NH}_3$  uptake by particles.

$\text{NH}_4\text{NO}_3$  is in thermodynamic equilibrium with gas-phase  $\text{NH}_3$  and  $\text{HNO}_3$ . The equilibrium constant is extremely sensitive to variations in relative humidity and temperature such that it varies over several orders of magnitude depending on atmospheric conditions, but in general, lower temperature and higher relative humidity (e.g., during winter) shifts the equilibrium towards condensed phase  $\text{NH}_4\text{NO}_3$ . The effects on phase partitioning are pronounced because of the large variation in the equilibrium constant,  $K$ , ( $\sim 10\text{--}10^3$  ppb<sup>2</sup>) between summer and winter conditions in many locations. Also, as noted by [Malm et al. \(2016\)](#),  $\text{NH}_4\text{NO}_3$  can volatilize and reform multiple times during transport away from sources of  $\text{NH}_3$  and  $\text{HNO}_3$ . Because the atmospheric lifetimes of  $\text{NH}_3$ ,  $\text{HNO}_3$ , and  $\text{NH}_4\text{NO}_3$  differ substantially from each other, local conditions of temperature and relative humidity, by implication, control how far these species can travel.

Although the above considerations apply to particles in general, it should be remembered that the mass of airborne particles is present in two distinct size fractions, each with its own characteristic composition [see [U.S. EPA \(2019\)](#)]. These differences determine the size fraction in which  $\text{pNO}_3^-$  will be found. Because  $\text{SO}_4^{2-}$  is found mainly in the fine particle mode these considerations tend to apply more to the atmospheric fine mode. Displacement of HCl (and other hydrohalic acids) from marine aerosol (found typically in the coarse mode) by gas-phase  $\text{HNO}_3$  has long been known to occur, resulting in particulate nitrate ( $\text{pNO}_3^-$ ) being associated with sodium in the coarse mode in many coastal areas. [Brimblecombe and Clegg \(1988\)](#) provided a detailed evaluation of the thermodynamic data and a discussion of this process. [Wolff \(1984\)](#) found that coarse-mode  $\text{pNO}_3^-$  is formed by adsorption of  $\text{HNO}_3$  on basic soil particles (i.e., those containing  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ ). These distinctions between the behavior of  $\text{pNO}_3^-$  in the fine and coarse modes are important as deposition rates for these two size modes can differ

appreciably and there can be large differences in the ratio of fine to coarse  $\text{pNO}_3^-$  as shown in [Appendix 2.5.2.1](#).

The composition of rainwater and of particles is strongly affected by pH. As described above, pH determines the distribution of S(IV) species in cloud water, rainwater and the aqueous phase of particles. This in turn impacts their oxidation processes ([Appendix 2.3.2](#)), the solubility of trace metals, and the partitioning of weak acids among other factors. As the most abundant base in the atmosphere,  $\text{NH}_3$  has a strong influence on pH of cloud water. However, the role of  $\text{NH}_3$  as a base is limited to atmospheric processes. Once deposited in soil, oxidation of  $\text{NH}_3$  and  $\text{NH}_4^+$  to  $\text{NO}_3^-$  (during nitrification) produces an amount of  $\text{H}^+$  equivalent to  $\text{HNO}_3$  deposition [[Scheffe et al. \(2014\)](#) and references therein].

---

#### 2.3.4 Organic Nitrogen and Sulfur

In addition to deposition of  $\text{NO}_y$  and  $\text{NH}_x$ , the deposition of other nitrogen compounds, in particular dissolved organic nitrogen (DON) also occurs. Proteins, amino acids, urea, amines, and other DON compounds can contribute to acidification in soils and be an important source of nutrients to terrestrial and aquatic environments ([Jickells et al., 2013](#); [Cape et al., 2011](#); [Cornell, 2011b](#); [Sutton et al., 2011](#)). The content of organic nitrogen in particles and rainwater can be characterized in two ways. First, it can be calculated as the difference between total N as measured by total elemental analysis [e.g., [Bronk et al. \(2000\)](#)] minus  $\text{NO}_3^-$  and  $\text{NH}_4^+$ . In the second way, the content of organic nitrogen in particles and rainwater can be characterized by measuring the concentrations of individual species. However, the number of species constituting DON at a particular location can be quite large. For example, [Altieri et al. \(2009a\)](#) detected several thousand organic N containing species in precipitation samples collected in New Jersey and found the overall composition was consistent with oligomerization of amino acids; in most compounds, N was in reduced form.

[Cornell \(2011a\)](#) estimated based on measurements reported in 58 published studies that organic N constitutes 35% of total N in rainwater in North America. [Jickells et al. \(2013\)](#) estimated based on data from a number of measurement sites ( $n = 115$  globally), that average DON in rainwater contributes ~25% of the flux of total nitrogen. They also reasoned that because it is correlated with total nitrogen in rainwater ( $R^2 = 0.57$ ), which has a large anthropogenic component, DON might also have a large anthropogenic component. Further description of DON measured at sites in the CONUS are deferred to [Appendix 2.6.2](#).

A large number of organosulfates (R-O-SO<sub>3</sub>H) have been detected in rainwater samples ([Altieri et al., 2009b](#)). However, their abundances could not be determined. [Tolocka and Turpin \(2012\)](#) estimated that organic sulfates could contribute up to 5 to 10% of organic mass on average to particle mass based on measurements taken at 12 sites across the U.S. [Liao et al. \(2015\)](#) found that organic sulfates accounted a few percent of particulate sulfate, mainly from the two most abundant forms, isoprene epoxydiol sulfate and glycolic acid sulfate. Organic sulfates such as these have high acid dissociation constants and are expected to act as singly charged species.

Phytoplankton emit copious amounts of dimethyl sulfide, which can be oxidized to sulfur dioxide and to methanesulfonic acid. The SO<sub>2</sub> that is formed can then be a source of H<sub>2</sub>SO<sub>4</sub> in coastal areas.

---

### 2.3.5 Organic Acids

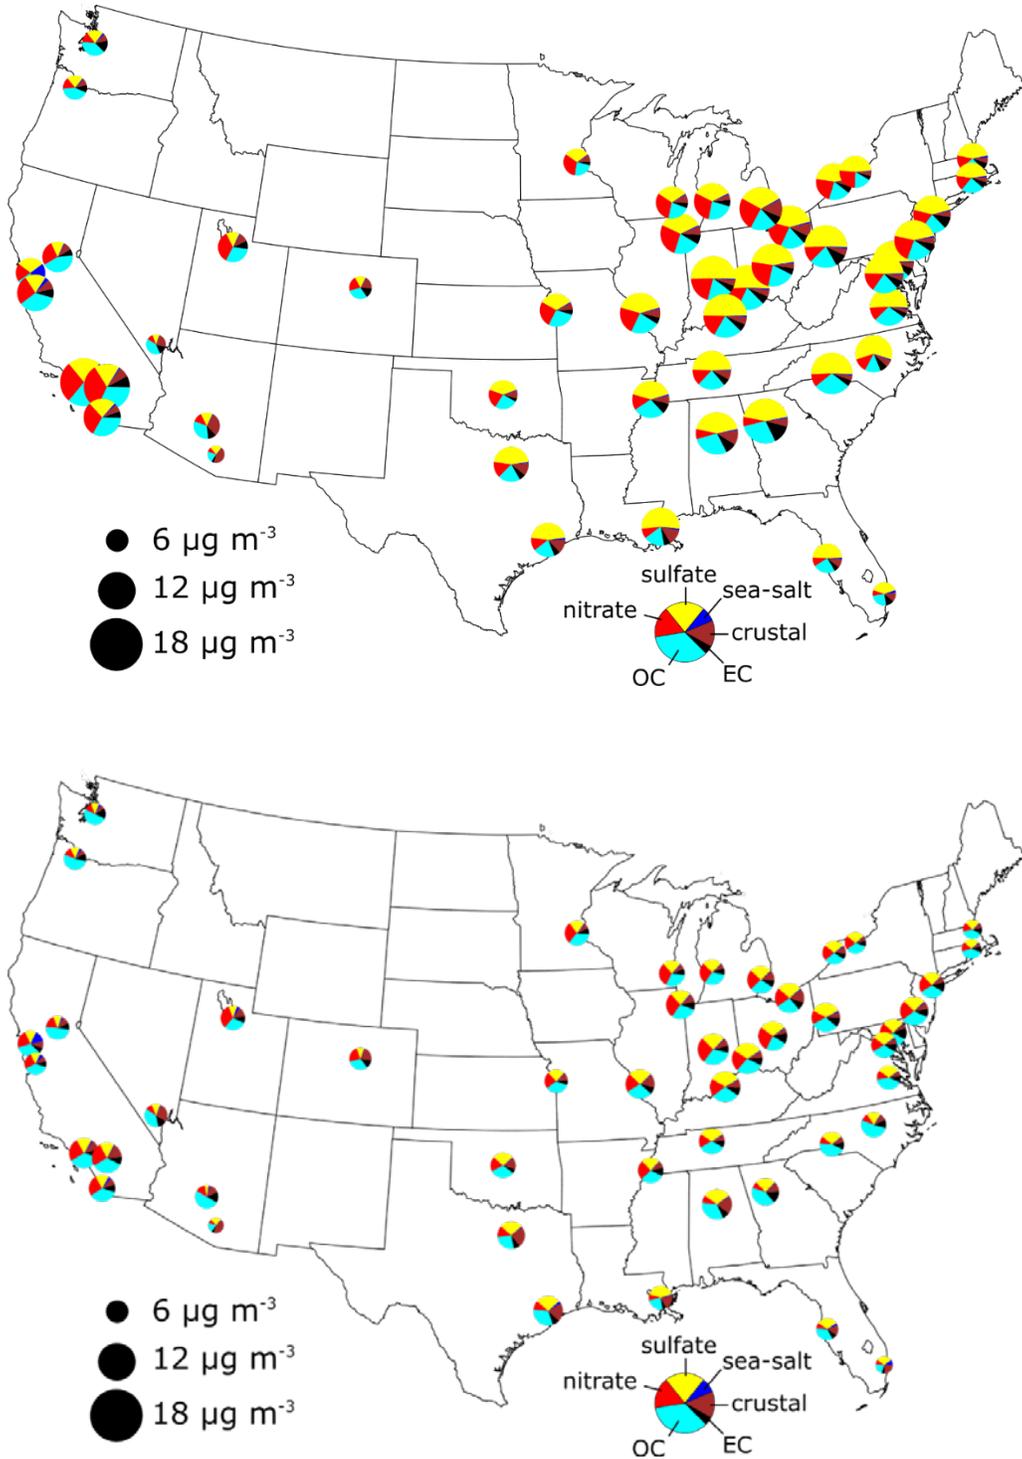

The effects of deposition of acidic sulfur and nitrogen should be considered in the context of a more complete description of the composition of rainwater, including organic acids. However, organic acids are not routinely measured by monitoring networks because they are unstable with respect to microbial degradation following collection. As a result, data for organic acids in rainwater are sparse. Formic and acetic acids are typically the most abundant organic acids found in rainwater in the U.S. ([Willey et al., 2011](#); [Avery et al., 2006](#); [Talbot et al., 1990](#)). They are largely secondary in origin (i.e., produced in the atmosphere by the photochemical oxidation of biogenic and anthropogenic hydrocarbons). [Paulot et al. \(2011\)](#) suggested that isoprene oxidation is the largest global source of formic and acetic acids. These acids are also produced by the oxidation of ethane and propylene emitted in automobile exhaust. Their abundances in rainwater and their effects on pH are not negligible. For example, [Willey et al. \(2011\)](#) found that formic acid (pK<sub>a</sub> = 3.75) and acetic acid (pK<sub>a</sub> = 4.76) were the major organic acids present and contributed ~22 and 5%, respectively, of free acidity (mean pH = 4.65) in rainwater samples collected at Wilmington, NC in 2008. In addition, other organic acids (e.g., oxalic acid, lactic acid) have been found to be present at much lower levels at this site ([Avery et al., 2006](#)). [Vet et al. \(2014\)](#) noted that organic acids should be monitored in areas where the concentration of H<sup>+</sup> is <5 µeq/L (or pH ≥ 5.3). As will be seen in [Appendix 2.6](#), this condition is met in areas like the Northwest where concentrations of NO<sub>3</sub><sup>-</sup> and SO<sub>4</sub><sup>2-</sup> in rainwater are low. Even in areas where the effects of organic acid neutralization by NH<sub>4</sub><sup>+</sup> might be small, the vapor pressures of some organic acids (e.g., oxalic acid) would be reduced by orders of magnitude, resulting in increased uptake of the organic acid from the gas phase and growth of particles ([Ortiz-Montalvo et al., 2014](#); [Paciga et al., 2014](#)).

---

## 2.3.6 Particulate Matter (PM)

The chemistry of  $\text{NO}_x$  and  $\text{SO}_2$  described in [Appendix 2.3.1](#) and [Appendix 2.3.2](#), and the neutralization reactions of  $\text{NH}_3$  described in [Appendix 2.3.3](#) are relevant not only to understanding the distribution of  $\text{NO}_y$  and  $\text{SO}_x$  species, but also in explaining a large fraction of  $\text{PM}_{2.5}$  in most of the U.S. [Figure 2-5](#) shows  $\text{PM}_{2.5}$  composition in numerous U.S. locations. In all locations  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  account for a substantial fraction, and in many cases the majority, of  $\text{PM}_{2.5}$ . In general,  $\text{SO}_4^{2-}$  accounts for an increasing fraction of  $\text{PM}_{2.5}$  moving east or south, and  $\text{NO}_3^-$  for a greater fraction moving west or north. [Figure 2-5](#) also shows that  $\text{PM}_{2.5}$  concentrations are lower and  $\text{SO}_4^{2-}$  accounts for a much greater fraction of  $\text{PM}_{2.5}$  mass in 2003–2005 than in 2013–2015. This reflects the steep decline in  $\text{SO}_2$  emissions over this period ([Appendix 2.2.1](#)) and demonstrates that it has greatly impacted  $\text{PM}_{2.5}$  composition and concentration in the U.S.

The decrease in  $\text{SO}_4^{2-}$  contribution is so large that in many locations where  $\text{SO}_4^{2-}$  was the greatest contributor to  $\text{PM}_{2.5}$  mass in 2003–2005, organic carbon was more abundant in 2013–2015. However, as described in [Appendix 2.1](#), organic matter does not contribute as much to acidification or nutrient enrichment as  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$ , and  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  still account for the majority of  $\text{PM}_{2.5}$  mass in many locations. The remaining mass of  $\text{PM}_{2.5}$  is composed of elemental carbon, sea salt (mostly Na and Cl), and crustal material (Si and Al are most abundant elements). Monitoring methods and spatial and temporal trends for  $\text{PM}_{2.5}$  species are further developed in the 2019 PM ISA ([U.S. EPA, 2019](#)). There is much less information on  $\text{PM}_{10}$  or  $\text{PM}_{10-2.5}$  composition because of the lack of routine monitoring on the scale that has been implemented for  $\text{PM}_{2.5}$  species.

## 2.4 Concentration and Deposition Measurements

An extensive review of techniques for measuring  $\text{NO}_x$ ,  $\text{NO}_z$ ,  $\text{NO}_y$ ,  $\text{NH}_x$ , and  $\text{SO}_x$  appeared in the 2008 ISA ([U.S. EPA, 2008a](#)). Updates to techniques for measuring  $\text{NO}_x$ ,  $\text{NO}_y$ , and  $\text{SO}_x$  species can be found in the latest ISAs for Oxides of Nitrogen ([U.S. EPA, 2016f](#)), Sulfur Oxides ([U.S. EPA, 2017d](#)), and PM, including  $\text{PM}_{2.5}$ ,  $\text{PM}_{10}$ , and  $\text{PM}_{10-2.5}$  ([U.S. EPA, 2019](#)) Health Criteria, to which the reader is referred for details. In the following sections, measurements of  $\text{NO}_x$ ,  $\text{SO}_2$ , and PM in national networks are only briefly discussed and the measurement of species most relevant to acid and nutrient deposition and measurement methods for wet and dry deposition are the main focus. [Appendix 2.4.1](#) explains the roles of various national and regional monitoring networks in place to support the NAAQS or to collect data used for estimating acid and nutrient deposition. [Appendix 2.4.2](#), [Appendix 2.4.3](#), and [Appendix 2.4.4](#) describe methods used to measure gas-phase oxides of nitrogen, reduced nitrogen, and sulfur oxides that are not based on filter collection. Each of these sections is divided into separate discussions of the methods used in monitoring networks, remote sensing methods, and recent advances in research methods and other methods that are effective for intensive field studies but impractical for routine monitoring. Satellite-based remote sensing methods are useful because network coverage is often sparse and satellite-based measurements are becoming a more widely used alternative to ground-based measurements. [Appendix 2.4.5](#) describes filter-based methods used in CASTNET and other networks for mainly particulate species, but also for some gases, including  $\text{HNO}_3$  and  $\text{SO}_2$ . [Appendix 2.4.6](#) describes wet and dry deposition measurement and recent advances.

---

### 2.4.1 Monitoring Networks

Federal Reference Methods (FRMs) have been established and national monitoring networks put in place for  $\text{NO}_2$  as the indicator of oxides of nitrogen,  $\text{SO}_2$  as the indicator of sulfur oxides, and  $\text{PM}_{2.5}$  and  $\text{PM}_{10}$  as indicators for PM. These methods and networks are described in detail in recent ISAs for Oxides of Nitrogen ([U.S. EPA, 2016f](#)), Sulfur Oxides ([U.S. EPA, 2017d](#)), and Particulate Matter ([U.S. EPA, 2019](#)) Health Criteria. However, in general the large fractions of N and S deposition accounted for by species other than  $\text{NO}_2$  and  $\text{SO}_2$  make measurements of these indicator species alone inadequate for estimating deposition amounts of total oxides of nitrogen and total sulfur oxides. Similarly, it has long been established that wet deposition of S is usually dominated by  $\text{SO}_4^{2-}$  rather than  $\text{SO}_2$  ([Dana, 1980](#)). In this respect,  $\text{PM}_{2.5}$  monitoring is potentially useful because it efficiently collects the range of PM species involved in acidification and N deposition. However, variability of  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  as a fraction of total  $\text{PM}_{2.5}$  presents a

challenge for relating  $PM_{2.5}$  mass to these effects. An additional challenge is the estimate of deposition from  $PM_{2.5}$  concentrations, because of the strong dependence of deposition flux on particle size (see [Appendix 2.5.2](#)) and general unavailability of size distribution measurements.

In principle, a multipurpose, multipollutant monitoring network could efficiently meet the needs of estimating N and S deposition and air monitoring for ecosystem protection, while at the same time addressing other national air monitoring priorities. Such a network could include measurements of other N and S species besides  $NO_2$  and  $SO_2$  as well as other species that are otherwise not routinely monitored to better understand a variety of air pollution processes. This is the overall concept behind the National Core Network (NCore), a newly developed multipollutant monitoring network, and measurements of  $NO_Y$  and  $NH_3$  were included as NCore monitoring in part because of their relevance to atmospheric deposition ([Scheffe et al., 2009](#)). NCore has been operating since January 1, 2011 and has 80 monitoring sites designed for measuring multiple pollutants ([Weinstock, 2012](#)). The network provides a core of sites that measure  $SO_2$ ,  $NO_2$ ,  $NO_Y$ , and PM components including ammonium, nitrate, and sulfate, but with sparser coverage than the FRM networks for  $SO_2$  or  $NO_2$ . Because  $NO_Y$  is measured rather than  $NO_X$ , and because of collocated  $SO_2$  and  $SO_4^{2-}$  measurements, ambient concentrations of both  $NO_Y$  and  $SO_X$  can be determined from NCore data, so that these data can be used to estimate total deposition of oxides of nitrogen and sulfur. However, because of the wide range of deposition velocities for different species,  $NO_Y$  measurements alone are not sufficient for estimating deposition and species concentrations are also necessary. A further disadvantage is that most NCore sites are located in urban areas.

Instead of using NCore or the national  $NO_2$ ,  $SO_2$ , and PM monitoring networks, national scale N and S deposition have relied on monitoring networks specifically designed for estimating deposition. [Table 2-3](#) lists monitoring networks that have been used for recent estimates of atmospheric N and S deposition for the NADP ([Schwede and Lear, 2014a](#)).

**Table 2-3 Summary of monitoring networks used by [Schwede and Lear \(2014a\)](#).**

Network	Chemical Species	Period of Record	Website
CASTNET	Concentration: HNO <sub>3</sub> , SO <sub>2</sub> , pSO <sub>4</sub> <sup>2-a</sup> , pNO <sub>3</sub> <sup>-a</sup> , pNH <sub>4</sub> <sup>+a</sup>	2000–2012	<a href="http://epa.gov/castnet/javaweb/index.html">http://epa.gov/castnet/javaweb/index.html</a>
AMoN	Concentration: NH <sub>3</sub>	2008–2012	<a href="http://nadp.slh.wisc.edu/amon/">http://nadp.slh.wisc.edu/amon/</a>
SEARCH	Concentration: HNO <sub>3</sub> , SO <sub>2</sub> , NH <sub>3</sub>	2005–2011	No longer in operation
NTN	Wet deposition: SO <sub>4</sub> <sup>2-</sup> , NO <sub>3</sub> <sup>-</sup> , NH <sub>4</sub> <sup>+</sup>	2000–2012	<a href="http://nadp.slh.wisc.edu/ntn/">http://nadp.slh.wisc.edu/ntn/</a>

Note: Summary of data from monitoring networks used in the methodology.

Source: [Schwede and Lear \(2014a\)](#).

Wet deposition is estimated as the product of pollutant concentration in precipitation and precipitation depth (e.g., in rain or snow). Concentration in precipitation is currently measured as a weekly average by the National Atmospheric Deposition Program/National Trends Network (NADP/NTN) across a national network of 250 sites using a standard precipitation collector described in the 2008 ISA ([U.S. EPA, 2008a](#)). The NADP precipitation network was initiated in 1978 to collect data on amounts, trends, and distributions of acids, nutrients, and cations in precipitation. It expanded to meet the needs of the National Acid Precipitation Assessment Program established in 1981 to understand causes and effects of acid precipitation. The NTN is the only network providing a long-term record of precipitation chemistry across the U.S. Sites are mainly located away from urban areas and pollution sources. An automated collector ensures that the sample is exposed only during precipitation (wet-only sampling). Species measured are free acidity (H<sup>+</sup> as pH), conductance, calcium (Ca<sup>2+</sup>), magnesium (Mg<sup>2+</sup>), sodium (Na<sup>+</sup>), potassium (K<sup>+</sup>), sulfate (SO<sub>4</sub><sup>2-</sup>), nitrate (NO<sub>3</sub><sup>-</sup>), chloride (Cl<sup>-</sup>), and ammonium (NH<sub>4</sub><sup>+</sup>). Relatively high confidence has been assigned to wet deposition estimates because of established capabilities for measuring relevant chemical components in precipitation samples ([U.S. EPA, 2011a](#)). The Atmospheric Integrated Research Monitoring Network (AIRMoN) started in 1992 and measures the same species as the NTN, but on a daily rather than weekly basis.

In contrast, direct measurements of dry deposition flux are rare and difficult, and dry deposition fluxes of gases and particles are estimated from concentration measurements by an inferential technique described in the 2008 ISA ([U.S. EPA, 2008a](#)). In the

inferential model approach, the deposition of a pollutant is accomplished by introducing a resistance component to account for the individual chemical and biological processes that control pollutant adsorption and capture at natural surfaces ([Hicks et al., 1987](#)).

Concentrations are measured in the Clean Air Status and Trends Network (CASTNET), which was established under the 1991 Clean Air Act Amendments to assess trends in acidic deposition. CASTNET is a long-term environmental monitoring network with 95 sites located throughout the U.S. and Canada, managed and operated by the U.S. EPA in cooperation with other federal, state, and local partners ([www.epa.gov/castnet](http://www.epa.gov/castnet)) including six Native American tribes. CASTNET is the only network in the U.S. that provides a consistent, long-term data record of acidic dry deposition fluxes. It complements the NTN, and nearly all CASTNET sites are collocated with or near an NTN site. Together, these two monitoring programs are designed to provide data necessary to estimate long-term temporal and spatial trends in total deposition (dry and wet) as well as ecosystem health. Species measured in CASTNET include: O<sub>3</sub>, SO<sub>2</sub>, HNO<sub>3</sub> in the gas phase and SO<sub>4</sub><sup>2-</sup>, NO<sub>3</sub><sup>-</sup>, NH<sub>4</sub><sup>+</sup>, Ca<sup>2+</sup>, Mg<sup>2+</sup>, K<sup>+</sup>, Na<sup>+</sup>, and Cl<sup>-</sup> in particles.

While CASTNET data are more useful for estimating dry deposition than data from FRM networks, monitors are generally sparse and deposition is only determined for discrete locations. Also, not all of the species that contribute to total sulfur and nitrogen deposition are measured in CASTNET ([Schwede et al., 2011](#)). Despite these disadvantages, CASTNET data still be very useful if used in combination with modeled data ([Schwede et al., 2011](#)). NH<sub>3</sub> is not measured in CASTNET, but the National Atmospheric Deposition Program (NADP) deployed a separate NH<sub>3</sub> monitoring network (AMoN) using Radiello<sup>®</sup> passive samplers starting in the fall of 2007 at 16 sites; currently there are more than 60 active AMoN sites, two-thirds of which are located at CASTNET sites.

A limitation of dry deposition derived from CASTNET and other dry deposition networks is that results cannot be spatially interpolated because of the complexity of the deposition field ([Schwede and Lear, 2014a](#); [Baumgardner et al., 2002](#)). Combined with the sparse coverage of the network, this complexity restricts the capability of routine monitoring networks to provide data on dry deposition. To some extent, this limitation can be addressed by considering data from other networks.

The remaining network in [Table 2-3](#) is the Southeastern Aerosol Research and Characterization network (SEARCH), which was a highly instrumented network of four urban and four rural stations in Alabama, Florida, Georgia, and Mississippi that was terminated in 2016 ([Hansen et al., 2003](#)). The four rural SEARCH sites have been used for dry deposition estimates. SEARCH began as a public-private collaboration in early 1998 and has continued operation with several objectives, including understanding

processes governing PM<sub>2.5</sub> and copollutants emissions, transport, and deposition in the southeastern U.S.

One additional network that has been identified as potentially suitable for use in future deposition estimates ([Schwede et al., 2011](#)) is the Interagency Monitoring of Protected Visual Environments (IMPROVE) network. The IMPROVE network consists of more than 100 monitoring sites in national parks and other remote locations and is primarily focused on visibility impairment, but has also provided a reliable, long-term record of particulate mass and species components. Several other monitoring networks are operated either by the U.S. EPA or jointly with other federal agencies; species measured and other details for networks making measurements relevant for deposition are shown in [Naess \(2016\)](#). Even if concentration data from other networks are combined with CASTNET data, large areas of the U.S. are still relatively far away from, or in a different environment than, the nearest monitor.

Another deficiency of both the NTN and CASTNET is that not all species that contribute to total sulfur and nitrogen deposition are measured. Reliable measurements of NO<sub>y</sub> and NO<sub>2</sub> concentrations, especially at the low concentrations observed in many areas far from sources, are crucial for evaluating the performance of three-dimensional, chemical transport models of oxidant and acid production in the atmosphere. To meet this need, NO<sub>y</sub> monitors have been installed at six sites in CASTNET as part of the NCore program. At most sites, however, NO<sub>2</sub> is not currently monitored in CASTNET. The same is true for HNO<sub>2</sub> and peroxyacyl nitrates, which can also contribute significantly to total gas-phase reactive nitrogen. These species can be important contributors to N deposition locally, especially near populated areas. Neither the NTN nor CASTNET monitor reduced organic nitrogen compounds, which can also contribute significantly to N deposition (see [Appendix 2.3.4](#)). The sparse geographic coverage and lack of measurements for key species in these networks along with the awareness of modeling uncertainties led to the initiation of the Total Deposition Science Committee [TDEP; [NADP \(2016\)](#)] to develop hybrid approaches to improve estimates of atmospheric deposition. The TDEP approach is described in [Appendix 2.6](#).

---

## 2.4.2 NO<sub>2</sub>, NO<sub>x</sub>, and NO<sub>y</sub>

---

### 2.4.2.1 Network Monitoring

As described in [Appendix 2.4.1](#), a nationwide monitoring network is in place for routine monitoring of NO<sub>2</sub>, and NO<sub>y</sub> is measured in the nationwide NCore network. NO<sub>2</sub> is

routinely measured using the FRM chemiluminescence method based on the catalytic reduction of  $\text{NO}_2$  to NO, followed by reaction NO with  $\text{O}_3$ . However, the reduction of  $\text{NO}_2$  to NO on the  $\text{MoO}_x$  catalyst substrate also reduces other oxidized nitrogen compounds (i.e.,  $\text{NO}_z$  compounds shown in the outer box of [Figure 2-3](#)) to NO. This interference by  $\text{NO}_z$  compounds has long been recognized following [Winer et al. \(1974\)](#) who found NO was also produced by catalytic reduction of  $\text{HNO}_3$ , PAN, and organic nitrates using this method. As a result of their experiments, [Winer et al. \(1974\)](#) concluded that, “the  $\text{NO}_x$  mode of commercial chemiluminescent analyzers must be viewed to a good approximation as measuring *total* gas-phase ‘oxides of nitrogen,’ not simply the sum of NO and  $\text{NO}_2$ .” Numerous later studies, as noted in the ISA for Oxides of Nitrogen ([U.S. EPA, 2016f](#)), have confirmed this conclusion. Further details were also described in the 2008 ISA ([U.S. EPA, 2008a](#)).

Commercially available  $\text{NO}_x$  monitors have been converted to  $\text{NO}_y$  monitors by moving the molybdenum oxide catalyst substrate to interface directly with the sample inlet to improve the efficiency of reduction of  $\text{NO}_z$  compounds susceptible to loss on inlet surfaces.  $\text{NO}_x$  concentrations cannot be considered as a universal surrogate for  $\text{NO}_y$ . However, near sources of fresh combustion emissions, such as highways, most of the  $\text{NO}_y$  is present as  $\text{NO}_x$ . To the extent that all the major oxidized nitrogen species can be reduced quantitatively to NO, measurements of  $\text{NO}_y$  concentrations should be more reliable than those for  $\text{NO}_x$  concentrations, particularly at typical ambient levels of  $\text{NO}_2$ . Exceptions might apply in locations near  $\text{NO}_x$  sources, where  $\text{NO}_x$  measurements are likely to be less biased and confidence in measurement accuracy increases.

---

#### **2.4.2.2 Remote Sensing**

Satellite-based methods have also been used to measure  $\text{NO}_2$ . Remote sensing by satellites is especially useful in areas where surface monitors are sparse. Retrieving  $\text{NO}_2$  column abundances from satellite data typically involves three steps: (1) determining the total  $\text{NO}_2$  integrated line-of-sight (slant) abundance by spectral fitting of measurements of backscattered solar radiation, (2) removing the stratospheric contribution by using data from remote regions where the tropospheric column abundance is small, and (3) applying an air mass factor to convert tropospheric slant columns into vertical columns. The retrieval uncertainty is largely determined by steps 1 and 2 over remote regions where there is little tropospheric  $\text{NO}_2$ , and by step 3, over regions of elevated tropospheric  $\text{NO}_2$  ([Boersma et al., 2004](#); [Martin et al., 2002](#)). Satellite retrievals are largely limited to cloud fractions <20%. A hybrid approach using data for  $\text{NO}_2$  tropospheric column abundances obtained by the Ozone Monitoring Instrument (OMI) on the Aura satellite coupled with results from the GEOS-Chem, global-scale, three-dimensional, chemistry-transport model

has been developed by [Lamsal et al. \(2008\)](#) with updates by [Lamsal et al. \(2010\)](#). In this approach, the surface mixing ratio divided by the column abundances calculated by the GEOS-Chem model are used as the scaling factors to derive surface mixing ratios from satellite-measured column abundances. This method provides estimates of surface NO<sub>2</sub> concentrations that are especially useful in data-sparse regions. The algorithm used to derive the tropospheric columns of NO<sub>2</sub> is given in [Bucsela et al. \(2013\)](#). Note that this algorithm was recently shown to produce NO<sub>2</sub> column abundances that are too high by ~20% ([Marchenko et al., 2015](#)). There have also been advances in satellite remote sensing of NH<sub>3</sub> with the implementation of Cross-Track Infrared Sounder Satellite measurements ([Kharol et al., 2018](#)).

---

### 2.4.2.3 Research and Nonroutine Methods

Alternatively, multiple methods for observing components of NO<sub>y</sub> have been developed and evaluated in some detail. As a result of these methods, as applied in the field and the laboratory, knowledge of the chemistry of odd-N species has evolved rapidly. Recent evaluations of methods can be found in [Arnold et al. \(2007\)](#) for HNO<sub>3</sub>, [Wooldridge et al. \(2010\)](#) for speciated PANs, and [Pinto et al. \(2014\)](#) for HONO. However, it is worth reiterating that the direct measurements of NO are still the most reliable of all.

---

## 2.4.3 Ammonia

---

### 2.4.3.1 Network Monitoring

The recently implemented AMoN for monitoring ammonia was described in [Appendix 2.4.1](#). The passive sampling method relies on diffusion across a membrane onto an absorbing substrate, which for NH<sub>3</sub> is H<sub>3</sub>PO<sub>3</sub>. The sampling period in AMoN is 2 weeks. [Puchalski et al. \(2011\)](#) compared the results from three passive samplers with annular denuder systems (taken to be the reference method). The median relative percentage difference between the Radiello passive samplers and the denuder systems was -37% and the coefficient of variation among triplicate Radiello samplers was 10%. [Puchalski et al. \(2015\)](#) further compared 2-week samples collected at five sites over the course of a year by Radiello passive samplers with collocated annular denuder systems (ADS) with different configurations. The mean relative percentage difference between the ADS and AMoN samplers was -9% to be compared to a precision of 5% for both the ADS and AMoN samplers. Ammonia was also been measured as a part of the SEARCH

network (see [Appendix 2.4.1](#)) from 2004 to 2016 by 24-hour collection on citric acid denuders and laboratory analysis with U.S. EPA method 350.1, based on chemiluminescence from reaction with indophenol ([Edgerton et al., 2007](#)).

---

### 2.4.3.2 Remote Sensing

In addition to these in situ techniques, remote sensing techniques have also been used to measure NH<sub>3</sub>. The Tropospheric Emission Spectrometer (TES) on the Aura satellite [[Shephard et al. \(2011\)](#), and references therein; [Beer et al. \(2008\)](#)] and the Infrared Atmospheric Sounding Interferometer (IASI) on the MetOp-A satellite ([Van Damme et al., 2014](#)) measured spectral features in the  $\nu_2$  vibrational band centered at around 950/cm (the so-called atmospheric window in the infrared). Operating specifications for TES (spectral resolution, 0.06/cm; footprint  $5.3 \times 8.3$  km<sup>2</sup>; 0.15–0.20 K noise) are generally better than for IASI (spectral resolution, 0.50/cm; footprint  $12 \times 12$  km<sup>2</sup>; 0.15–0.20 K noise). Although TES has higher spectral resolution, it has less dense spatial coverage. Unlike satellite detection of atmospheric molecules by backscattered solar radiation (e.g., NO<sub>2</sub> and SO<sub>2</sub>), NH<sub>3</sub> is detected in the thermal infrared spectral range, so data for both day and night can be obtained (satellite overpasses at the Equator at approximately 1:30 a.m. and 1:30 p.m. for TES and 9:30 a.m. and 9:30 p.m. for IASI). The sensitivity of the IR sounding technique for NH<sub>3</sub> increases with the thermal contrast between the surface and the temperature of the air in the lower troposphere, and thus the daytime crossing allows for increased detectability of NH<sub>3</sub> ([Clarisse et al., 2010](#)). NH<sub>3</sub> is confined largely to the planetary boundary layer (PBL), with much lower concentrations aloft in the free troposphere. TES retrievals are most sensitive to NH<sub>3</sub> at atmospheric pressures between 700 and 900 hPa. The TES level of detectability for NH<sub>3</sub> is given by a profile with a peak concentration of 1 ppbv, or equivalently a constant mixing ratio of 0.4 ppbv distributed over the pressure range of maximum sensitivity, provided there is substantial thermal contrast.

[Pinder et al. \(2011\)](#) found that TES retrievals of NH<sub>3</sub> in the PBL captured the spatial and seasonal variability of NH<sub>3</sub> over eastern North Carolina measured by surface observations. Similarly, [Sun et al. \(2015a\)](#) found that column abundances measured by TES over the San Joaquin Valley agreed with those measured by upward looking instruments at the surface to within 2% and to within 6% for aircraft measurements. TES columns were also shown to be reasonably well correlated ( $R^2 = 0.67$ ) with median NH<sub>3</sub> measured at the surface by quantum cascade laser, thereby demonstrating the ability of the satellite-based measurements to capture spatial variability in NH<sub>3</sub> between individual pixels.

[Alvarado et al. \(2011\)](#) derived emissions factors for NH<sub>3</sub> in biomass burning plumes over Canada using data from TES. Using data from IASI [R'Honi et al. \(2013\)](#) found total column abundances for NH<sub>3</sub> in the plumes of Russian wildfires during the summer of 2010 that were two orders of magnitude larger than background values.

---

### 2.4.3.3 Research and Nonroutine Methods

Ambient instruments with much higher time resolution were compared by [Schwab et al. \(2007\)](#) and [von Bobruzki et al. \(2010\)](#). [Schwab et al. \(2007\)](#) conducted a laboratory-based intercomparison of ambient NH<sub>3</sub> instruments with seven instruments using six methods sampling from a common manifold, including tunable diode laser (TDLAS) absorption spectrometer, wet scrubbing long-path absorption photometer (LOPAP), wet effusive diffusion denuder (WEDD), ion mobility spectrometer (IMS), Nitrolux laser acousto-optical absorption analyzer, and a modified CL analyzer. [Schwab et al. \(2007\)](#) reported that all instruments agreed to within ~25% of the expected calibration value, with the exception of the CL analyzer which suffered from problems related to its MoO<sub>x</sub> conversion of NO<sub>z</sub> to NO.

[von Bobruzki et al. \(2010\)](#) conducted a field intercomparison of ambient NH<sub>3</sub> measurements with 11 instruments using 8 methods including 3 wet techniques (annular rotating batch denuders, 1 with offline analysis and 2 with online analysis [AMANDA, AiRRmonia]), 2 Quantum Cascade Laser Absorption Spectrometers (c-QCLAS, DUAL-QCLAS), 2 photo-acoustic spectrometers, a cavity ring down spectrometer, a chemical ionization mass spectrometer, an ion mobility spectrometer, and an open-path Fourier transform infrared spectrometer. This study was unique in that the surrounding field was fertilized with urea halfway through the campaign to increase average concentrations of NH<sub>3</sub> from 10 to 100 ppb. Overall,  $R^2$  was >0.84 with respect to the ensemble mean for all instruments over the entire range of concentrations (<120 ppb), with slopes ranging from 0.67 to 1.13. Higher variability was found at lower concentrations (<10 ppb) with  $R^2 > 0.52$  and slopes ranging from 0.42 to 1.15. Perhaps the most consistent agreement between two instruments was found for the c-QCLAS and AiRRmonia ( $R^2 = 0.91$ , slope = 0.86, intercept = 0.84 ppb for NH<sub>3</sub> <10 ppb; and  $R^2 = 0.91$ , slope = 0.83, intercept = 0.34 ppb over the entire range of NH<sub>3</sub> concentrations).

Nitrolux-100 denuders were used both in the intercomparison study of [von Bobruzki et al. \(2010\)](#) and in the one by [Puchalski et al. \(2011\)](#). Compared to the ensemble mean, the slope was 0.97, the intercept was 1.86 ppb, and  $R^2 = 0.98$  over the entire concentration range. As noted by [von Bobruzki et al. \(2010\)](#), comparisons of this sort only show relative performance of the instruments and not a functional relationship to a standard.

---

## 2.4.4 Sulfur Dioxide

---

### 2.4.4.1 Network Monitoring

In the nationwide monitoring network for SO<sub>2</sub>, SO<sub>2</sub> is routinely measured by pulsed UV fluorescence. This technique is a Federal Equivalence Method (FEM). The method's principles and potential interferences have been described in detail in the 2008 ISA ([U.S. EPA, 2008a](#)). However, measurements using this method are not as widely used as measurements from the CASTNET. In the CASTNET, SO<sub>2</sub> is collected by capturing it on filters and measured as sulfate following procedures described in [Appendix 2.4.5](#).

---

### 2.4.4.2 Remote Sensing

In addition to the above in situ methods, satellite-based measurements have also been used to measure tropospheric SO<sub>2</sub> and to infer surface SO<sub>2</sub> concentrations with the aid of the GEOS-Chem chemistry-transport model ([Nowlan et al., 2014](#); [Lee et al., 2011](#)). Tropospheric column abundances of SO<sub>2</sub> are obtained by the Ozone Monitoring Instrument (OMI) on the Aura satellite or the Scanning Imaging Absorption Spectrometer for Atmospheric Cartography (SCIAMACHY) on Envisat and are combined with results from the GEOS-Chem, global-scale, three-dimensional, chemistry-transport model to derive surface concentrations of SO<sub>2</sub> (as they are for NO<sub>2</sub>). [Lee et al. \(2011\)](#) associated annual mean surface mixing ratios of SO<sub>2</sub> derived from the hybrid satellite/model technique with ambient measurements of SO<sub>2</sub>, ( $R^2 = 0.66$  and  $0.74$ , slope =  $0.70$  and  $0.93$ ,  $n = 121$  and  $115$ , for OMI and SCIAMACHY, respectively).

The algorithms used to derive vertically integrated SO<sub>2</sub> abundances in the troposphere undergo continuing refinement. For example, [Theys et al. \(2015\)](#) applied an algorithm based on differential optical absorption spectroscopy ([Platt and Stutz, 2008](#)) combined with a radiative transfer model. [Li et al. \(2013\)](#) developed an algorithm based on principal components analysis, which has replaced the earlier standard algorithm developed by [Krotkov et al. \(2008\)](#). The methods applied by [Theys et al. \(2015\)](#) and [Li et al. \(2013\)](#) are designed to be operational for retrieving SO<sub>2</sub> in the PBL with an estimated detection limit of ~0.5 Dobson units (1 DU =  $2.69 \times 10^{16}$  molec/cm<sup>2</sup> corresponding to a concentration of ~3 ppb if SO<sub>2</sub> is well mixed in a 2-km-deep mixed layer), or about half that in the older standard method. [Table 2-4](#) summarizes sources of uncertainty for individual OMI measurements of NO<sub>2</sub> and SO<sub>2</sub>.

**Table 2-4 Sources of uncertainty for individual Ozone Monitoring Instrument measurements in the study of [Nowlan et al. \(2014\)](#).**

Source	NO <sub>2</sub>	SO <sub>2</sub>
OMI fitting error	~10 <sup>15</sup> molec/cm <sup>2</sup>	~10 <sup>16</sup> molec/cm <sup>2</sup>
Air mass factor	20%	15–45%
Stratospheric correction	2 × 10 <sup>14</sup> molec/cm <sup>2</sup>	N/A
SO <sub>2</sub> offset correction	N/A	2 × 10 <sup>14</sup> molec/cm <sup>2</sup>
Profile shape	30%	10%

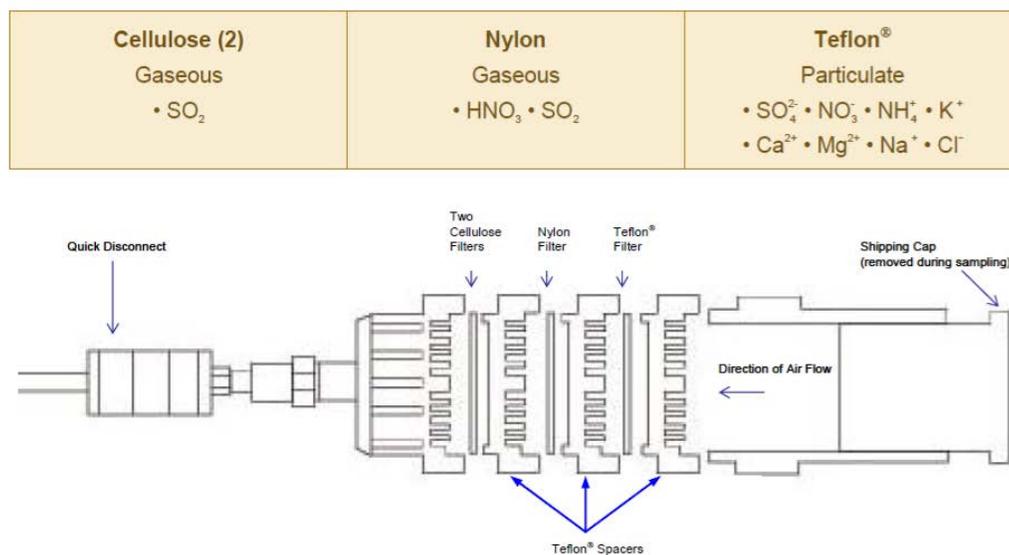

molec = molecules; N/A = not applicable; NO<sub>2</sub> = nitrogen dioxide; OMI = Ozone Monitoring Instrument; SO<sub>2</sub> = sulfur dioxide.  
Source: [Nowlan et al. \(2014\)](#).

The errors in the column measurements result mainly from uncertainties in the vertical profiles of NO<sub>2</sub> and SO<sub>2</sub>, cloud fraction, cloud pressure, surface reflectivity, and particles used in the calculation of air mass factor. A correction is required to account for NO<sub>2</sub> in the stratosphere (produced from N<sub>2</sub>O oxidation and cosmic ray interactions dissociating with N<sub>2</sub>). The SO<sub>2</sub> offset correction refers to a global background correction arising from issues in spectral fitting, such as spectral correlations with O<sub>3</sub> and stray light within the instrument.

#### 2.4.5 Filter-Based Concentration Measurements

As described in [Appendix 2.4.1](#), most measurements used for estimating deposition are from CASTNET, rather than from monitoring networks based on FRM and FEM methods. The CASTNET filter pack is shown in [Figure 2-6](#). Particulate matter is collected on the open-face Teflon filter, extracted in deionized water, and analyzed by ion chromatography (IC) for sulfate, nitrate, ammonium, and other species identified in [Figure 2-6](#). In the CASTNET filter pack, gases are collected downstream of the particulate species, with nitric acid collected on nylon filters and analyzed as NO<sub>3</sub><sup>-</sup> by ion chromatography, and SO<sub>2</sub> on carbonate impregnated cellulose filters and analyzed as SO<sub>4</sub><sup>2-</sup> by ion chromatography. Extensive intercomparisons of CASTNET methods with other measurement methods were described in the 2008 ISA ([U.S. EPA, 2008a](#)).

**Figure I-4 Three-Stage Filter Pack**

Ca<sup>2+</sup> = calcium ion; Cl<sup>-</sup> = chloride; HNO<sub>3</sub> = nitric acid; K<sup>+</sup> = potassium ion; Mg<sup>2+</sup> = magnesium ion; Na<sup>+</sup> = sodium ion; NH<sub>4</sub><sup>+</sup> = ammonium; NO<sub>3</sub><sup>-</sup> = nitrate; SO<sub>2</sub> = sulfur dioxide; SO<sub>4</sub><sup>2-</sup> = sulfate.

Air flows from right to left.

Source: [MACTEC \(2010\)](#).

**Figure 2-6 Clean Air Status and Trends Network filter pack.**

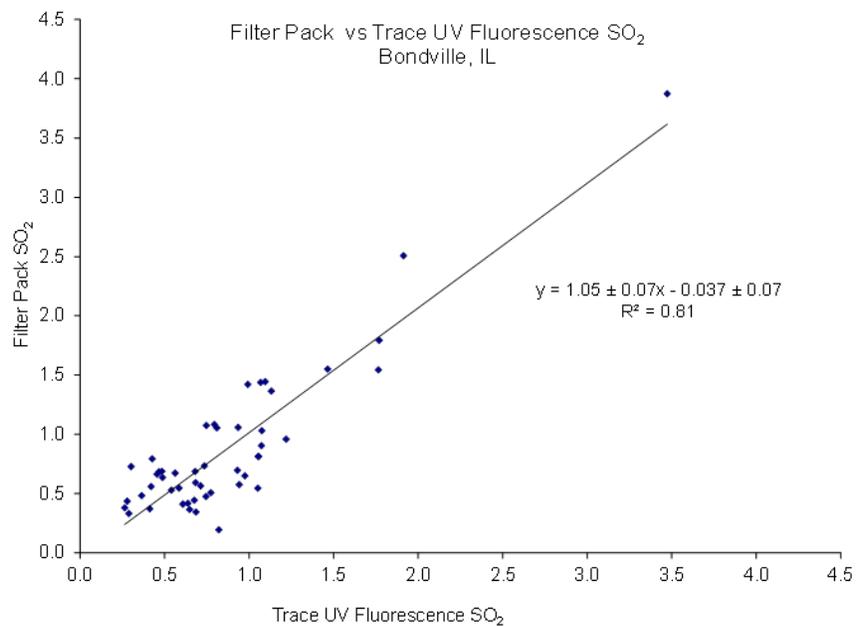

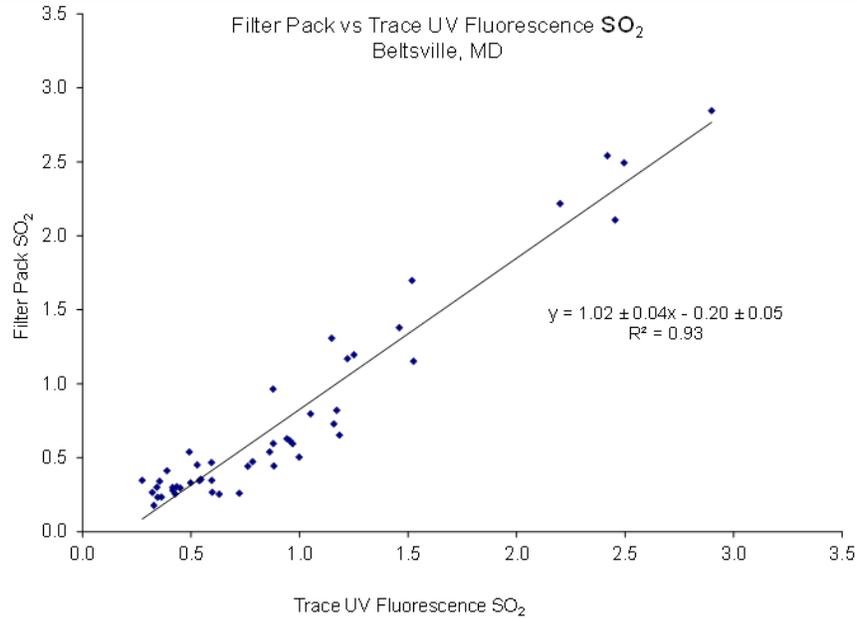

As can be seen in [Figure 2-6](#), SO<sub>2</sub> is measured by the CASTNET filter pack by IC analysis of extracts from the cellulose filters. Because the nylon filter adsorbs some of the SO<sub>2</sub> ([Sickles et al., 1999](#); [Sickles and Hodson, 1999](#)), SO<sub>4</sub><sup>2-</sup> is also measured on nylon and added to the SO<sub>2</sub> (expressed as SO<sub>4</sub><sup>2-</sup>) collected on the backup cellulose-fiber filters.

Uncertainties in CASTNET data are reported quarterly in a quality assurance report ([U.S. EPA, 2016c](#)). Precision is determined as the absolute value of quarterly or annually aggregated relative percentage difference for duplicate sample pairs collected with collocated samplers at two sites. Data quality objectives for ammonium, nitrate, and sulfate are within 20%, but reported precision for 2016 was well under this target, 2–5% for sulfate, 5–13% for nitrate, and 2–6% for ammonium, where the range reflects that there are two sites. Analytical accuracy was reported within 2% based on spiked calibration verification samples. Further detail on uncertainty and data quality can be found in ([U.S. EPA, 2016c](#)). Additional unknown uncertainty is associated with volatilization of NH<sub>4</sub><sup>+</sup> from collected PM. Substantial loss during sampling can occur because collected NH<sub>4</sub>NO<sub>3</sub> in PM is in a temperature dependent equilibrium with NH<sub>3</sub> and HNO<sub>3</sub> (see [Appendix 2.3.3](#)), leading to volatilization of both species after PM

collection. Loss of  $\text{NH}_4^+$  during sampling was thoroughly reviewed in the 2008 ISA ([U.S. EPA, 2008a](#)).

Results of an intercomparison of weekly average  $\text{SO}_2$  data (ppbv) collected by the CASTNET filter pack and trace level  $\text{SO}_2$  monitors during all of 2014 at Bondville, IL and Beltsville, MD are shown in [Figure 2-7 \(AMEC Environment & Infrastructure, 2015\)](#).

In addition to CASTNET,  $\text{pSO}_4^{2-}$ ,  $\text{pNO}_3^-$  are monitored in the Chemical Speciation Network (CSN), and the Interagency Monitoring of Protected Visual Environments (IMPROVE) network. Sampling and measurement methods for these networks were described in detail by [Solomon et al. \(2014\)](#). In the CSN network,  $\text{pNH}_4^+$  is also measured, but as for CASTNet, it may be subject to volatilization error (volatilization of  $\text{NO}_3^-$  is corrected).

SO<sub>2</sub> = sulfur dioxide; UV = ultraviolet.

Results for Beltsville, MD are shown in the upper panel and results for Bondville, IL are shown in the lower panel.

**Figure 2-7 Comparison between weekly average measurements of sulfur dioxide using the Clean Air Status and Trends Network filter pack and the trace ultraviolet pulsed fluorescence monitor in 2014.**

---

## 2.4.6 Deposition Measurements

Wet deposition is estimated as the product of pollutant concentration in precipitation and precipitation depth (e.g., in rain or snow; see [Appendix 2.4.1](#)). Concentration in precipitation is currently measured by the National Atmospheric Deposition Program/National Trends Network (NADP/NTN) across a national network of sites using a standard precipitation collector described in the 2008 ISA ([U.S. EPA, 2008a](#)).

Relatively high confidence has been assigned to wet deposition estimates because of established capabilities for measuring relevant chemical components in precipitation samples ([U.S. EPA, 2011a](#)). Measurement precision determined as the average absolute percentage differences of replicate samples in the 2016 annual quality assurance report was 1% or less for sulfate, nitrate, and ammonium, and absolute percentage difference was no greater than 5% for sulfate and ammonium or 7% for nitrate for any single sample pair ([U.S. EPA, 2016c](#)). Bias determined from internal blind samples was 2% or less for sulfate and nitrate, and 6% or less for ammonium ([U.S. EPA, 2016c](#)).

In contrast, direct measurements of dry deposition flux are rare and difficult. Methods for estimating dry deposition from field measurements fall into two major categories: surface analysis methods, which include all types of estimates of contaminant accumulation on surfaces of interest, and atmospheric deposition rate methods, which use measurements of contaminant concentrations in the atmosphere and micrometeorological measurements of atmospheric turbulence ([U.S. EPA, 2008a](#)). Emphasis here is placed on the latter class of methods, which are more widely applicable because the accumulation methods are subject to limitations such as the site specificity of the measurements and the restriction to elements that are largely conserved within the vegetative system. Dry deposition estimates using atmospheric deposition rate methods are based on field measurements of a species or particle concentration gradient along with a measurement or estimate of its turbulent diffusivity under the field conditions of the measurement ([Myles et al., 2012](#); [Businger, 1986](#)). Examples include eddy covariance and aerodynamic gradient techniques ([U.S. EPA, 2008a](#)). In the eddy covariance method, flux is calculated from the covariance between fluctuations in wind velocity and concentration. Historically, empirical estimates of deposition for wind tunnel and field conditions often have not agreed well with theoretical predictions, probably because transport phenomena and turbulence structure near surfaces are not well characterized ([U.S. EPA, 2004](#)). However, improvement of dry deposition measurements is an active research area, both to reduce measurement uncertainties and to improve modeling capabilities by better understanding deposition processes and their parameterization in chemical transport models.

Progress in improving measurement capabilities has been triggered by the development of continuous air sampling measurement techniques with higher sensitivity and temporal

resolution, with the objective of improving costs and measurement quality using atmospheric deposition rate measurement methods. Concluding that the main reason for the shortage of dry deposition measurements is the expense and complexity of measurement methods, [Almand-Hunter et al. \(2015\)](#) tested a dynamic flux chamber using automated, inexpensive multispecies gas flux monitoring system for measurement of a variety of pollutants, including NO<sub>x</sub>, that would be needed to contend with the large spatial and temporal variability in air-surface exchange rates of reactive compounds. A dynamic chamber system was also developed to allow measurements of NO, NO<sub>2</sub>, and O<sub>3</sub> measurements so that compensation points and deposition velocities (see [Appendix 2.5.2](#)) could be estimated ([Breuninger et al., 2012](#)).

As part of a series of measurements to be tested at several CASTNET sites, [Rumsey and Walker \(2016\)](#) evaluated the ability of the MARGA 2S (Monitoring for AeRosols and GAses) system to simultaneously measure fluxes of NH<sub>3</sub>-HNO<sub>3</sub>-NH<sub>4</sub>NO<sub>3</sub> using the aerodynamic gradient method to allow for an assessment of the errors due to the instability of the particle phase, as well as SO<sub>2</sub> and SO<sub>4</sub><sup>2-</sup>, to allow for the investigation of ammonium sulfate neutralization and codeposition between SO<sub>2</sub> and NH<sub>3</sub>. Over a range of meteorological conditions, median flux uncertainty was found to range from ≈31% for NH<sub>3</sub> to ≈120% for NH<sub>4</sub><sup>+</sup>. The flux gradient technique was also applied to a forest clearing as an example of a complex ecosystem with the objectives of improving deposition rate accuracy and model parameterization for SO<sub>2</sub> ([Myles et al., 2012](#)). Deposition velocities fluctuated considerably with a mean of 1.00 ± 0.48 cm/s, and the large variation was not fully captured by estimates from widely used models ([Myles et al., 2012](#)). Uncertainties in canopy resistance, including stomatal and nonstomatal processes were identified as probable sources of uncertainty ([Myles et al., 2012](#)).

This approach has been successfully applied to measurements of a wide variety of species. However, it is less suitable for HNO<sub>3</sub> and NH<sub>3</sub> because they are subject to interactions with inlet surfaces of measuring devices. For example, in one study a correction factor of 1.62 was reported for inlet surface interactions ([Breuninger et al., 2012](#)). To address the problem of loss of HNO<sub>3</sub>, NH<sub>3</sub>, and other substances that interact with sampling inlet surfaces during measurement, [Roscioli et al. \(2016\)](#) developed a method to passivate inlet surfaces and thereby overcome this difficulty by allowing for more rapid response measurements. [Min et al. \(2014\)](#) determined the net flux of NO and NO<sub>2</sub> (at a frequency of 5 Hz) over a forest with estimated total systematic uncertainties of <8 and <6%, and random errors of <25 and <21%, respectively.

Measurement methods are well developed for ideal conditions of flat, homogeneous, and extensive landscapes and for chemical species for which accurate and rapid sensors are available ([U.S. EPA, 2008a](#)). However, the strong dependence of dry deposition on

surface characteristics, which are highly spatially variable, causes in situ measurements to be limited in applicability, especially in areas of high topographic relief [e.g., [Weathers et al. \(2006\)](#)]. The lifetime in the boundary layer (~1 km depth) for rapidly depositing species is ~1 day, implying that distances from source to deposition are relatively short and that the deposition flux depends strongly on the nature and strength of nearby sources. Deposition also shows strong temporal variability on timescales ranging from diurnal to seasonal, as do wind regimes affecting a particular site. In addition, cost and logistics make the eddy covariance and aerodynamic gradient techniques impractical for monitoring networks.

Instead, dry deposition fluxes of gases and particles are estimated in CASTNET and by chemistry-transport models, such as CMAQ, by an inferential technique described in the 2008 ISA ([U.S. EPA, 2008a](#)). In the inferential model approach, the deposition of a pollutant is estimated by introducing a resistance component to account for the individual chemical and biological processes that control pollutant adsorption and capture at natural surfaces ([Hicks et al., 1987](#)). Ambient pollutant concentrations of  $O_3$ ,  $SO_4^{2-}$ ,  $NO_3^-$ ,  $NH_4^+$ ,  $SO_2$ , and  $HNO_3$  are routinely collected at CASTNET dry deposition sites. Deposition velocities based on local meteorological measurements were calculated using the Multi-Layer Model (MLM) at U.S. EPA-sponsored CASTNET sites until 2010, when meteorological measurements were discontinued at all but five U.S. EPA CASTNET sites. Dry deposition fluxes are still reported at sites with discontinued meteorological measurements using historical data. A disadvantage to this approach is that relevant atmospheric species are not routinely measured. For example,  $NO_2$  and peroxyacetyl nitrate, which together consistently contribute 15 to 25% of estimated oxidized nitrogen dry deposition, are not measured at CASTNET sites. Even for those species that are routinely measured, network spatial coverage is sparse ([U.S. EPA, 2011a](#)).

Satellite-based measurements offer a potential means of greater coverage, but only a limited number of deposition related applications have been described. [Nowlan et al. \(2014\)](#) combined satellite data with modeled  $NO_2$  and  $SO_2$  surfaces and vertically integrated concentrations and deposition velocities to estimate deposition fluxes.  $SO_2$  dry deposition fluxes compared well with surface network-based deposition fluxes. Uncertainties in depositional flux estimates in this approach result from the combined uncertainties in the satellite-derived surface concentrations and model-derived deposition velocities and were estimated to be ~30% on average for both  $NO_2$  and  $SO_2$  over land. In the absence of routine measurements, dry deposition is often modeled with CMAQ or other modeling tools using relevant emissions, meteorological, and land use data, rather than estimated from measured concentration measurements ([U.S. EPA, 2011a](#)).

Modeling dry deposition is particularly challenging over varying terrain and under extremely stable conditions such as those occurring at night. Under optimal conditions over a relatively small area where dry deposition measurements have been made, uncertainties on the order of  $\pm 30\%$  have been reported and larger uncertainties are likely when the surface features in the built environment are not well known or when the surface comprises a patchwork of different surface types, as is common in the eastern U.S. ([U.S. EPA, 2008a](#)). For this reason, dry deposition is routinely estimated from concentration measurements, usually from CASTNET data ([Appendix 2.4.5](#)) using a hybrid approach based on both measured and modeled data ([Appendix 2.6](#)).

---

## 2.5 Modeling Chemistry, Transport, and Deposition

In this section, advances in modeling transport and deposition of species relevant to acid and nutrient deposition are discussed, along with research progress on understanding underlying transport and deposition processes. The use of chemical transport models (CTMs) to model deposition was discussed extensively in the 2008 ISA ([U.S. EPA, 2008a](#)). Relevant new research and improvements in CTM modeling in general are described in [Appendix 2.5.1](#). [Appendix 2.5.2](#) discusses environmental processes relevant to understanding and modeling acid and nutrient deposition. [Appendix 2.5.2.1](#) begins with an overview of fundamental processes of atmospheric deposition of gases and particles, along with deposition velocities for some key gas-phase species. It also contains discussions of research advances in three key processes that serve as major structural uncertainties (lack of knowledge of the underlying science) in modeling deposition: NO<sub>x</sub> canopy processes, which involve both bidirectional gas exchange and NO<sub>x</sub> chemistry ([Appendix 2.5.2.2](#)); bidirectional exchange of ammonia ([Appendix 2.5.2.3](#)); and transference ratios relating average ambient concentration to deposition flux ([Appendix 2.5.2.4](#)). [Appendix 2.5.3](#) discusses model evaluation and uncertainty, including comparisons between CTM and network-based wet deposition results.

---

### 2.5.1 Advances in Chemistry-Transport Model (CTM) Modeling

To understand the lifetime and fate of the varied forms of atmospheric sulfur and nitrogen from emission to deposition, it is necessary to account for both atmospheric transport and chemical transformations. CTMs simulate the relevant atmospheric transport processes (e.g., horizontal and vertical advection and diffusion), as well as chemistry, aerosol physics, deposition, and cloud processes. The 2008 ISA ([U.S. EPA, 2008a](#)) provided a detailed description of the CTM models and their application to estimating deposition. Continental-scale CTMs include CMAQ ([Appel et al., 2017](#)) and CAMx ([Koo et al.,](#)

2015), while GEOS-Chem (Zhang et al., 2012a) is an example of a global-scale model. Most major regional-scale, air-related modeling efforts at U.S. EPA use the Community Multiscale Air Quality (CMAQ) modeling system (Byun and Schere, 2006; Byun and Ching, 1999). Recent updates to CTM model design, and in particular to CMAQ, are described here.

A number of complex atmospheric processes influence pollutant behavior between emission and deposition and must be taken into account to achieve good model performance. A variety of mechanisms operating over a wide range of spatial and temporal scales transport heat, water, and pollutants horizontally and vertically through the atmosphere. These mechanisms range from local-scale circulations (e.g., urban heat islands) to hemispheric-scale transport by the jet stream. Long-range transport of pollutants in the lower free troposphere associated with large-scale synoptic systems is possible because flows are largely uncoupled from surface friction. Flows in the upper planetary boundary layer (PBL), especially during the day, might not be as effective for transporting pollutants over long distances because air can be mixed down to the surface by turbulence. If these pollutants react with surface material or are taken up by vegetation, they can be removed within a relatively short distance from their sources.

In addition to wind velocity, the distance scale for transport of a pollutant that is relatively stable in the troposphere with respect to gas-phase reactions (i.e., chemical lifetime > a few days) depends strongly on the pollutant's interactions with solid and liquid surfaces and subsequent chemical transformations. Because NO and NO<sub>2</sub> are only slightly soluble, they can be transported over longer distances in the gas phase than can more soluble species like HNO<sub>3</sub> (and its anhydride, N<sub>2</sub>O<sub>5</sub>) and NH<sub>3</sub> that are depleted by deposition to moist surfaces or taken up more readily on aqueous surfaces of particles or on cloud drops. For example, measurements of the ratio of NH<sub>3</sub> to CH<sub>4</sub> in the San Joaquin Valley indicate substantial loss of NH<sub>3</sub> to the surface within a few km of sources of these gases (Miller et al., 2015), consistent with an NH<sub>3</sub> lifetime of minutes to a few hours in this environment. On the other hand, a combination of models, remote sensing, and in situ measurements over the eastern U.S. indicate an atmospheric lifetime for SO<sub>2</sub> of 19 ± 7 hours in summer increasing to 58 ± 20 hours in winter (Lee et al., 2011), which indicates the potential for much longer-range transport of SO<sub>2</sub>.

Numerous advances in atmospheric science have been codified in CTMs, including gas-phase oxidant chemistry relevant for the formation of aerosol precursors and dry deposition by gravitational settling (Nolte et al., 2015), improved representation of meteorological processes in CTMs and interactions with aerosols (Tuccella et al., 2015), and improved algorithms for understanding the influence of weather on emissions of ammonia from agricultural lands (Flechar et al., 2013). Over the U.S. and Europe,

substantial reductions in sulfur dioxide and nitrogen oxides have created an opportunity to compare the model results with the trends in ambient observations ([Banzhaf et al., 2015](#); [Xing et al., 2015](#); [Civerolo et al., 2010](#)). Studies have shown that CMAQ is skilled at capturing the seasonal and long-term changes in sulfate PM<sub>2.5</sub> and nitrate PM<sub>2.5</sub> as well as total PM<sub>2.5</sub> mass; however, the model performs less well for seasonal variability in nitrate PM<sub>2.5</sub>, owing to uncertainties in ammonia emission trends ([Banzhaf et al., 2015](#); [Xing et al., 2015](#)).

---

## 2.5.2 Modeling Deposition

---

### 2.5.2.1 Wet and Dry Deposition of Gases and Particles

Considerable advances in both our understanding of atmospheric deposition and modeling approaches to characterize it have taken place recently. Deposition is a complicated process influenced by numerous atmospheric and deposition surface properties, as well as chemical reactions and other processes that take place within canopies of vegetation.

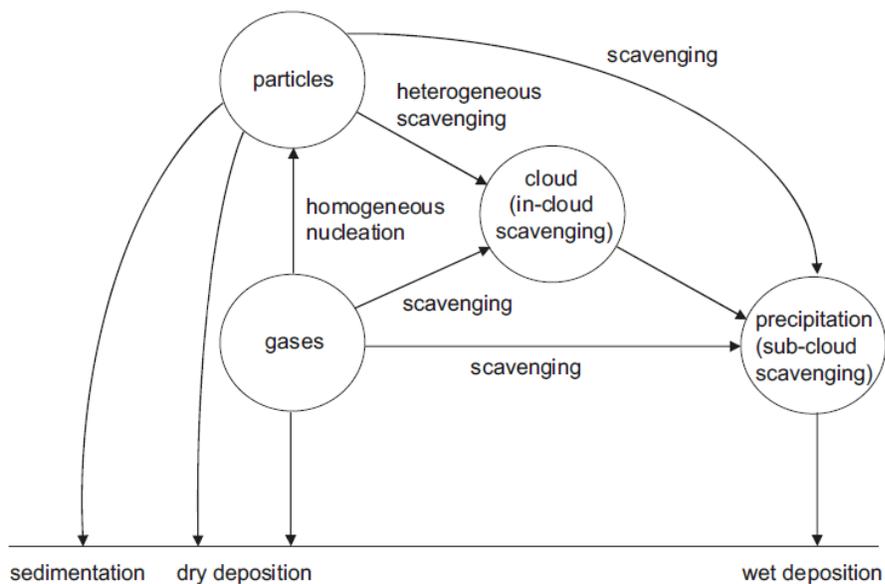

In [Figure 2-8](#), [Möller \(2014\)](#) illustrated the pathways that transfer gaseous and particulate pollutants from the atmosphere to the surface by deposition. Wet deposition occurs when particulate and gaseous species are removed by cloud drops or by falling precipitation (washout). Dry deposition occurs when they are removed without precipitation by processes like turbulence and gravitational settling. In mountainous areas, a third important type of deposition occurs, referred to as occult deposition ([Dollard et al., 1983](#)), which is not shown in [Figure 2-8](#), and results from the impaction of droplets in fogs or clouds on vegetation. Wet deposition is determined as the simple product of concentration in precipitation and precipitation rate. Receptor (i.e., vegetation) surface properties have little effect on wet deposition. Dry deposition is more difficult to determine. It can be described as a flux  $F_d$ , the mass of pollutant deposited per unit area of the Earth's surfaces where it deposits, or a deposition velocity that relates the dry deposition flux  $F_d$  to a pollutant's ambient concentration:

$$F_d = v_d C$$

Equation 2-12

where  $C$  is the pollutant's concentration in mass in per unit volume, and  $v_d$  is the deposition velocity, which relates a pollutant's deposition flux to its ambient concentration.

Dry deposition of gases depends on leaf area, surface resistance to gas uptake, interactions with biota through both stomatal and plant surface pathways, and atmospheric reactivity, which can vary among depositing gases. Measurements of average dry deposition velocities for gases over land surfaces are shown in [Table 2-5](#), and an indication of the seasonal variability of deposition velocities over different land surface types can be seen in [Table 2-6](#), which shows the variability in  $v_d$  for  $\text{SO}_2$ . Deposition velocities of other species are also expected to be spatially and temporally variable.

Con. = coniferous; Dec. = deciduous; Su = summer; Wi = winter.

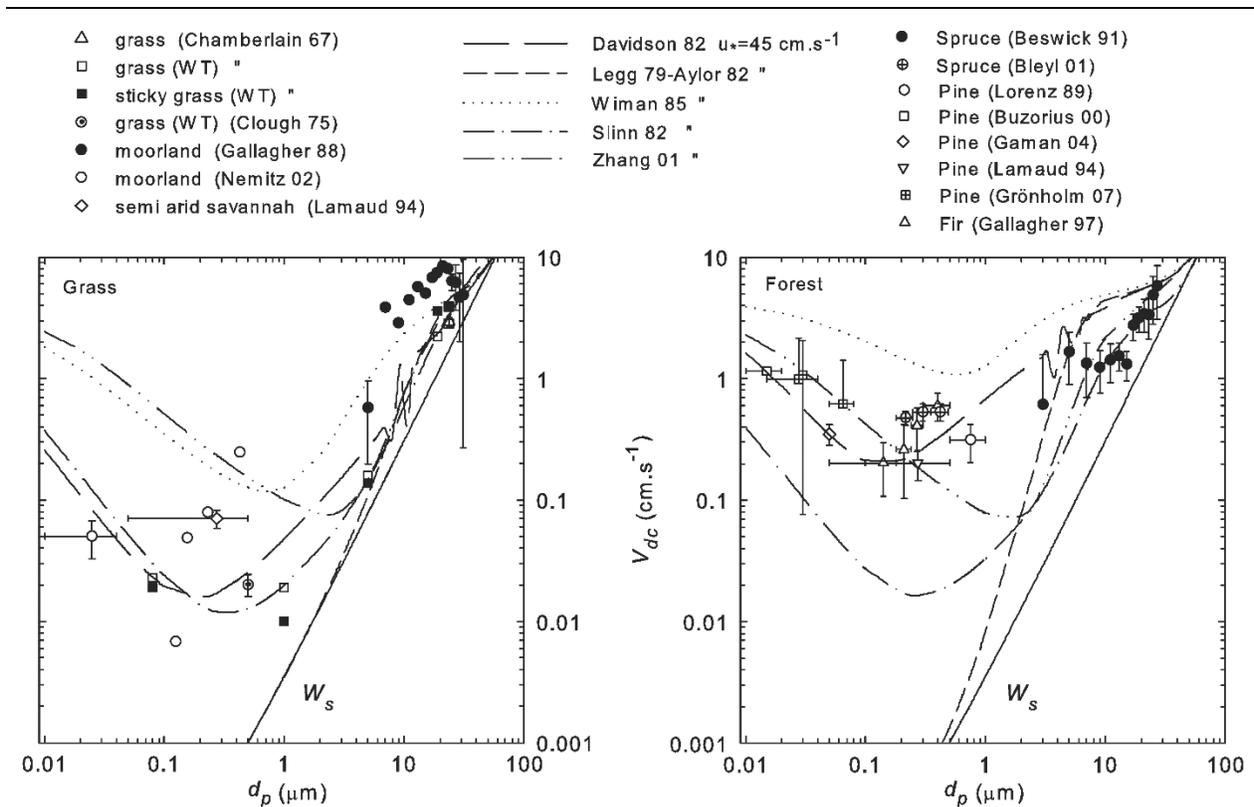

Source: [Möller \(2014\)](#).

A wide range of deposition velocities is observed among different atmospheric gas-phase species. HNO<sub>3</sub> is an example of gas with straightforward deposition behavior. It sticks easily to vegetative surfaces, i.e., there is a negligible surface resistance to HNO<sub>3</sub> uptake by vegetation, and its deposition rates are independent of leaf area or stomatal conductance, implying that deposition occurs to branches, soil, and the leaf cuticle as well as leaf surfaces. The HNO<sub>3</sub>  $v_d$  typically exceeds 1 cm/s and exhibits a diel pattern controlled by turbulence characteristics of midday maxima and lower values at night in the more stable boundary layer ([U.S. EPA, 2008a, 2004](#)). In contrast, NO<sub>2</sub> interaction with vegetation is more complicated. The uptake rate by foliage is related to stomatal conductance and is more variable. It may also be associated with concentrations of reactive species such as ascorbate in the plant tissue that react with NO<sub>2</sub>. At very low NO<sub>2</sub> concentrations, emission from foliage is observed. Internal NO<sub>2</sub> appears to derive from plant N metabolism, and there is evidence for a compensation point, typically near

~1 ppb, at which uptake and emission rates are equal and net flux is zero ([U.S. EPA, 2008a](#)).

Dry deposition of PM is influenced by a number of variables, including particle diameter, atmospheric stability, deposition surface roughness, and the shape, stickiness, roughness, and cross-sectional area of leaves. Greater roughness and leaf shape complexity increase deposition. The diversity of particle sizes, atmospheric conditions, and surface characteristics makes it difficult to estimate dry deposition ([U.S. EPA, 2008a, 2004](#)). The appreciable effects of particle size, local micrometeorological conditions and surface characteristics on deposition velocity can be seen in [Figure 2-9](#). The key to measurements of  $v_d$  over surfaces covered by low vegetation is given in the left column and over forest in the right column. These measurements are compared to six model formulations which are shown as lines in the center column.

For particles  $>10 \mu\text{m}$ ,  $v_d$  varies between 0.5 and 1.1 cm/s, and a minimum particle  $v_d$  of 0.03 cm/s exists for particles in the size range 0.1 to 1.0  $\mu\text{m}$ , while deposition of particles from the atmosphere to a forest canopy has been estimated as 2 to 16 times greater than deposition in adjacent open terrain like grasslands or other low vegetation ([U.S. EPA, 2004](#)).

$d_p$  = aerodynamic diameter of particle;  $v_{dc}$  = deposition velocity;  $W_s$  = Stokes settling velocity.

**Figure 2-9 Modeled and measured deposition velocities over grass (left figure) and coniferous forest canopies (right figure) for particles of density  $1 \text{ gm/cm}^3$  depositing under similar friction velocity ( $u^*$ ) ( $35 < u^* < 56 \text{ cm/s}$ ).**

### 2.5.2.2 NO<sub>x</sub> Canopy Processes

There are a number of ways that landscape characteristics influence the deposition process ([U.S. EPA, 2008a, 2004](#)). In terrain containing extensive vegetative canopies, any material deposited via precipitation to the upper stratum of foliage is likely to be intercepted by several foliar surfaces before reaching the soil. Deposition velocity ( $v_d$ ) is usually greater for a forest than for a nonforested area and greater for a field than for a water surface. The upwind leading edges of forests, hedgerows, and individual plants are

primary sites of coarse particle deposition, and upper canopy foliage tends to receive maximum exposure to coarse and fine particles, but foliage within the canopy tends to receive primarily fine particles ([U.S. EPA, 2008a, 2004](#)). Several  $N_r$  species are deposited to vegetation, among them  $HNO_3$ ,  $NO_2$ , PAN (and other  $RONO_2$ ), and  $NH_3$ .

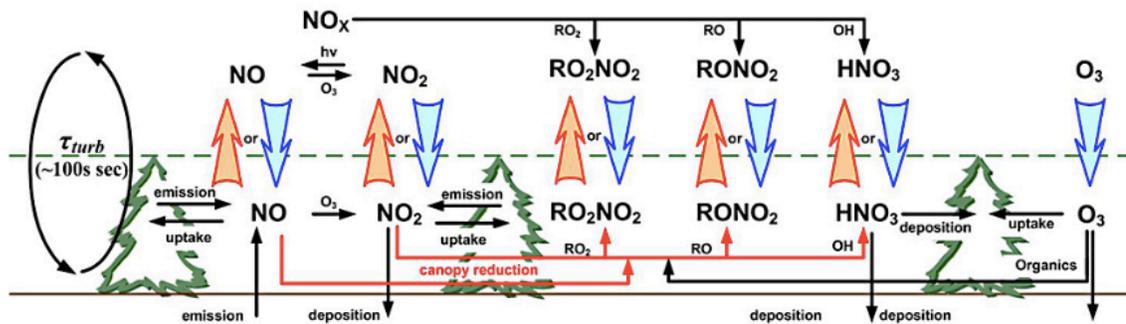

Wet, dry, and occult deposition all contribute N and S species to the forest canopy in varying proportions. Deposited species can react on surfaces within the canopy, be taken up by vegetation through stomata, be resuspended during stormy weather, or simply pass through the canopy to the forest floor. Surface characteristics can influence foliar uptake, chemical transformation, and resuspension. Landscape characteristics can affect wet deposition via orographic effects and by the closer aerodynamic coupling to the atmosphere of tall forest canopies as compared to the shorter shrub and herbaceous canopies. The rainwater that passes directly through a canopy or is initially intercepted by aboveground vegetative surfaces and subsequently drips from the canopy is measured as throughfall. The fraction of the precipitation that drains from outlying leaves and branches and is channeled to the stem of plants is classified as stemflow. Throughfall and stemflow inputs constitute the majority of incident precipitation in forests and can account for 70 to 90% of incoming precipitation in most cases, with the remainder lost to interception within the canopy ([Levia and Frost, 2003](#)). Compared to wet deposition measurements in the open, the magnitude of deposition from throughfall and stemflow can either be smaller (e.g., from evaporation from canopy surfaces) or larger (e.g., from resuspension of previously deposited material). The type of vegetation is important for characterizing throughfall. For example, [Templer et al. \(2015a\)](#) found that the cycling of N, particularly the rate of throughfall for  $NH_4^+$ , is significantly different in conifer compared to deciduous forest sites. Rainfall introduces new wet deposition and also redistributes previously dry-deposited particles throughout the canopy. Intense rainfall may contribute substantial total particulate inputs to the soil, but it also removes bioavailable or injurious pollutants from foliar surfaces, while low-intensity events may enhance foliar uptake through the hydrating of some previously dry-deposited particles ([U.S. EPA, 2004](#)).

Chemistry within the canopy can also be important. Very fast measurements of  $NO_2$  flux are confounded by the rapid interconversion of NO and  $NO_2$  with  $O_3$ , and the biosphere also interacts with  $NO_x$  through hydrocarbon emissions and their subsequent reactions to form multifunctional  $RONO_2$ , including isoprene nitrates, which can account for a substantial fraction of total N deposition.  $NO_2$  emissions also show UV dependence, and both photo-induced and dark production of  $HNO_2$  from  $NO_2$  have been observed on leaf surfaces, especially wet surfaces, although there is no consensus concerning chemical mechanisms ([U.S. EPA, 2008a](#)). It was recently reported that  $NO_2$  deposition velocities would have been overestimated by up to 80% if  $NO_2$  photolysis had not been considered

([Breuninger et al., 2012](#)). Both biotic interactions and reaction chemistry further complicate our understanding of N deposition and our ability to estimate deposition velocity.

Some species, most prominently  $\text{HNO}_3$ , can be characterized by unidirectional exchange, whereas bidirectional exchange is more appropriate for most other species. Bidirectional exchange is often described in terms of a compensation point, defined as the ambient concentration above which a net uptake of the trace gas occurs and below which the trace gas is released ([Ganzeveld et al., 2002](#)). A two-pathway process description can be used to describe bidirectional exchange in a forest canopy [e.g., [Fowler et al. \(2009\)](#); [Loubet et al. \(2001\)](#)]: (1) a stomatal pathway, which is bidirectional and modeled using a stomatal compensation point and (2) a plant surface pathway, which denotes exchange with water or waxes on the plant surface.

Understanding the exchange of reactive nitrogen species in the forest canopy has always been challenging. One of the most comprehensive studies focusing on this question has been the Biosphere Effects on AeRosols and Photochemistry Experiment (BEARPEX) conducted in 2009 ([Min et al., 2014](#)) that examined fluxes and transformations of  $\text{NO}_x$  within a forest canopy on the western slope of the Sierra Madre Range in 2009. The study's results, shown schematically in [Figure 2-10](#), indicate the existence of active chemical interactions within the forest canopy in which  $\text{NO}$  emitted from soil or transported from elsewhere is oxidized to  $\text{NO}_2$  and then to peroxy and alkyl nitrates and  $\text{HNO}_3$ . These pathways represent alternative mechanisms to plant uptake that have the net effect of reducing the soil  $\text{NO}$  that escapes the forest canopy as  $\text{NO}_x$  is converted to peroxy nitrates and alkyl nitrates that can be transported to the atmosphere above the canopy on very short time scales ( $\sim 100$ s of seconds). The fraction of  $\text{NO}$  emitted by soil that can be lost to the atmosphere above the canopy depends on the relative time scales for transport through the canopy versus chemical transformation and foliar uptake. Likewise,  $\text{NO}$  or  $\text{NO}_2$  transported from elsewhere can also be oxidized to organic nitrates within the canopy. The organic nitrates formed can either be taken up within the canopy or transported upward through the forest canopy to act as reservoirs of  $\text{NO}_x$  that can reform downwind.

HNO<sub>3</sub> = nitric acid; hv = solar photon; OH = hydroxyl radical; NO = nitric oxide; NO<sub>2</sub> = nitrogen dioxide; NO<sub>x</sub> = sum of NO and NO<sub>2</sub>; O<sub>3</sub> = ozone; RO = alkoxy radicals; RO<sub>2</sub> = organic peroxy radicals; RONO<sub>2</sub> = alkyl nitrates; RO<sub>2</sub>NO<sub>2</sub> = peroxy nitrates.

Bold arrows in blue (downward) and red (upward) represent the direction of the flux of each species across the canopy surface. Red thin arrows within canopy indicate the nitrogen oxides removal processes within the canopy in addition to plant uptake.

Source: [Min et al. \(2014\)](#).

**Figure 2-10 Schematic of the interactions involved in the exchange of nitrogen oxides between the atmosphere and the forest canopy as identified by [Min et al. \(2014\)](#).**

The organic nitrates consist in large measure of isoprene- and monoterpene-derived nitrates. [Nguyen et al. \(2015\)](#) measured fluxes of organic nitrates on a tall tower in the Talladega National Forest (AL) in June 2013 as part of the Southern Oxidant and Aerosol Study (SOAS). They found that fluxes of organic nitrogen formed by reactions of nitrogen oxides (NO, NO<sub>2</sub>, NO<sub>3</sub>) with isoprene and monoterpene oxidation products constituted ~15% of the flux of oxidized N to the forest canopy, with most of the rest from HNO<sub>3</sub>.

### 2.5.2.3 Bidirectional Exchange of NH<sub>3</sub>

NH<sub>3</sub> can also be both emitted and deposited from plants and soils in a bidirectional exchange. [Farquhar et al. \(1980\)](#) observed the existence of a compensation point for ammonia due to gas exchange through the stomata of leaves. NH<sub>3</sub> in the stomata results from dissociation equilibria of NH<sub>4</sub><sup>+</sup> produced physiologically in the leaves, followed by equilibrium partitioning into air in the stomata ([Sutton et al., 1998](#)). Further research indicated that NH<sub>3</sub> deposition rates to leaf surfaces were often faster than stomatal uptake ([Sutton et al., 1993](#)) and that NH<sub>3</sub> can both react to form particulate NH<sub>4</sub><sup>+</sup> and evaporate from deposited PM within the canopy ([Nemitz et al., 2004](#); [Brost et al., 1988](#)). Moisture and plant type are strong influences, because deposition is more efficient on wet surfaces ([Sutton et al., 1995](#)), evaporation occurs under drying conditions ([Fowler et al., 2009](#)),

and plant emissions are controlled by the physiological importance of  $\text{NH}_4^+$  in intercellular fluids of plants ([Sutton et al., 1998](#)). Copollutants also play a role because  $\text{NH}_3$  deposition is enhanced by the presence of atmospheric acids like  $\text{SO}_2$  ([Sutton et al., 1995](#); [McLeod et al., 1990](#)).

The complex pattern of  $\text{NH}_3$  sources and sinks with strong horizontal gradients of  $\text{NH}_3$  concentration ([Fowler et al., 2009](#)) presents problems for simple bidirectional exchange models ([Sutton et al., 1998](#)). These problems have been addressed through the concept of a canopy compensation point to include exchange with leaf surfaces ([Flechard et al., 1999](#); [Sutton et al., 1998](#)), as well as decomposing leaf litter and soil surfaces ([Nemitz, 2000](#)) in addition to stomatal exchange to describe bidirectional exchange ([Burkhardt et al., 2008](#); [Sutton et al., 1998](#)). Emission flux is particularly high from recently fertilized soils ([Fowler et al., 2009](#); [Sutton et al., 1998](#)) and after leaf-cutting events ([Nemitz et al., 2009](#)).

According to the 2008 ISA ([U.S. EPA, 2008a](#)), large areas of the U.S. are very near the  $\text{NH}_3$  compensation point for most of the year, resulting in a highly dynamic air-surface flux, which is prone to shifts in magnitude and direction. Bidirectional  $\text{NH}_3$  fluxes with some periods of deposition and some periods of emission are typical for fertilized and grazed agricultural ecosystems, while forests and other unfertilized ecosystems are usually sinks for  $\text{NH}_3$  ([Fowler et al., 2009](#)). Smaller emissions can also occur in semi natural ecosystems ([Fowler et al., 2009](#)).

Recently, regional scale modeling studies began to include canopy compensation points and parameterize bidirectional exchange ([Kruit et al., 2012](#); [Dennis et al., 2010](#); [Kruit et al., 2010](#)), and a bidirectional exchange model for  $\text{NH}_3$  based on observations from North Carolina field sites ([Walker et al., 2013](#)) was developed for the CMAQ modeling system and an agroecosystem model was included in CMAQ Version 5.0 to estimate  $\text{NH}_3$  emissions, transport, and deposition from agricultural practices ([Bash et al., 2013](#)). Including bidirectional exchange in deposition modeling substantially improves agreement between modeling results and ambient observations. A large bias of  $-19\%$  has been observed in annual wet deposition of  $\text{NH}_4^+$  when modeling results were compared with ambient measurements without bidirectional exchange included in the model ([Appel et al., 2011](#)).  $\text{NH}_4^+$  was underestimated throughout the year, but the largest underestimations were for winter and spring in the Eastern U.S. ([Appel et al., 2011](#)). The  $\text{NH}_4^+$  wet deposition bias was reduced by a factor 3, from  $-19$  to  $-6\%$ , by including bidirectional exchange in CMAQ ([Appel et al., 2011](#)).

Poor temporal and spatial representation of  $\text{NH}_3$  emissions in areas with fertilizer application was also identified as a source of bias ([Appel et al., 2011](#)). When CMAQ was coupled with the U.S. Department of Agriculture's (USDA) Environmental Policy

Integrated Climate (EPIC) agroecosystem model to improve characterization of fertilizer emissions in annual simulations, NH<sub>3</sub> dry deposition decreased by 45%, total NH<sub>x</sub> deposition decreased by 15%, and total N deposition decreased by 5% compared to modeling without bidirectional exchange ([Bash et al., 2013](#)). In sensitivity tests of key parameters in dry deposition modeling, the largest uncertainty was observed for the change of unidirectional to bidirectional flux, but uncertainties of 5% or less in total nitrogen deposition were reported ([Dennis et al., 2013](#)). Although this is a small difference nationwide, changes can locally be up to 50%, and only 66% of the 12 × 12 grid cells modeled showed changes of less than 10% ([Dennis et al., 2013](#)).

Recent modeling studies have also improved insight into local areas and conditions under which bidirectional flux most strongly affects deposition estimates. For example, accounting for bidirectional flux resulted in a 17% increase in NH<sub>3</sub> emissions from agricultural operations ([Massad et al., 2010](#)) compared with a 5% increase in domain-wide NH<sub>3</sub> emissions ([Dennis et al., 2013](#)). Increases in NH<sub>3</sub> emissions from including bidirectional flux in semi natural ecosystems mostly occurred in areas of the western U.S. with low emissions, where emissions were not included in existing inventories. Seminal ecosystems in the eastern U.S. isolated from agricultural emissions exhibited changes of less than 1%. Seasonal differences were also observed, with greater NH<sub>3</sub> emissions observed in summer and winter, but emissions up to 45% lower in fall and in spring when bidirectional exchange was included ([Bash et al., 2013](#)).

---

#### 2.5.2.4 Transference Ratios

Ratios of modeled or measured concentrations of SO<sub>x</sub> and NO<sub>y</sub> to their deposition, or transference ratios (TR<sub>SO<sub>x</sub></sub>, TR<sub>NO<sub>y</sub></sub>) were proposed by [Scheffe et al. \(2011\)](#) as a means to link ambient air quality to deposition, and can be extended to NH<sub>x</sub>. Transference ratios for NO<sub>y</sub>, SO<sub>x</sub>, and NH<sub>x</sub> are given by:

- $TR_{NO_y} = (\text{annual wet} + \text{dry deposition of } NO_y) / \text{annual average ambient concentration of } NO_y$
- $TR_{SO_x} = (\text{annual wet} + \text{dry deposition of } SO_x) / \text{annual average ambient concentration of } SO_x$
- $TR_{NH_x} = (\text{annual wet} + \text{dry deposition of } NH_x) / \text{annual average ambient concentration of } NH_x$

These ratios are expressed in units of distance/time (as a velocity). In the 2011 Policy Analysis for the NO<sub>x</sub>/SO<sub>x</sub> NAAQS review ([U.S. EPA, 2011a](#)), the transference ratios were multiplied by measured ambient concentrations of NO<sub>y</sub> and SO<sub>x</sub> to estimate a flux.

The transference ratio is an aggregate of multiple forms of nitrogen or sulfur. For example, the transference ratio for  $\text{NO}_Y$  includes  $\text{NO}_2$  and  $\text{HNO}_3$ , which have very different deposition rates, chemical reaction rates, and atmospheric lifetimes. Close to emission sources where fresh  $\text{NO}_X$  emissions have had little time to react, the ratio of  $\text{HNO}_3$  to  $\text{NO}_2$  is smaller than farther from emission sources. Accordingly, there is considerable spatial and temporal variability ([Sickles et al., 2013](#)) in transference ratios, in part governed by the relative abundance of compounds with short and relatively longer atmospheric lifetimes.

In practice, a regional modeling approach using a modeling system such as CMAQ or CAMx is used in the calculation of transference ratios by simulating the relevant transport processes discussed in [Appendix 2.5.1](#). [Sickles and Shadwick \(2013\)](#) estimated that  $\text{TR}_{\text{SO}_X}$  and  $\text{TR}_{\text{NO}_Y}$  could be given to within 25–35% of observed values using observations of atmospheric concentration and deposition at some monitoring sites in the eastern U.S. The study noted that accounting for year-to-year variability in precipitation could lower the uncertainty. The transport processes described in [Appendix 2.5.1](#) imply that wet deposition should not necessarily be well correlated with surface concentrations due to differences in the direction or spatial extent of transport in the boundary layer compared to cloud levels. Dry deposition fluxes are more directly related to surface concentrations. In a follow-on study, [Sickles et al. \(2013\)](#) calculated transference ratios using measurements from CASTNET and NADP monitoring networks with CMAQ model results and found the relative difference ranged from –37 to 64%. The authors caution that this range should not be considered a definitive assessment of uncertainty because relative differences do not reflect the extent to which the monitor is representative of the grid-cell average modeled by CMAQ.

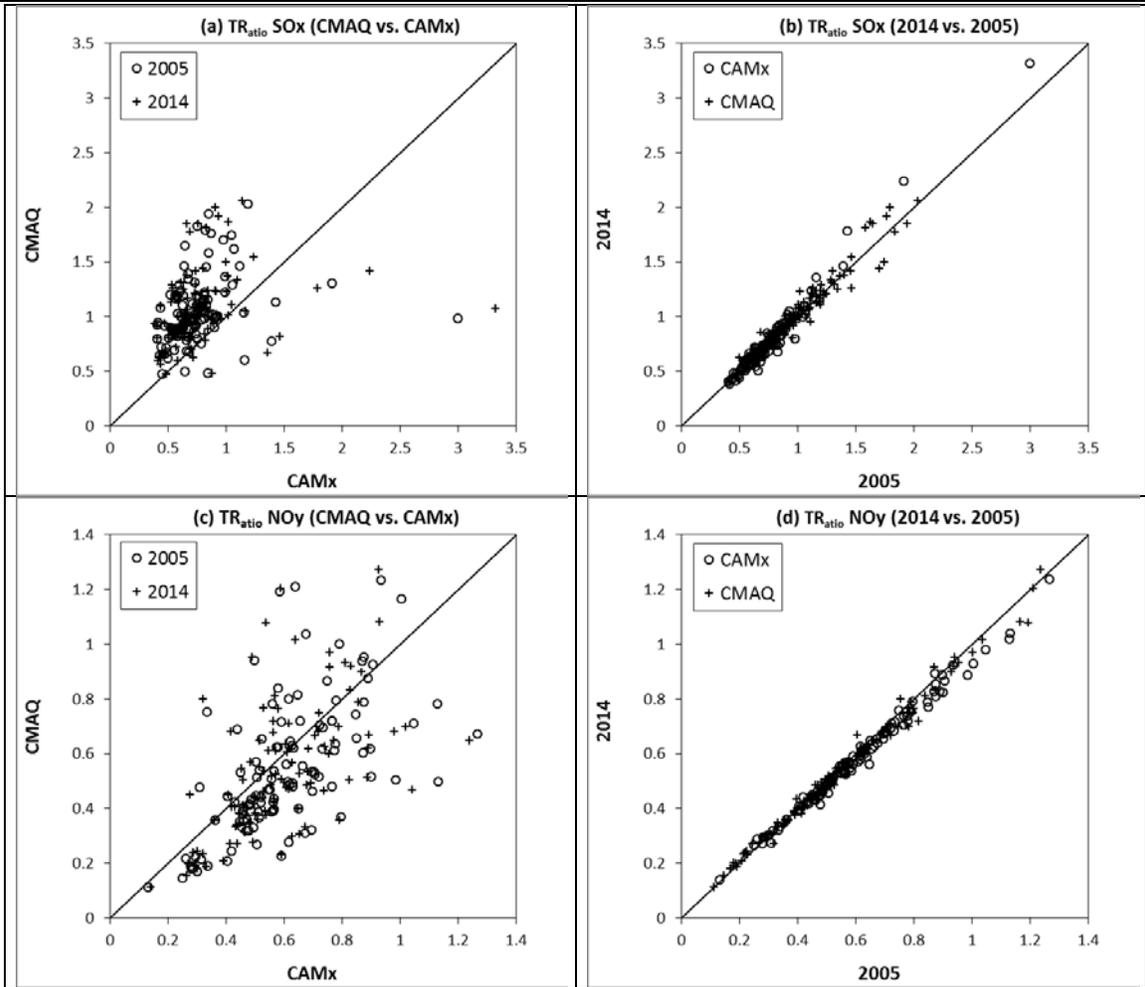

[Koo et al. \(2012\)](#) and [Koo et al. \(2015\)](#) raised the issue of model dependence on the calculation of depositing species and transference ratios. [Koo et al. \(2012\)](#) compared model results for concentrations of  $\text{SO}_2$ ,  $\text{SO}_4^{2-}$ ,  $\text{HNO}_3$ , and  $\text{NO}_3^-$  and corresponding dry deposition fluxes from CMAQ and CAMx to those measured at CASTNET sites. They also compared model results for wet deposition to NADP/NTN measurements. On an annualized basis, mean normalized errors (MNEs) in gas-phase concentrations ranged from ~25 to ~100%. MNEs in dry deposition were much larger and ranged from ~50 to >300% and MNE in wet deposition ranged from ~40 to ~100% with no clear preference for one model over another. MNE for  $\text{NH}_4^+$  in dry and wet deposition ranged from ~35 to 70%. [Koo et al. \(2012\)](#) also found evidence for spatial variability in  $\text{TR}_{\text{SO}_X}$  and  $\text{TR}_{\text{NO}_Y}$  across the U.S. and within selected ecosystems (roughly a few hundred km across).

[Koo et al. \(2015\)](#) compared simulations of transference ratios computed using CMAQ and CAMx for two model years, 2005 and 2014, (see [Figure 2-11](#)) and found that  $\text{TR}_{\text{SO}_X}$

was much higher in CMAQ than in CAMx; however, differences were much smaller for  $TR_{NO_Y}$ .  $R^2$  values for  $TR_{NO_Y}$  between the two models was 0.37 for 2005 and 0.33 for 2014. For  $TR_{SO_X}$ ,  $R^2$  was 0.073 for 2005 and 0.072 for 2014. Note that each point shown in [Figure 2-11](#) represents the average over  $365 \times 24$  model entries and are dissimilar to measurement artifacts. The outlying point (in the lower right) is from the Weminuche Wilderness IMPROVE site (WEMI) in the Rockies and likely is the result of the difficulty mesoscale models have in simulating precipitation and flow patterns in areas of high relief and indicates further work is needed in this regard. Note that the disagreement in  $TR_{SO_X}$  by CMAQ is mostly due to an error in CMAQ emissions of  $SO_2$  that has since been corrected. There is no consistent geographic pattern of agreement or disagreement between the two simulations.

A more complete understanding of the causes of differences between model simulations requires understanding the differences in how major chemical and physical processes have been parameterized, thus underscoring the importance of accurately representing emissions, transport, chemistry, and deposition. Both models used different modules to represent these processes. In addition, these results might imply that the metrics used need further scrutiny. Note again that the results shown in [Koo et al. \(2012\)](#) and [Koo et al. \(2015\)](#) were obtained using older versions of CMAQ and CAMx and that CTMs are continually undergoing improvement. In this regard, detailed comparisons with observations and intercomparisons between the most current versions of these models might help explain these findings.

[Koo et al. \(2015\)](#) also found very small differences between simulations for model years 2005 and 2014 from either CMAQ or CAMx for both  $NO_Y$  and  $SO_X$ , indicating the ratios are relatively invariant at least over an annual time scale. This result is not surprising, because with the long averaging time, concentrations and deposition rates can better track emissions changes.

CAMx = Comprehensive Air Quality Model with Extensions; CMAQ = Community Multiscale Air Quality;  $\text{NO}_y$  = oxides of nitrogen;  $\text{SO}_x$  = sulfur oxides;  $\text{TR}_{\text{ratio}}$  = transference ratio.

Source: Adapted from [Koo et al. \(2015\)](#).

**Figure 2-11 Scatterplots showing transference ratios for oxidized nitrogen and sulfur oxides comparing the Community Multiscale Air Quality model to the Comprehensive Air Quality Model with Extensions in (a) and (c) and comparing 2005 to 2014 in (b) and (d).**

To summarize, recent studies have found that using transference ratios for estimating the deposition flux from atmospheric measurements has lower uncertainty when applied at an annual timescale. The transference ratio can vary spatially, and an estimate of uncertainty and variability depends on the spatial scale of interest. Finally, previous studies have highlighted some of the uncertainties when using models to calculate the transference

ratio, but a comprehensive assessment of uncertainty is not available. When the transference ratio is calculated using observations of atmospheric concentrations from monitoring networks, the deposition flux for oxidized sulfur and oxidized nitrogen can be estimated to within 25 to 35%.

---

### 2.5.3 Model Evaluation and Uncertainty

CMAQ model estimates were recently compared to monitoring network observations and results were reported as normalized mean bias statistics ([U.S. EPA, 2011a](#), [2009c](#)). Total nitrate concentrations were overestimated by CMAQ, with predictions averaged over each of 4 years ranging from 22 to 26% higher than observed concentrations ([U.S. EPA, 2011a](#)). Model performance was described as good for total SO<sub>x</sub>, but the ability to partition SO<sub>x</sub> into sulfate and SO<sub>2</sub> was identified as an area that needed improvement ([U.S. EPA, 2011a](#)). SO<sub>2</sub> concentrations were overestimated, with CMAQ predictions ranging from 39 to 47% higher than observed concentrations. Sulfate concentrations were underestimated, with CMAQ predictions ranging from 9 to 17% lower than observed concentrations ([U.S. EPA, 2011a](#)). A disadvantage of this type of comparison is that modeled concentrations are outputted for a 12 × 12 km grid, while measured concentrations are from a single point within that grid.

Wet deposition estimates from CTMs were extensively evaluated using wet deposition data collected over the U.S. as part of the National Atmospheric Deposition Program's National Trends Network. [Simon et al. \(2012\)](#) summarized model evaluation studies published before 2010, and [Table 2-7](#) summarizes the studies since 2010.

While measurements comparing model outputs to observations provide one perspective on the uncertainty in the fate and transport of atmospheric N and S, another approach to quantifying uncertainty is to estimate the sensitivity of the model results with respect to the uncertain range of parameters relevant to deposition calculations. A study by [Dennis et al. \(2013\)](#) examined a range of uncertainties relevant to dry deposition using the CMAQ model. This study found little change (<5%) in total deposition, despite changes in dry deposition parameters because competing processes in the model tended to rebalance and compensate. Changes in a single grid cell were as large as 20%.

There are also structural uncertainties that are difficult to assess in applying CTM models to estimate deposition. The main structural uncertainties are associated with canopy effects of NO<sub>x</sub>, bidirectional exchange of NH<sub>3</sub>, and transference ratios that relate average concentration to deposition. These factors are discussed in [Appendix 2.5.2](#).

**Table 2-7 Reported comparisons of chemical transport models and observations of nitrogen and sulfur wet deposition**

## 2.6 Geographic Distribution of Concentration and Deposition

Maps of national distributions of emissions, atmospheric concentrations, and deposition fluxes of relevant species are presented in this section. The first two sections are limited to deposition maps and are intended to provide a broad overview of the extent and recent trends for acid deposition ([Appendix 2.6.1](#)) and total nitrogen deposition, including relative contributions of reduced and oxidized nitrogen ([Appendix 2.6.2](#)). The subsequent three sections contain data on geographic distributions of emissions, ambient

concentrations and deposition of oxidized nitrogen ([Appendix 2.6.3](#)), reduced nitrogen ([Appendix 2.6.4](#)), and sulfur oxides ([Appendix 2.6.5](#)), including key species in each of these classes.

Emission maps in [Appendix 2.6.3](#), [Appendix 2.6.4](#), and [Appendix 2.6.5](#) are from U.S. EPA's National Emissions Inventory described in [Appendix 2.2](#). Ambient concentration maps in these sections are from a variety of sources, depending on the availability of data. Deposition maps in [Appendix 2.6.1](#), [Appendix 2.6.2](#), [Appendix 2.6.3](#), [Appendix 2.6.4](#), and [Appendix 2.6.5](#) are based on the approach of [Schwede and Lear \(2014a\)](#) which combines measured and modeled values to produce spatially aggregated maps of wet, dry, and total (wet plus dry) deposition of nitrogen and sulfur species across the U.S. Wet deposition is based on concentrations measured in rainwater collected at NADP/NTN monitoring sites combined with precipitation estimates interpolated by PRISM (Parameter-elevation Regression Slopes Model) using inverse distance weighting (IDW). In their approach to dry deposition, [Schwede and Lear \(2014a\)](#) measured values of species concentrations in air at monitoring site locations and used bias-corrected modeling results from CMAQ (currently at 12-km horizontal resolution) to fill in gaps between sites and provide composition and deposition information for species not measured (PANs, NO<sub>2</sub>, and HONO) in the routine monitoring networks. Distributions of species that undergo dry deposition are derived mainly by fusion of data from the Clean Air Status and Trends Network (CASTNET), the National Atmospheric Deposition Program (NADP), Ammonia Monitoring Network (AMoN), and the Southeastern Aerosol Research and Characterization (SEARCH) network. Parameterizations in CMAQ are used to calculate deposition velocities for gases and particles ([Pleim and Ran, 2011](#)). Note that CMAQ includes bidirectional exchange for NH<sub>3</sub> ([Bash et al., 2012](#)), but not for other species such as NO<sub>2</sub>. Dry deposition fluxes are then combined with wet fluxes to estimate total deposition. Details on interpolation, special treatment for particulate species calculations, and procedures to correct for bias are described in detail by [Schwede and Lear \(2014a\)](#).

Efforts have also been made to achieve greater consistency by relying more heavily on WRF/CMAQ simulations for estimating wet deposition. Effects of biases in CMAQ wet deposition are corrected by adjusting the modeled wet deposition by the ratio of observed precipitation interpolated by PRISM to WRF precipitation. In this approach, it is assumed that the ratio of observed to modeled precipitation is well correlated with the ratio of observed to modeled wet deposition, but not (necessarily) that wet deposition scales linearly with precipitation ([Appel et al., 2011](#)). Likewise, estimates of dry deposition could be obtained using CMAQ evaluated by comparison with monitoring results.

This approach resulted from efforts to improve estimates of atmospheric deposition by advancing the science of measuring and modeling atmospheric wet, dry, and total deposition of atmospheric species. Recognizing that the thin geographic coverage and the lack of species measurements described in [Appendix 2.4.6](#) are not ideal for estimating dry deposition on a national scale, the NADP established the Total Deposition Science Committee (TDEP) with this mission in 2011, with an initial goal of providing estimates of total S and N deposition across the U.S. for use in estimating critical loads and other assessments, where loading results in the acidification and eutrophication of ecosystems ([NADP, 2016](#)). Following this hybrid approach to mapping total deposition that combines measured and modeled values, measured values are given more weight at the monitoring locations, and modeled data are used to fill in spatial gaps and provide information on chemical species that are not measured by routine monitoring networks. This effort provides continuous spatial and temporal coverage of total deposition estimates in the U.S., something previously unavailable ([NADP, 2016](#)).

Limitations to the TDEP approach are: (1) interpolation leads to a minimization of extreme values and a lower than actual variability, (2) data are limited to sites that meet network completion criteria, (3) discontinuities in trends can occur for intermittent monitoring data, (4) characterization of wet and dry organic nitrogen components is uncertain and likely incomplete, (5) deposition in urban areas is not well represented because the monitoring sites used are primarily in rural areas, and (6) occult deposition is not well understood and might not be characterized accurately. An additional potential drawback is that a mass balance is not maintained, although the mass balance error was small in a similar effort combining measured wet deposition and bias corrected modeled deposition ([Schwede and Lear, 2014a](#)).

Differences in wet deposition of  $\text{NH}_4^+$ ,  $\text{NO}_3^-$ , and  $\text{SO}_4^{2-}$  and N + S expressed as  $\text{H}^+$  equivalents between the two, 3-year periods 1989–1991 and 2012–2014 across the U.S. are shown in [Figure 2-13](#), [Figure 2-27](#), [Figure 2-34](#), and [Figure 2-43](#). These figures are based on data obtained by the NADP/NTN. The maps were constructed by summing gridded values and then taking the difference between the two, 3-year averages using data from the NADP website. These maps are meant to provide a general indication of large-scale features in the patterns and long-term changes in deposition, with potential for error from extensive interpolation between monitoring sites, which are often distant from each other. The TDEP values shown on the maps are derived from NADP/NTN wet deposition measurements at 4-km resolution coupled with CMAQ results for dry deposition at 12 km. [Weathers et al. \(2006\)](#) found evidence for substantial spatial variability in deposition with altitude, generally at smaller scales than used for TDEP. In particular, they found evidence for factors of 4–6 variability in N and S deposition throughout Acadia National Park (121 km<sup>2</sup>) and Great Smoky Mountains National Park

(2,074 km<sup>2</sup>); deposition rates averaged over the two parks were ~70% higher than inferred using only in situ point measurements. As might be expected, deposition increased with elevation because of the increased importance of cloud deposition and dry deposition (due to higher winds and hence increased turbulence). As noted by the NADP, uncertainty within maps of wet deposition varies geographically and has not been quantified.

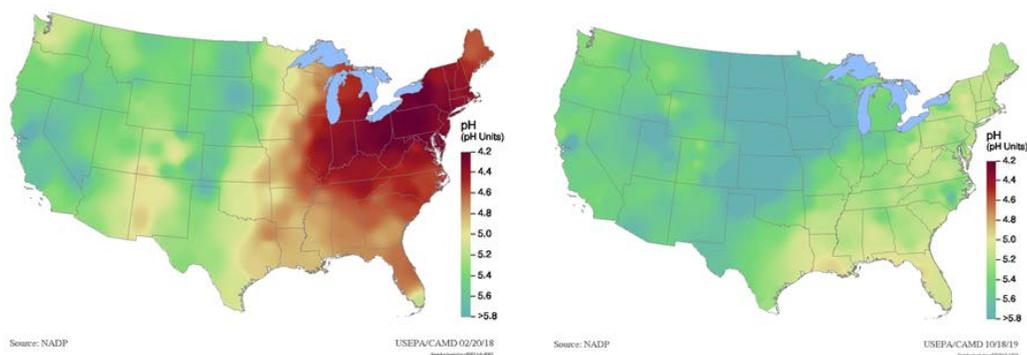

[Appendix 2.6.6](#) and [Appendix 2.6.7](#) summarize concentration and deposition data from other approaches. [Appendix 2.6.6](#) describes distributions of dry deposition of NO<sub>2</sub> and SO<sub>2</sub> from satellite-based measurements of tropospheric vertical column abundance and model input derived by [Nowlan et al. \(2014\)](#). [Appendix 2.6.7](#) describes recent estimates of background concentrations, deposition fluxes, and sources and methods used to obtain them.

Additional maps on the portion of the NADP website dedicated to the Total Deposition (TDEP) program (<http://nadp.slh.wisc.edu/committees/tdep/tdepmaps/>) are shown in [Appendix 2.7](#). They present a comprehensive overview of changes in various parameters related to deposition from 2000–2018. Each map shows two 3-year periods, 2000–2002 and 2016–2018. Although uncertainty has not been fully characterized using the TDEP approach, they are instructive because they give an indication of how various estimates carried out with the same approach have changed over the past decade.

---

## 2.6.1 pH and H<sup>+</sup> Equivalents

Long-term trends in rainwater pH over the CONUS between the two periods 1989 to 1991 and 2016 to 2018 are shown in [Figure 2-12](#). Substantial improvement in the quality of rainwater in terms of pH has occurred from the earlier to the later period. [Figure 2-12](#) is a remarkable demonstration of the effectiveness of the Clean Air Act Amendments, showing that the steep reductions of NO<sub>x</sub> and SO<sub>2</sub> emissions described in [Appendix 2.2](#) coincide with a sharp decline in pH.

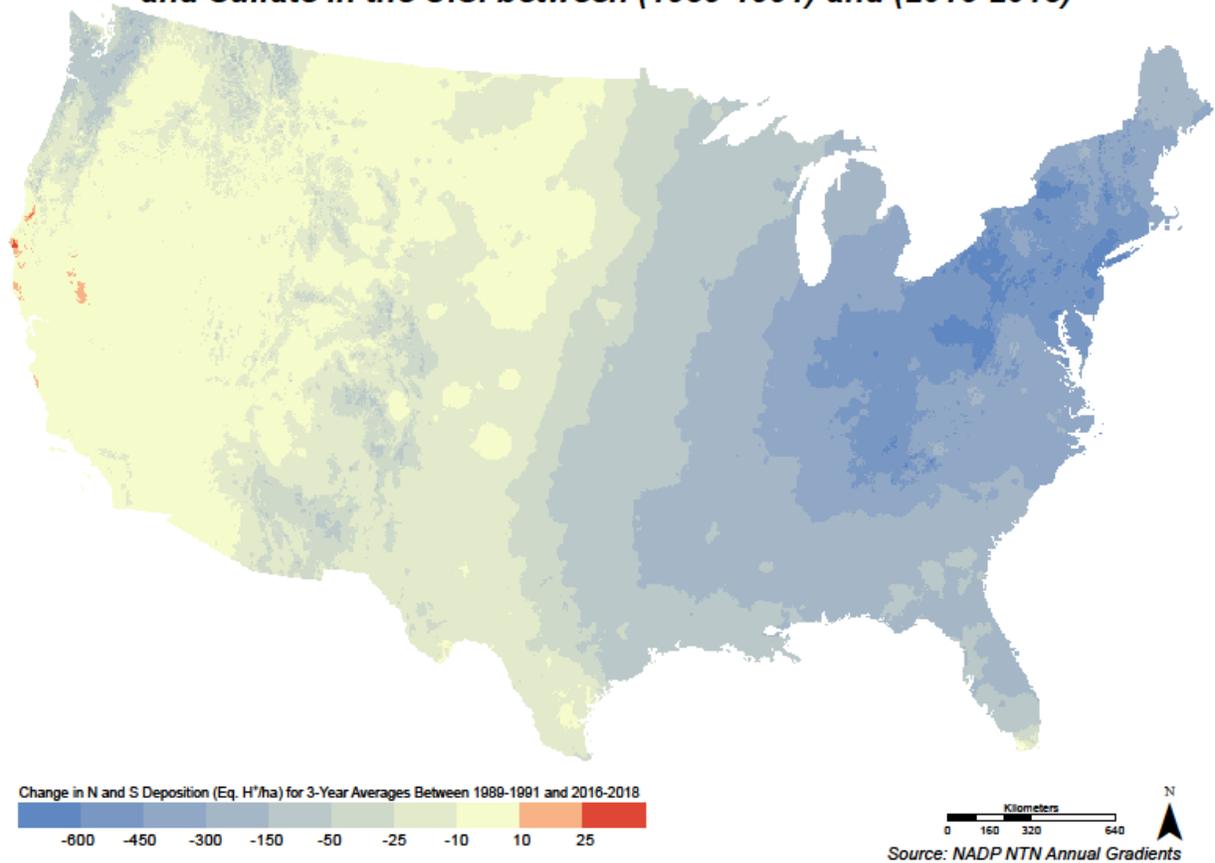

Source: NADP/U.S. EPA/CAMD. We acknowledge the Total Deposition (TDep) Science Committee of the National Atmospheric Deposition Program (NADP) for their role in making the TDep data and maps available.

**Figure 2-12 (Left) pH of rainwater, 1989–1991; (Right) pH of rainwater, 2016–2018.**

However, there are areas, especially in the eastern U.S. near the upper Ohio River Valley, where the pH of rainwater is still much lower than the reference pH of  $\sim 5.65$  (for equilibrium with  $\text{CO}_2$ ) that has often been used as a benchmark when characterizing the excess acidity of rainwater. (Note that the reference  $\text{CO}_2$  concentration used to determine this value is 316 ppm, atmospheric  $\text{CO}_2$  concentrations are now over 400 ppm, resulting in a lowering of pH by  $\sim 0.05$  units.) As noted by [Galloway et al. \(1976\)](#), the major contributors to free acidity in rainwater for  $\text{pH} < 5.6$  are the strong mineral acids  $\text{HNO}_3$  and  $\text{H}_2\text{SO}_4$ . However, weak acids (e.g., organic acids) can contribute substantively to free acidity at pH levels seen throughout much of the U.S. (see [Appendix 2.3.5](#)). For example, concentrations of formic acid and acetic acid ( $\text{pK}_a = 3.75, 4.76$ ) measured in rainwater at  $\text{pH} \sim 5$  by [Avery et al. \(2006\)](#) are on the order of  $10 \mu\text{M}$ , which is comparable to concentrations of  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$  measured in rainwater. Additionally, in areas like the Northwest where the pH of stream water can be around or even larger than 5.6, acidification of streams by  $\text{CO}_2$  might also need to be considered ([Ou et al., 2015](#)).

The change in acid loading ( $\text{H}^+$  equivalents) due to wet deposition of  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ , and  $\text{SO}_4^{2-}$  ions in precipitation expressed as  $\text{H}^+$  equivalents between the two, 3-year periods 1989–1991 and 2016–2018 across the U.S. based on data obtained by the NADP/NTN is shown in [Figure 2-13](#). Substantial decreases in acid loading are seen in the eastern U.S., with most of the central and western U.S. showing smaller negative changes or essentially no change.

**Change in Nitrogen and Sulfur Wet Deposition from Nitrate, Ammonium, and Sulfate in the U.S. between (1989-1991) and (2016-2018)**

eq = H<sup>+</sup> equivalent; H<sup>+</sup> = hydrogen ion.

Source: CPHEA analysis of CASTNET/CMAQ/NTN/AMON/SEARCH data.

**Figure 2-13** Difference in wet deposition of nitrate, ammonium, and sulfate expressed as hydrogen ion equivalents (eq/ha/yr) over the contiguous U.S. between 1989 to 1991 and 2016 to 2018.

This map was constructed by summing gridded values and then taking the difference between the two, 3-year averages using data from the NADP website. Although instructive, these results should be viewed with some caution, as errors are incurred because development of a map spanning the CONUS requires extensive interpolation between monitoring sites, which are often distant from each other. As noted by the NADP, uncertainty within maps of wet deposition varies geographically and has not been quantified. Therefore, these maps are meant to provide a general indication of large-scale features in the patterns and long-term changes in deposition.

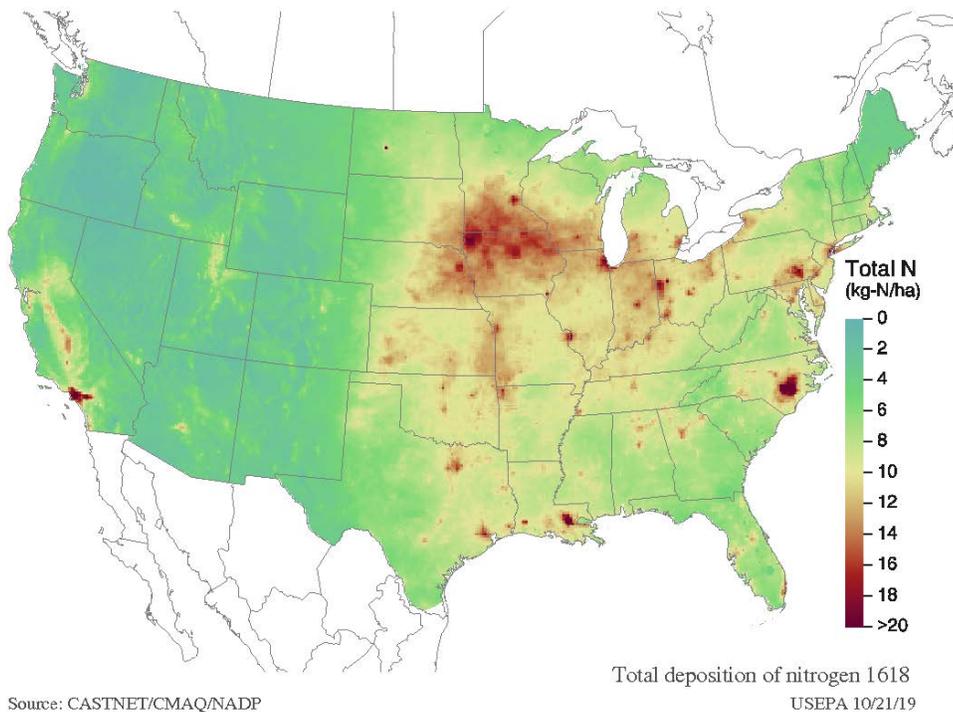

---

## 2.6.2 Total Nitrogen

[Figure 2-14](#) shows total deposition of N averaged over 2016–2018. This is determined from the sum of dry and wet deposition for all  $\text{NO}_Y$  and  $\text{NH}_X$  species considered by CMAQ. Fluxes are based on the method developed by [Schwede and Lear \(2014a\)](#) as outlined above and are given in terms of kg N/ha/yr.

As can be seen from [Figure 2-14](#), the highest deposition of nitrogen occurs in a broad swath across the Midwest, and in more localized patches across the U.S. Total N deposition can be put in context by comparing the deposition amounts in [Figure 2-14](#) to estimates of critical load, which is the N deposition amount below which no significant harmful effects on sensitive elements of the environment occur. These are typically below 10 kg N/ha/yr and can be as low as 2–3 kg N/ha/yr in both eastern and western locations ([Lee et al., 2016](#); [Ellis et al., 2013](#)), amounts which are firmly below the estimated deposition amounts in [Figure 2-14](#) over wide areas of the U.S. [Ellis et al. \(2013\)](#) observed that critical loads were exceeded in 24 of 45 parks, and [Lee et al. \(2016\)](#) observed that critical loads were exceeded at more locations in the western U.S., but by larger amounts in the eastern U.S.

Inspection of [Figure 2-15a](#) and [Figure 2-15b](#) shows that many of these areas are dominated either by deposition of  $\text{NH}_X$  emitted mainly by agriculture (e.g., California's Central Valley, Upper Midwest), or  $\text{NO}_Y$  resulting from oxidation of nitrogen oxides emitted mainly by combustion sources (e.g., the Northeast, Southwest). As might be expected when considering all forms of  $\text{NO}_Y$ , total deposition tends to be much higher near urban and suburban areas. Note also that deposition of  $\text{N}_r$ , based on the hybrid measurements/modeling approach, is dominated by reduced forms across the CONUS as a whole. This is consistent with Cross-Track Infrared Sounder Satellite measurements ([Appendix 2.4.2.2](#)) combined with dry deposition modeling to show that  $\text{NH}_3$  deposition fluxes were greater than  $\text{NO}_Y$  in most regions of North America ([Kharol et al., 2018](#)). [Figure 2-16](#) illustrates how this has changed over time by comparing trends in oxidized and reduced nitrogen deposition and changes in contributions of major species and type of deposition from 2000–2017 ([NADP, 2019](#)).

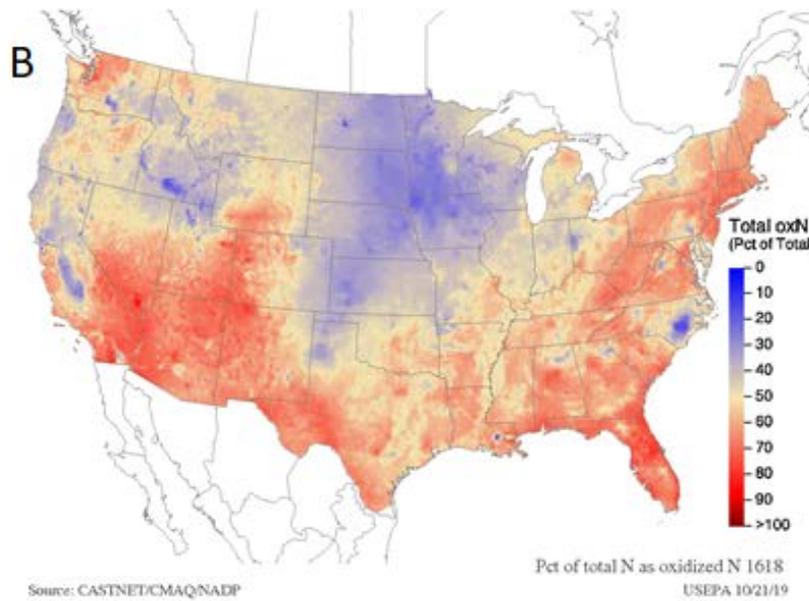

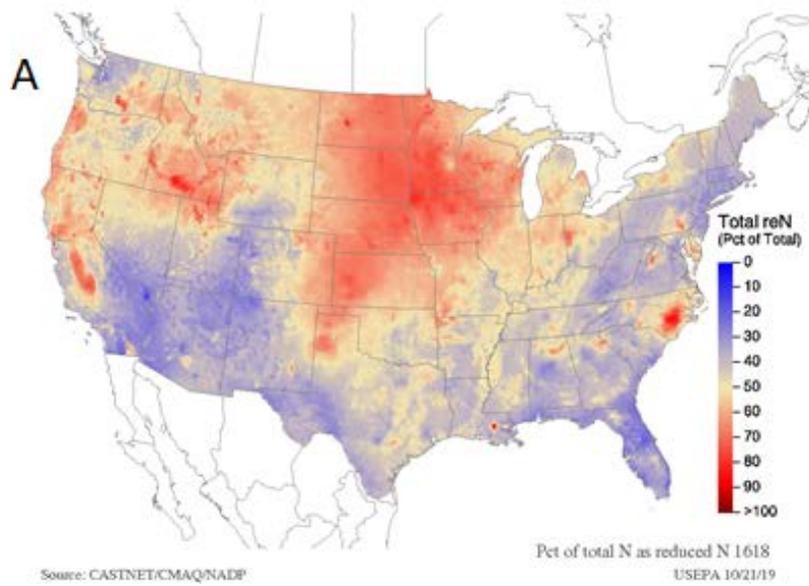

N = nitrogen; Nr = reactive nitrogen.

Source: CASTNET/CMAQ/NTN/AMON/SEARCH. We acknowledge the Total Deposition (TDep) Science Committee of the National Atmospheric Deposition Program (NADP) for their role in making the TDep data and maps available.

**Figure 2-14 Total (wet + dry) deposition of nitrogen (kg N/ha/yr) over the contiguous U.S. 2016–2018.**

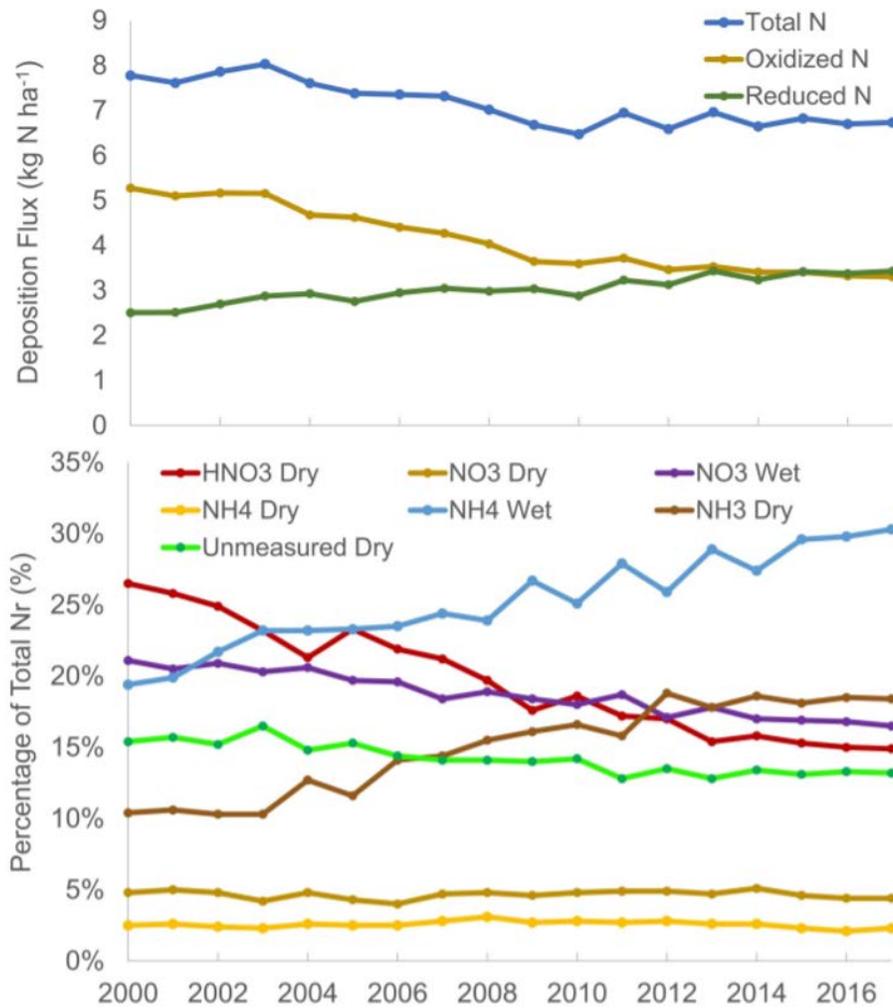

Dry deposition of gas-phase N (as  $\text{HNO}_3$  and  $\text{NH}_3$ ) exceeds dry deposition of particulate forms ( $\text{pNO}_3^-$ ,  $\text{NH}_4^+$ ) over most of the CONUS according to the hybrid method. Overall, deposition of N is mainly as reduced forms, with a maximum over the north-central U.S. The Central Valley of California, northern Utah, and eastern North Carolina are among other areas of high deposition of reduced N. In general, dry deposition of N, in either oxidized or reduced form, exceeds wet deposition across the CONUS. However, as discussed in earlier sections, uncertainties for dry deposition are likely much larger than for wet deposition.

Also as mentioned earlier, several species potentially important for deposition are not measured in CASTNET. [Figure 2-17](#) shows dry deposition for oxidized nitrogen species (e.g., PAN, other organic nitrates, HONO) calculated by CMAQ.

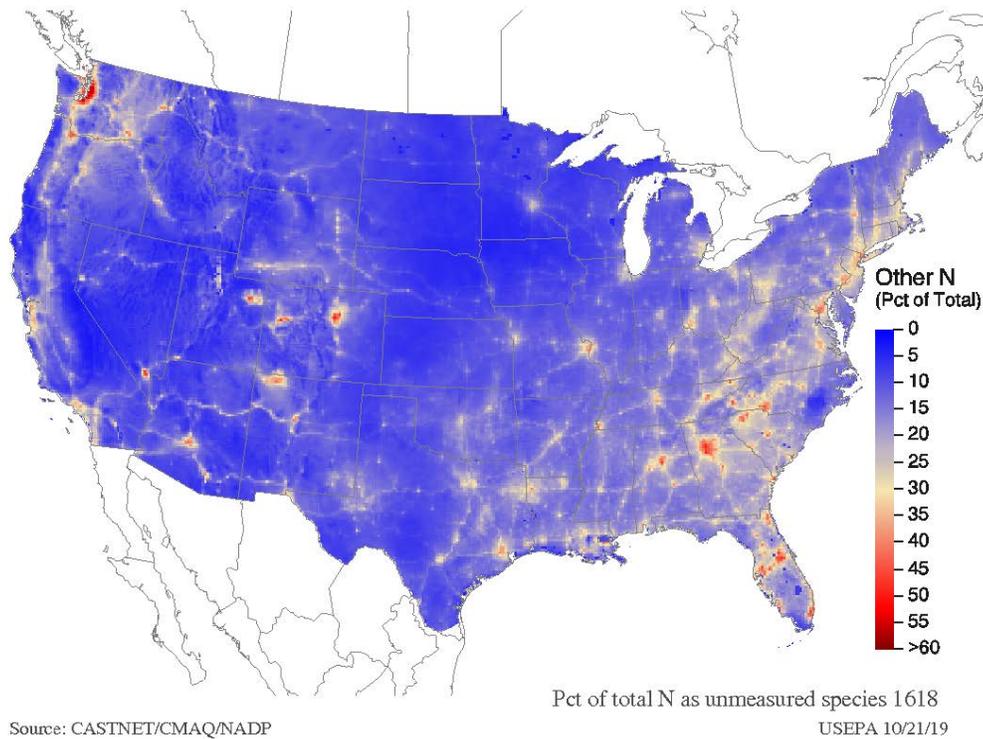

Note: We acknowledge the Total Deposition (TDep) Science Committee of the National Atmospheric Deposition Program (NADP) for their role in making the TDep data and maps available.

**Figure 2-15 (A) Percentage of total nitrogen deposition as reduced inorganic nitrogen over the contiguous U.S. 2016–2018. (B) Percentage of total nitrogen deposition as oxidized nitrogen over the contiguous U.S. 2016–2018.**

**Figure 2-17 Three-year average percentage of total nitrogen deposition by species (i.e., those species that are not measured in the networks) simulated by the Community Multiscale Air Quality modeling system for 2016–2018.**

As seen in [Figure 2-17](#), deposition of these species can contribute substantially to N deposition, especially near strong sources, in particular large urban areas. [Turnipseed et al. \(2006\)](#) also indicated that not accounting for these species can result in significant underestimates of N deposition.

[Figure 2-18](#) illustrates the long-term trend in total wet deposition of N ( $\text{NH}_4^+ + \text{NO}_3^-$ ) by showing maps for two 3-year periods (2016–2018 and 1989–1991) binned in increments of 2 kg N/ha/yr for comparison to critical loads estimates. Although it is apparent that N wet deposition has decreased overall across the U.S., there are areas showing increases. Also shown are NTN sites active during either period.

**Sum  $\text{NO}_3^-$  and  $\text{NH}_4^+$  Wet Deposition by 3-Year Averages**

N = nitrogen;  $\text{NH}_4^+$  = ammonium;  $\text{NO}_3^-$  = nitrate; NTN = National Trends Network.  
Source: CPHEA analysis of CASTNET/CMAQ/NTN/AMON/SEARCH data.

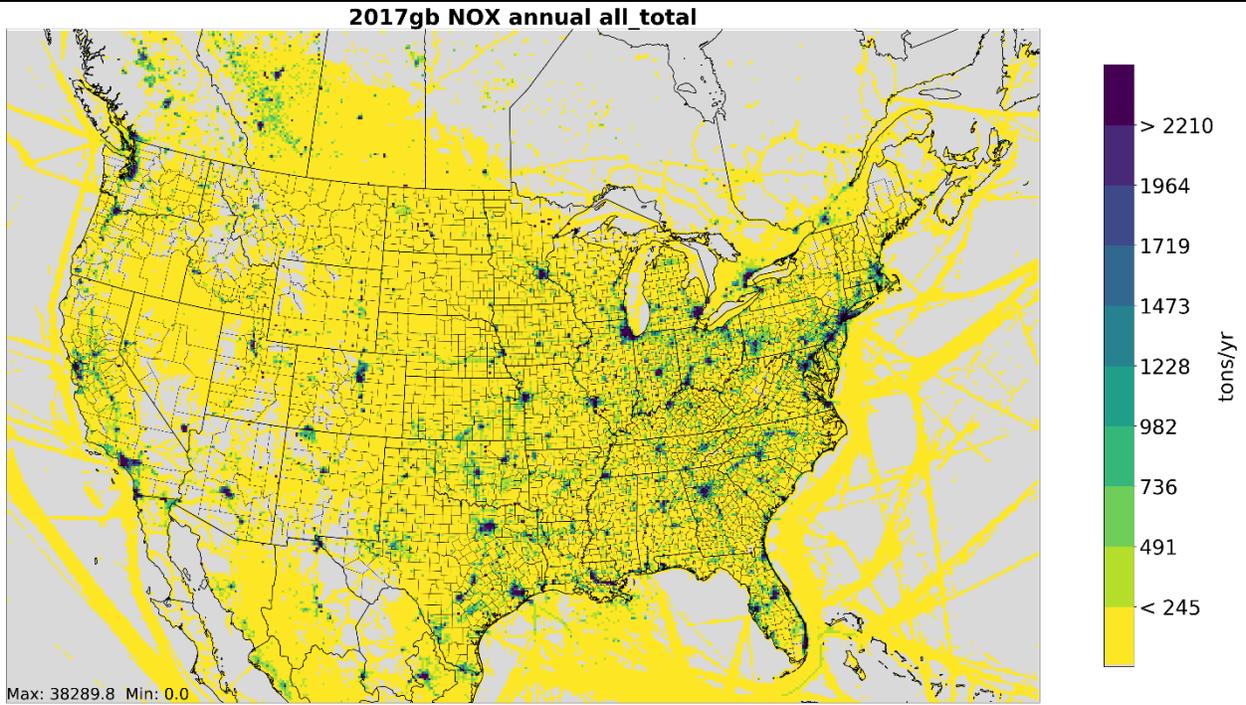

**Figure 2-18** Wet deposition of ammonium + nitrate (kg N/ha/yr) over the contiguous U.S. in two, 3-year periods, 2016 to 2018 and 1989 to 1991. Also shown are active National Trends Network sites in either period.

Studies at individual sites (e.g., on the coast of North Carolina) have shown that about 30% of wet deposition of N consisted of organic N, 20–30% of which was then available to primary producers on timescales of hours to days ([Peierls and Paerl, 1997](#)). In addition, [Benedict et al. \(2013\)](#) found that wet deposition of organic nitrogen contributed 18% of total quantified reactive nitrogen deposition and 25% of wet nitrogen deposition at Rocky Mountain National Park between November 2008 and November 2009. Trends in total (wet + dry) deposition of total ( $\text{NO}_Y + \text{NH}_X$ ) nitrogen between 2000 and 2018 are described with maps in [Appendix 2.7](#).

---

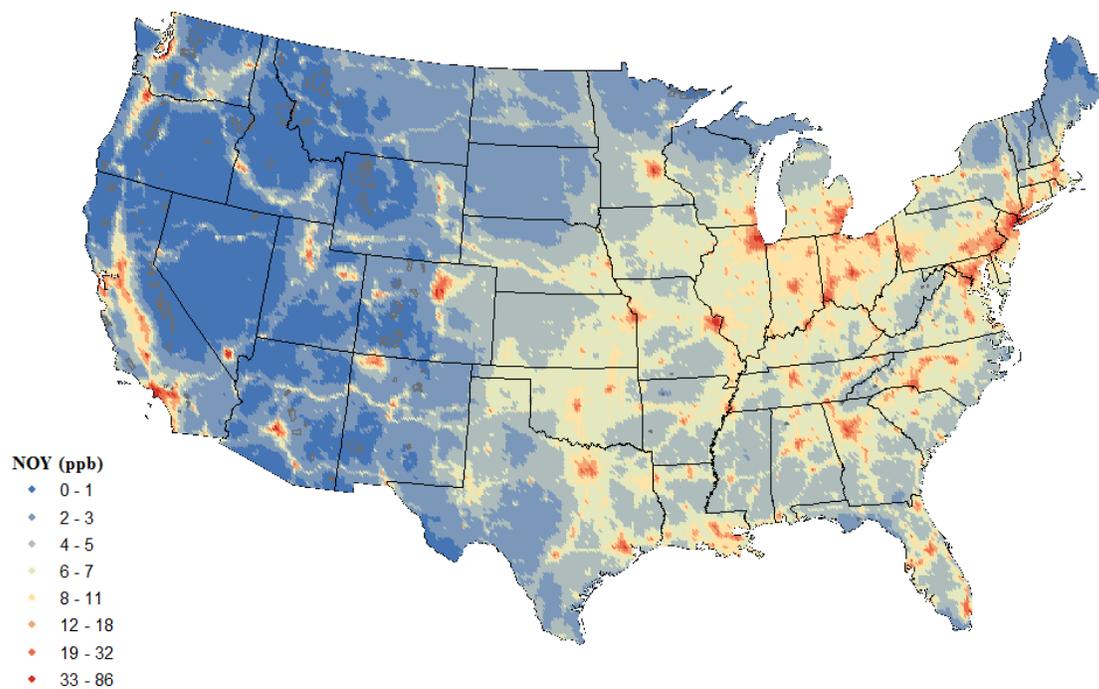

### 2.6.3 Oxidized Nitrogen

The geographic distribution of annual U.S.  $\text{NO}_X$  emissions for 2017 is shown in [Figure 2-19](#). Areas of higher emissions are apparent in urban areas and along the major travel routes between them, especially in the eastern U.S. and states along the west coast. The distribution of ambient  $\text{NO}_Y$  concentrations is shown in [Figure 2-20](#). However, because  $\text{NO}_Y$  is only measured at a small number of sites, this map is based solely on CMAQ model output. Although these model results for  $\text{NO}_Y$  are not as up to date as the network concentration measurement results or the modeled deposition of  $\text{NO}_Y$  component species that follow in this section, the same basic patterns observed for emissions also apply to ambient concentrations, with higher concentrations in the eastern U.S. than in the western U.S., as well as along the west coast, in urban areas and along major travel routes. The distribution of  $\text{NO}_2$  (shown in [Figure 2-21](#)) is derived from satellite data (OMI) and output from the GEOS-Chem model using the method outlined in [Appendix 2.6.3](#). Distributions of  $\text{HNO}_3$ ,  $\text{pNO}_3^-$ ,  $\text{pNH}_4^+$ ,  $\text{SO}_2$ , and  $\text{pSO}_4^{2-}$  are based on data from the CASTNET. Note, however, that because of artifacts relating to measurement of  $\text{HNO}_3$  and  $\text{pNO}_3^-$  ([Appendix 2.4.5](#)), the measurement of total nitrate ( $\text{TN} = \text{HNO}_3 + \text{pNO}_3^-$ ) is judged to be more reliable than measurements of its components.

## OMI-derived surface NO<sub>2</sub> (ppb)

DJF = December, January, February; JJA = June, July, August; NO<sub>2</sub> = nitrogen dioxide; OMI = Ozone Monitoring Instrument.

Note: Images shown were constructed by Dr. Lok Lamsal of Universities Space Research Association from data obtained by the OMI on the Aura satellite (<http://aura.gsfc.nasa.gov/scinst/omi.html>) using the algorithm described in [Bucseles et al. \(2013\)](#). Output from the GEOS-Chem, global-scale, three-dimensional, chemistry-transport model to derive surface concentration fields from the satellite data as described in [Lamsal et al. \(2008\)](#) and [Lamsal et al. \(2010\)](#).

Top panel (winter: December, January, February). Lower panel (summer: June, July, August).

**Figure 2-21** Seasonal average surface nitrogen dioxide mixing ratios in parts per billion for winter (upper panel) and summer (lower panel) derived by the Ozone Monitoring Instrument/GEOS-Chem model for 2009–2011. The Ozone Monitoring Instrument has an overpass at approximately 1:30 p.m. local standard time.

As seen in the figure, the highest values are found in and around urban areas. In general, much broader areas of high concentrations ( $>5$  ppb) are found in the eastern U.S., with many areas in the western U.S. subjected to concentrations  $<1$  ppb, which implies that concentrations of components that might pose a hazard are also lower than 1 ppb because  $\text{NO}_Y$  refers to the sum of oxidized N species.

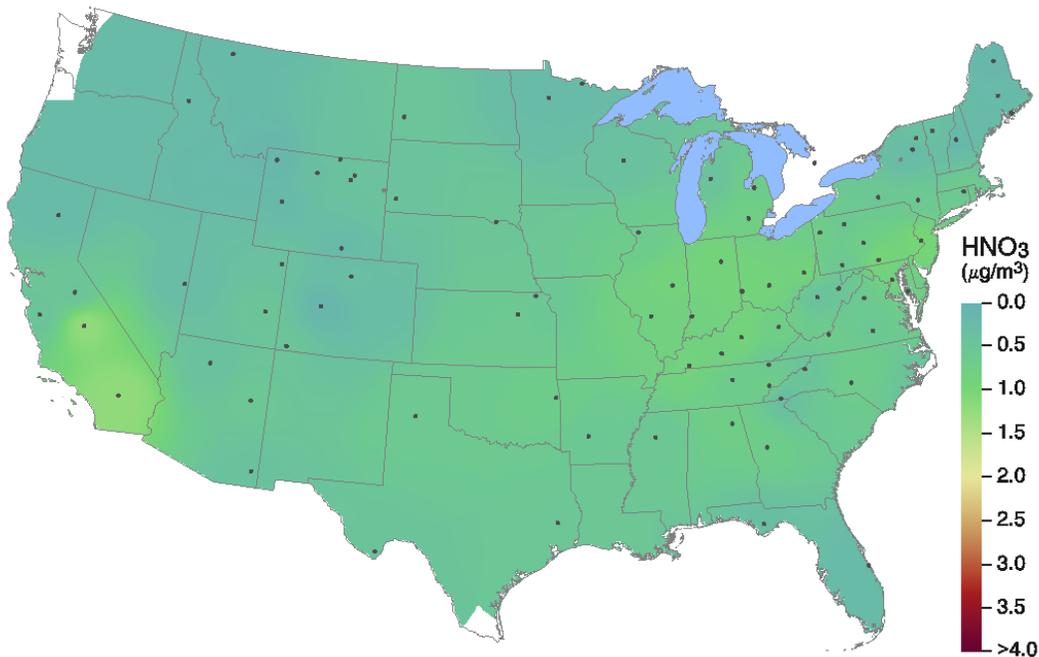

[Figure 2-21](#) through [Figure 2-23](#) describe geographic concentration patterns for  $\text{NO}_Y$ ,  $\text{HNO}_3$ , and  $\text{pNO}_3^-$ . [Figure 2-21](#) shows seasonal average  $\text{NO}_2$  concentrations derived using the hybrid (OMI-satellite/GEOS-Chem-model) approach described in [Appendix 2.4.2.2](#). Large variability in  $\text{NO}_2$  concentrations is apparent in [Figure 2-21](#). As expected, the highest  $\text{NO}_2$  concentrations are seen in large urban regions, such as in the Northeast Corridor, and lowest values are found in sparsely populated regions located mainly in the West. Minimum hourly values can be less than  $\sim 10$  ppt, leading to a large range between maximum and minimum concentrations. Although overall patterns of spatial variability are consistent with the current understanding of the behavior of  $\text{NO}_2$ , there are limitations in the satellite retrievals (see [Appendix 2.4.2.2](#)). Surface  $\text{NO}_2$  concentrations tend to be higher in January than in July, largely reflecting lower planetary boundary layer heights in winter. Such seasonal variability is also evident on a local scale, as measured by surface monitors. For example, in Atlanta, GA,  $\text{NO}_X$  measurements also exhibited higher concentrations in winter and lower concentrations in summer, when  $\text{NO}_X$  is more rapidly removed by photochemical reactions. For example, see [U.S. EPA \(2008b\)](#). 98th percentile  $\text{NO}_2$  concentrations from the national  $\text{NO}_2$  monitoring network, which has monitors mainly in urban areas, decreased by 53% from 1990 to 2017.

[Figure 2-22](#) shows ambient concentrations of  $\text{HNO}_3$ . Elevated concentrations of  $\text{HNO}_3$  are notable in southern California, the Midwest, the south-central U.S., and the Mid-Atlantic states. Conversion of  $\text{NO}_2$  to  $\text{HNO}_3$  takes place over a timescale of 1 to several hours, during which time appreciable transport can occur.

[Figure 2-23](#) shows 3-year average concentrations of particulate nitrate ( $\text{pNO}_3^-$ ) across the CONUS. Average  $\text{pNO}_3^-$  concentrations were highest in the Upper Midwest with a notable maximum at the junction of Iowa, Wisconsin, Missouri, and Illinois. The high values in the Upper Midwest are expected to be found during winter for reasons noted in [Appendix 2.3.3](#). Elevated levels were also observed in central California in the San Joaquin Valley, central Pennsylvania, central Florida, and through much of the Midwest. Based on IMPROVE and CSN monitoring network data, ammonium nitrate concentrations are highest in California and the Midwest ([Hand et al., 2012c](#)).

[Figure 2-24](#) shows decreasing trends in particulate  $\text{NO}_3^-$  based on CASTNET monitoring data for 34 eastern U.S. and 16 western U.S. monitoring sites, showing on average a 51% decrease in the eastern U.S. and a 37% decrease in the western U.S. from 1989 to 2017

(U.S. EPA, 2017b). It is worth noting that at several monitoring sites in the IMPROVE network in the central and northern Great Plains,  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$  are increasing at a rate of over 5% per year (Hand et al., 2012a). Hand et al. (2012a) suggested that this increase might be related to oil and gas exploration and production in the region, transport from oil and gas fields in Alberta, and also to expansion of EGUs to meet the demands of population growth.

**Figure 2-24 Trends in particulate nitrate concentration 1990–2017: (A) average eastern U.S. concentration based on 34 sites; (B) average western concentration based on 16 sites.**

Figure 2-25 shows the depositional flux of  $\text{NO}_Y$  over the CONUS for 2016–2018. In constructing Figure 2-25 and maps that include  $\text{pNO}_3^-$  deposition estimates, the assumption was made that 80% of  $\text{pNO}_3^-$  is in the fine mode and 20% is in the coarse mode. Note also, the monitors in CASTNET do not use size-selected inlets. As shown in Figure 2-9 (Appendix 2.5.2.1), the deposition velocity of particles increases dramatically with particle size due to gravitational settling, resulting in higher deposition rates than calculated if  $\text{pNO}_3^-$  were found mainly in the fine mode. However, there is displacement of  $\text{HNO}_3$  by acid S species in fine particles as occurs in the eastern U.S. due to much higher emissions of  $\text{SO}_2$  than in the western U.S. [e.g., Wolff (1984); especially in coastal areas where displacement of  $\text{Cl}^-$  in marine aerosol occurs]. Under these circumstances higher levels of  $\text{pNO}_3^-$  would be found in coarse mode particles (see Appendix 2.3.3). In

a field study in Tampa Bay, FL, , measured and modeled (using CMAQ) concentrations of  $\text{HNO}_3$  and  $\text{pNO}_3^-$  in  $\text{PM}_{10-2.5}$  were much higher than  $\text{pNO}_3^-$  in  $\text{PM}_{2.5}$ . [Wolff \(1984\)](#) found that most  $\text{pNO}_3^-$  (as  $\text{NH}_4\text{NO}_3$ ) is found in the fine mode in Denver but in the coarse mode (associated with  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ ) in measurements made in Detroit and rural South Dakota, Louisiana, and Virginia. [Blanchard et al. \(2013\)](#) found a range of 32 to 63% for the fraction of  $\text{pNO}_3^-$  in  $\text{PM}_{10-2.5}$  versus  $\text{PM}_{2.5}$  particles in the Southeast. [Lee et al. \(2008\)](#) found that most  $\text{pNO}_3^-$  was in the coarse mode at Grand Canyon and Great Smoky Mountains, corroborating earlier findings at Yosemite and Big Bend national parks. They also found that both coarse and fine mode  $\text{pNO}_3^-$  were important at Brigantine National Wildlife Refuge, NJ and San Geronio Wilderness Area, CA. [Lefer and Talbot \(2001\)](#) also found that  $\text{NO}_3^-$  sampled at Harvard Forest, MA between March and October was mainly found in the coarse mode with a mass median diameter of  $4.8 \pm 1.5 \mu\text{m}$ . These results indicate considerable regional variability in the ratio of  $\text{pNO}_3^-$  in the fine and coarse modes and consequently additional uncertainty in estimates of  $\text{pNO}_3^-$  deposition.

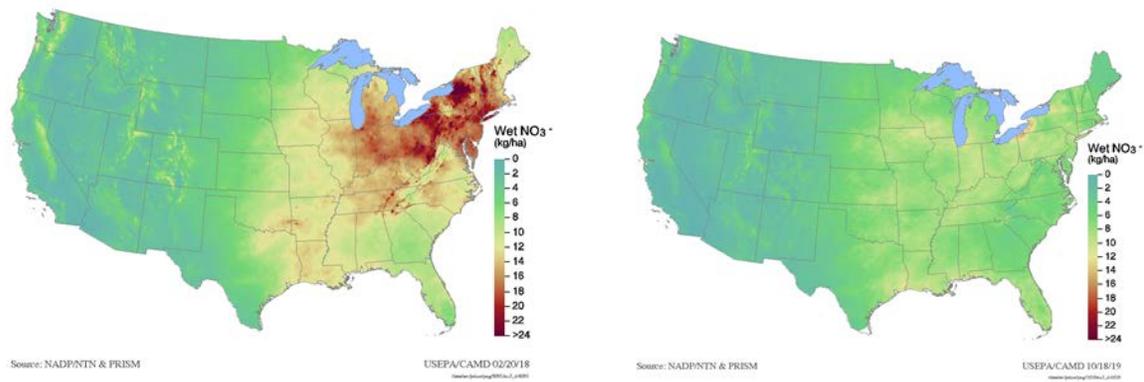

oxN = oxidized nitrogen.

**Figure 2-25 Total oxidized nitrogen deposition over the contiguous U.S. 2016–2018.**

[Figure 2-26](#) and [Figure 2-27](#) show decreases in wet deposition of  $\text{NO}_3^-$  at most locations in the U.S. These decreases are associated with  $\text{NO}_x$  emissions control measures since the passage of the 1990 Clean Air Act amendments. However, some areas, located mainly in the West show increases. As noted earlier, [Hand et al. \(2012a\)](#) suggested that this increase might be related to oil and gas exploration and production in the region, transport from oil and gas fields in Alberta, and also to expansion of motor vehicles and EGUs to meet the demands of population growth. The large area with the strongest increases in the north-central U.S. corresponds to oil and gas operations in the Bakken Shale region. Trends in total (wet + dry) deposition of oxidized nitrogen between 2000 and 2013 are described with maps in [Appendix 2.7](#).

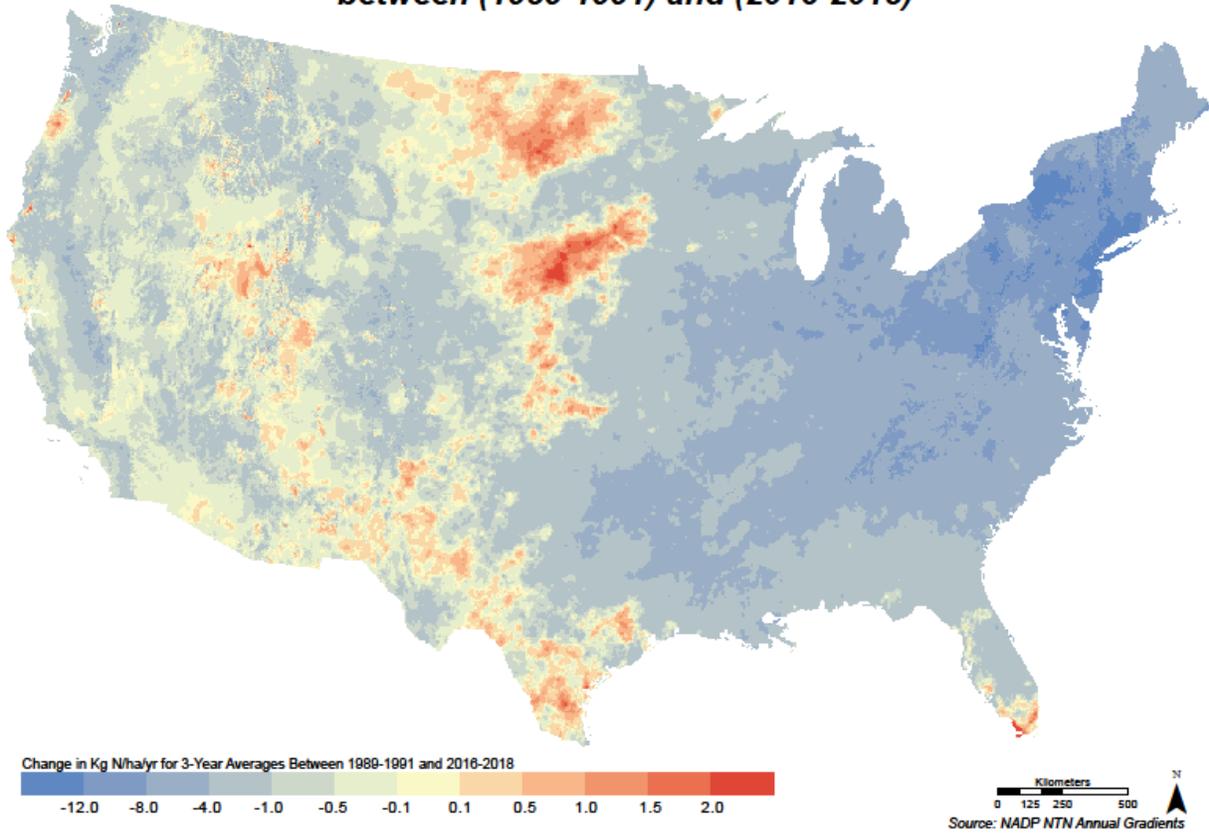

Overall, total U.S. oxidized nitrogen deposition has decreased since 2000, reflecting the substantial decline in nitrogen oxides emissions, as indicated in [Figure 2-28 \(NADP, 2019\)](#).

## 2.6.4 Reduced Nitrogen

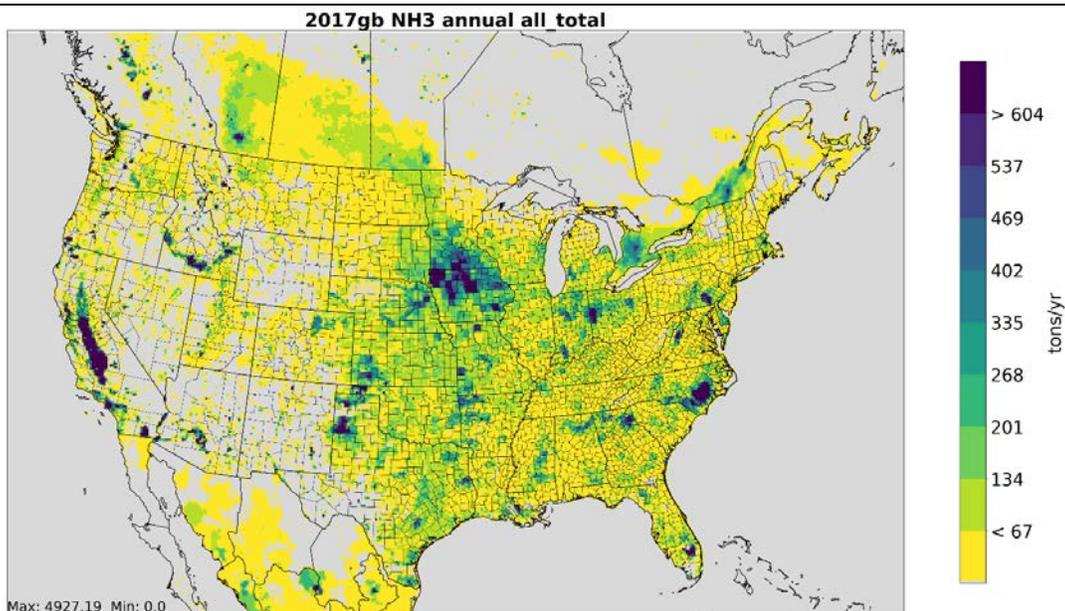

[Figure 2-29](#) shows the geographic distribution of annual total  $\text{NH}_3$  emissions. The observed pattern is somewhat different than for  $\text{NO}_x$  emissions ([Appendix 2.6.3](#)), reflecting the widely distributed and rural nature of  $\text{NH}_3$  emissions, compared to  $\text{NO}_x$  emissions, which are largely urban or from large point sources. Widespread areas of high emissions are in the Midwest, California, and several other hot spots.

[Figure 2-30](#) and [Figure 2-31](#) show maps for the concentrations of the reduced inorganic nitrogen species,  $\text{NH}_3$  and  $\text{pNH}_4^+$ . The distribution of  $\text{NH}_3$  was obtained from the Ammonia Monitoring Network (AMoN). The highest concentrations of  $\text{NH}_3$  were

measured in Salt Lake City, UT at  $16.9 \mu\text{g}/\text{m}^3$ . All other annual average concentrations for 2017 were lower than  $5 \mu\text{g}/\text{m}^3$  except eastern North Carolina. The Salt Lake City site is located near feed lots, perhaps explaining in large part why levels were much higher there than at other sites. In general, areas with the highest  $\text{NH}_3$  concentrations in [Figure 2-30](#) correspond well with areas of the highest  $\text{NH}_3$  emissions, as shown in [Figure 2-29](#). Note that confidence in the magnitude and inter-monitor precision of  $\text{NH}_3$  measurements has increased since the 2008 ISA ([U.S. EPA, 2008a](#)), also see [Appendix 2.4.3.1](#). However, sparseness of the monitoring network still presents uncertainty in describing the nationwide distribution of  $\text{NH}_3$  concentrations. National  $\text{NH}_3$  monitoring is too recent for evaluating long-term concentration trends. In the Southeastern U.S., SEARCH network observations indicated slight upward trends in ammonia concentrations from 2004–2012, but the trend was statistically significant at only monitoring site ([Saylor et al., 2015](#)).

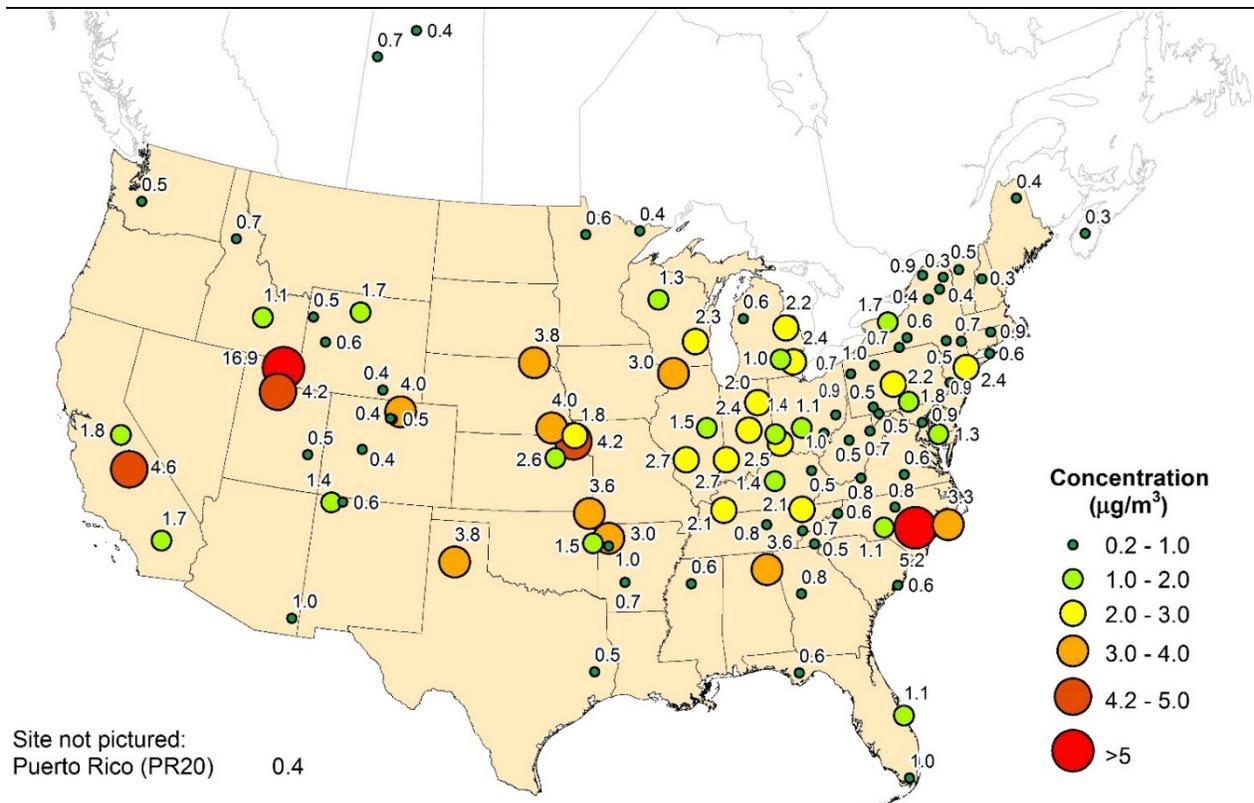

Particulate  $\text{NH}_4^+$  concentrations were obtained from CASTNET and were highest in Illinois-Indiana-western Ohio, along with high values in central Pennsylvania and central California. These locations correspond generally to the highest concentrations of  $\text{pNO}_3^-$  and moderate-to-high concentration locations for  $\text{NH}_3$ .

**Figure 2-32 Total reduced inorganic nitrogen deposition over the contiguous U.S. 2016–2018.**

[Figure 2-33](#) and [Figure 2-34](#) shows large increases in wet deposition of  $\text{NH}_4^+$  throughout the north-central U.S. with hot spots along the eastern Great Lakes, eastern Pennsylvania and North Carolina, the Texas gulf coast, and parts of Utah and California. The situation is more nuanced than shown in that some sites show small increases and others small decreases. In general, large-scale increases in wet deposition of  $\text{NH}_4^+$ , rather than decreases, are seen across the U.S. in agreement with the analysis of [Li et al. \(2016d\)](#). Trends in total (wet + dry) deposition of reduced nitrogen between 2000 and 2013 are described with maps in [Appendix 2.7](#).

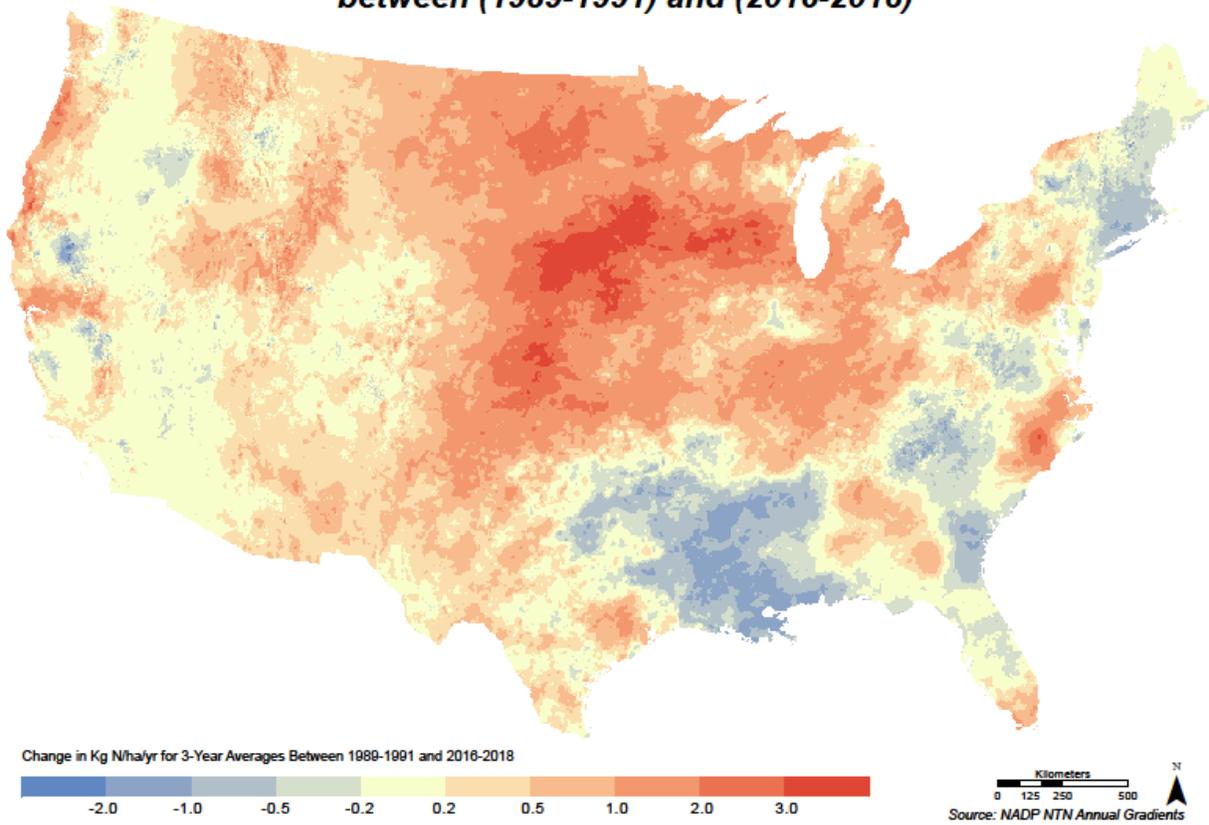

Overall, total U.S. reduced nitrogen deposition has slightly increased since 2000, even though annual national  $\text{NH}_3$  emissions data have fluctuated with no obvious trend during this period. However, during the last few years both national  $\text{NH}_3$  emissions and total reduced nitrogen deposition estimates have increased, as indicated in [Figure 2-35 \(NADP, 2019\)](#).

Source: NADP/U.S. EPA/CAMD.

## 2.6.5 Sulfur Oxides

[Figure 2-36](#) shows the west-to-east increasing gradient in SO<sub>2</sub> emissions, with greater emissions in most areas east of the Mississippi than in the West. Widespread areas of high emissions are in the Northeast and Mississippi Valley. [Figure 2-37](#) shows that sulfur dioxide emissions have declined by 89% from 1990 to 2017 and continue to decline steeply ([U.S. EPA, 2020a](#)).

Source: OAQPS analysis of [U.S. EPA \(2020a\)](#).

**Figure 2-36** Geographic distribution of annual U.S. sulfur dioxide (SO<sub>2</sub>) emissions by county from the 2017 National Emissions Inventory.

Source: [\(U.S. EPA, 2020a\)](#).

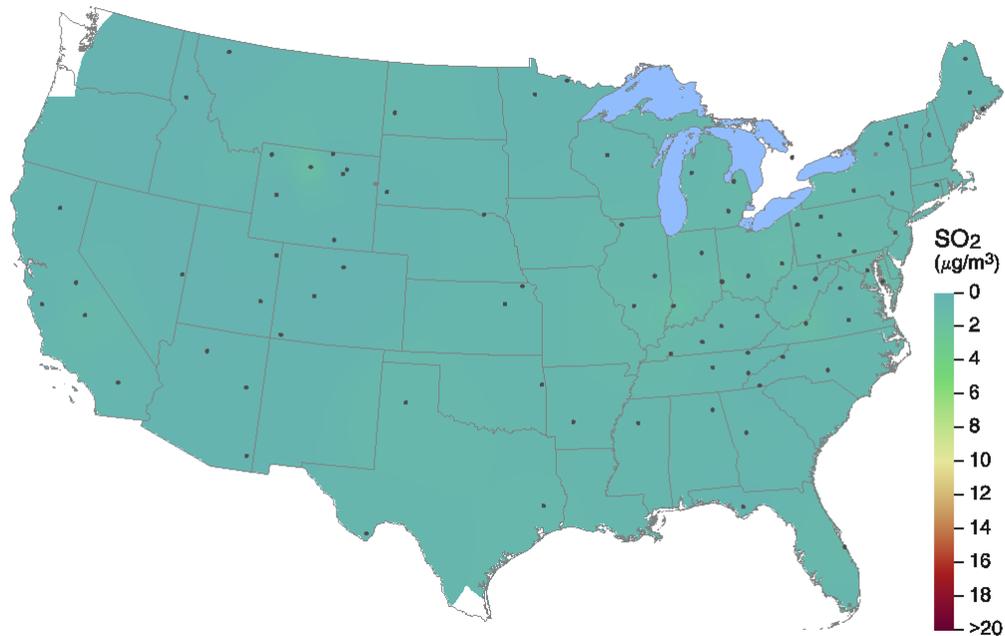

**Figure 2-37** Trends in total national sulfur dioxide emissions.

[Figure 2-38](#) and [Figure 2-39](#) show the distribution of atmospheric concentrations of gas-phase SO<sub>2</sub> and particulate phase SO<sub>4</sub><sup>2-</sup>. Concentrations have decreased substantially over the last decade throughout the eastern U.S. Comparison between the national SO<sub>2</sub> distributions ([Figure 2-38](#)) for 2016–2018 and the ones for 1989–1991 and 2003–2005 presented in the 2008 ISA ([U.S. EPA, 2008a](#)) demonstrated continual decreases in SO<sub>2</sub> concentrations across the nation.

Both concentrations and seasonal variability of sulfate are substantially higher in the eastern U.S. than in the West ([Hand et al., 2012c](#)). The higher concentrations in the eastern U.S. are consistent with greater emissions indicated in [Figure 2-36](#). Based on air pollution monitoring network data (IMPROVE and CSN), sulfate concentrations on a national scale are steadily decreasing across the U.S. Between 1992 and 2010, annual mean sulfate concentrations at rural sites decreased fairly consistently at a rate of –2.7% per year. This decline has become even steeper more recently, with annual mean concentrations decreasing by an average of –4.6% per year from 2002 to 2010. The decrease appears to be due to decreasing SO<sub>2</sub> emissions from power plants ([Hand et al., 2012b](#)). While the nationwide trend is for a reduction in sulfate concentrations, there are seasonal and regional increasing trends, specifically in the central and northern Great Plains in winter, and in the western U.S. in spring ([Hand et al., 2012a](#)). Both sulfate and nitrate are increasing at a rate of over 5% per year at several monitoring sites in the central and northern Great Plains ([Hand et al., 2012c](#)).

[Figure 2-40](#) shows trends based on CASTNET data for SO<sub>2</sub> and SO<sub>4</sub><sup>2-</sup> concentrations for 34 eastern and 16 western U.S. monitoring sites. An average SO<sub>2</sub> concentration decline of 89% was observed in the eastern U.S. and a 45% decrease was observed on average for the western U.S. from 1989–2017. For the same monitoring sites, SO<sub>4</sub><sup>2-</sup> concentrations decreased by 75% in the eastern U.S. and 35% in the western U.S. on average ([U.S. EPA, 2017b](#)).

[Figure 2-41](#) shows wet plus dry deposition of SO<sub>x</sub> (SO<sub>2</sub> + SO<sub>4</sub><sup>2-</sup>) over the CONUS. Greater deposition occurs over the Ohio River Valley (southeastern Ohio, West Virginia, and western Pennsylvania), Gulf coast (Texas and Louisiana), and Northern Great Plains (North Dakota), than in other areas of the U.S. [Figure 2-42](#) shows a good deal of spatial variability in the percentage of dry deposition across the CONUS. In the Mid-Atlantic states, dry deposition of SO<sub>2</sub> is dominant and dry deposition of pSO<sub>4</sub><sup>2-</sup> is very minor component of dry deposition of SO<sub>x</sub>. Wet deposition dominates in the Pacific Northwest, northern New England and in general in the central U.S. Note that deposition of organic sulfur species (e.g., methane sulfonic acid) or SO<sub>2</sub> and/or SO<sub>4</sub><sup>2-</sup> produced by the oxidation of organic S species is not included.

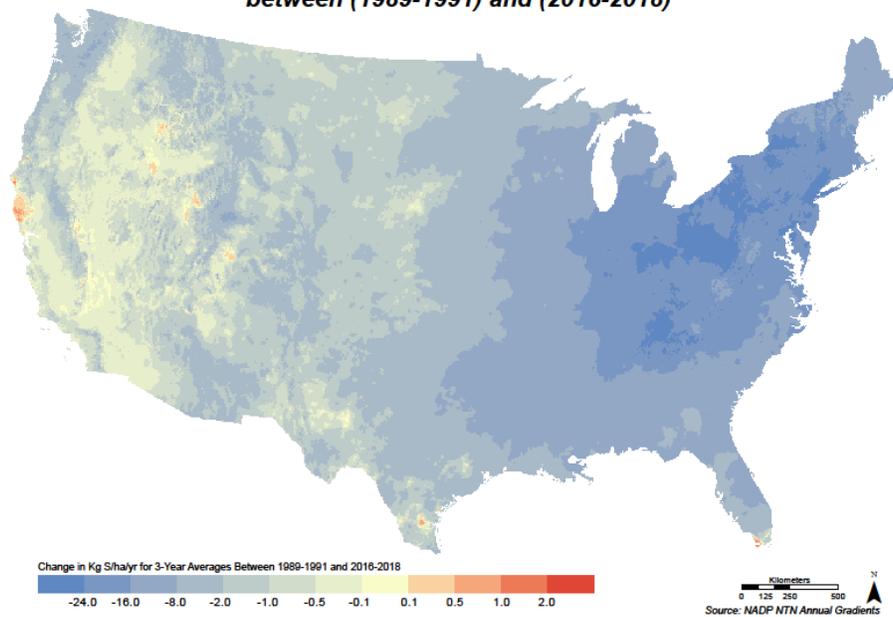

**Figure 2-42 Percentage of deposition of total sulfur as dry deposition over the contiguous U.S. 2016–2018.**

[Figure 2-43](#) and [Figure 2-44](#) show that the pattern for changes in wet deposition of  $\text{SO}_4^{2-}$  is similar to that for  $\text{NO}_3^-$  with strongest decreases in the East, but with many areas in the western U.S. showing some increase. Reasons for this increase are similar to those for  $\text{NO}_3^-$  as noted by [Hand et al. \(2012a\)](#).

**Figure 2-43** (Left) sulfate wet deposition, 1989–1991; (Right) sulfate wet deposition, 2016–2018.

**Change in  $SO_4^{2-}$  Wet Deposition in the U.S. between (1989-1991) and (2016-2018)**

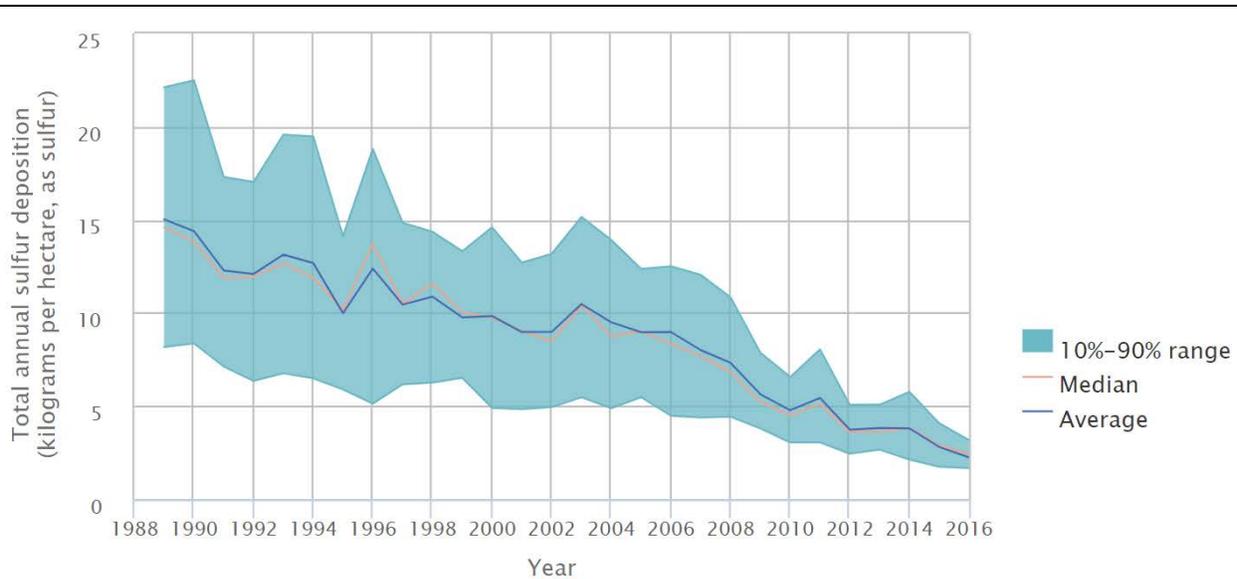

S = sulfur;  $SO_4^{2-}$  = sulfate.

Source: CPHEA analysis of CASTNET/CMAQ/NTN/AMON/SEARCH data.

**Figure 2-44** Difference in wet deposition of sulfate (kg S/ha/yr) over the contiguous U.S. between 1989 to 1991 and 2016 to 2018. The range of positive values is much smaller than for negative values.

The increases in wet deposition of  $\text{SO}_4^{2-}$  in the north-central U.S. correspond to those for  $\text{NO}_3^-$  and are in the immediate vicinity of the Bakken Shale. There is a high degree of interannual variability in deposition in some areas, especially those showing increases (e.g., Logan, UT/Idaho), making source attribution difficult. Trends in total (wet + dry) deposition of sulfur between 2000 and 2018 are described with maps in [Appendix 2.7](#).

Overall, U.S. sulfur deposition has decreased since 2000, reflecting the steep decline in  $\text{SO}_2$  emissions. This is especially evident in the eastern U.S., where  $\text{SO}_2$  emissions are higher (see [Figure 2-36](#)) and concentrations have decreased more rapidly than in the western U.S. (see [Figure 2-40](#)). [Figure 2-45](#) shows the decreasing trend of sulfur deposition for 34 CASTNET monitoring sites in the western U.S.

Coverage: 34 monitoring sites in the eastern U.S.

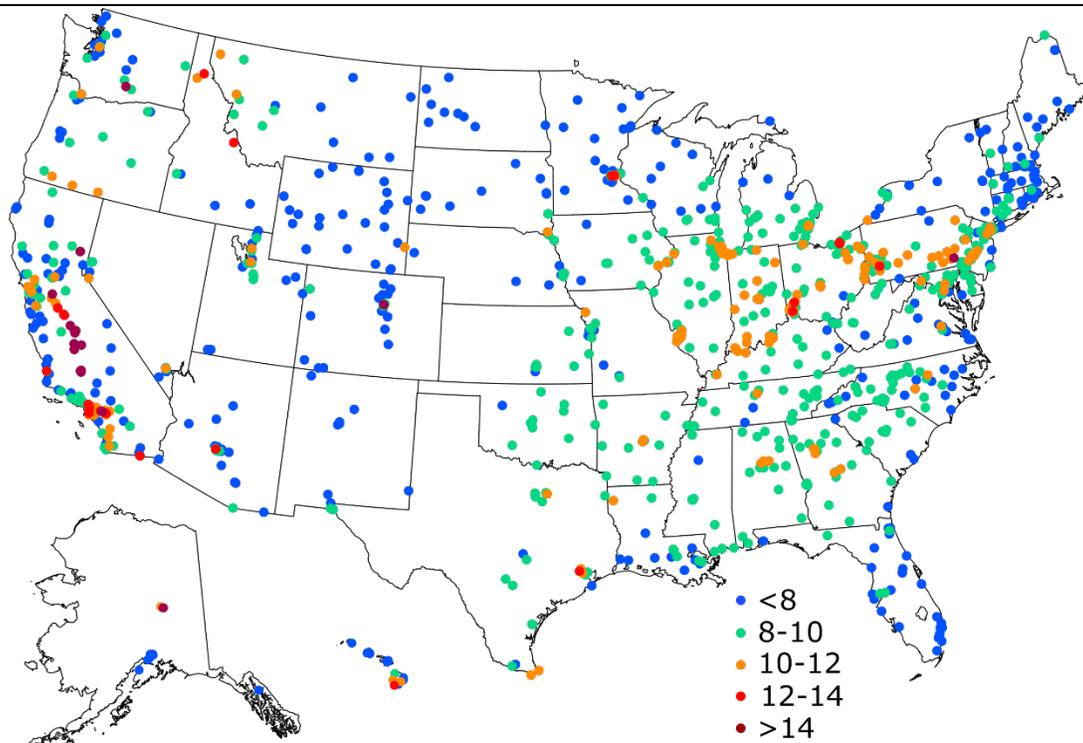

Source: [\(U.S. EPA, 2020b\)](#).

**Figure 2-45 Trends in average sulfur deposition flux for 34 monitoring sites in the eastern U.S. 1989–2017.**

## 2.6.6 Particulate Matter (PM)

[Figure 2-46](#) shows the 3-year mean of the 24-hour  $\text{PM}_{2.5}$  concentrations for  $\text{PM}_{2.5}$  network monitoring sites across the U.S. from 2013–2015. Emissions are not shown

because the majority of  $PM_{2.5}$  mass is often produced by atmospheric reactions (see [Appendix 2.3](#)). Some of the highest  $PM_{2.5}$  concentrations are in the San Joaquin Valley and the Los Angeles-South Coast Air Basin of California. However, in general 3-year average 24-hour  $PM_{2.5}$  concentrations are higher in the Eastern U.S. than in the western U.S. An area of the highest concentrations in the Eastern U.S. can be seen in the Ohio Valley. From [Appendix 2.3.6](#) is the same area where  $SO_4^{2-}$  and  $NO_3^-$  account for the greatest fraction of  $PM_{2.5}$ , indicating that at least in the eastern U.S., the highest  $PM_{2.5}$  concentrations also correspond to PM with greatest the fraction of mass accounted for by  $SO_4^{2-}$  and  $NO_3^-$ .

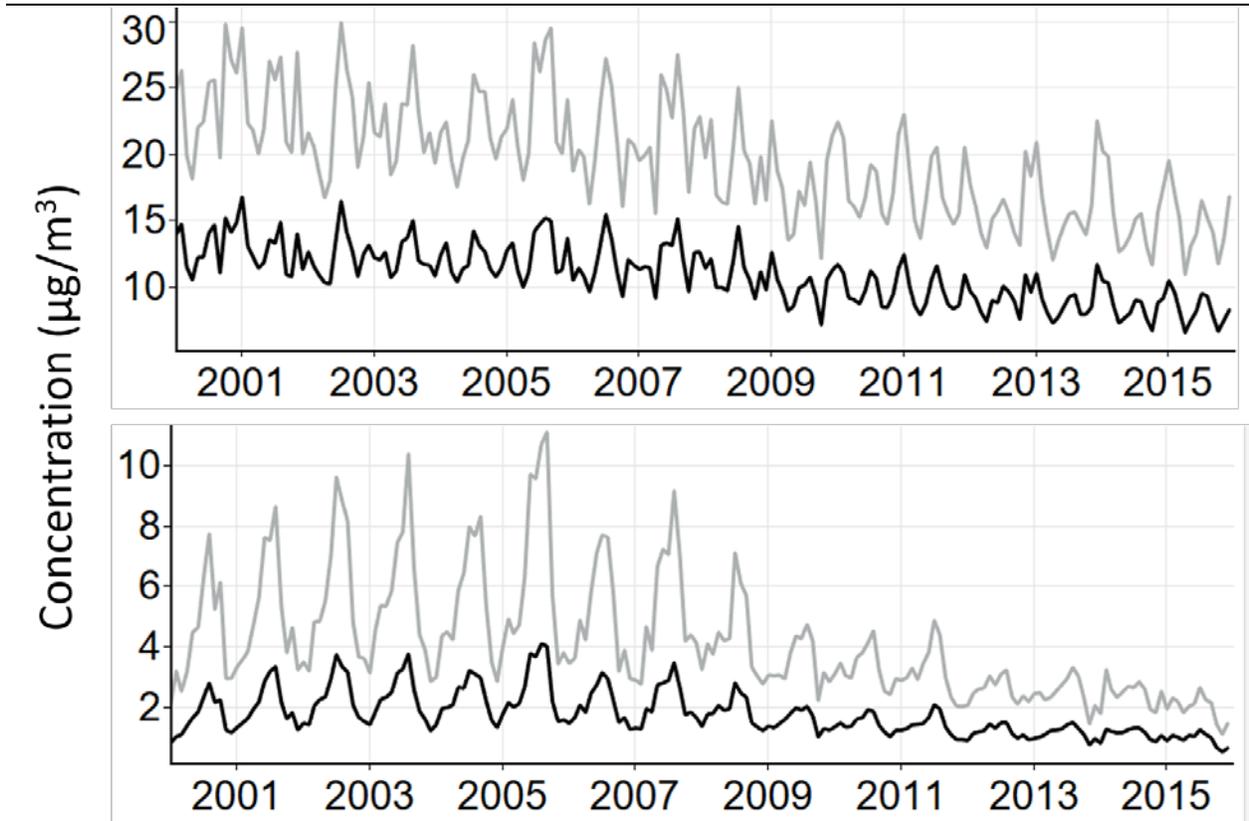

Source: ([U.S. EPA, 2019](#)).

**Figure 2-46** Three-year average concentrations of particulate matter smaller than 2.5 μm diameter ( $PM_{2.5}$ ) 2013–2015.

A further indication that the fraction of mass contributed by  $SO_4^{2-}$  and  $NO_3^-$  may increase with increasing  $PM_{2.5}$  concentration is demonstrated by [Figure 2-47](#). [Figure 2-47](#) shows that a decrease in national average  $PM_{2.5}$  between 2000 and 2016 is paralleled by a similar decrease in  $SO_4^{2-}$ . Since  $SO_4^{2-}$  has been the most abundant component of  $PM_{2.5}$ , the steep decline in  $SO_2$  emissions ([Appendix 2.2](#)) has led to a sharper decrease in  $SO_4^{2-}$

concentrations than in concentrations of other  $PM_{2.5}$  components. As indicated by [Figure 2-46](#), in those areas where  $SO_4^{2-}$  concentrations remain high, the  $SO_4^{2-}$  fraction of  $PM_{2.5}$  mass is also still high in the eastern U.S.

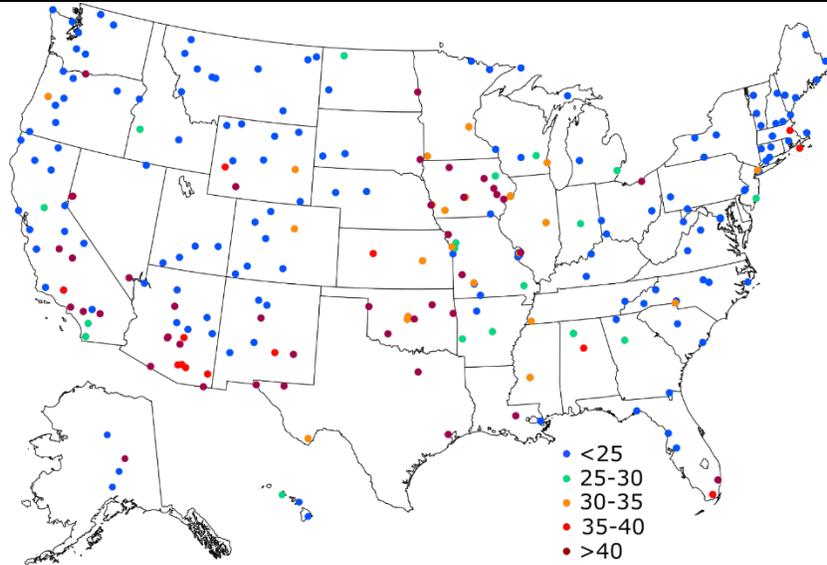

Notes: Black = mean, gray = 90th percentile.

Source: [Chan et al. \(2018\)](#).

**Figure 2-47 National monthly average concentrations of particulate matter smaller than 2.5 µm diameter ( $PM_{2.5}$ ; top) and sulfate in  $PM_{2.5}$  (bottom) from 2000–2016 (concentrations in  $\mu\text{g}/\text{m}^3$ ).**

For completeness, [Figure 2-48](#) shows  $PM_{10-2.5}$  concentrations. The highest concentrations are observed in Southwest and Great Plains. These are the same areas where crustal material accounts for the greatest fraction of  $PM_{2.5}$  as described in [Appendix 2.3.6](#), and  $PM_{10-2.5}$  is also largely composed of crustal material, which has little impact on acid or nutrient deposition.

### 2.6.7 Distributions of Dry Deposition of Nitrogen Dioxide and Sulfur Dioxide Derived Using Satellite-Based Measurements and Chemistry Transport Models

[Figure 2-49](#) shows the annual average dry deposition velocities and fluxes of NO<sub>2</sub> and SO<sub>2</sub> for 2005 to 2007 and their estimated uncertainties derived by [Nowlan et al. \(2014\)](#) using data derived from the Ozone Monitoring Instrument (OMI) on board the Aura satellite and model parameters from the GEOS-Chem three-dimensional, chemistry-transport model.

As shown in [Figure 2-49](#), higher fluxes for both NO<sub>2</sub> and SO<sub>2</sub> occur in the East than in the West. In particular, there is a band of high dry deposition for NO<sub>2</sub> and SO<sub>2</sub> along the Ohio River. High depositional fluxes for NO<sub>2</sub> are also seen along the Northeast Corridor and in scattered locations throughout the East. In addition, there is a noticeable plume of SO<sub>2</sub> over the western Atlantic Ocean. Average, relative uncertainty in the flux estimates for both NO<sub>2</sub> and SO<sub>2</sub> are ~30% over land and are not much higher over the Atlantic Ocean south of Massachusetts and Nova Scotia. Increased SO<sub>2</sub> deposition, especially near shore, is expected based on the likelihood of off-shore transport of SO<sub>2</sub> and NO<sub>2</sub> along with other pollutants by synoptic weather systems. Note that bidirectional exchange for NO<sub>2</sub> (and a number of other gases) has not been implemented yet in GEOS-Chem or

in CMAQ. Note also that in this study, the algorithms used to derive NO<sub>2</sub> and SO<sub>2</sub> columns are older than more recent ones with lower detection limits. These results, however, do illustrate the potential of the hybrid, satellite/model approach for mapping deposition at the continental scale.

N = nitrogen;  $\text{NO}_2$  = nitrogen dioxide; S = sulfur;  $\text{SO}_2$  = sulfur dioxide.

Source: [Nowlan et al. \(2014\)](#).

---

## 2.6.8 Background Concentrations and Deposition

Background refers here to those concentrations or fluxes that do not result from U.S. anthropogenic emissions. Background sources of N include natural sources like lightning, wildfires, and emission from soils. Background sources of SO<sub>x</sub> include natural sources, such as volcanos or oxidation of reduced sulfur species (H<sub>2</sub>S, [CH<sub>3</sub>]<sub>2</sub>S) emitted in anaerobic environments, and anthropogenic sources from outside the U.S. Background levels so defined facilitate separation of pollution levels that can be controlled by U.S. regulations (or through international agreements with neighboring countries) from levels that are generally uncontrollable by the U.S.

[Kim et al. \(2014a\)](#) found increases in nitrate concentrations in the mixed layer of the North Pacific Ocean, extending to near-shore areas off the west coast of the U.S., with attendant changes in the status of N limitation. Because NH<sub>3</sub> and NH<sub>4</sub><sup>+</sup> are so highly soluble, they are likely to be removed in rain during ascent before trans-Pacific transport. Because SO<sub>2</sub> is much less soluble than NH<sub>3</sub>, it can be transported to the free troposphere by the warm conveyor belt system before it is oxidized to SO<sub>4</sub><sup>2-</sup> in cloud droplets or on the surfaces of mineral dust particles. The survivability of nitrate is intermediate, depending on the form the nitrate takes.

[Zhang et al. \(2012a\)](#) computed N deposition rates from background sources and from domestic anthropogenic sources using GEOS-Chem. According to their estimates, most of the eastern U.S. and parts of states along the Pacific Coast received >10 kg/ha/yr N deposition. The version of GEOS-Chem used (8.2.3) is the same as described in [Zhang et al. \(2011a\)](#) and used in the 2013 ISA for Ozone and Other Photochemical Oxidants ([U.S. EPA, 2013c](#)). [Figure 2-50](#) shows contributions from domestic anthropogenic, foreign anthropogenic, and natural emissions to total (wet + dry) annual nitrogen deposition over the CONUS for 2006 calculated by [Zhang et al. \(2012a\)](#) using the GEOS-Chem global scale CTM with a horizontal resolution of 1/2° by 2/3°.

Source: [Zhang et al. \(2012a\)](#).

**Figure 2-50** Contributions to oxidized and reduced nitrogen deposition from U.S.: anthropogenic (top), foreign anthropogenic (middle), and natural sources (bottom).

The upper panel of [Figure 2-50](#) shows that the highest values from U.S. anthropogenic sources are found in the eastern U.S., in and downwind of the Ohio River Valley, and in and around urban areas. The middle panel of [Figure 2-50](#) shows the highest contributions from foreign anthropogenic sources in regions of the CONUS bordering Canada and Mexico. Note the band of the highest contributions in upper New York State as a result of emissions in southern Canada. There is also some indication in the Pacific Northwest of smaller contributions due to transport from Eurasia. The pattern of N deposition in the simulation for natural sources in [Figure 2-50](#) (bottom panel), however, shows maximum

deposition throughout the central U.S., with the highest values over the Midwest, reflecting a combination of  $\text{NO}_y$  emissions from lightning in the south-central U.S., from biomass burning throughout the Southeast, and from soils, mainly in the Midwest. The background contribution to N deposition is typically <30% over the eastern U.S. and typically 30 to 50% in the western U.S. where N deposition is already lower. Overall, according to these simulations, U.S. anthropogenic emissions account for 78% of  $\text{N}_r$  deposition over the CONUS. Foreign anthropogenic emissions and natural emissions account for 6 and 16% respectively of total N deposition in this model simulation.

Background concentrations of  $\text{SO}_2$  were calculated using the MOZART-2 global model of tropospheric chemistry (Horowitz et al., 2003) and were presented in the 2008 ISA for Sulfur Oxides (U.S. EPA, 2008c). Background  $\text{SO}_2$  concentrations are estimated to be below 10 parts per trillion (ppt) over much of the U.S. Maximum background concentrations of  $\text{SO}_2$  of ~30 ppt are found in the western U.S. In the Northwest, where there are large geothermal sources of  $\text{SO}_2$ , the contribution of background sources to total  $\text{SO}_2$  is 70 to 80%; however, absolute  $\text{SO}_2$  concentrations are still on the order of ~2 ppb or less. With the exception of the West Coast, where volcanic  $\text{SO}_2$  emissions cause high background concentrations, background sources contribute <1% to present-day  $\text{SO}_2$  concentrations in surface air in the CONUS. Over the eastern U.S., the predicted background contribution to  $\text{SO}_x$  deposition was <10% and even smaller (<1%) where present-day  $\text{SO}_x$  deposition is the highest. The predicted contribution of background sources to S deposition was the highest in the western U.S. at >20% because of the geothermal sources of  $\text{SO}_2$  and oxidation of DMS in surface water of the eastern Pacific. In comparison, values observed at several relatively remote sites cited in the 2008 ISA for Sulfur Oxides (U.S. EPA, 2008c) ranged from 20 to 40 ppt.

As noted earlier, volcanic sources of  $\text{SO}_2$  in the U.S. are found in the Pacific Northwest, Alaska, and Hawaii. The greatest potential domestic effects from volcanic  $\text{SO}_2$  occur on the island of Hawaii. Nearly continuous venting of  $\text{SO}_2$  from Mauna Loa and Kilauea produces  $\text{SO}_2$  in high concentrations of ~5 ppm lasting for periods of up to 1 hour [see Figure 2-34 and Figure 2-35 in the 2008 ISA for Sulfur Oxides; U.S. EPA (2008c)] at two national park sites near the Kilauea caldera and the nearby east rift zone. The latter emits several times as much  $\text{SO}_2$  as the Kilauea caldera. The two measurement sites within the national park are <3 km from the summit emission source and ~10 km from the east rift source and are affected by the two sources during southerly and easterly winds. A number of communities and population centers are within the same distance from the east rift gas source that affects these two monitoring sites. When the normal trade wind flows are disrupted, emissions from the sources can be brought directly to these various communities. Because these communities are located at a similar distance from the large east rift emission source as the national park monitoring stations, it is

probable that these communities are subjected to SO<sub>2</sub> concentrations as high as those measured within Hawaii Volcanoes National Park.

When considering emission sources further afield, intercontinental transport of O<sub>3</sub> and PM has been the focus of efforts by the Task Force on Hemispheric Transport of Air Pollution (HTAP). To the extent that N and S species are transported along with O<sub>3</sub> and PM, they also contribute to deposition following subsidence to the surface. Modeling studies estimate that only a small fraction of nitrogen and sulfur emissions are transported to and deposited within a continent different than the source of the emissions ([Stock et al., 2013](#); [Roy et al., 2012](#); [Sanderson et al., 2008](#)). Global-scale modeling results reported in the 2008 ISA ([U.S. EPA, 2008a](#)) and in the latest ISAs for Oxides of Nitrogen Health Criteria ([U.S. EPA, 2016f](#)) and Sulfur Oxides Health Criteria ([U.S. EPA, 2017d](#)) also indicate that intercontinental transport of oxidized and reduced nitrogen, SO<sub>2</sub>, and SO<sub>4</sub><sup>2-</sup> are likely minor background sources of these species. Of greater importance are localized emissions from natural sources. These include emissions of NO from soils and lightning and emissions of SO<sub>2</sub> from geothermal and biogenic sources.

Background PM that would occur in the U.S. in the absence of anthropogenic emissions originates from natural and international sources. Natural sources include windblown dust, wildfires, and sea salt. International contributions include intercontinental transport of dust, wildfire smoke, and pollution as well as transboundary transport of these contributors from Canada and Mexico. Background PM includes both primary and secondary natural and anthropogenic contributions and usually makes a relatively small contribution to urban annual average PM<sub>2.5</sub> concentrations. However, it is an important contributor to PM<sub>2.5</sub> concentrations in the southwestern U.S. and affects PM<sub>2.5</sub> concentrations elsewhere on an episodic basis. Background contributions to PM<sub>10-2.5</sub> can be substantial, as it is generally dominated by dust and sea salt ([U.S. EPA, 2019](#)).

Estimated PM<sub>2.5</sub> background concentrations were estimated to be less than 1 µg/m<sup>3</sup> on an annual basis, with maximum daily average values in a range from 3 to 20 µg/m<sup>3</sup> and a peak of 63 µg/m<sup>3</sup> at the nine national park sites across the U.S. ([U.S. EPA, 2009a](#)).

According to the 2019 PM ISA ([U.S. EPA, 2019](#)), there has not been a similar national-scale effort to update background PM<sub>2.5</sub> concentration estimates since the 2009 PM ISA, but there has been considerable research focused on better understanding the sources and processes that influence background contribution to PM<sub>2.5</sub> in the U.S. Background PM can be viewed as a combination of two conceptually separate components: 1) a baseline component characterized by reasonably consistent distribution of daily values each year, with some variability by region and season, and 2) an episodic component consisting of infrequent contributions from high-concentration events, including volcanic eruptions, wildland fires, and dust storms. On average, natural sources

including soil dust and sea salt have been estimated to account for approximately 10% of U.S. urban PM<sub>2.5</sub> ([U.S. EPA, 2019](#)). However, PM concentrations of several hundred µg/m<sup>3</sup> in areas impacted by wildland fires and >5,000 µg/m<sup>3</sup> during intense dust storms were reported in the 2019 PM ISA, and longer fire seasons resulting from invasive species, historical fire management practices, more frequent droughts, and extreme heat have led to more large fires ([U.S. EPA, 2019](#)). Intercontinental transport contributes 0.05 to 0.15 µg/m<sup>3</sup> to annual average PM<sub>2.5</sub> concentrations in the U.S. Although concentrations are typically less than 1 µg/m<sup>3</sup> at U.S. sites, episodic contributions as high as 20 µg/m<sup>3</sup> have been estimated ([U.S. EPA, 2019](#)).

Just as pollutants can be transported into the U.S., they can also be transported outward. For example, wet deposition of pollutants emitted in eastern North America occurs over the North Atlantic Ocean. Deposition of N species is an important source of nutrients to the western North Atlantic ([Zamora et al., 2011](#)). [Dennis et al. \(2013\)](#), based on CMAQ modeling results, estimated that ~1/3 of oxidized N emissions and slightly less than 1/3 of NH<sub>3</sub> emissions in the U.S. are transported out over the North Atlantic Ocean. Although the average pH of rainwater at Bermuda is ~5, reflecting deposition of acidic species emitted in North America, this additional source of acidity is at most only ~2% of that due to anthropogenic CO<sub>2</sub> ([Bates and Peters, 2007](#)).

With well-validated models, it is possible to compare the relative role of different emission and removal processes. Adjoint models ([Henze et al., 2009](#)) are particularly useful for understanding the relative contribution of emission sources to dry and wet deposition of different nitrogen and sulfur containing compounds. For example, [Lee et al. \(2016\)](#) found that half of nitrogen deposition at Federal Class I areas, such as national parks, can be attributed to emission sources within 500 km and 90% of nitrogen deposition is due to emission sources within 1,500 km. [Malm et al. \(2013\)](#) simulated conservative tracer transport from ammonia source regions with the GEOS-Chem model to estimate that roughly equal amounts of ammonia deposition in Rocky Mountain National Park (RMNP), CO was from within or outside Colorado, with most of the transport into Colorado coming from the West. [Thompson et al. \(2015\)](#) reported that 40% reduced nitrogen deposition in RNMP was from outside Colorado.

Background rainwater pH and background deposition in remote areas worldwide has considerably lower H<sup>+</sup> and N deposition levels than in more populated areas, as described in [Appendix 2.6](#). [Galloway et al. \(1982\)](#) measured the pH of rainwater at five remote sites worldwide and measured pH values ranging from 4.8 to 5.0. At some sites, acidity was attributed to long-range transport of acid sulfate, while at others a mixture of strong and weak acids attributed to both anthropogenic and natural sources was observed. They concluded that a pH of 5 was a good lower limit estimate for natural contributions. [Curtis](#)

[et al. \(2018\)](#) estimated nitrogen and sulfur deposition in remote inland areas of Greenland and reported 0.13 to 0.19 kg N/ha/yr for total nitrogen, 0.8 to 0.11 kg N/ha/yr for  $\text{NO}_3^-$ , 0.05 to 0.09 kg N/ha/yr for  $\text{NH}_4^+$ , and 0.08 to 0.13 kg S/ha yr for  $\text{SO}_4^{2-}$ .

---

## 2.7 Supplemental Material on Changes in Deposition since 2000

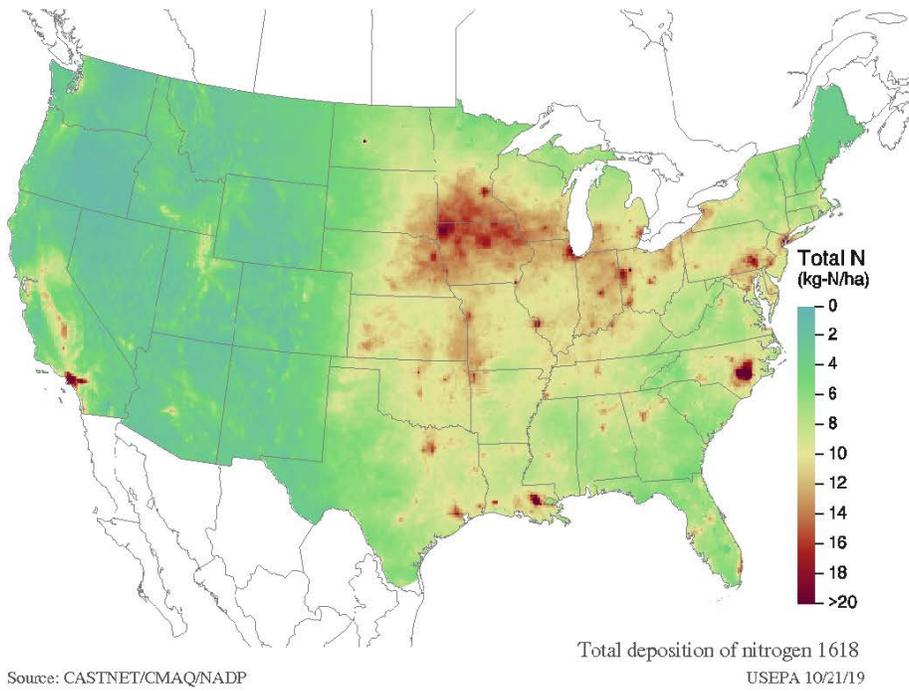

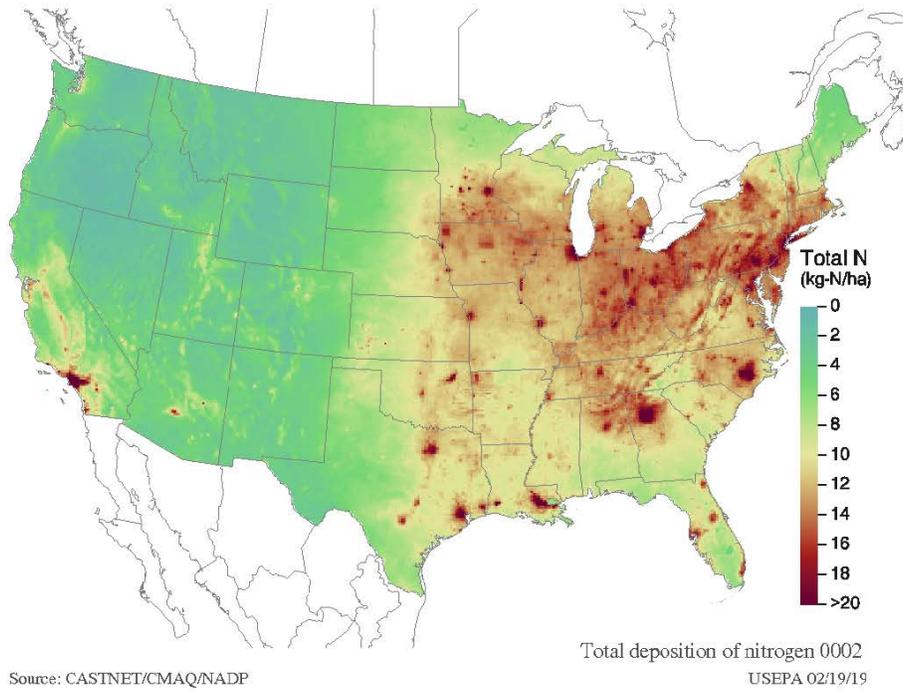

Maps on the portion of the NADP website dedicated to the Total Deposition (TDEP) program (<http://nadp.slh.wisc.edu/committees/tdep/tdepmaps/>) and shown in this section present a comprehensive overview of changes in various parameters related to deposition over 2000–2018. Changes between two, 3-year periods, 2000 through 2002 and 2016 through 2018 are summarized in this section. The most notable changes in the geographical distribution of total (wet + dry) deposition of  $\text{NO}_Y + \text{NH}_X$  between these two time periods are the large increase in total deposition of N in the upper Midwest centered in Iowa and Minnesota, with an accompanying decrease in a large area further east, extending from Illinois and Indiana to Pennsylvania and further south (see [Figure 2-51](#)). There are also shifts in the distribution of wet and dry deposition in these areas (see [Figure 2-52](#), [Figure 2-53](#), and [Figure 2-54](#)). Deposition of oxidized nitrogen has declined markedly throughout the eastern U.S. and southern California between the periods 2000–2002 and 2016–2018 (see [Figure 2-55](#), [Figure 2-56](#), [Figure 2-57](#), and [Figure 2-58](#)) due mainly to large decreases in dry deposition of total nitrate ( $\text{TNO}_3 = \text{HNO}_3 + \text{pNO}_3^-$ ; see [Figure 2-59](#)). The decreases in total nitrate deposition across the CONUS are generally due to decreases in  $\text{HNO}_3$  deposition (see [Figure 2-60](#)). Decreases in dry deposition of  $\text{pNO}_3^-$  have generally been smaller, reflecting the smaller contribution of  $\text{pNO}_3^-$  to  $\text{TNO}_3$ . Exceptions include areas such as Florida, Texas, and southern California where dry deposition of  $\text{pNO}_3^-$  has been much greater than  $\text{HNO}_3$  in the earlier period and has decreased substantially (see [Figure 2-61](#)). Other N species, mainly  $\text{NO}_2$  also show large decreases (see [Figure 2-62](#) and [Figure 2-63](#)), especially near urban source areas. Using OMI data, [Krotkov et al. \(2016\)](#) found decreases in column (vertically integrated) abundances of  $\text{NO}_2$  of ~40% from 2005 to 2014 over the U.S.

In contrast to deposition of oxidized N, deposition of reduced inorganic N has seen large increases (see [Figure 2-64](#) and [Figure 2-65](#)). Several areas, including the upper Midwest and San Joaquin Valley, have increased markedly in size or intensity (see [Figure 2-64](#)) between the two periods. Dry deposition of  $\text{NH}_3$  has been the major contributor to the increase (see [Figure 2-66](#)), and although dry deposition of  $\text{pNH}_4^+$  has largely decreased between the two periods (see [Figure 2-67](#)), the greater contribution of  $\text{NH}_3$  has resulted in an overall increase of total reduced nitrogen deposition in affected areas. Between the two periods, emissions of  $\text{NO}_X$  have decreased resulting in lower formation rates of  $\text{HNO}_3$  that could react with  $\text{NH}_3$  to form  $\text{pNH}_4\text{NO}_3$ .

Deposition of oxidized and reduced N have undergone geographic shifts with corresponding shifts in the contributions of each to total N deposition on regional and smaller scales (compare [Figure 2-55](#) and [Figure 2-56](#) to [Figure 2-64](#) and [Figure 2-65](#)). For example, deposition of oxidized N in the Northeast has decreased substantially, but deposition of reduced N has increased in the central U.S. Sizable shifts are also seen in the fractional contributions of total N deposition as dry deposition of both oxidized and reduced forms (compare [Figure 2-58](#) and [Figure 2-69](#)).

Declines in the deposition of S since 2000 have also occurred, particularly in the Ohio River Valley (see [Figure 2-70](#)), with generally much smaller declines in wet deposition (see [Figure 2-71](#)) than for dry deposition (see [Figure 2-72](#)). The proportion of S dry deposited has also decreased, especially in the Ohio Valley and the rest of the eastern U.S. (see [Figure 2-73](#)). Dry deposition of both SO<sub>2</sub> and pSO<sub>4</sub><sup>2-</sup> have both decreased in areas with the greatest deposition ([Figure 2-74](#) and [Figure 2-75](#)). These decreases are consistent with those derived by [Krotkov et al. \(2016\)](#) who detected decreases in the column (vertically integrated) abundance of SO<sub>2</sub> of ~75 % for the period 2005 to 2014 over the Ohio River Valley and southwestern Pennsylvania. These decreases reflect reductions in emissions mandated by the Clean Air Act Amendments and other regulatory requirements.

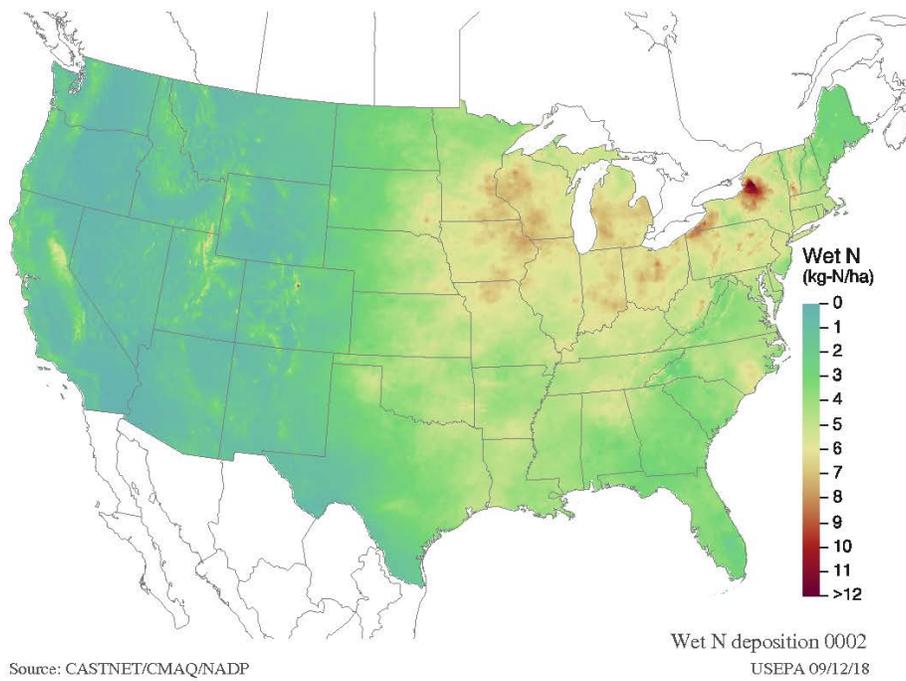

As noted earlier, these estimates of change in deposition were derived from CMAQ output and data from measurement networks. Each of these components has its own set of uncertainties, and the estimates of deposition and the changes over time should be viewed in this light.

## APPENDIX 3 DIRECT PHYTOTOXIC EFFECTS OF GASEOUS OXIDIZED NITROGEN AND SULFUR ON VEGETATION

This appendix provides a brief overview of the exposure and phytotoxic effects of gaseous forms of oxidized nitrogen (N) and sulfur (S) compounds on vegetation. The main focus of this ISA is understanding the ecological impact of oxidized N and S and that the major effects of these compounds on ecosystems are through acidifying deposition and N enrichment deposition. However, direct effects of gaseous oxidized N and S could augment the effects of deposition on vegetation, and direct effects of gaseous N and S may be apparent in some areas. The effect of sulfur dioxide (SO<sub>2</sub>) gas on vegetation is discussed in [Appendix 3.2](#). [Appendix 3.3](#) discusses the effects of nitric oxide (NO), nitrogen dioxide (NO<sub>2</sub>), and peroxyacetyl nitrate (PAN) on vegetation. [Appendix 3.4](#) presents information on the direct effects of nitric acid (HNO<sub>3</sub>) vapor on vegetation, including lichens. A summary section with causal determinations based on a synthesis of the body of information on the biological effects of exposure to these gases is presented in [Appendix 3.5](#).

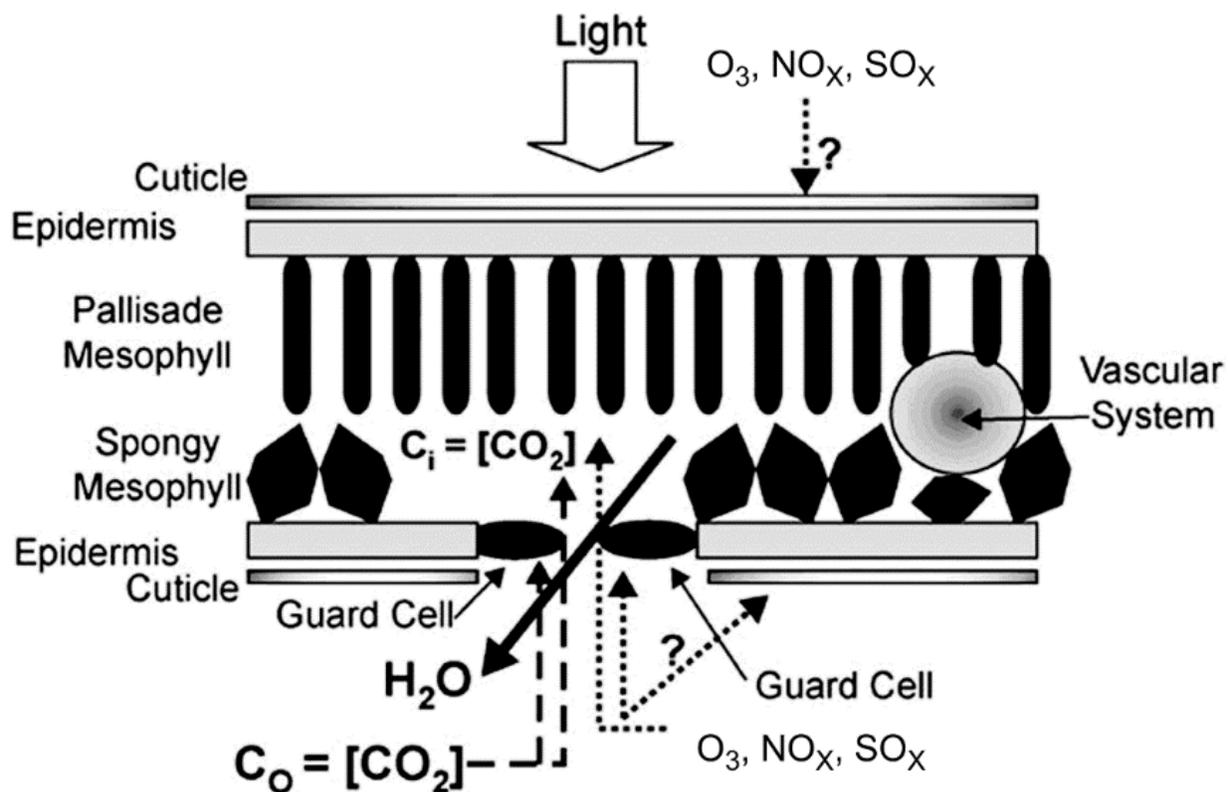

---

### 3.1 Introduction

The effects of gaseous pollutants such as SO<sub>2</sub>, NO<sub>2</sub>, NO, HNO<sub>3</sub>, and ozone (O<sub>3</sub>) on vegetation have been studied since at least the early 19th century ([Holmes et al., 1915](#); [Haywood, 1905](#)). Methodologies have been developed to study the effects of gaseous exposures to these pollutants in the laboratory, greenhouse, and in the field. The methodologies to study the effects of gaseous pollutants on vegetation have been recently reviewed in the 2013 Ozone ISA and 2006 Ozone AQCD [Air Quality Criteria Document; [U.S. EPA \(2013c\)](#); [U.S. EPA \(2006a\)](#)]. A thorough description of the methodologies used to expose vegetation to gaseous pollutants can be found in Section 9.2 of the 2013 Ozone ISA ([U.S. EPA, 2013c](#)), AX9.1 of the 2006 Ozone AQCD ([U.S. EPA, 2006a](#)), and Section 9.2 in the 1993 Oxides of Nitrogen AQCD ([U.S. EPA, 1993](#)).

Uptake of gaseous pollutants in a vascular plant canopy is a complex process involving adsorption to surfaces (leaves, stems, and soil) and absorption into leaves. These pollutants penetrate into leaves primarily in gaseous forms through the stomata. The surface cuticle provides a protective barrier to gaseous pollutant exposure, although there is evidence for limited uptake across the cuticle ([Zhang et al., 2003](#); [Kerstiens et al., 1992](#)). Pollutants must be transported from the bulk air to the leaf boundary layer to reach

the stomata. The transport of pollutants through a boundary layer into the stomatal region is by diffusion. Studies of transport through the boundary layer are based on aerodynamic concepts and usually relate to smooth surfaces that are not typical of leaf-surface morphology ([Gates, 1968](#)). Once through the boundary layer, the gas enters the leaf through the stomata. The entry of gases into a leaf is dependent upon gas-phase chemical processes and physical characteristics of surfaces, including stomatal aperture. The aperture of the stomata is controlled largely by the prevailing environmental conditions, such as humidity, temperature, light intensity, and water availability. When the stomata are closed, as occurs under dark or drought conditions, resistance to gas uptake is very high and the plant has a very low degree of susceptibility to injury ([Figure 3-1](#)). The stomatal control of uptake of gaseous pollutants is described in more detail in AX9.2 of the 2006 Ozone AQCD ([U.S. EPA, 2006a](#)) and Section 9.3.1.5 of the 1993 Oxides of Nitrogen AQCD ([U.S. EPA, 1993](#)). Note that unlike vascular plants, mosses and lichens do not have a protective cuticle barrier to gaseous pollutants, which is a major reason for their sensitivity to gaseous S and N.

C<sub>i</sub> = internal CO<sub>2</sub> in leaf; C<sub>o</sub> = CO<sub>2</sub> of the atmospheric air; CO<sub>2</sub> = carbon dioxide; H<sub>2</sub>O = water; SO<sub>x</sub> = sulfur oxides; NO<sub>x</sub> = oxides of nitrogen; O<sub>3</sub> = ozone.

Source: U.S. Environmental Protection Agency ([U.S. EPA, 2008a](https://www.epa.gov/2008a)).

**Figure 3-1** The microarchitecture of a dicot leaf. While details among species vary, the general overview remains the same. Light that drives photosynthesis generally falls upon the upper (adaxial) leaf surface. Carbon dioxide, oxides of sulfur, oxides of nitrogen, and ozone gases generally enter by diffusion through the guard cells (or stomata) on the lower (abaxial) leaf surface, while water vapor exits through the stomata (transpiration).

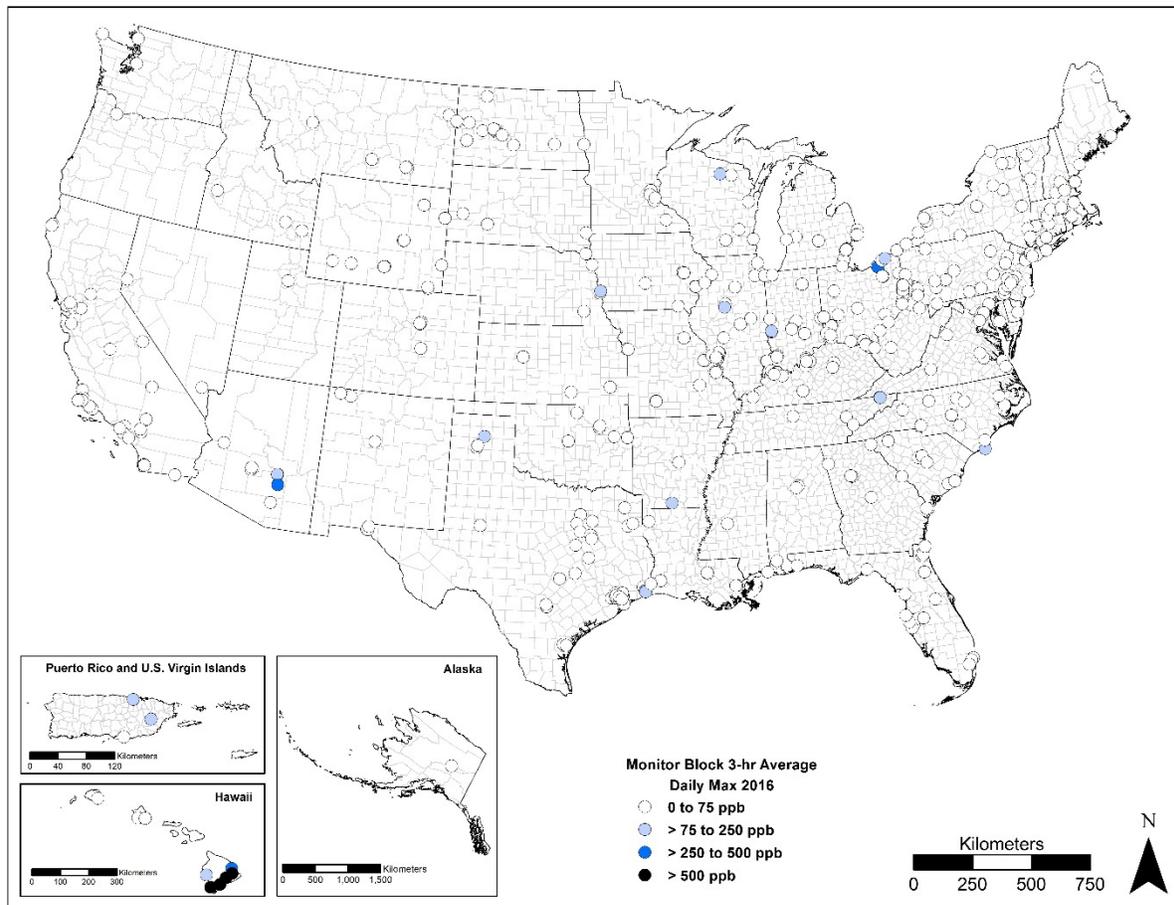

### 3.2 Direct Phytotoxic Effects of Sulfur Dioxide on Vegetation

It has been known since the early 1900s that exposure to SO<sub>2</sub> can cause plant damage and death ([Wislicenus, 1914](https://www.ncbi.nlm.nih.gov/pmc/articles/PMC1363144/)). The large sources of historic SO<sub>2</sub> emissions were ore smelters. Sulfides in the ore were oxidized during smelting and resulted in large releases of SO<sub>2</sub>. Emissions from large ore smelters in the U.S. and Canada resulted in large areas denuded of vegetation surrounding these facilities ([Thomas, 1951](https://www.ncbi.nlm.nih.gov/pmc/articles/PMC1363144/); [Swain, 1949](https://www.ncbi.nlm.nih.gov/pmc/articles/PMC1363144/)). Much of the

damage to the vegetation was due to acute effects of high concentrations of SO<sub>2</sub>. However, as early as 1923, researchers recognized that SO<sub>2</sub> might decrease plant growth without producing acute symptoms of foliar injury ([Stoklasa, 1923](#)). In the 1950s through the early 1980s, there was much research on the effects of SO<sub>2</sub> on vegetation, as well as the interaction with pollutants such as O<sub>3</sub> and NO<sub>2</sub>. Since then, there has been much less research on the effects of SO<sub>2</sub> on vegetation, especially in the U.S., due to the decreasing ambient concentrations of SO<sub>2</sub> [[U.S. EPA \(2012a\)](#); see [Figure 3-2](#) for max 3-hour SO<sub>2</sub> concentrations for 2016]. The effects of SO<sub>2</sub> on vegetation are summarized below.

Currently, SO<sub>2</sub> is the only criteria pollutant with a secondary NAAQS distinct from the primary standard. Other criteria air pollutants produce adverse welfare effects, but the secondary and primary NAAQS have been set to be identical. The SO<sub>2</sub> NAAQS is to protect acute foliar injury resulting from SO<sub>2</sub> exposure. The standard is a 3-hour average of 0.50 ppm and was promulgated in 1971 to protect against the adverse effects of acute foliar injury in vegetation. The 1982 AQCD for Particulate Matter and Sulfur Oxides concluded that controlled experiments and field observations of vegetation supported retaining this secondary standard ([U.S. EPA, 1982b, d, 1971](#)).

Acute foliar injury usually occurs within hours of exposure, involves a rapid absorption of a toxic dose, and involves a collapse or necrosis of plant tissues. Another type of visible injury is termed chronic injury and is usually a result of variable SO<sub>2</sub> exposures over the growing season. After entering the leaf, SO<sub>2</sub> is converted to sulfite (SO<sub>3</sub><sup>2-</sup>) and bisulfite (HSO<sub>3</sub><sup>-</sup>) ions, which may be oxidized to sulfate (SO<sub>4</sub><sup>2-</sup>). Sulfate is about 30 times less toxic than sulfite and bisulfite. The conversion of sulfite and bisulfite to sulfate results in net H<sup>+</sup> production in the cells. [Kropff \(1991\)](#) proposed that the appearance of SO<sub>2</sub>-induced leaf injury was likely due to a disturbance of intracellular pH regulation. [Kropff \(1991\)](#) listed several studies in which the pH of homogenates of leaf cells only shifted towards greater acidity when plants were lethally damaged from long-term SO<sub>2</sub> exposures ([Jäger and Klein, 1977](#); [Grill, 1971](#); [Thomas et al., 1944](#)). The appearance of foliar injury can vary significantly among species and growth conditions (which affect stomatal conductance). Currently, there is no regular monitoring for SO<sub>2</sub> foliar injury effects in the U.S.

Source: U.S. Environmental Protection Agency 2016 analysis of data from state and local air monitoring stations.

**Figure 3-2** Map of maximum 3-hour daily max average sulfur dioxide concentration reported at Air Quality System monitoring sites for 2016.

Besides foliar injury, long-term lower SO<sub>2</sub> concentrations can result in decreased photosynthesis, growth, and yield of plants. These effects are cumulative over the growing season and are often not associated with visible foliar injury. As with foliar injury, the effects of these injuries vary among species and growing environment. The 1982 Particulate Matter and Oxides of Sulfur (PM-SO<sub>x</sub>) AQCD summarized the concentration-response information available at the time ([U.S. EPA, 1982b](#)). Effects on growth and yield of vegetation were associated with increased SO<sub>2</sub> exposure concentration and time of exposure. However, that document concluded that more definitive concentration-response studies were needed before useable exposure metrics could be identified. Because ambient SO<sub>2</sub> concentrations declined and focus on O<sub>3</sub> vegetation effects research increased, relatively few studies have emerged to better

inform a metric and levels of concern for effects of SO<sub>2</sub> on growth and productivity of vegetation.

SO<sub>2</sub> is considered to be the primary factor causing the death of lichens in many urban and industrial areas, with fruticose lichens being more susceptible to SO<sub>2</sub> than many foliose and crustose species ([Hutchinson et al., 1996](#)). Damage to lichens in response to SO<sub>2</sub> exposure includes reduced photosynthesis and respiration, damage to the algal component of the lichen, leakage of electrolytes, inhibition of N fixation, reduced K<sup>+</sup> absorption, and structural changes ([Hutchinson et al., 1996](#); [Belnap et al., 1993](#); [Farmer et al., 1992](#)). Significant reductions in lichen photosynthesis have been measured at concentrations as low as 91 ppb over 2–4 hours ([Sanz et al., 1992](#); [Huebert et al., 1985](#)). Damage to the algal component of the thallus is evidenced by its discoloration. The entire thallus dies soon after algal cells are damaged ([Hutchinson et al., 1996](#)). At higher concentrations, SO<sub>2</sub> deactivates enzymes by chemical modification, leading to reduced metabolic activity and loss of membrane integrity ([Nieboer et al., 1976](#); [Ziegler, 1973](#)). In addition, SO<sub>2</sub> binds to the central metal atoms of enzymes, adversely affecting membrane function and cell osmolality. SO<sub>2</sub> also competitively inhibits bicarbonate (HCO<sub>3</sub><sup>-</sup>) and dihydrogen phosphate (H<sub>2</sub>PO<sub>4</sub><sup>-</sup>) interactions with enzymes ([Hutchinson et al., 1996](#)). Low pH increases the toxicity of SO<sub>2</sub> action ([Farmer et al., 1992](#)). The toxic effects of atmospheric deposition of SO<sub>2</sub> are lessened when lichens are attached to a substrate, typically bark or rock, that has high pH or superior buffering capacity ([Richardson and Cameron, 2004](#)). [van Herk \(2001\)](#) evaluated relationships between bark pH and air pollution levels as two significant variables affecting epiphytic lichen composition and concluded that bark pH was the primary factor regulating the distribution of acidophilic species in the Netherlands. In studies of unpolluted areas, differences in bark chemistry also affect the presence and distribution of epiphytes ([Farmer et al., 1992](#)). Indirect changes to bark pH, caused by acidification and high SO<sub>2</sub> concentrations, also affect lichen distribution ([Farmer et al., 1992](#)). More recently, [Geiser and Neitlich \(2007\)](#) reported that direct SO<sub>2</sub> damage to lichens in the Pacific Northwest may have been confined to major urban areas such as Seattle, Portland, and Bellingham. However, lichen monitoring plots were not colocated with SO<sub>2</sub> monitors and the authors were not able to quantify SO<sub>2</sub> exposure. More information on the N effects reported in this study is found in [Appendix 6.3.7](#) and [Appendix 6.5.2](#).

More recent research has been performed in areas of Europe where ambient SO<sub>2</sub> concentrations are generally higher than in the U.S. Since the 2008 ISA, several studies in Germany and some eastern European countries have indicated that direct effects of SO<sub>2</sub> caused growth reductions in trees during the last century ([Cavlovic et al., 2015](#); [Hauck et al., 2012](#); [Rydval and Wilson, 2012](#); [Elling et al., 2009](#)). [Elling et al. \(2009\)](#) evaluated a large database providing long-term growth records of 1,010 silver firs (*Abies*

*alba*), long-term climate records, and long-term air pollution data from 51 sites in southern Germany. In this analysis, silver fir growth was influenced by SO<sub>2</sub> pollution more than any other factor in the second half of the last century. The study authors also reported an almost immediate increase in growth in response to falling SO<sub>2</sub> emissions in the 1980s. This rapid response indicates a direct effect of gaseous SO<sub>2</sub> rather than an indirect effect of soil acidification, which would have a longer response time. Annual average concentrations above 10 µg SO<sub>2</sub>/m<sup>3</sup> (approximately 4 ppb) appeared to reduce growth of silver fir. (See [Figure 2-15](#) for recent concentrations in the continental U.S.). In a later publication, [Bošela et al. \(2014\)](#) argued a combination of SO<sub>2</sub> and NO<sub>x</sub> gas emissions has historically reduced growth in silver fir in the western Carpathian Mountains of the Czech Republic.

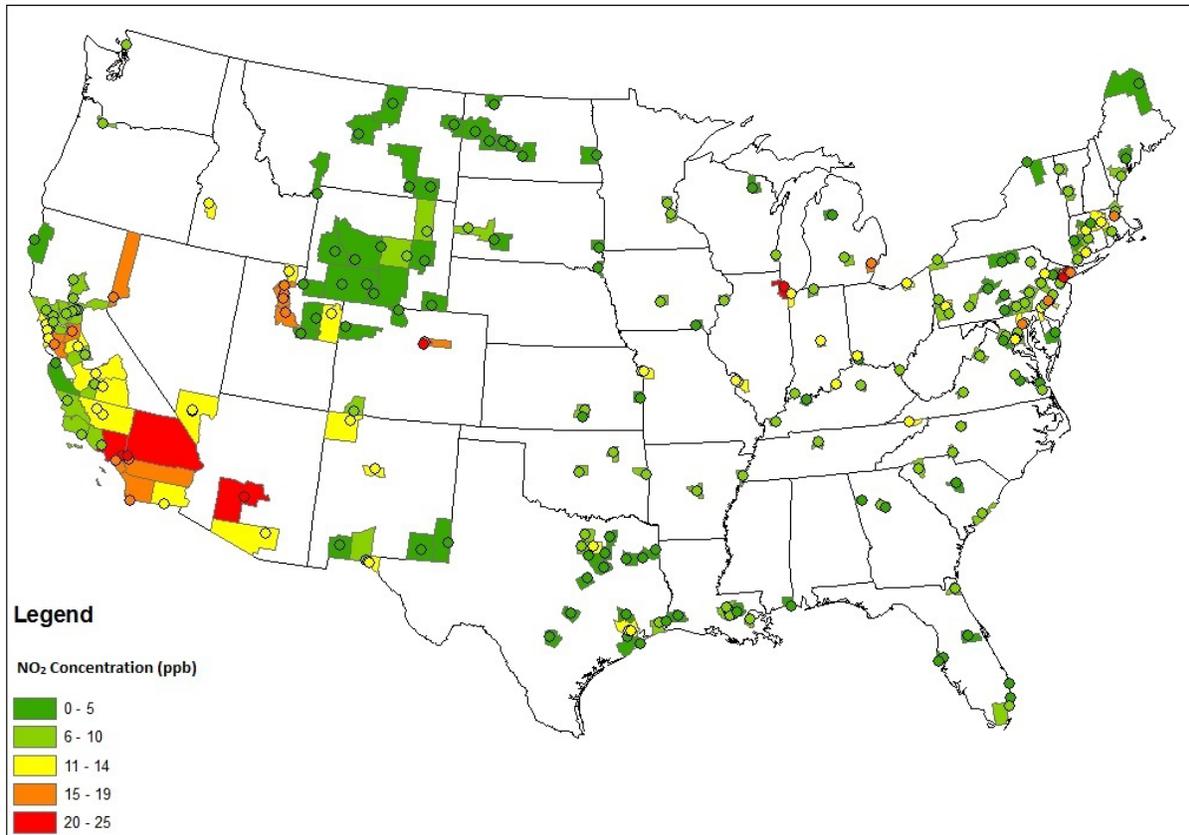

A similar gaseous SO<sub>2</sub> effect on tree growth may have been occurring in the eastern U.S. Using tree ring analysis, [Thomas et al. \(2013\)](#) reported significant growth increases in old-growth eastern red cedar (*Juniperus virginiana*) in West Virginia following decreases in SO<sub>2</sub> emissions since 1980. Growth continued to increase as SO<sub>2</sub> emissions further declined in the 1990s and 2000s. [Thomas et al. \(2013\)](#) also found evidence of physiological changes in response to SO<sub>2</sub> emissions. The authors attributed the growth response to an indirect effect of decreasing acidifying deposition, and thus, recovery from soil acidification. However, a historical record of acidifying deposition was not available. As in Europe, the trees studied in West Virginia also had a relatively rapid recovery in response to declining SO<sub>2</sub> emissions that could indicate the effects were from direct exposure to gases in the atmosphere rather than soil acidification. Further, a response to this study from other researchers suggested that the eastern red cedars in the West Virginia study were found on a limestone outcrop that could be well buffered from soil acidification ([Schaberg et al., 2014](#)). This study may indicate that gaseous SO<sub>2</sub> alone or in combination with other gases may have inhibited red cedar growth. See [Appendix 5.2.1.3](#) for further discussion of this study.

---

### **3.3 Direct Phytotoxic Effects of Nitric Oxide, Nitrogen Dioxide, and Peroxyacetyl Nitrate**

In sufficient concentrations, nitric oxide (NO) and nitrogen dioxide (NO<sub>2</sub>) can have phytotoxic effects on plants by decreasing photosynthesis and inducing visible foliar injury ([U.S. EPA, 1993](#)). The current secondary (welfare) and primary (human health) standard for oxides of nitrogen is a NO<sub>2</sub> annual mean of 0.053 ppm. See [Figure 3-3](#) for recent concentrations of NO<sub>2</sub>. The 1993 Oxides of Nitrogen AQCD concluded that concentrations of NO<sub>2</sub> or NO in the atmosphere are rarely high enough to have phytotoxic effects on vegetation ([U.S. EPA, 1993](#)). Since the 1993 Oxides of Nitrogen

AQCD, very little new research has been done on these phytotoxic effects to alter this conclusion ([Bender and Weigel, 2011](#)). However, it is known that these gases alter the N cycle in some ecosystems, especially in the western U.S., and contribute to N saturation ([Sparks, 2009](#); [Fenn et al., 2003a](#); [Bytnerowicz and Fenn, 1996](#)). See [Appendix 6.1](#) for a discussion of the nutrient effects of N.

NO<sub>2</sub> = nitrogen dioxide.

Note: Concentrations indicated are the highest concentration in the county and do not represent countywide concentrations.

Source: U.S. Environmental Protection Agency 2014 analysis of data from state and local air monitoring stations ([U.S. EPA, 2016f](#)).

**Figure 3-3**      **Map of U.S. annual average nitrogen dioxide concentrations for 2013.**

In general, NO and NO<sub>2</sub> enters leaves through the stomata ([Saxe, 1986](#)). However, the leaf cuticle could be an important receptor for NO<sub>2</sub>, and there is evidence of transport of NO and NO<sub>2</sub> across isolated cuticles ([Lendzian and Kerstiens, 1988](#)). Several studies

have demonstrated that plant canopies can directly assimilate N in the form of  $\text{NO}_2$ , but canopy uptake of  $\text{NO}_2$  is generally small relative to total plant uptake ([Vallano and Sparks, 2008](#); [Ammann et al., 1995](#); [Nussbaum et al., 1993](#); [Segschneider et al., 1993](#); [von Ballmoos et al., 1993](#); [Hanson et al., 1989](#)). After entering the leaves,  $\text{NO}_2$  dissolves in the extracellular water of the substomatal cavity to form  $\text{HNO}_2$  and  $\text{HNO}_3$ , which then dissociate to form  $\text{NO}_2^-$ ,  $\text{NO}_3^-$ , and  $\text{H}^+$  ([Bytnerowicz et al., 1998](#)). Both cell and tonoplast membranes contain ATP-dependent  $\text{H}^+$  pumps, and the tonoplast pumps are strongly inhibited by  $\text{NO}_3^-$  ([Bytnerowicz et al., 1998](#)). If extra protons are deposited in vacuoles of the plant cells during normal cellular regulation, then additional acidity will occur in combination with additional  $\text{NO}_3^-$ . This combination can cause disruptions in cellular control ([Taylor and MacLean, 1970](#)).  $\text{NO}_3^-$  and nitrite ( $\text{NO}_2^-$ ) are metabolized to amino acids and proteins through a series of enzymatic reactions mainly involving  $\text{NO}_3^-$  and nitrite reductases ([Amundson and MacLean, 1982](#)). The ability of plants to reduce  $\text{NO}_3^-$  and  $\text{NO}_2^-$  to amino acids and proteins determines the potential of the plant to detoxify NO and  $\text{NO}_2$  ([Wellburn, 1990](#)). Reduction of  $\text{NO}_3^-$  takes place outside of the chloroplast while the reduction of  $\text{NO}_2^-$  is coupled with the light reactions of photosynthesis. Therefore, when leaves are exposed to NO and  $\text{NO}_2$  in the dark, highly phytotoxic levels of  $\text{NO}_2^-$  accumulate and may lead to greater toxicity to NO and  $\text{NO}_2$  at night ([Amundson and MacLean, 1982](#)). Exposure to NO produces both  $\text{NO}_3^-$  and  $\text{NO}_2^-$  in the leaves, but the rate of  $\text{NO}_3^-$  accumulation is much slower than  $\text{NO}_2^-$ . Thus, plants exposed to high NO could be at risk to elevated concentrations of  $\text{NO}_2^-$  ([Wellburn, 1990](#)). More detailed information on the cellular effects of NO and  $\text{NO}_2$  can be found in the 1993 Oxides of Nitrogen AQCD.

The functional relationship between ambient concentrations of NO or  $\text{NO}_2$  and a specific plant response, such as foliar injury or growth, is complex. Factors such as inherent rates of stomatal conductance and detoxification mechanisms and external factors, including plant water status, light, temperature, humidity, and the particular pollutant exposure regime, all affect the amount of a pollutant needed to cause symptoms of foliar injury. Plant age and growing conditions and experimental exposure techniques also vary widely among studies quantifying the response of plants to  $\text{NO}_2$ . An analysis conducted in the 1993 Oxides of Nitrogen AQCD of over 50 peer-reviewed reports on the effects of  $\text{NO}_2$  on foliar injury indicated that plants are relatively resistant to  $\text{NO}_2$ , especially compared to foliar injury caused by exposure to  $\text{O}_3$  ([U.S. EPA, 1993](#)). With few exceptions, visible injury has not been reported at concentrations below 0.20 ppm, and these exceptions occurred when the cumulative duration of exposures extended to 100 hours or longer. At 0.25 ppm, increased leaf abscission was reported on navel orange trees (*Citrus sinensis*), but only after exposures in excess of 1,000 hours ([Thompson et al., 1970](#)). Green bean (*Phaseolus vulgaris*) plants used as bioindicators of  $\text{NO}_2$  injury in Israel developed foliar injury symptoms when ambient concentrations exceeded 0.5 ppm ([Donagi and Goren,](#)

[1979](#)). In most plants, injury occurred in less than 1 day only when concentrations exceeded 1 ppm ([U.S. EPA, 1993](#)). In recent years (2011–2013), ambient hourly NO<sub>2</sub> concentrations in the U.S. have been well below the exposures in the above studies with maximum highest 1-hour daily concentrations less than 0.075 ppm [see Section 2.5.2 of [U.S. EPA \(2016f\)](#)].

Decreased rates of photosynthesis have been recorded in experimental exposures of plants to both NO and NO<sub>2</sub>, but usually at concentrations significantly higher than would normally be encountered in ambient air. For example, [Sabaratnam et al. \(1988\)](#) reported that soybeans (*Glycine max*) exposed 7 hours/day for 5 days showed an increase in photosynthesis at a concentration of 0.2 ppm but a decrease in net photosynthesis at a concentration of 0.5 ppm. Short-term exposures of soybean to 0.6 ppm NO<sub>2</sub> for 2 to 3 hours also had no effect on net photosynthesis ([Carlson, 1983](#)). Most plants appear to be more susceptible to NO than to NO<sub>2</sub>, as shown by [Saxe \(1986\)](#), who exposed a variety of horticultural plants raised in greenhouses (species of *Hedera*, *Ficus*, *Hibiscus*, *Nephrolepis*, and *Dieffenbachia*) to both NO and NO<sub>2</sub>. [Saxe \(1986\)](#) reported that decreases in net photosynthesis occurred at doses of NO that were 22 times less than that for NO<sub>2</sub>. However, these decreases in net photosynthesis required concentrations as high as 1 ppm NO for 12 hours to elicit a response in these plants.

In the 1970s and 1980s, hundreds of studies were conducted on the effects of NO<sub>2</sub> on growth and yield of plants. These studies varied widely in plant species, growing conditions, exposure equipment, concentrations, durations, exposure regimes, and environmental conditions during exposures. No clear dose-response relationships for exposure to NO<sub>2</sub> and reductions in growth and/or yield of plants emerged from these experiments. Readers are referred to the analysis of over 100 studies conducted in the 1993 Oxides of Nitrogen AQCD. A few key studies are highlighted in this section. The growth of several plant species appears to be susceptible to concentrations of NO<sub>2</sub> less than 0.2 ppm, particularly when exposure occurs during low light conditions. For example, nearly continuous exposure to 0.1 ppm NO<sub>2</sub> for 8 weeks significantly reduced growth of Kentucky blue grass [*Poa pratensis*; [Ashenden \(1979\)](#); [Whitmore and Mansfield \(1983\)](#)]. Eight species of tree seedlings were exposed to 0.1 ppm NO<sub>2</sub> for 6 hours/day for 28 days, resulting in reduced shoot or root growth in two species, white ash (*Fraxinus americana*) and sweetgum (*Liquidambar styraciflua*), reduced height growth in two clones of loblolly pine (*Pinus taeda*), and no effects on the other species ([Kress and Skelly, 1982](#)). No effects of NO<sub>2</sub> at 0.1 ppm or lower were observed on numerous other species, including potato (*Solanum tuberosum*), black poplar (*Populus nigra*), radish (*Raphanus sativus*), soybean, or peas [*Pisum sativum*; [U.S. EPA \(1993\)](#)]. No effects of NO<sub>2</sub> were observed on soybeans grown in field plots subjected to a series of 10 episodic exposures averaging 0.4 ppm for 2.5 or 3 hours ([Irving et al., 1982](#)).

Numerous studies have reported negative effects on growth of a variety of plants exposed to 0.5 ppm NO<sub>2</sub> and above ([U.S. EPA, 1993](#)), but these concentrations are very high relative to current ambient levels of NO<sub>2</sub> (see [Appendix 2.6.1](#)).

The 1993 Oxides of Nitrogen AQCD reviewed the extensive literature on the effects of NO<sub>2</sub> in combination with other gaseous air pollutants, particularly SO<sub>2</sub> and O<sub>3</sub>, and concluded that combinations of pollutants can cause foliar injury or decreases in photosynthesis at concentrations lower than those associated with NO<sub>2</sub> acting alone. However, the plant responses occur at concentrations much higher than typically found in ambient air in the U.S. ([U.S. EPA, 1993](#)). In addition, the presence of NO<sub>2</sub> in studies combining other gases did not produce symptoms different from those caused by the dominant pollutant, either SO<sub>2</sub> or O<sub>3</sub>, such that a plant response produced by combinations of NO<sub>2</sub> with other air pollutants in the field would be difficult, if not impossible, to distinguish from those of the other single pollutants ([U.S. EPA, 1993](#)).

Since the 1993 Oxides of Nitrogen AQCD was completed, most new research on NO<sub>2</sub> exposure to vegetation has taken place in Europe and other areas outside the U.S. For example, foliar NO<sub>3</sub> reductase activity was increased in Norway spruce (*Picea abies*) growing near a highway in Switzerland with average exposures of about 0.027 ppm compared to trees growing 1,300 m away from the highway with NO<sub>2</sub> exposures less than 0.005 ppm ([Ammann et al., 1995](#)). This result was consistent with other studies on Norway spruce in the field and laboratory ([von Ballmoos et al., 1993](#); [Thoene et al., 1991](#)). [Muller et al. \(1996\)](#) found that the uptake rate of NO<sub>3</sub><sup>-</sup> by roots of Norway spruce seedlings was decreased by exposure to 0.1 ppm of NO<sub>2</sub> for 48 hours. Similarly, soybean plants grown in Australia had decreased NO<sub>3</sub> uptake by roots and reduced growth of plants exposed to 1.1 ppm of NO<sub>2</sub> for 7 days ([Qiao and Murray, 1998](#)). In a Swiss study, poplar (*Populus × euramericana*) cuttings exposed to 0.1 ppm of NO<sub>2</sub> for approximately 12 weeks resulted in decreased stomatal density and increased specific leaf weight, but did not result in other effects such as leaf injury or a change in growth ([Günthardtgoerg et al., 1996](#)). However, NO<sub>2</sub> enhanced negative effects of ozone on poplars, including leaf injury, when the pollutants were applied in combination ([Günthardtgoerg et al., 1996](#)).

Since the 2008 ISA for Oxides of Nitrogen and Oxides of Sulfur-Ecological Criteria [hereafter referred to as the 2008 ISA ([U.S. EPA, 2008a](#))], very few studies have been published on the direct effects of NO and NO<sub>2</sub> on vegetation. [Hu et al. \(2015b\)](#) exposed clonal hybrid poplar (*Populus alba × Populus berolinensis*) saplings to 4 ppm of NO<sub>2</sub>. The authors reported significant declines in photosynthesis and dark respiration with exposures of 48 hours. They also reported stomatal dysfunction at this level of exposure resulting in partial stomatal closure and a decline in stomatal conductance. However, 4 ppm of NO<sub>2</sub> is very high relative to current ambient levels of NO<sub>2</sub> in the U.S. (see

[Appendix 2.6.1](#)). These results are consistent with past studies of plants with relatively high NO<sub>2</sub> exposure.

As part of a broad study of N deposition of a native serpentine grassland in California, [Vallano et al. \(2012\)](#) exposed five native grasses and forbs (*Plantago erecta*, *Layia gaillardoides*, *Lasthenia californica*, *Vulpia microstachys*, and *Cryptantha flaccida*) and the most common invasive grass *Lolium multiflorum* to NO<sub>2</sub> and soil N addition. The plants were exposed in a growth chamber to very low levels of NO<sub>2</sub> (0.03 ppm) to simulate recent ambient air concentrations for this ecosystem. At this relatively low NO<sub>2</sub> exposure, no significant effects were found on shoot biomass, root biomass, photosynthesis, or stomatal conductance. The authors reported that despite not finding species responses to NO<sub>2</sub> exposure, the additive effects of NO<sub>2</sub> combined with soil N on plant performance indicate that uptake of NO<sub>2</sub> may play a role in species responses to increasing N deposition. The authors found that the combined NO<sub>2</sub> and N addition resulted in a strong positive growth and competitive response in the invasive *Lolium*. This result is consistent with previous findings that low levels of NO<sub>2</sub> that are not phytotoxic to plants can add to the N load to an ecosystem from uptake through leaves ([Sparks, 2009](#)).

In a study in the Grand Canyon National Park, AZ, [Kenkel et al. \(2016\)](#) found that NO<sub>x</sub> concentrations measured by Ogawa passive samplers were about 52% higher along roadsides than 30 m away from the road. The pattern of the amount of <sup>15</sup>N in pinyon pine (*Pinus edulis*) mirrored the concentration gradient of NO<sub>x</sub> concentrations from the road, indicating that the vegetation is taking up N from the vehicle traffic in the park. The authors reported that sustained chronic N deposition on this arid environment could result in deleterious effects for these ecosystems.

Peroxyacetyl nitrate (PAN) is a well-known photochemical oxidant that often co-occurs with O<sub>3</sub> during high photochemical episodes and that has been shown to cause injury to vegetation [see reviews by [Cape \(2003\)](#), [Kleindienst \(1994\)](#), and [Temple and Taylor \(1983\)](#)]. Acute foliar injury symptoms resulting from exposure to PAN are generally characterized as a glazing, bronzing, or silvering of the underside of the leaf surface; some sensitive plant species include spinach, Swiss chard, lettuces, and tomatoes ([Temple and Taylor, 1983](#)). Petunias (*Petunia hybrida*) have also been characterized as sensitive to PAN exposures and have been used as bioindicators in areas of Japan ([Nouchi et al., 1984](#)). Controlled experiments have also shown significant negative effects on the net photosynthesis and growth of petunias and kidney beans (*Phaseolus vulgaris*) after exposure of 30 ppb of PAN for 4 hours on each of 3 alternate days ([Cape, 2003](#); [Izuta et al., 1993](#)). As mentioned previously, it is known that oxides of N, including PAN, could be altering the N cycle in some ecosystems, especially in the western U.S.,

and contributing to N saturation ([Fenn et al., 2003a](#); [Bytnerowicz and Fenn, 1996](#)). Although PAN continues to persist as an important component of photochemical pollutant episodes, there is little evidence in recent years to suggest that PAN poses a significant risk to vegetation in the U.S.

---

### 3.4 Direct Phytotoxic Effects of Nitric Acid

Relatively little is known about the direct effects of HNO<sub>3</sub> vapor on vegetation. Recent information on HNO<sub>3</sub> concentrations are given in [Appendix 2.6.3](#). The deposition velocity of HNO<sub>3</sub> is very high compared to other pollutants (see [Table 2-2](#)) and HNO<sub>3</sub> may be an important source of N for plants ([Hanson and Garten, 1992](#); [Hanson and Lindberg, 1991](#); [Vose and Swank, 1990](#)). This deposition could contribute to N saturation of some ecosystems close to sources of photochemical smog ([Fenn et al., 1998](#)). For example, in mixed conifer forests of the Los Angeles basin mountain ranges, HNO<sub>3</sub> has been estimated to provide 60% of all dry deposited N ([Bytnerowicz et al., 1998](#)). Since the 2008 ISA, a controlled exposure study ([Padgett et al., 2009a](#)) reported that 10 to 60% of the HNO<sub>3</sub> retained by foliage was incorporated into the biologically active N pool. The remainder of the HNO<sub>3</sub> was bound to foliar surfaces. This new study provides further evidence for HNO<sub>3</sub> as a contributor of biologically available N to southern California forests.

[Norby et al. \(1989\)](#) reported that exposure of 75 ppb of HNO<sub>3</sub> for 1 day increased nitrate reductase activity in red spruce (*Picea rubens*) foliage. In another study, foliar nitrate reductase activity was also increased in California black oak (*Quercus kelloggii*), canyon live oak (*Quercus chrysolepis*), and ponderosa pine (*Pinus ponderosa*) seedlings with exposure to 65 to 80 ppb of HNO<sub>3</sub> for 24 hours ([Krywult and Bytnerowicz, 1997](#)). Because the induction of nitrate reductase activity is a step in a process leading to the formation of organic N compounds (amino acids), the nitrate from HNO<sub>3</sub> could function as an alternative source of N for vegetation ([Calanni et al., 1999](#)). However, in plants under stress, the reduction of nitrate to amino acids consumes energy needed for other metabolic processes.

At high ambient concentrations, HNO<sub>3</sub> can cause vegetation damage. Seedlings of ponderosa pine and California black oak subjected to short-term exposures from 50–250 ppb of HNO<sub>3</sub> vapor for 12 hours showed deterioration of pine needle cuticle at 50 ppb in light ([Bytnerowicz et al., 1998](#)). Oak leaves, however, appeared to be more resistant to HNO<sub>3</sub> vapor, with 12-hour exposures in the dark at 200 ppb producing damage to the epicuticular wax structure ([Bytnerowicz et al., 1998](#)). The observed changes in wax chemistry caused by HNO<sub>3</sub> and accompanying injury to the leaf cuticle

([Bytnerowicz et al., 1998](#)) may predispose plants to various environmental stresses such as drought, pathogens, and other air pollutants. Because elevated concentrations of HNO<sub>3</sub> and ozone co-occur in photochemical smog ([Solomon et al., 1988](#)), synergistic interactions between the two pollutants are possible ([Bytnerowicz et al., 1998](#)). Note, however, that the experiments described above were observed at relatively short-term exposures at above ambient concentrations of HNO<sub>3</sub>. Studies of long-term effects of lower air concentrations that more closely approximate ambient HNO<sub>3</sub> are needed.

Since the 2008 ISA, [Padgett et al. \(2009b\)](#) investigated dry deposition of HNO<sub>3</sub> on the foliage of ponderosa pine, white fir (*Abies concolor*), California black oak, and canyon live oak in southern California. Using a chamber system within a greenhouse, leaves and needles were exposed to control (0 µg/m<sup>3</sup> HNO<sub>3</sub>), moderate (30 to 60 µg/m<sup>3</sup> peak HNO<sub>3</sub>), and high (95 to 160 µg/m<sup>3</sup> peak HNO<sub>3</sub>) concentrations. The high concentrations represented a high ambient concentration that occurs periodically in California. The experimental exposures resulted in a suite of damage symptoms that intensified with increasing exposure. The exposures caused substantial perturbations to the epicuticular surfaces of foliage of all four tree species studied. The damage caused by dry deposition may leave foliage more vulnerable to other copollutants such as ozone.

It has been suspected that HNO<sub>3</sub> may have caused a dramatic decline in lichen species in the Los Angeles basin ([Nash and Sigal, 1999](#)). The suggestion was strengthened by transplant of *Ramalina* lichen species from clean air habitats (Mount Palomar and San Nicolas Island) to analogous polluted habitats in the Los Angeles basin and observing death of the lichens over a few weeks in the summer ([Boonpragob and Nash, 1991](#)). Associated with this death was a massive accumulation of H<sup>+</sup> and NO<sub>3</sub><sup>-</sup> in the lichen thalli ([Boonpragob et al., 1989](#)). [Riddell et al. \(2008\)](#) exposed healthy *R. menziesii* thalli to moderate (8–10 ppb) and high (10–14 ppb) HNO<sub>3</sub> in month-long fumigations and reported a significant decline in chlorophyll content and carbon exchange capacity compared to thalli in control chambers. Thalli treated with HNO<sub>3</sub> showed visual signs of bleaching and by Day 28 were clearly damaged and dead. The damage may have occurred through several mechanisms, including acidification of pigments and cell membrane damage ([Riddell et al., 2008](#)). The authors concluded that *R. menziesii* has an unequivocally negative response to HNO<sub>3</sub> concentrations common to ambient summer conditions in the Los Angeles air basin. They believed it was very likely that HNO<sub>3</sub> contributed to the disappearance of this sensitive lichen species from the Los Angeles air basin, as well as other locations with arid conditions with high HNO<sub>3</sub> deposition loads ([Riddell et al., 2008](#)).

Since the 2008 ISA, there have been more studies published on HNO<sub>3</sub> effects on lichen in the Los Angeles basin. [Riddell et al. \(2012\)](#) studied six lichen species with differing

morphology and physiology that were collected near the Los Angeles basin. All were found to be sensitive to HNO<sub>3</sub> exposures (daily peak levels near 50 ppb) in controlled chambers. Measurements of effects included decreased chlorophyll content and chlorophyll fluorescence, decreased photosynthesis and respiration, and increased electrolyte leakage. The species showed differential sensitivity to the HNO<sub>3</sub> exposures ([Riddell et al., 2012](#)). In the same study, lichens were not reported to be sensitive to ozone exposure. This study adds to evidence that the main agent of decline of lichen in the Los Angeles basin is HNO<sub>3</sub> exposure.

In another study, [Riddell et al. \(2011\)](#) resampled 18 plots from a 1976–1977 study in the Los Angeles basin. The 1976–1977 study ([Sigal and Nash, 1983](#)) had documented an air pollution-related 50% decline of lichens described and collected in the same region in the early 1900s ([Hasse, 1913](#)). In the 2008 resampling, [Riddell et al. \(2011\)](#) found community shifts, declines in the most pollutant-sensitive lichen species, and increases in abundance of nitrogen-tolerant lichen species compared to 1976–1977. The authors also reported that these lichen communities have not recovered from the damaged state of the late 1970s, and the 2008 survey data suggest that lichen communities are further degrading. This recent observational field study further supports the evidence air pollutants such as HNO<sub>3</sub> may be causing declines in lichens in the Los Angeles basin.

---

### 3.5 Direct Phytotoxic Effects of Reduced Nitrogen Gases

Ammonia gas (NH<sub>3</sub>) can have direct phytotoxic effects. [Section 2.6.4](#) discusses recent concentrations of NH<sub>3</sub> in the U.S. The literature on effects of NH<sub>3</sub> exposure to vegetation is limited in the U.S., where fumigation studies using NH<sub>3</sub> are particularly lacking. Reduced N gases such as ammonia are not criteria air pollutants or oxides of N and therefore are not the focus of this review of the gas-phase effects. However, there are similar phytotoxic effects to oxides of N, and NH<sub>3</sub> can be a source of N nutrient effects. This section briefly covers these ammonia effects.

As with other gases, NH<sub>3</sub> is taken up through the leaf stomata in higher plants. The uptake increases as ambient air concentrations rise. In higher plants, NH<sub>3</sub> dissolves into the mesophyll and becomes toxic if the rate of uptake exceeds the ability of a plant to detoxify and assimilate NH<sub>3</sub>. This can depend on the N content of the plant, species of plant, and age of leaf ([Krupa, 2003](#)). Direct visible damage to foliage has been reported at relatively high concentrations of NH<sub>3</sub> [annual averages of about 110 ppb; 77 µg/m<sup>3</sup>; [Bytnerowicz et al. \(1998\)](#); [Van der Eerden \(1982\)](#)]. Historically, field studies on phytotoxic effects of NH<sub>3</sub> have generally been performed in Europe in close proximity to livestock farms and manure storage facilities ([Van der Eerden, 1982](#)). Because of the

rapid deposition and transformation of NH<sub>3</sub>, effects have been generally found close to sources.

Ammonia exposure can also directly affect bryophytes and lichens. These nonstomatal plants have acidic surfaces that facilitate the deposition of NH<sub>3</sub>. Several European studies have reported effects on lichen and bryophytes and have found them to be more sensitive to NH<sub>3</sub> than higher plants ([Cape et al., 2009](#)). Often less tolerant lichens disappear and are replaced by more tolerant species.

In a recent study, [Sheppard et al. \(2011\)](#) reported the effects of ammonia on vegetation in a Whim peat bog in Scotland that included stomatal and nonstomatal plants. A free air release system created a gradient of ammonia from 70 kg NH<sub>3</sub>/ha/yr down to 3–4 kg NH<sub>3</sub>/ha/yr. Three years exposure to 20–56 kg NH<sub>3</sub>/ha/yr led to large declines in species cover of *Calluna vulgaris* (a flowering shrub), *Sphagnum capillifolium* (a bryophyte), and *Cladonia portentosa* (a lichen). The authors reported that the effects were due to direct uptake by the foliage and interactions with other stresses. Whim peat bogs do not occur in the U.S. (see [Appendix 11](#) for more discussion of peat bogs), but this study may provide information about potential effects of NH<sub>3</sub> in other areas relevant to U.S. ecosystems. Studies at this site ([Sheppard et al., 2009](#); [Sheppard et al., 2008](#)) and other European studies ([Wolseley et al., 2006](#)) have been referenced as evidence for changing the European critical level to protect bryophytes, lichens, and herbaceous plants ([Cape et al., 2009](#)).

Besides being potentially phytotoxic to vegetation, NH<sub>3</sub> exposure can lead to more N inputs into plants and ecosystems through foliage uptake. In general, N content of leaves increases with NH<sub>3</sub> exposure ([Krupa, 2003](#)). Ammonia deposition that leads to N enrichment is an important consideration when evaluating total N deposition. These N nutrient effects to vegetation are discussed in [Appendix 6](#).

---

## 3.6 Summary

---

### 3.6.1 Sulfur Dioxide

The current secondary standard for SO<sub>2</sub> is a 3-hour average of 0.50 ppm, which is designed to protect against acute foliar injury in vegetation. There has been limited research on acute foliar injury since the 1982 PM-SO<sub>x</sub> AQCD, and there is no clear evidence of acute foliar injury below the level of the current standard. The limited

research since 2008 adds more evidence on acute effects of SO<sub>2</sub> on vegetation but does not change conclusions from the 2008 ISA on the levels producing the effects.

Effects on growth and yield of vegetation are associated with increased SO<sub>2</sub> exposure concentration and time of exposure. The 1982 PM-SO<sub>x</sub> AQCD concluded that more definitive concentration-response studies were needed before useable exposure metrics could be identified. Very few studies have been reported on the effects of SO<sub>2</sub> on growth of U.S. vegetation since the 1982 PM-SO<sub>x</sub> AQCD. Recent studies from eastern Europe indicate recovery of tree growth correlated to falling SO<sub>2</sub> concentrations since the 1980s. [Elling et al. \(2009\)](#) reported that annual SO<sub>2</sub> concentrations of 4 ppb appeared to reduce silver fir (*Abies alba*) growth. There may be similar effects of SO<sub>2</sub> emissions on trees in West Virginia ([Thomas et al., 2013](#)), but more research is needed to further investigate the mechanisms of the apparent recovery of tree growth to link this phenomenon with declines in ambient SO<sub>2</sub> that have occurred since the 1980s.

Limited new evidence from 2008 to the present continue to support the causal findings of the 2008 ISA. As a whole, **the body of evidence is sufficient to infer a causal relationship between gas-phase SO<sub>2</sub> and injury to vegetation.**

---

### 3.6.2 Nitrogen Oxide, Nitrogen Dioxide, and Peroxyacetyl Nitrate

It is well known that in sufficient concentrations, NO, NO<sub>2</sub>, and PAN can have phytotoxic effects on plants through decreasing photosynthesis and induction of visible foliar injury ([U.S. EPA, 1993](#)). However, the 1993 Oxides of Nitrogen AQCD concluded that concentrations of NO, NO<sub>2</sub>, and PAN in the atmosphere are rarely high enough to have phytotoxic effects on vegetation ([U.S. EPA, 1993](#)). Since the 1993 Oxides of Nitrogen AQCD, very little new research has been performed on these phytotoxic effects at concentrations currently observed in the U.S.

Since the 2008 ISA ([U.S. EPA, 2008a](#)), very few studies have been published on the direct effects of NO, NO<sub>2</sub>, and PAN on vegetation; thus, **the body of evidence is sufficient to infer a causal relationship between gas-phase NO, NO<sub>2</sub>, and PAN and injury to vegetation.**

---

### 3.6.3 Nitric Acid

The 2008 ISA reported experimental exposure of HNO<sub>3</sub> resulted in damage to the leaf cuticle of pine and oak seedlings, which could predispose those plants to other stressors such as drought, pathogens, and other air pollutants ([U.S. EPA, 2008a](#)). Since the 2008

ISA, [Padgett et al. \(2009b\)](#) investigated dry deposition of HNO<sub>3</sub> on the foliage, with findings that supported the earlier research. The 2008 ISA also reported several lines of evidence in lichen studies, including transplant and controlled exposure studies, indicating that past and current HNO<sub>3</sub> concentrations contributed to the decline in lichen species in the Los Angeles basin ([U.S. EPA, 2008a](#)). Since the 2008 ISA, there have been more exposure and field survey studies published on the effects of HNO<sub>3</sub> on lichen in the Los Angeles basin ([Riddell et al., 2012](#); [Riddell et al., 2011](#)). These new studies continue to support the causal findings of the 2008 ISA. As a whole, **the body of evidence is sufficient to infer a causal relationship between gas-phase HNO<sub>3</sub> and changes to vegetation.**

---

## APPENDIX 4 SOIL BIOGEOCHEMISTRY

This appendix characterizes how nitrogen (N) and sulfur (S) deposition contribute to total loading of N and S in the soils of nonagricultural terrestrial ecosystems ([Appendix 4.2](#)) and how this loading causes soil acidification and eutrophication by altering soil chemical pools and processes ([Appendix 4.3](#)). Additional topics are discussed, including soil monitoring and databases ([Appendix 4.4](#)), soil biogeochemistry models ([Appendix 4.5](#)), national-scale soil sensitivity to N and S deposition ([Appendix 4.6](#)), climate modification of soil response to N ([Appendix 4.7](#)), and a summary ([Appendix 4.8](#)). The effects of altered soil biogeochemistry on terrestrial biota due to soil acidification and eutrophication are discussed in [Appendix 5](#) and [Appendix 6](#), respectively. Soil biogeochemistry that has been altered by N may also be linked to aquatic biogeochemistry, which is discussed in [Appendix 7](#).

---

### 4.1 Introduction

The *2008 ISA for Oxides of Nitrogen and Oxides of Sulfur—Ecological Criteria* (hereafter referred to as the 2008 ISA) documented that the main effects of N and S deposition on terrestrial soils were N enrichment and acidification. Since the 2008 ISA, there is new evidence on how deposition contributes to total N and S loading in terrestrial ecosystems, as well as the effects of deposition on soil chemical pools and processes. This evidence is from addition, gradient, and time-series studies. Many of the new studies focus on the effects of N deposition, with relatively little work focusing on S deposition. There are improved models to evaluate ecosystem responses to deposition, most of which are applicable at watershed scales. Some may be applied regionally. Soil N enrichment and soil acidification occur in sensitive ecosystems across the U.S. at recent levels of deposition. Decreasing emissions of S have led to early signs of recovery from soil acidification in some northeastern watersheds; however, areas in the Southeast do not show any appreciable recovery of soils. There are no signs of recovery of N enrichment effects in soils. Critical load (CL) determinations for soils have been made at the ecoregion scale for  $\text{NO}_3^-$  leaching and some soil acidification indicators. **The body of evidence is sufficient to infer a causal relationship between N and S deposition and alteration of soil biogeochemistry in terrestrial ecosystems**, which is consistent with the conclusions of the 2008 ISA.

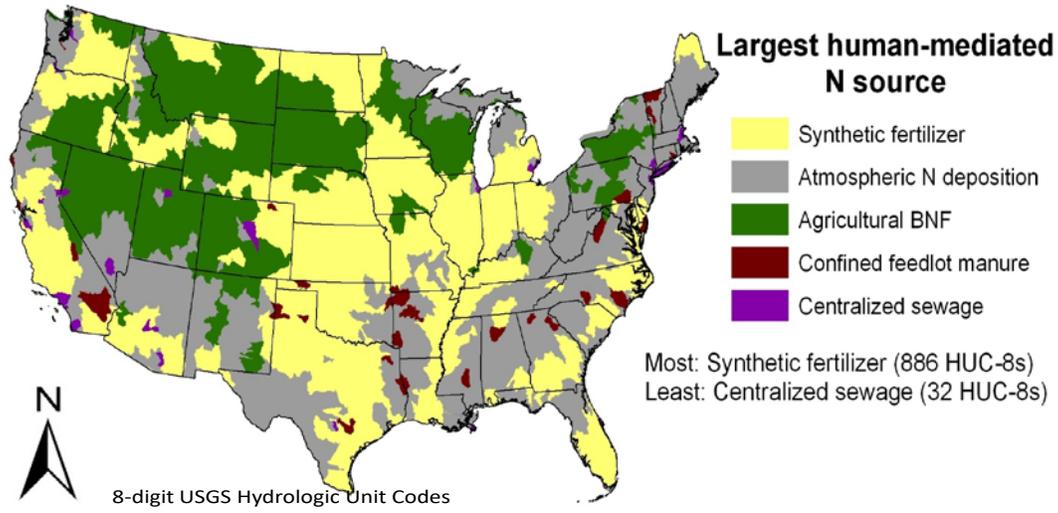

---

## 4.2 Nitrogen and Sulfur Sources to Soil

The 2008 ISA documented that atmospheric deposition is the main source of anthropogenic N to nonagricultural and nonurban terrestrial ecosystems and headwater streams. In 2008 it was well known that the global pool of reactive N ( $N_r$ ) had increased over the previous century, largely due to three main causes: (1) widespread cultivation of legumes, rice, and other crops that support bacteria capable of converting diatomic nitrogen gas ( $N_2$ ) to organic N through biological N fixation; (2) fossil fuel combustion converting atmospheric  $N_2$  and fossil N to total oxidized N ( $NO_Y$ ); and (3) the Haber-Bosch process, which converts nonreactive  $N_2$  to  $N_r$  for N fertilizer production and some industrial activities ([Galloway et al., 2003](#); [Galloway and Cowling, 2002](#)). Food production was known to account for much of the conversion of  $N_2$  to  $N_r$ . N was shown to be geographically redistributed through food shipment to meet human needs and often returned to the environment via wastewater.  $N_r$  was known to accumulate in the environment on local, regional, and global scales ([Galloway et al., 2003](#); [Galloway and Cowling, 2002](#); [Galloway, 1998](#)) in the atmosphere, soil, and water ([Galloway and Cowling, 2002](#)), with a multitude of effects on humans and ecosystems ([Townsend et al., 2003](#); [Rabalais, 2002](#); [van Egmond et al., 2002](#); [Galloway, 1998](#)). The term the “N cascade” was coined to refer to the sequence of transfers, transformations, and environmental effects ([Galloway et al., 2003](#); [Galloway and Cowling, 2002](#)).

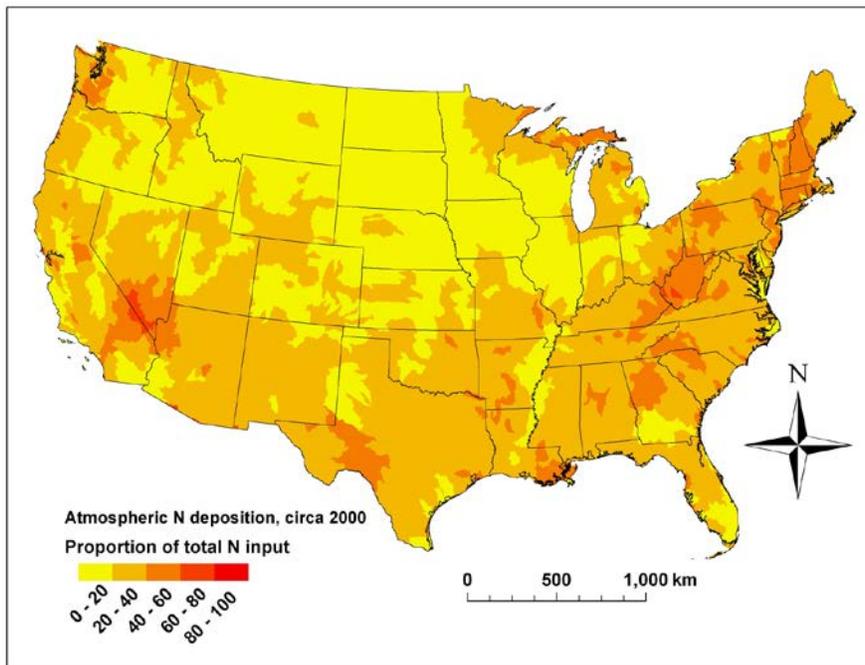

Since 2008, a number of estimates have been made of the relative contribution of sulfate, oxidized N, and reduced N from atmospheric deposition. The most recent estimates are summarized in [Appendix 2](#). Maps showing the geographic distribution of deposition are presented for total acidifying (N + S) deposition ([Figure 2-12](#)), total N deposition ([Figure 2-13](#)), and total S deposition ([Figure 2-31](#)). Maps depicting how the relative contribution of oxidized and reduced N species varies across the U.S. are presented in [Figure 2-14](#).

Several new studies have been published since the 2008 ISA on the source of N inputs to ecosystems; however, no new studies on S sources to ecosystems have been identified. [Sobota et al. \(2013\)](#) quantified sources and fluxes of reactive N inputs to U.S. lands and waterways and found human-mediated N inputs are spatially heterogeneous across the country, ranging up to 34.6-fold the background N input across all of the 8-digit hydrologic unit codes (HUC-8s). Across the contiguous U.S. (CONUS), synthetic N fertilizer and atmospheric N deposition are the largest and second-largest overall human-mediated N inputs to ecosystems, and the single largest sources in 41 and 33% of HUC-8s, respectively ([Figure 4-1](#) and [Figure 4-2](#)).

BNF = biological nitrogen fixation; HUC-8 = 8-digit hydrologic unit code; N = nitrogen; USGS = U.S. Geological Survey.  
Source: Map presented in [Sobota et al. \(2013\)](#).

**Figure 4-1** Dominant sources of nitrogen across the U.S. at 8-digit hydrologic unit codes.

N = nitrogen.  
Source: Modified from data presented in [Sobota et al. \(2013\)](#).

**Figure 4-2** Percentage of nitrogen input from nitrogen deposition at 8-digit hydrologic unit codes.

At the global scale, [Fowler et al. \(2013\)](#) estimated the relative contributions of five sources of N that contribute to emissions and deposition, all of which are predicted to change through the end of this century. Two new studies, both in the western U.S., have confirmed that N from the weathering of sedimentary and metasedimentary rock can be a source of N to some ecosystems ([Montross et al., 2013](#); [Morford et al., 2011](#)), although [Sobota et al. \(2013\)](#) suggested that anthropogenic sources of N are more significant at the landscape scale.

---

### 4.3 Soil Pools and Processes

Eutrophication and acidification are two biogeochemical processes that can occur in response to the inputs of N and S deposition. These processes can alter the biogeochemistry in terrestrial ecosystems, and they may occur either in sequence or simultaneously in a given geographic area. N driven eutrophication is typically indicated by N accumulation (e.g., increased soil N concentrations or decreased C:N ratios). These indicators of N accumulation are directly linked to biological effects in the soil, including changes in microbial-mediated decomposition and nitrification. N added to terrestrial ecosystems can also be lost through leaching from the soil, typically as nitrate ( $\text{NO}_3^-$ ), or through emissions to the atmosphere, primarily via denitrification ([Galloway et al., 2003](#); [Galloway and Cowling, 2002](#)). Denitrification is a microbial process that reduces  $\text{NO}_3^-$  to either unreactive  $\text{N}_2$  gas, nitrogen oxide (NO), or the potent greenhouse gas nitrous oxide ( $\text{N}_2\text{O}$ ). S addition to an ecosystem typically causes S accumulation and variable amounts of leaching from the soil, which in turn leads to acidification because demand for S as a nutrient is low compared to human-caused soil stores of organic and inorganic S.

Soil acidification results from the accumulation of hydrogen ions ( $\text{H}^+$ ). This occurs naturally through the production of carbonic acid and organic acids, as well as through plant cation uptake ([Charles and Christie, 1991](#); [Turner et al., 1991](#)). The rate of soil acidification can increase as a result of soil acidification caused by the deposition of the inorganic acids  $\text{HNO}_3$  and  $\text{H}_2\text{SO}_4$ . In addition,  $\text{NH}_x$  deposition contributes to soil acidification by stimulating nitrifying bacteria that derive energy by oxidizing the  $\text{NH}_4^+$  to  $\text{NO}_3^-$ . A byproduct of nitrification is the production of a  $\text{H}^+$  ion, but whether there is a net effect on soil acidity depends upon the fate of the  $\text{NO}_3^-$ . If the  $\text{NO}_3^-$  is leached with a base cation, then the  $\text{H}^+$  is left behind and the soil become more acidic. If, however, the  $\text{NO}_3^-$  is denitrified, then the  $\text{H}^+$  from nitrification is neutralized by  $\text{OH}^-$  generated by denitrification. Likewise, if  $\text{NO}_3^-$  is taken up by a plant root, the root will exude an  $\text{OH}^-$  in exchange.

Decreases in soil pH attributable to acid deposition have been documented throughout the U.S. ([Sullivan et al., 2006b](#); [Bailey et al., 2005](#); [Johnson et al., 1994b](#); [Johnson et al., 1994a](#)). Inorganic and organic acids can be neutralized by soil weathering or base cation exchange, in addition to denitrification. However, because soils vary in their capacity to neutralize incoming acidity, the effects of acidification have been heterogeneous across the U.S. In addition, pollutant loadings vary across the U.S. The primary chemical effects of acidification in soils that have biological effects include the loss of important base cation nutrients such as Ca and Mg, as well as the mobilization of aluminum (Al) cations of varied speciation, several of which are toxic to many organisms. The quantities of precipitation and runoff are important determinants of base cation leaching and acidification ([Van Breemen et al., 1984](#)). The accelerated loss of base cations through leaching, decrease in base saturation, and decreased in soil solution Ca:Al ratio all serve as indicators of soil acidification.

Studies published since the 2008 ISA augment our knowledge of previously identified effects of N addition on soils. The following sections document the empirical evidence of N effects on multiple pools, processes, and indicators associated with the general effects of N enrichment and eutrophication ([Table 4-1](#)). These sections summarize the empirical effects of N and S addition on soil biogeochemistry, often based on results from addition or gradient studies. The publications summarized here present information on multiple processes and indicators; therefore, individual papers are often discussed in more than one section.

**Table 4-1 Summary of key soil geochemical processes and indicators associated with eutrophication and acidification.**

### 4.3.1 Nitrogen Pathways and Pools

The 2008 ISA documented that N is stored primarily in the soil in forest ecosystems, and soil N often exceeds 85% of the total ecosystem N ([Cole and Rapp, 1981](#); [Bormann et al.,](#)

1977). Experimental  $^{15}\text{N}$  addition studies showed that trees typically take up only a small fraction of added  $^{15}\text{N}$ ; most is retained in the soil N pool (Providoli et al., 2005; Templer et al., 2005; Nadelhoffer et al., 1999a; Tietema et al., 1998). However, these experiments were criticized for applying  $^{15}\text{N}$  directly to the soil surface, thereby precluding direct canopy uptake of N from wet or dry deposition and limiting inference for N deposition effects (Sievering et al., 2000; Sievering, 1999). Forest canopies take up an average of 16% of total atmospheric N input (Lovett, 1992), but this uptake could be considerably higher (up to 90%) in some N limited forests with large epiphyte loads (Klopatek et al., 2006). It is unclear how much of the N from deposition retained by vegetation was used in photosynthetic enzymes and would thus contribute to increased productivity (Bauer et al., 2004).

Most soil N is contained in organic matter, typically bound in organo-mineral complexes or large-molecular-weight organic compounds (Schmidt et al., 2011; Schimel and Bennett, 2004). These pools of N are not directly available for uptake by plants or microbes, and the relative immobility of these compounds means they contribute little to the leaching loss of N into ground or surface waters. To enter the actively cycling portion of the ecosystem N pool, recalcitrant organic N must be converted into inorganic forms (e.g.,  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ ) or small-molecular-weight organic compounds (e.g., amino acids, amino sugars), typically through the activity of extracellular enzymes produced by soil microorganisms. The size of this N pool often controls net primary productivity (NPP; see Appendix 6), but plants compete with microorganisms for available N.

Since 2008 there is new research using  $^{15}\text{N}$  to trace pathways and pools in ecosystems (Table 4-2), including a new paper confirming the previous conclusion that ecosystem N is primarily stored in forest mineral soil (Perakis et al., 2011). There is also new evidence that litter is the largest sink for added N in grasslands, shrublands, and wetlands (Templer et al., 2012).

New studies have also been conducted tracing pathways of N in ecosystems through time. In Swiss grasslands, N addition increased ecosystem N storage in plant biomass, both in living plant biomass as well as litter, but did not affect soil N (Bassin et al., 2015). In a temperate forest ecosystem in Switzerland, application of  $^{15}\text{N}$  tracer in a solution to simulate wet deposition showed increased dissolved organic N and enrichment of soil microbes and plant roots within the first day. When plots were resampled a year later, litter and soil pools, particularly soil organic matter, were enriched with the N tracer (Morier et al., 2008). These results confirm that deposited N is incorporated rapidly into ecosystem pools and is stored primarily in litter and recalcitrant organic matter in the soil.

**Table 4-2 Pathways and pools.**

Process/Indicator	Type of Ecosystem	Region	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Effect of Deposition	Reference
Mineralization	Semiarid	Southern California	Up to 35–45 for N	Two applications per yr of 30 kg N	N fertilizer additions resulted in faster gross N cycling rates. Greater net release or greater net immobilization of N was observed at different sampling times and likely related to seasonality of C availability.	<a href="#">Sirulnik et al. (2007b)</a>
N pools	Temperate hardwood forest	Swiss Prealps	16		The litter layer retained approximately 19–28% of the <sup>15</sup> N tracer after 1 day. The authors concluded that the processes relevant for the fate of atmospherically deposited N take place rapidly and that N recycling within the microbe-plant-soil organic matter system prevents further losses in the long term.	<a href="#">Morier et al. (2008)</a>
N turnover times	Semiarid grassland	Not specified	Not specified	5 as NH <sub>4</sub> NO <sub>3</sub>	Model for N cycling was developed using observations of <sup>15</sup> N. The temporal dynamics of <sup>15</sup> N fractions (labeled-N fractions) in plant and microbial biomass are closely tied to the turnover time of these N pools	<a href="#">Dijkstra (2009)</a>
N pathway		Höglwald, Bavaria, Germany	45		After two to three decades of high loads of N deposition, a new equilibrium was reached, characterized by substantial losses of N to the groundwater (approximately 20 kg NO <sub>3</sub> <sup>-</sup> ) and to the atmosphere (16 kg N in form of N <sub>2</sub> O, NO, and N <sub>2</sub> ). Ecosystem N retention is dominated by microbial immobilization, which was about a factor of three higher than plant N uptake.	<a href="#">Kreutzer et al. (2009)</a>
N pathway	Simulated northern hardwood forest	Michigan, Great Lakes region	7 to 12	30	Tracing <sup>15</sup> NO <sub>3</sub> <sup>-</sup> revealed that N accumulated in soil organic matter by first flowing through soil microorganisms and plants, and that the shedding of <sup>15</sup> N-labeled leaf litter enriched soil organic matter.	<a href="#">Zak et al. (2008)</a>

**Table 4-2 (Continued): Pathways and pools.**

Process/Indicator	Type of Ecosystem	Region	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Effect of Deposition	Reference
N pools	Temperate forest	Oregon coast range	2.0	None	Mineral soil accounted for 96–98% of total ecosystem N. Soil water $^{15}\text{NO}_3^-$ patterns suggested a shift in relative N losses from denitrification to $\text{NO}_3^-$ leaching as N accumulated, and simulations identified $\text{NO}_3^-$ leaching as the primary N loss pathway that constrains maximum N accumulation.	<a href="#">Perakis et al. (2011)</a>
N pools	Soil $^{15}\text{N}$	Global	Varied across 48 studies	Varied across 48 studies	A meta-analysis of studies at 48 sites across four continents shows the largest sinks for $^{15}\text{N}$ tracers among ecosystem types were organic soil in forests (35.5%, n = 31) and foliage in tundra (12.1%, n = 3). Litter was the largest sink in grasslands (25.5%, n = 9), shrublands (33.8%, n = 6), and wetlands (34.1%, n = 2).	<a href="#">Templer et al. (2012)</a>
N pools	Common garden experiment, five broadleaved tree species	Denmark	13 to 19 for broadleaf forest 18 to 26 for Norway Spruce		Tree species influenced N cycling and $^{15}\text{N}$ patterns through multiple species-specific traits. The type of mycorrhiza association, light regime, and ground vegetation differed between ash and sycamore and beech, lime, oak, and Norway spruce.	<a href="#">Callesen et al. (2013)</a>
Pools and pathway N uptake	Subalpine (seminatural) pasture	Alp Flix, a high plateau near Sur, Grosons, Switzerland	4	0, 5, 10, 25, and 50 as $\text{NH}_4\text{NO}_3$	Plant N pools increased by 30–40% after N addition, while soil pools remained unaffected.	<a href="#">Bassin et al. (2015)</a>
N cycling	All	Global	Not specified	None	Synthesis of recent literature that did not include new quantitative analysis.	<a href="#">Niu et al. (2016)</a>

**Table 4-2 (Continued): Pathways and pools.**

Process/Indicator	Type of Ecosystem	Region	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Effect of Deposition	Reference
Throughfall NH <sub>4</sub> <sup>+</sup> , NO <sub>3</sub> <sup>-</sup> , and SO <sub>4</sub> <sup>2-</sup> Base cations Dry N deposition	<i>Quercus ilex</i> forests ranging from Mediterranean climate to a drier, more seasonal climate		Not specified	None	Rainfall and net NH <sub>4</sub> <sup>+</sup> throughfall were negatively correlated at all sites. Rainfall and net NO <sub>3</sub> <sup>-</sup> -N throughfall correlation varied between negative and positive. Rainfall and net SO <sub>4</sub> <sup>2-</sup> throughfall were positively correlated at wet sites and negatively correlated at the drier site.	<a href="#">Aguillaume et al. (2017)</a>
Canopy throughfall	Holm oak forests ( <i>Quercus ilex</i> L.) in the north, center, and north-east of the Iberian Peninsula	Europe-Iberian Peninsula	Wet deposition ranged between 1.2 to 5.8, and dry deposition ranged from 1.5 to 14		Canopies retained ranged between 0.5 and 12 ka/ha/yr. Both NH <sub>4</sub> <sup>+</sup> and NO <sub>3</sub> <sup>-</sup> showed higher retention at the agricultural and rural sites (50–60%) than at sites located close to big cities (20–35%).	<a href="#">Avila et al. ### 4.3.2 Nitrogen Accumulation, Saturation, and Leaching

In the 2008 ISA, a documented indicator of terrestrial N driven eutrophication was the accumulation of N in soil. Atmospherically deposited N can accumulate in soil as inorganic N or by incorporating N into organic matter. The ability of atmospheric N pollution to cause an accumulation of N in soil is indicated by a positive correlation between the atmospheric deposition rate and total N concentration in the Oa horizon observed at sites in New York, Vermont, New Hampshire, and Maine ([Driscoll et al., 2001b](#)). Accumulation of soil N as a result of N deposition has been either documented or suggested to occur across large areas of the U.S. ([Aber et al., 2003](#)) including semiarid ecosystems ([Padgett et al., 1999](#)). There is also evidence for soil N accumulation from mass-balance studies of experimental N additions ([Campbell et al., 2004b](#)). Further evidence that atmospheric deposition increased the availability of N in soil is provided by the strong negative correlation between atmospheric N deposition and the C:N ratio of the Oa soil horizon across the northeastern U.S. ([Aber et al., 2003](#)). Soil N accumulation is linked to increased N leaching.

New studies ([Table 4-3](#)) confirm that, across terrestrial ecosystem types, N addition increases soil N concentrations. In semiarid shrublands in southern California, [Vourlitis and Fernandez \(2012\)](#) observed that N additions increased soil N. [Lu et al. \(2011a\)](#) conducted a meta-analysis of N cycle responses to N additions using data from 206 peer-reviewed studies. They observed mean increases in N leaching, soil inorganic N, soil total N pool, as well as increases in the litter N, organic horizon N, and mineral soil N; the only pool that decreased was microbial N ([Figure 4-3](#)).

Thresholds of N deposition associated with the onset of elevated  $\text{NO}_3^-$  leaching have been previously identified. Atmospheric deposition of 8 to 10 kg N/ha/yr resulted in the onset of  $\text{NO}_3^-$  leaching to surface waters throughout the eastern U.S. Slightly lower N deposition levels (5–10 kg N/ha/yr) led to  $\text{NO}_3^-$  leaching in the Rocky Mountains, and this was attributable to colder temperatures, shorter growing season, slow soil development, extensive exposed bedrock, and rapid melting of large snowpacks ([Williams and Tonnessen, 2000](#); [Williams et al., 1996c](#); [Baron et al., 1994](#)). Lastly, deposition loads of 17 kg N/ha/yr led to the onset of  $\text{NO}_3^-$  leaching in the Sierra Nevada and San Bernardino mountains ([Fenn et al., 2008](#)).

Den = denitrification; DON = dissolved organic N; N = nitrogen; N-min = net N mineralization; Nit = nitrification; Ps = photosynthesis; SIN = soil inorganic N; SNP = soil N pool.

Source: [Lu et al. \(2011a\)](#).

**Figure 4-3** A conceptual framework for the responses of the ecosystem nitrogen (N) cycle to nitrogen (N) addition.

The 2008 ISA documented that N saturation occurred when the input of N to the terrestrial ecosystem chronically exceeded the uptake capacity of the soils and biota, causing a large fraction of the incoming N to leach from soils to surface waters ([Stoddard, 1994](#); [Aber et al., 1989](#)). N saturation had been observed or suggested to occur across large areas of the U.S. ([Adams et al., 2000](#); [Aber et al., 1998](#); [Adams et al., 1997](#); [Peterjohn et al., 1996](#); [Cook et al., 1994](#); [Edwards and Helvey, 1991](#); [Aber et al., 1989](#)).

New evidence ([Table 4-3](#)) from an N tracer study confirms that N retention varies across ecosystem types and is highest in shrublands (89.5%) and wetlands (84.8%), followed by forests (74.9%), and grasslands [51.8%; [Templer et al. \(2012\)](#)]. Other significant factors affecting long-term  $^{15}\text{N}$  recovery (a proxy for N retention in N tracer studies) were mycorrhizal association (ericoid > ecto > arbuscular), plant growth form, and site history (less retention on former agricultural sites). The influence of biotic processes on N retention is evident at smaller scales. Among nine forested sites along an urban-to-rural landscape gradient in the Boston, MA area, throughfall inorganic N deposition increased with proximity to the urban core, with inorganic N deposition rates positively correlated with rates of soil inorganic N leaching across the sites ([Rao et al., 2014](#)). Measurements of  $\delta^{15}\text{N}$  and  $\delta^{18}\text{O}$  in soil  $\text{NO}_3^-$  leachate indicated no clear relationship between microbial nitrification and proximity to the urban core—evidence that factors other than N availability influenced N processing. Overall, it is clear from recent research that N retention is strongly influenced by biotic factors (e.g., mycorrhizae, plant growth form) and environmental conditions (e.g., precipitation).

Leaching of N tends to increase with increasing N addition. Where  $^{15}\text{N}$  tracer studies were conducted as part of N addition experiments, the N additions decreased  $^{15}\text{N}$  retention. In  $^{15}\text{N}$  studies with multiple N addition treatments, a negative correlation between retention and the rate of N additions was observed ([Templer et al., 2012](#)). In Europe, [Dise et al. \(2009\)](#) documented approximately 95% of forests receiving less than 8 kg N/ha/yr still had leaching, typically less than 1 kg N/ha/yr. Additional work on monitoring data in Sweden by [Khalili et al. \(2010\)](#) showed a clear sudden increase in  $\text{NO}_3^-$  leaching in regions where N deposition exceeded 7.5 kg/ha/yr ([Appendix 4.4](#)). In the U.S. there are new studies modeling N leaching in eastern U.S. forests [[Phelan et al. \(2016\)](#); [Fakhraei et al. \(2016\)](#); [Table 4-3](#)].

N leaching is an indicator of ecosystem N saturation. New studies ([Table 4-3](#)) suggest the N saturation concept ([Aber et al., 1998](#)) may need revision in response to observations of N cycling in temperate forests ([Lovett and Goodale, 2011](#)) and chaparral ([Homyak et al., 2014](#)). [Lovett and Goodale \(2011\)](#) proposed a new model of N saturation that distinguished capacity N saturation, in which the vegetation and soil sinks for N have been filled, from kinetic N saturation, in which the plant and soil sinks are accumulating

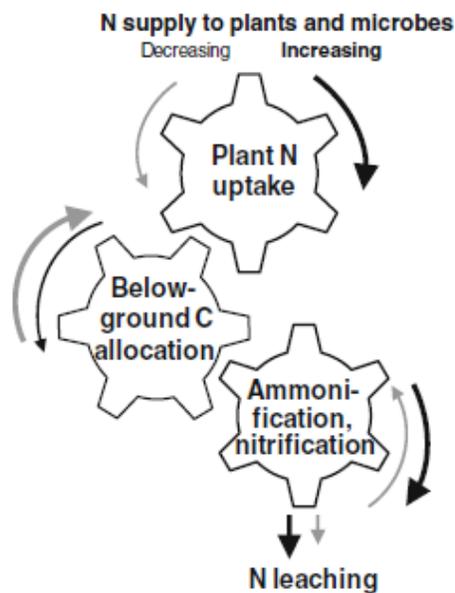

N, but the rate of N accumulation is slower than the N input rate. One implication of this new model is that  $\text{NO}_3^-$  leaching can occur even if the ecosystem N retention capacity has not yet been saturated, as is observed at many sites [e.g., [Lovett and Goodale \(2011\)](#); [Talhelm et al. \(2012\)](#); [Homyak et al., 2014](#)]. New information confirms the applicability of the capacity N saturation concept in northwest forests ([Perakis and Sinkhorn, 2011](#)), although the new idea of kinetic N saturation is particularly useful in describing N cycling processes in California chaparral ([Homyak et al., 2014](#)). At chaparral sites, N added during the dry season is lost from the ecosystem, while N added during the growing season is retained in plant biomass ([Vourlitis and Pasquini, 2009](#); [Grulke et al., 2005](#)). In these systems, water scarcity limits plant productivity, microbial C availability, and denitrification, all of which cause  $\text{NO}_3^-$  to be flushed from surface soils during large precipitation events ([Menon et al., 2010](#)). Large leaching losses of N in arid ecosystems are evidence for kinetic saturation.

New research highlights the importance of deposition of N from mobile sources along roadsides ([Fenn et al., 2018](#); [Bettez et al., 2013](#)). The higher deposition along roadsides in Cape Cod, MA was associated with a two- to fourfold greater rate of nitrate leaching from the soils. Approximately 15% less N from deposition was retained 10 m from the road than sites more distant removed from the road. N deposition contribution to N in the watershed may be underestimated by 13–25% when roadside deposition and the associated leaching are not included. In a U.S. nationwide evaluation of on road emissions of ammonia, [Fenn et al. \(2018\)](#) found  $\text{NH}_4^+:\text{NO}_3^-$  ratios in urban deposition reflected elevated  $\text{NH}_3$  from emissions, and that on-road  $\text{NH}_3$  emissions exceeded agricultural emissions in locations where 40% of the population resides.

New research highlights the role of the microbial community in N saturation. [Kopáček et al. \(2013\)](#) developed a conceptual model in which N saturation is associated with shifts in the microbial community, namely a decrease in the fungi-to-bacteria ratio, and a transition from N to C limitation. In N enriched systems, three mechanisms could lead to lower amounts of bioavailable dissolved organic C (DOC) for the microbial community and to C limitation: (1) lower plant allocation of nutrients to roots in response to increased nutrient availability, leading to a decrease in plant exudates; (2) chemical suppression of DOC solubility by soil acidification; and (3) enhanced bacterial mineralization of DOC due to increased abundance of electron acceptors in the form of  $\text{NO}_3^-$  in anoxic soil. In support of this model, recent studies indicate that N retention in semiarid shrublands is driven more by spatial and temporal variations in labile C availability than exceedance of N storage capacity ([Vourlitis and Fernandez, 2015](#)). Furthermore, [Högberg et al. \(2013\)](#) found that forest soils with low concentrations of  $\text{NO}_3^-$  and Al had a higher fungi:bacteria ratio compared with stands having higher concentrations of  $\text{NO}_3^-$  and Al (negative correlation,  $r = -0.857$ ). Fungi:bacteria ratio,

and a second indicator, stem growth, explained 70% of the variation in N and Al leaching (see broader discussion of N effects on microbial community composition in [Appendix 6](#)).

[Högberg et al. \(2013\)](#) proposed a hypothetical model to account for the effects of N supply on plant N uptake and belowground C allocation, microbial production of inorganic N, and N leaching ([Figure 4-4](#)). Shifts in N mineralization, nitrification, and leaching from forests might occur in response to N loading as a result of decreasing tree allocation of C to belowground roots, and ultimately, to ectomycorrhizal fungi and other C limited soil microbes. When N supply increases, ectomycorrhizal fungi and other rhizosphere microbes become progressively more C limited, and their abundance and activity decline. Microbial assimilation of N diminishes, and N mineralization increases, whereas the fungi:bacteria ratio decreases. Increasing  $\text{NH}_4^+$  levels and decreasing organic C supply stimulate leaching, and denitrification. Increasing N loading can alter plant C allocation, causing shifts in microbial activity and community composition that in turn increase  $\text{NO}_3^-$  leaching from the ecosystem ([Figure 4-4](#)).

C = carbon; N = nitrogen.

Thick arrows indicate an increasing rate whereas thin arrows mean decreasing rate. Nitrogen supply increases are indicated by black arrows.

Source: [Högberg et al. \(2013\)](#).

**Figure 4-4** A hypothetical model to account for the effects of nitrogen supply on plant nitrogen uptake and belowground carbon allocation, microbial production of inorganic nitrogen, and nitrogen leaching.

**Table 4-3 Nitrogen accumulation, saturation, and leaching.**

Process/Indicator	Type of Ecosystem	Region	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Effect of Deposition	Reference
N leaching	Forest	248 sites (plot and catchment scale) from 15 countries in Europe	Varied	Not reported	<b>Gradient:</b> The most consistent indicators of N leaching were throughfall N deposition, organic horizon C:N ratio, and mean annual temperature. Sites receiving low levels of N deposition (8 kg N/ha/yr) showed very low output fluxes of N. In general, the models successfully predicted N leaching (mean of $\pm 5$ kg N/ha/yr between observed and predicted) from forests at early to intermediate stages of N saturation but not from N saturated sites.	<a href="#">Dise et al. (2009)</a>
N accumulation N leaching	Mesic desert	Spanish Spring Valley, NV	Not specified	None	<b>Field experiment:</b> Concluded that vadose soil resources (water and organic C) are rare. Unused $\text{NO}_3^-$ from low biological demand is transported and accumulated in the deeper vadose zone with occasional deep leaching events.	<a href="#">Menon et al. (2010)</a>
N saturation	Oak forest	Southeastern New York State	9	100 $\text{NH}_4\text{NO}_3$ (1996–1999) 50 $\text{NH}_4\text{NO}_3$ (2000–2006)	<b>Conceptual model:</b> New N saturation model based on an N addition study of an oak forest in southeastern New York State.	<a href="#">Lovett and Goodale (2011)</a>
N accumulation	Meta-analysis		Varied	Varied	<b>Meta-analysis:</b> N cycle responses to N additions using data from 206 peer-reviewed studies and observed a mean increase in N soil pools except microbial biomass N ( <a href="#">Figure 4-12</a> ).	<a href="#">Lu et al. (2011a)</a>

**Table 4-3 (Continued): Nitrogen accumulation, saturation, and leaching.**

Process/Indicator	Type of Ecosystem	Region	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Effect of Deposition	Reference
N saturation N accumulation N mineralization nitrification	Douglas fir forest	Oregon coast range	2.0	None	<b>Gradient:</b> This is a test of the N saturation theory along a natural N gradient. Higher N content of surface (0–10 cm) soil was linearly related to higher net N mineralization. Lower pH was related to lower nitrification. The ratio of net to gross N mineralization to higher nitrification increased along the gradient, indicating progressive saturation of microbial N demand.	<a href="#">Perakis and Sinkhorn (2011)</a>
N leaching	Douglas fir forest	Oregon coast range	2.0	None	<b>Gradient:</b> Hydrologic N losses were dominated by dissolved organic N at low N sites, with increased nitrate loss causing a shift to dominance by nitrate at high N sites, particularly where net nitrification exceeded plant N demands.	<a href="#">Perakis and Sinkhorn (2011)</a>
N leaching	48 sites across four continents  Grassland, forest, wetland, shrubland	Global	Varied across 48 studies	Varied across 48 studies	<b>Meta-analysis:</b> The greatest recoveries of ecosystem <sup>15</sup> N tracer occurred in shrublands (mean, 89.5%) and wetlands (84.8%) followed by forests (74.9%) and grasslands (51.8%).	<a href="#">Templer et al. (2012)</a>
Soil N, C:N	Chaparral and coastal sage scrub (CSS)	Southern California	6–8.1	56 to 58	<b>Addition:</b> In this 6-yr field experiment, chaparral and CSS vegetation communities were found to have the capacity to immobilize 6.2 and 11.9 g N/m <sup>2</sup> /yr, respectively. Soil extractable N increased significantly after 7–10 g/m <sup>2</sup> of cumulative N exposure, resulting in a simultaneous increase in the N concentration and a decline in the C:N ratio of shrub tissue. Similar results were observed for the surface litter pool and litter production but at a higher cumulative N exposure.	<a href="#">Vourlitis and Fernandez (2012)</a>

**Table 4-3 (Continued): Nitrogen accumulation, saturation, and leaching.**

Process/Indicator	Type of Ecosystem	Region	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Effect of Deposition	Reference
NO <sub>3</sub> <sup>-</sup> leaching	Forest	Cape Cod, MA	Annual throughfall deposition was 8.7 (±0.4) and 6.8 (±0.5) TDN at sites 10 and 150 m away from the road	None	<b>Roadside gradient:</b> 25 to 30% higher N deposition to forests 10 m away from roads on Cape Cod, compared to hundreds of meters away from the road; the higher deposition was associated with a two to four-fold greater rate of nitrate leaching from the soils. 73% of the deposition was retained in the forest away from roads, compared to 58% retention at 10 from the road. Results scaled to the entire watershed indicate an underestimate of the amount of N deposition to the watershed by 13–25% by not including roadside deposition and leaching.	<a href="#">Bettez et al. (2013)</a>
Soil [NO <sub>3</sub> <sup>-</sup> ] Soil [Al] Fungi:bacteria ratio	19 <i>Picea abies</i> (L.) Karst. Stands	South Sweden	Throughfall N includes wet and dry inputs and ranged from 2.7 to 19	Ammonium NO <sub>3</sub> <sup>-</sup> at 20	<b>Addition:</b> Microbial community composition in the organic horizon and soil solution chemistry below the rooting zone were highly correlated. Stands with low concentrations of NO <sub>3</sub> <sup>-</sup> and Al had higher fungi:bacteria ratio compared with stands with higher concentrations of NO <sub>3</sub> <sup>-</sup> and Al. Microbial community composition in the soil was more closely related to the soil solution than to the soil chemistry. The study found a significant negative correlation between the fungi:bacteria ratio in the soil and NO <sub>3</sub> <sup>-</sup> and Al in soil solution ( $r = -0.533$ and $-0.857$ , respectively).	<a href="#">Högberg et al. (2013)</a>
N saturation	None (theoretical)	None (theoretical)	Not specified	None	<b>Conceptual model:</b> N addition alleviates N limitation, and together with SO <sub>4</sub> <sup>2-</sup> deposition, causes soil acidification and increases availability of electron acceptors for soil microbial processes. Increasing N and SO <sub>4</sub> <sup>2-</sup> decreases fungal biomass, increases bacterial DOC mineralization, and decreases DOC leaching.	<a href="#">Kopáček et al. (2013)</a>

### 4.3.3 Sulfate Accumulation, Adsorption, and Leaching

The 2008 ISA showed that  $\text{SO}_x$  deposition may be assimilated by vegetation or microbes, accumulate in the soil, or act as a mobile ion and leach out of the soil to aquatic ecosystems. Plant demand for S is typically low, particularly in comparison to the large pools of S stored in the soil in recalcitrant organic compounds; consequently, almost all S deposited in terrestrial ecosystems enters soil rather than plant pools. At many locations in the U.S. that receive high levels of S deposition, notably the glaciated Northeast and upper Midwest, much of the deposited S leaches through soils into streams and lakes. The physical process of charge balance pairs sulfate ( $\text{SO}_4^{2-}$ ) leaching with leaching of countercharged cations from the soil matrix, and this process contributes to acidification of soil, soil water, and surface water. As the base cations become depleted in the soil matrix, charge balance in the soil is maintained by an increase in acidic cations ( $\text{H}^+$  and inorganic Al), sometimes resulting in toxic conditions for plant roots and aquatic organisms ([Charles and Christie, 1991](#); [Turner et al., 1991](#)).

In the 2008 ISA, regional trends of  $\text{SO}_4^{2-}$  soil accumulation and leaching were identified in the U.S. In the Southeast, accumulation of atmospherically deposited S in soil resulted from  $\text{SO}_4^{2-}$  adsorption to soil particles as well as incorporation of S into soil organic matter through biological assimilation. Accumulated S can be slowly released from soil pools into drainage water, and this process can temporarily delay ecosystem recovery in response to decreases in S deposition ([Sullivan et al., 2004](#); [Elwood et al., 1991](#); [Turner et al., 1991](#)). In the Northeast, there was a demonstrated accumulation of S in soil ([Driscoll et al., 2001a](#)). Two new studies on  $\text{SO}_4^{2-}$  accumulation, leaching, and adsorption are described below ([Table 4-4](#)).

The net loss of S from soils is occurring in a number of northeastern watersheds in response to decreased levels of atmospheric S deposition. In a new study evaluating watersheds in the Northeast, [Mitchell and Likens \(2011\)](#) calculated that annual discrepancies in the watershed S budgets ( $\text{SO}_4^{2-}$  flux in drainage waters minus total atmospheric S deposition) have become more negative, indicating the increasing importance of the release of S from internal ecosystem sources. The release of S from forest soils is controlled (57%) by water flux and soil moisture ([Mitchell and Likens, 2011](#)).

In the southeastern U.S., [Rice et al. \(2014\)](#) calculated  $\text{SO}_4^{2-}$  mass balances for 27 forested, unglaciated watersheds from Pennsylvania to Georgia by using total atmospheric deposition (wet plus dry) as input. Unlike their counterparts in the northeastern U.S. and southern Canada, many of these watersheds still retain  $\text{SO}_4^{2-}$ . [Rice](#)

[et al. \(2014\)](#) predicted that many of the watersheds in the study will begin releasing  $\text{SO}_4^{2-}$  over the next two decades. The specific years when the watersheds cross over from retaining to releasing  $\text{SO}_4^{2-}$  correspond to a general geographical pattern from north to south of later net watershed release. For instance, the three watersheds in West Virginia have crossover years that ranged from 2006 to 2011, and crossover years for five of the watersheds in Virginia range from 2012 to 2021. The runoff ratio, computed as the ratio of annual mean discharge to annual mean precipitation, was the single best watershed-scale predictor of the crossover year ( $r^2 = 0.72$ ). Watersheds with higher runoff ratios tend to convert sooner from net retention to net release of  $\text{SO}_4^{2-}$  ([Rice et al., 2014](#)). More recently, [Fakhraei et al. \(2016\)](#) used PnET-BGC to model 30 stream watersheds during 1981–2014 in the Great Smoky Mountains National Park. Hindcast modeling (beginning ca. 1850) to 2014 showed that the soil  $\text{SO}_4^{2-}$  pools increased from 20.2 g/m<sup>2</sup> (preindustrial) to 145.6 g/m<sup>2</sup> (ambient median). Soils with high  $\text{SO}_4^{2-}$  adsorption capacity also had a faster rate of base cation depletion. In general, soils with high  $\text{SO}_4^{2-}$  adsorption capacity will have more  $\text{SO}_4^{2-}$  release for longer periods of time during the recovery period from acidification, thereby having a faster rate of base cation depletion compared to soils with low  $\text{SO}_4^{2-}$  adsorption capacity during the recovery period.

**Table 4-4 Sulfate adsorption, accumulation, and leaching.**

Process/Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference
Sulfate adsorption and cation leaching	Upland forests, low-lying areas and wetlands	Athabasca oil sands region (AOSR) in Alberta, Canada	Not specified	None	<b>Field comparison:</b> SO <sub>4</sub> <sup>2-</sup> adsorption capacity was relatively low (50 to 500 mg SO <sub>4</sub> <sup>2-</sup> /kg) in both watersheds as compared to other acid-sensitive soils in eastern North America.	<a href="#">Jung et al. (2011)</a>
S budget	Varied	15 sites southeastern Canada and northeastern U.S.	~0.1 to 14		<b>Long-term deposition:</b> The net annual fluxes of SO <sub>4</sub> <sup>2-</sup> showed a strong relationship with hydrology; the sensitivity of S budgets is likely greatest in watersheds with the greatest wetland area, which are particularly sensitive to drying and wetting cycles.	<a href="#">Mitchell et al. (2011)</a>
Sulfate accumulation and leaching	Forest	HBEF in the White Mountains of New Hampshire	~7 to 20	None	<b>Long-term deposition:</b> S released from internal sources is increasing over time. Watershed wetness, as a function of log <sub>10</sub> annual water flux explained 57% (n = 157) of the annual variation for four watersheds. The biogeochemical control of annual SO <sub>4</sub> <sup>2-</sup> export in stream water draining from forested watersheds has shifted from control by atmospheric S deposition to soil moisture driven by climate.	<a href="#">Mitchell and Likens (2011)</a>

**Table 4-4 (Continued): Sulfate adsorption, accumulation, and leaching.**

Process/Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference
SO <sub>4</sub> <sup>2-</sup> leaching	Watersheds ranging from Pennsylvania to Georgia	27 forested, unglaciated watersheds	Not specified	None	<b>Long-term deposition:</b> Calculated SO <sub>4</sub> <sup>2-</sup> mass balances for 27 watersheds showed that over the next two decades, many of the study's watersheds will begin releasing SO <sub>4</sub> <sup>2-</sup> . The single most important variable that explained the crossover year was the runoff ratio, defined as the ratio of annual mean stream discharge to precipitation.	<a href="#">Rice et al. (2014)</a>
Soil SO <sub>4</sub> <sup>2-</sup>	Forest	Great Smoky Mountains National Park	3.1 kg S/ha/yr (19.3 mmolc/m <sup>2</sup> /yr)	None	<b>Model:</b> PnET-BGC used to model 30 stream watersheds during 1981–2014 when SO <sub>4</sub> <sup>2-</sup> and NO <sub>3</sub> <sup>-</sup> deposition decreased (81 and 53%, resp.). AOSR = Athabasca oil sands region; HBEF = Hubbard Brook Experimental Forest; kg = kilogram; NO<sub>3</sub><sup>-</sup> = nitrate; S = sulfur; SO<sub>4</sub><sup>2-</sup> = sulfate; yr = year.

---

#### 4.3.4 Base Cation Leaching and Exchange

In the 2008 ISA, it was known that acidifying deposition changes concentrations of exchangeable base cations in soil by accelerating natural rates of base cation leaching until stores become depleted ([Lawrence et al., 1999](#); [Cronan et al., 1978](#)). Base cations include the essential plant nutrients (e.g., Ca, Mg, and K), and the loss of exchangeable base cations from the soil may have adverse effects on flora. When  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  leaching occur in equal magnitude to base cation leaching, the drainage water is not acidified. However, in the process of neutralizing the acidity of drainage water, base cation release from soil eventually can cause decrease of the base saturation of the soil. Soil base saturation expresses the concentration of exchangeable bases (Ca, Mg, potassium [K], sodium [Na]) as a percentage of the total cation exchange capacity (which includes exchangeable  $\text{H}^+$  and inorganic Al).

Under conditions of low soil base saturation (approximately <20%) and elevated concentrations of strong acid anions, Al is mobilized from soil to drainage water ([Cronan and Schofield, 1990](#); [Reuss, 1983](#)), with potentially harmful consequences for sensitive terrestrial plants and aquatic organisms ([Appendix 7](#)) throughout the food web ([Appendix 4.3.6](#)).

Leaching of base cations by acidifying deposition has been documented in sensitive regions in the U.S., including the Adirondack Mountains, New England, the Catskill Mountains, and northwestern Pennsylvania ([U.S. EPA, 2008a](#)). Base cation loss increases the sensitivity of the watershed to further acidifying deposition. Watersheds that were capable of fully neutralizing a particular level of acidifying deposition in the past may no longer be capable of fully neutralizing that level today or in the future due to the cumulative effect of acidifying deposition on soil base saturation.

Base saturation values less than 10% predominate in the soil B-horizon in the areas in the U.S. where soil and surface water acidification from acidifying deposition have been most pronounced, including conifer and hardwood forests in the Adirondack Mountains ([Sullivan et al., 2006b](#)), red spruce forests throughout the Northeast ([David and Lawrence, 1996](#)), hardwood forests in the Allegheny Plateau ([Bailey et al., 2004](#)), and conifer and hardwood forests in the southern Appalachian Mountains ([Sullivan et al., 2003](#)). In a study of sugar maple decline throughout the Northeast, [Bailey et al. \(2004\)](#) found threshold relationships between base cation availability in the upper B soil horizon and sugar maple mortality at Ca saturation less than 2%, and Mg saturation less than 0.5% ([Bailey et al., 2004](#)). The authors concluded that base saturation varied as a function of topography, geologic parent material, and acidifying deposition.

New publications further support findings from the 2008 ISA that N and S deposition cause base cation depletion from soils ([Table 4-5](#)). In the Rocky Mountains, [Lieb et al. \(2011\)](#) observed that soil acid buffering capacity decreased as N inputs increased (40% decrease at highest N input). An acidification threshold was calculated for significant loss of soil acid buffering capacity of around 28 kg N/ha/yr. In another U.S. study, long-term trends in base cation depletion at Bear Brook Watershed, ME, showed N and S addition over a 17-year time period (while ambient S deposition was simultaneously decreasing) resulted in little evidence of continued soil exchangeable base cation depletion or recovery [expected because of decreasing S deposition; [SanClements et al. \(2010\)](#)]. A study of the forest understory herb community in West Virginia found that N addition lowered plant-available Ca and, to a lesser degree, Mg, but not K, illustrating how biogeochemical cycling of forest ecosystems is altered ([Gilliam et al., 2016a](#)).

A meta-analysis of 107 studies found N addition alters the availability of base cations in terrestrial and aquatic ecosystems ([Lucas et al., 2011](#)): although short-term N and S deposition cause base cation depletion, long-term trends across all studies are unclear and may be affected by confounding disturbances. Evaluating the strength of these results is difficult because they are based on averages from various biome types and there are few long-term studies.

Field studies in forests in Europe confirm that N deposition and N addition lower soil pH and decrease base cations ([Chen et al., 2015](#); [Ferretti et al., 2014](#)). As acidifying deposition decreased, base cation concentration in the soil increased ([Berger et al., 2016](#)). Two studies from grasslands in Asia report mixed results, with N addition causing base cation levels to decrease in one study ([Chen et al., 2015](#)) and increase in another ([Tian et al., 2016b](#)). A study of European grasslands found that base cation depletion increased with N addition over a 10-year period, leading to a loss of 23 to 35% of total available bases ( $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{K}^+$ , and  $\text{Na}^+$ ) from the soil and acidifying it by 0.2 to 0.4 pH units ([Horswill et al., 2008](#)).

Base cation weathering rates are uncertain, but substantial advancements have been made in this field since the 2008 ISA ([Appendix 4.5.1.1](#)). New model estimates have been published for two forested areas in Canada ([Williston et al., 2016](#); [Watmough et al., 2014](#)).

Major sources of base cations to ecosystems are either from atmospheric deposition or weathering from soils. Two additional studies from Spain considered the sources of base cations in ecosystems from deposition ([Aguillaume et al., 2017](#)) or as compared with sources from different types of soil parent material ([Eimil-Fraga et al., 2016](#)).

Additional literature that evaluates how base cation depletion from acidification may recover in response to the addition of base cations to the soil is also noted here; however, this literature does not describe the effects of N and S deposition, but rather a method for recovering ecosystems to a more natural state. This literature includes several publications from a 15-year Ca addition study at Hubbard Brook Experimental Forest (HBEF), NH ([Shao et al., 2016](#); [Johnson et al., 2014](#); [Green et al., 2013](#); [Nezat et al., 2010](#)).

**Table 4-5 Base cation leaching and exchange.**

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference
Base cation depletion Soil pH Soil [Al], [Fe], [Mg]	Grasslands	Peak District National Park, England	Not specified	Plots treated for 8 to 10 yr with 0, 35, or 140 N as NH <sub>4</sub> NO <sub>3</sub>	<b>Addition:</b> Treatments caused grassland soils to lose 23 to 35% of their total available bases (Ca <sup>2+</sup> , Mg <sup>2+</sup> , K <sup>+</sup> , and Na <sup>+</sup> ), and they became acidified by 0.2 to 0.4 pH units. Al, Fe, and Mn were mobilized and taken up by limestone grassland forbs and were translocated down the acid grassland soil. Mineral N availability increased in both grasslands and many species showed foliar N enrichment. N deposition depletes base cations from grassland soils.	<a href="#">Horswill et al. (2008)</a>
Base cation depletion	Hardwood forest	Eastern U.S., Bear Book watershed, ME		28.8 S and 25.2 N as (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub>	<b>Addition:</b> Compared treated and untreated watersheds after N and S manipulation over a 17-yr time period. Found little evidence of continued soil exchangeable base cation concentration depletion or recovery, possibly because a 1998 ice storm increased litterfall and accelerated mineralization, obscuring temporal trends in soil chemistry.	<a href="#">SanClements et al. (2010)</a>
Base cation depletion Critical load	Forest stands with mature white ash	Niwot Ridge in southern Rocky Mountains	8	20, 40, 60 N	<b>Addition:</b> Soil acid buffering capacity decreased with increasing N inputs (40% decrease at highest input), and was associated with a decrease in pH, loss of extractable Mg <sup>2+</sup> and increases in Mn and Al <sup>3+</sup> . The threshold at which acidification occurred was around 28 kg N/ha/yr.	<a href="#">Lieb et al. (2011)</a>
Base cation depletion	Boreal forest, temperate forest, tropical forest, and grassland	107 sites globally	Not specified	Median N addition across the studies was 38, and 71% of the studies added 70 or less	<b>Meta-analysis:</b> Evaluation of 107 independent studies to determine whether N fertilization alters the availability of base cations (Bc) in terrestrial and stream ecosystems. Results suggest N fertilization may accelerate Bc loss from terrestrial ecosystems over time periods less than 5 yr.	<a href="#">Lucas et al. (2011)</a>

**Table 4-5 (Continued): Base cation leaching and exchange.**

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference
Base cation leaching	Jack pine ( <i>Pinus banksiana</i> ) and aspen ( <i>Populus tremuloides</i> ) in upland forests and black spruce ( <i>Picea mariana</i> ) in low-lying areas and wetlands.	Athabasca oil sands region (AOSR), Alberta, Canada	Not specified for AOSR	30 N, 30 S (2006 through 2009)	<b>Addition:</b> No evidence of N saturation in the studied forest ecosystem after 4 yr of N and S additions. No long-term increase of inorganic N concentrations in the soil; leaching of N beyond the main rooting zone in the soil profile was minimal, and tree growth was increased by N addition, all indications of N limitation in the studied forest stand. However, exchangeable Ca <sup>2+</sup> and Mg <sup>2+</sup> concentrations in the surface mineral soil layer were reduced by N and S additions because of increased cation leaching associated with increased SO <sub>4</sub> <sup>2-</sup> leaching caused by S addition and increased nutrient uptake associated with increased tree growth resulting from N addition.	<a href="#">Jung and Chang (2012)</a>
Hydrologic flowpath	Forest	HBEF, NH	Not specified	41 metric tons of the mineral wollastonite (CaSiO <sub>3</sub> ) was applied to an 11.8-hectare watershed	<b>Addition:</b> The flow path of the added Ca was followed through time. The deepest flowpaths to the streams were penetrated by 3–9 yr after application. It was estimated that only ~360 kg out of 19 metric tons of Ca applied as wollastonite had been exported from the watershed in stream flow 9 yr after its application and it would take 1,000 yr for all of the added Ca to be transported from the watershed.	<a href="#">(Nezat et al. (2010)</a>
Evapotranspiration	Forest	HBEF, NH	Not specified	1,028 kg Ca/ha (as wollastonite) in 1999	<b>Field observation:</b> 25, 18, and 19%, evapotranspiration, increased in years 1–3 after addition and then returned to pretreatment levels. Watershed soil retained Ca from the wollastonite, indicating a watershed-scale fertilization effect on transpiration. That response is unique in being a measured manipulation of watershed runoff attributable to fertilization.	<a href="#">Green et al. (2013)</a>

**Table 4-5 (Continued): Base cation leaching and exchange.**

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference
Total Ca, exchangeable Ca, cation exchange capacity, base saturation	Forest	Hubbard Brook Experimental Forest, NH	Not specified	1,028 kg Ca/ha (as wollastonite) in 1999	<b>Field observation:</b> Compared to conditions before the 1999 Ca addition, total Ca increased 596% in the Oie-horizon in 2000, 81% in the Oa-horizon in 2002, and 146% in the 0–10 cm mineral soil in 2006.  Oie-horizon exchangeable Ca tripled in 2000 and remained significantly higher through 2010. Significant increases occurred in 2002 in Oa; modest increases measured in upper mineral soil in 2006 and 2010. Total Ca pool in O-horizon and mineral soils was 250 kg/ha greater than pretreatment. In total, 92.4% of Ca added was estimated to dissolve and enter the ecosystem as labile Ca. Cation exchange capacity CEC increased by 106% in the Oie-horizon in 2010 but decreased 52 and 32% in the Oa and mineral soil. Oie, Oa, and mineral soil base saturation rose 69, 84, and 58%, resp. by 2010.	<a href="#">Johnson et al. (2014)</a>
pH Base cations	Forest soils	Italy	4.5 to 28.8 throughfall N (NO <sub>3</sub> <sup>-</sup> + NH <sub>4</sub> <sup>+</sup> )	Not applicable	<b>Gradient:</b> Exchangeable base cations and pH decreased with increasing N deposition, and foliar nutrient N ratios (especially N:P and N:K) increased. Comparison between bulk open-field and throughfall data suggested possible canopy uptake of N, levelling out for bulk deposition >4–6 kg/ha/yr.	<a href="#">Ferretti et al. (2014)</a>
Bc weathering rate	Boreal plains	NE Alberta, Canada	S = 118, NH <sub>4</sub> <sup>+</sup> = 93, NO <sub>3</sub> <sup>-</sup> = 49 in units of mmolc m <sup>2</sup> /yr	Not applicable	<b>Modeling:</b> base cation weathering rate estimated for 63 sites using PROFILE was 17 mmolc m <sup>2</sup> /yr, however acidification was not expected because base cations from fugitive dust sources were a comparatively high 250 mmolc m <sup>2</sup> /yr, offsetting much of the acidifying input of N and S deposition.	<a href="#">Watmough et al. (2014)</a>
pH Soil N Base cations Fungi:bacteria ratio Belowground biomass Microbial community Structure	Semiarid grassland	Mongolia	Not specified	0, 17.5, 52.5, 105.0, 175, and 280 NH <sub>4</sub> NO <sub>3</sub> fertilizer	<b>Addition:</b> Soil pH decreased across the N addition gradient by 0.3–1.8 units in 2010 and by 0.1–1.7 units in 2011. Decreased concentrations of mineral cations Ca <sup>2+</sup> , Mg <sup>2+</sup> , and Na <sup>+</sup> were observed. The observed increases in above- and belowground biomass and changes in plant community structure were mainly (57–69%) attributed to the increase in soil N availability and changes in soil base cations. N addition increased the fungi:bacteria ratio by 5–18% in 2010 and by 2–10% in 2011.	<a href="#">Chen et al. (2015)</a>

**Table 4-5 (Continued): Base cation leaching and exchange.**

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference
Base saturation		Adirondack Mtns. region, NY	SO <sub>4</sub> <sup>2-</sup> = 290.3–365.7 eq/ha/yr; NO <sub>3</sub> <sup>-</sup> = 172. 5–233.5 eq/ha/yr	None	<b>Model:</b> PnET-BGC was used to evaluate biophysical factors that affect CLs of acidity. Model simulations included a range of future scenarios of decreases in atmospheric nitrate, ammonium, and sulfate deposition from the present to 2,200; historical forest harvesting; supply of naturally occurring organic acids; and variations in lake hydraulic residence time.  Assuming the current soil base saturation of 6.4%, a decrease in SO <sub>4</sub> <sup>2-</sup> deposition from 0 to 100% resulted in a soil percentage BS range of 6.2 to 15.3%, respectively, after 200 yr. (Preindustrial soil percentage BS ~22%).	<a href="#">Zhou et al. (2015c)</a>
Bc	Predominantly beech	Vienna Woods, Austria	Not specified locally	None	<b>Time Series:</b> In 1984 and 2012, soil samples were taken from 20 cm downhill and 3 m away from the base of a beech tree stem. Exchangeable Ca <sup>2+</sup> , Mg <sup>2+</sup> , and pH increased in 0–5 cm soil from 1984 to 2012. Recovery appeared delayed in deeper soils. Foliar base cations Ca, Mg, and K decreased. (Foliar K declined the most at 48%).	<a href="#">Berger et al. (2016)</a>
Bc	Maritime pine forest	Northwest Spain	Not specified	None	<b>Field observation:</b> The soil parent material (slate, biotitic schist, mica schist, and granite) significantly affected base cation concentrations.	<a href="#">Eimil-Fraga et al. (2016)</a>
Foliar base cation	Eastern U.S. temperate, hardwood forest herbaceous layer ( <i>Viola rotundifolia</i> , <i>Rubus allegheniensis</i> )	Fernow Experimental Forest, WV	~10 kg N/ha/yr (wet)	35 kg N/ha/yr (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub>	<b>N Addition:</b> Foliar measurements were used as a proxy for soil micronutrient availability under N addition. Excess N lowered plant-available Ca and, to a lesser degree, Mg, but not K. N addition significantly affected Ca:Al ratios in <i>Viola</i> sp. and <i>Rubus</i> sp.	<a href="#">Gilliam et al. (2016a)</a>

#### 4.3.5 Aluminum Mobilization

The 2008 ISA documented that when soil base saturation is 15 to 20% or lower, acidifying deposition can mobilize inorganic Al, which can lead to its leaching into soil solution and into surface waters ([Cronan and Schofield, 1990](#); [Reuss and Johnson, 1985](#); [Reuss, 1983](#)). Leaching of inorganic Al is an extremely important effect of acidifying deposition because some forms of inorganic monomeric Al, including  $\text{Al}^{3+}$  and various hydroxide species, are toxic to tree roots, fish, algae, and aquatic invertebrates ([Appendix 5](#) and [Appendix 8](#)). Increased concentrations of exchangeable inorganic Al in the soil have been identified through repeated sampling in the U.S. and Europe over periods ranging from 17 to 41 years in studies by [Billett et al. \(1990\)](#), [Falkengren-Grerup and Eriksson \(1990\)](#), [Bailey et al. \(2005\)](#), and [Lawrence et al. \(1995\)](#).

The negative biological effects of Al mobilization are discussed in [Appendix 5](#); in general, Al disrupts Ca uptake by tree roots ([Shortle and Smith, 1988](#)). Substantial evidence of this relationship has been provided through field studies ([Kobe et al., 2002](#); [Minocha et al., 1997](#); [Shortle et al., 1997](#); [McLaughlin and Tjoelker, 1992](#); [Schlegel et al., 1992](#)) and laboratory studies ([Cronan and Grigal, 1995](#); [Sverdrup and Warfvinge, 1993](#)). These studies make clear that high inorganic Al concentration in soil water can be toxic to plant roots. The toxic response is often related to the concentration of inorganic Al relative to the concentration of Ca, expressed as the molar ratio of Ca to inorganic Al in soil solution. From an exhaustive literature review, [Cronan and Grigal \(1995\)](#) estimated a 50% risk of adverse effects on tree growth if the molar ratio of Ca to Al in soil solution was as low as 1.0. They estimated a 100% risk for adverse effects on growth at a molar ratio value Ca:Al <0.2 in soil solution and minimal to no risk is thought to occur at Ca:Al >10.

New studies on Al in soils are summarized in [Table 4-6](#) and include an investigation of long-term soil solution chemistry trends in Hubbard Brook Experimental Forest ([Fuss et al., 2015](#)), an investigation of the influence of increasing dissolved organic matter (DOM) on toxic inorganic Al ( $\text{Al}_i$ ) concentration in 52 Adirondack and Hubbard Brook watersheds ([Fakhraei and Driscoll, 2015](#)), an investigation of the effects of soil parent material on Al ([Eimil-Fraga et al., 2016](#)), a model comparison of three models' predictions of soil solution Al concentrations in three monitored Swiss and German forests ([Bonten et al., 2015](#)), and a study showing that N addition increased Al mobilization on grasslands in England ([Horswill et al., 2008](#)).

[Fakhraei and Driscoll \(2015\)](#) evaluated the influence of increasing DOM on  $\text{Al}_i$  concentration in the Adirondacks and Hubbard Brook. The authors linked a PnET-BGC

model chemical equilibrium subroutine with an optimization algorithm. They determined that accounting for the increasing concentration of DOM (as acid deposition decreases and ANC increases) and its binding capacity for  $Al_i$  is necessary in the model to avoid substantial overestimation of available toxic  $Al_i$  in waters. In an empirical study, [Fuss et al. \(2015\)](#) found that  $Al_i$  in soil solution in the mineral horizon decreased over the period of 1984–2011 (also discussed in the recovery [Appendix 4.6.1](#)).

---

### 4.3.6 Nitrification and Denitrification

Nitrification is the microbial oxidation of ammonia or ammonium to form nitrite followed by the oxidation of the nitrite to form  $\text{NO}_3^-$ . The 2008 ISA documented that oxidation of ammonia into nitrite is performed by two groups of organisms, ammonia-oxidizing bacteria and ammonia-oxidizing archaea. The rate of nitrification is controlled by numerous factors, including substrate availability (presence of  $\text{NH}_4^+$ ), aeration (availability of  $\text{O}_2$ , often as well-drained soils with <60% soil moisture), and acidity (pH). N addition may increase nitrification, which is often stimulated in soils with a C:N ratio below about 20 to 25 (Ross et al., 2004; Aber et al., 2003). The microbial process of autotrophic nitrification is an acidifying process, releasing 2 moles of hydrogen ion ( $\text{H}^+$ ) per mole of  $\text{NH}_4^+$  converted to  $\text{NO}_3^-$  (Reuss and Johnson, 1986). As the N cycle becomes enriched through cumulative N addition, N becomes more abundant, competition among organisms for N decreases, net nitrification rates often increase, and  $\text{NO}_3^-$  can leach from the soil (Aber et al., 2003; Aber et al., 1989).

Soils with a C:N ratio below about 20 to 25 are associated with stimulated mineralization, nitrification, and cation leaching (Ross et al., 2004; Aber et al., 2003). This observation makes the C:N ratio an especially useful field measurement that provides a relative index rather than a quantitative rate of N leaching (Ross et al., 2004). C:N ratios in the forest floor are generally inversely related to acidifying deposition levels, although the relationship is stronger for hardwood stands than conifer stands (Aber et al., 2003). The C:N ratio is a reliable and relatively straightforward measure for identifying forest ecosystems that may be experiencing soil acidification and base leaching as a result of N input and increased nitrification.

Denitrification is the microbial process that transforms  $\text{NO}_3^-$  by anaerobically reducing it to nitrite ( $\text{NO}_2^-$ ), nitric oxide (NO), the greenhouse gas nitrous oxide ( $\text{N}_2\text{O}$ ) and  $\text{N}_2$ . The 2008 ISA documented that in terrestrial ecosystems, denitrification mainly occurs in oxygen-depleted soils (e.g., during periods of water saturation), groundwater, and riparian zones. Soil pH has a marked effect on denitrification, with lower rates in acidic as compared with alkaline conditions (Yamulki et al., 1997). Soil denitrification and  $\text{N}_2\text{O}$  production and consumption are extremely variable in time and space (McClain et al., 2003).

New information published since 2008 is summarized in Table 4-7. New empirical work along an N deposition gradient in Oregon found that nitrification increased with increasing N deposition (Perakis and Sinkhorn, 2011); likewise, denitrification increased with N deposition in northeastern forests (Morse et al., 2015a). In a deposition exclusion

study in Europe, after two decades of deposition exclusion, net nitrification and  $\text{NO}_3^-$  concentration in soils were not detectable, and in fact, the soil switched from a net source of  $\text{NO}_y$  to a net sink ([Eickenscheidt and Brumme, 2012](#)).

A growing body of information indicates that increased N deposition also alters the soil microbial community ([Freedman et al., 2013](#)). Discussion of this is provided in [Appendix 6](#). [Marusenko et al. \(2013\)](#) explored the role of fungi in  $\text{NO}_3^-$  and  $\text{N}_2\text{O}$  production in soils from regions across the southwestern U.S. and found that fungi are significant sources of  $\text{N}_2\text{O}$  production in soils in semiarid grasslands and deserts. [Russow et al. \(2008\)](#) found that soils with high soil organic matter adsorbed added  $\text{NH}_4^+$ , making it difficult to determine microbial activity.

Several new syntheses evaluated N addition effects on denitrification and nitrification in terrestrial ecosystems ([Yang et al., 2017](#); [Bouwman et al., 2013](#); [Lu et al., 2011a](#); [Liu and Greaver, 2009](#)). Globally, the amount of N removed from ecosystems by denitrification may be higher in terrestrial ecosystems than from groundwater or riparian zones ([Bouwman et al., 2013](#)); however, other older estimates have indicated more denitrification may occur in riparian wetlands and in first-order streams than in terrestrial ecosystems ([Van Breemen et al., 2002](#)), although the authors acknowledged this estimate likely underestimated terrestrial N. [Liu and Greaver \(2009\)](#) showed that N addition significantly increased denitrification from all ecosystems tested (coniferous forest, deciduous forest, tropical forest, wetland, grassland) except heathland. Among the five chemical forms of N fertilizer added to ecosystems in studies,  $\text{NO}_3^-$  showed the strongest stimulation of  $\text{N}_2\text{O}$  emission ([Figure 4-5](#)). [Lu et al. \(2011a\)](#) further confirmed that N addition stimulates nitrification and denitrification ([Figure 4-6](#)). Using data extracted from 206 peer-reviewed papers, the meta-analysis showed that the largest changes caused by N addition in the ecosystem N cycle were increased nitrification (154%), nitrous oxide emission (134%), and denitrification (84%). In addition, [Yang et al. \(2017\)](#) evaluated N cycling in five biomes in California and found a strong ( $r^2 = 0.34$ ) significant linear correlation between  $\text{NO}_3^-$  and nitrification rates. They also found a strong negative relationship between gross nitrification and soil C:N in forests that had soil C:N ratios greater than 20. However, the authors noted that not all forests have such high soil C:N ratios as those in their study that were dominated by coniferous trees. Coniferous forests generally have higher litter C:N ratios than deciduous forests, and deciduous forests with lower C:N ratios may also have negative relationship with C:N and nitrification.

**Table 4-7 Nitrification and denitrification.**

Process Endpoint	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference
Nitrification and denitrification	Agricultural black earth soils (haplic chernozem); two sites: high and normal SOM	Central Germany	Not specified	81.3 (KNO <sub>3</sub> , Ca[NO <sub>3</sub> ] <sub>2</sub> ); 80 kg (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub>	<b>Isotopic tracer:</b> Addition of <sup>15</sup> N revealed denitrification of NO <sub>3</sub> <sup>-</sup> represents the main pathway of soil N <sub>2</sub> O release. On average, 76 and 54% of N <sub>2</sub> O was emitted during denitrification from soils with high and normal SOM content, respectively. Denitrification contributed, on average, only 17 and 12% of released NO from soil with high and normal SOM content, respectively.	<a href="#">Russow et al. (2008)</a>
Nitrification	Spruce plantation	Höglwald, Bavaria, Germany	30 (two decades)	None	<b>Time series:</b> Dynamic internal N cycle within the soil, driven by growth and death of the microbial biomass, which turns over approximately seven-fold each year.	<a href="#">Kreutzer et al. (2009)</a>
Denitrification	Agricultural crop, forest, grassland, wetland, tundra, heathland, and desert	Global	Not specified	10 to 562	<b>Meta-analysis:</b> Analysis of 313 observations across all ecosystems show N addition increased N <sub>2</sub> O emission by 216%.	<a href="#">Liu and Greaver (2009)</a>
Nitrification Denitrification	Agriculture and nonagriculture	Not specified	Mean = 105 Tg N/yr	0 to >100	<b>Meta-analysis:</b> included 206 papers on responses of ecosystem N cycle in response to N addition. Increases in nitrification (154%), N <sub>2</sub> O emission (134%), and denitrification (84%) were found. Increased N <sub>2</sub> O emissions and N leaching under N addition tended to export the N out of the systems rather than benefit plant uptake over the long term, suggesting a leaky terrestrial N system.	<a href="#">Lu et al. (2011a)</a>

**Table 4–7 (Continued): Nitrification and denitrification.**

Process Endpoint	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference
Nitrification and denitrification Microbial N demand	Temperate hardwood and conifer forests (unfertilized)	Nine sites in the north-central Oregon coast range, U.S.	Not specified	None	<b>Soil and foliar N gradient:</b> As future reductions in N deposition to polluted sites occurs, symptoms of N saturation are most likely to persist where soil N content remains elevated. Temperate and hardwood forests of the north-central Oregon coast range showed the ratio of net to gross N mineralization and nitrification increased along the gradient, indicating progressive saturation of microbial N demands at high soil N.	<a href="#">Perakis and Sinkhorn (2011)</a>
Nitrification	Common garden experiment, five broadleaved tree species	Denmark	13 to 19 for broadleaf forest; 18 to 26 for Norway spruce		<b>Isotopic tracer:</b> Litter $\delta^{15}\text{N}$ was positively correlated with N status based on nitrification, as well as other factors. A linear relationship was found between fungal mycelia production and net nitrification rate in lab incubations of soils collected in the field.	<a href="#">(Callesen et al., 2013)</a>
Denitrification	Forested watershed	Pond Branch in Maryland, U.S.	$10 \pm 4$	None	<b>Isotopic tracer:</b> Spatial and temporal extrapolations of measured rates suggest that a minimum of 16–27% of atmospheric N deposition is lost to denitrification.	<a href="#">Duncan et al. (2013)</a>
Fungal nitrification and denitrification	Semiarid grasslands	Arizona and New Mexico	Not specified	10 g soil to a 100 mL solution of 50 mmol/L $(\text{NH}_4)_2\text{SO}_4$ , 0.2 mol/L $\text{K}_2\text{HPO}_4$ , and 0.2 mol/L $\text{KH}_2\text{PO}_4$ , with a pH of 7.2.	<b>Moisture X biocide:</b> Fungi are significant sources of $\text{N}_2\text{O}$ production in soils from semiarid grasslands and deserts, expanding evidence that fungi play a vital role in the N cycle of arid lands.	<a href="#">Marusenko et al. (2013)</a>

**Table 4–7 (Continued): Nitrification and denitrification.**

Process Endpoint	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference
Denitrification	Agricultural land and natural ecosystems	Global	24 to 46 Tg N/yr from 1900–2050	Not applicable	<b>Model:</b> N <sub>2</sub> production from denitrification increased from 52 to 96 Tg/yr between 1900 and 2000, and N <sub>2</sub> O emissions increased from 10 to 12 Tg N/yr. The scenarios suggest a further increase to 142 Tg N <sub>2</sub> and 16 Tg N <sub>2</sub> O–N/yr by 2050. Riparian buffer zones are an important source of N <sub>2</sub> O, contributing an estimated 0.9 Tg N <sub>2</sub> O–N/yr in 2000.	<a href="#">Bouwman et al. (2013)</a>
Nitrification and denitrification Microbial community	Sugar maple dominated northern hardwood forest	Upper Michigan	15 to 20	30 kg N in the form of NaNO <sub>3</sub> pellets delivered to the forest floor over the growing season	<b>Addition:</b> NO <sub>3</sub> <sup>-</sup> addition to forest stands across a 500-km climatic gradient decreased the abundance and richness of key protein-coding genes in archaea and bacteria responsible for N fixation, ammonification, denitrification, and assimilatory NO <sub>3</sub> <sup>-</sup> reduction; the same was true for bacterial genes mediating nitrification and dissimilatory NO <sub>3</sub> <sup>-</sup> reduction.	<a href="#">Freedman et al. (2013)</a>
Denitrification	Northern hardwood forest	HBEF, White Mountain National Forest, NH	6 to 8	None	<b>Method comparison:</b> Both the isotopic tracer and gas-flow soil core method indicate that denitrification is higher and N <sub>2</sub> O:N <sub>2</sub> ratios are lower (<0.02) than previously thought in the northern hardwood forest and that short-term abiotic and biotic transformations of atmospheric N deposition to gas are significant in this ecosystem.	<a href="#">Kulkarni et al. (2014)</a>

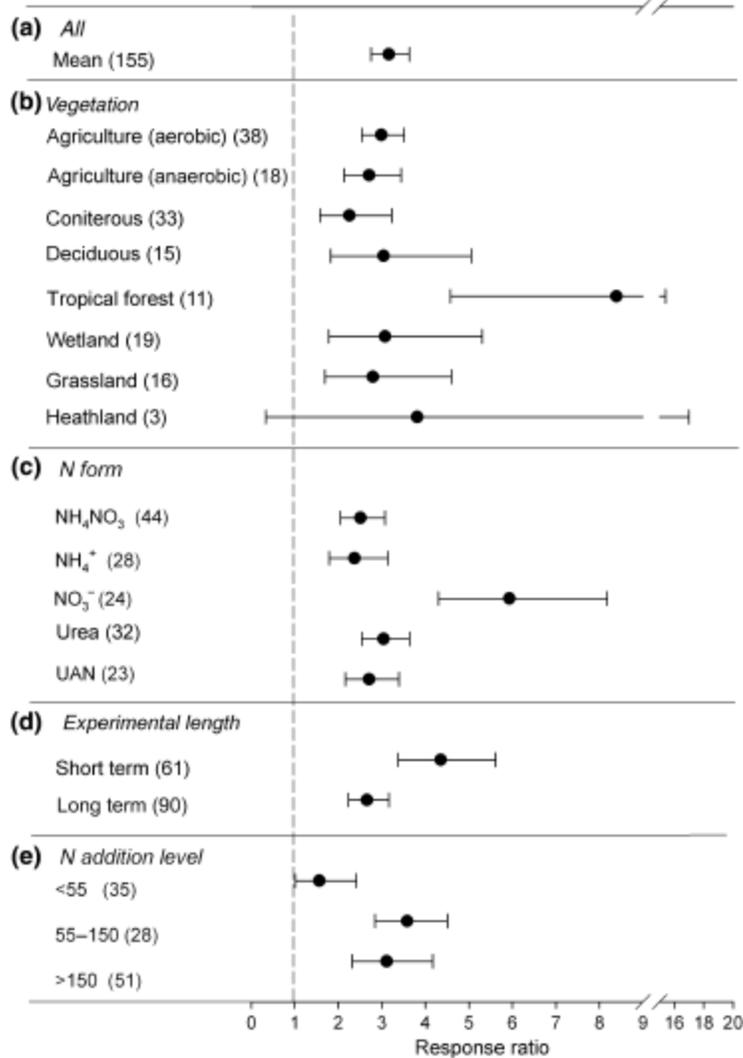

**Table 4–7 (Continued): Nitrification and denitrification.**

Process Endpoint	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference
Nitrification	Mixed hardwood forested headwater catchments	South-central Ontario, Canada	Average NO <sub>3</sub> <sup>-</sup> N deposition 2.78 ± 1.22; average NH <sub>4</sub> <sup>+</sup> N deposition 3.90 ± 1.39	Not applicable	<p><b>Time series:</b> Seasonal differences in nitrification were largely driven by temperature, soil moisture, and inorganic N concentration in soil.</p> <p>Annual nitrification fluxes were almost two orders of magnitude greater than N deposition or NO<sub>3</sub><sup>-</sup> leaching. Nitrification rates scaled up to annual catchment-scale production of NO<sub>3</sub><sup>-</sup>; the resulting fluxes are 64.9 ± 8.7 and 59.7 ± 3.1 kg N/ha/yr, which greatly exceed seasonal inputs in deposition.</p> <p>Rates of nitrification and mineralization were similar, indicating that almost all mineralized N is converted to NO<sub>3</sub><sup>-</sup> (ranging from 71 to 99%).</p>	<a href="#">Casson et al. (2014a)</a>
Nitrification denitrification	Deciduous and coniferous forests	Ontario, Canada; New Hampshire; and Maine	Three sites along a gradient: 4.5, 7, and 11	Not applicable	<p><b>Gradient:</b> N gas flux increased systematically with natural N enrichment from soils with high nitrification rates.</p> <p>N gas fluxes were linked to patterns of N availability in forests; results do not suggest that these fluxes respond to increases in atmospheric N deposition at the study sites.</p>	<a href="#">Morse et al. (2015a)</a>

**Table 4–7 (Continued): Nitrification and denitrification.**

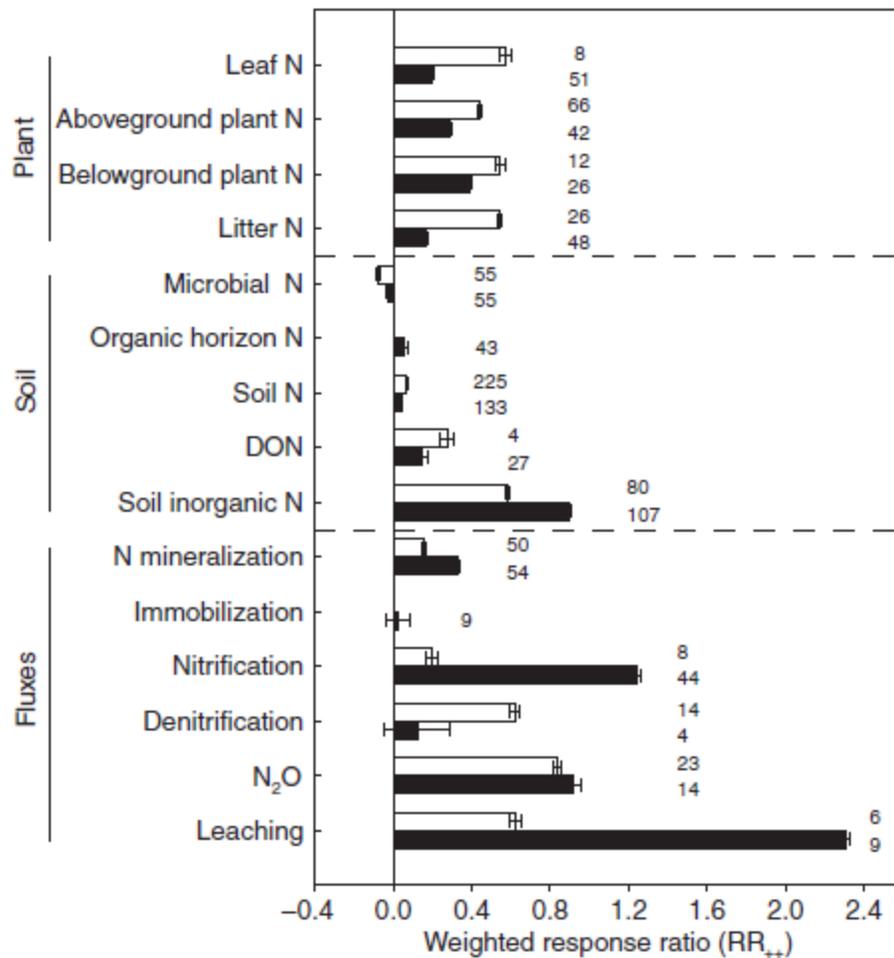

Process Endpoint	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference
Nitrification C:N	Five biome classes in California: desert, grassland, shrubland, forest, wetland	California	0.6–18.4 kg N/ha/yr	Grassland soil: 76.4 kg N/ha/yr as NPK (29:3:4); desert soil: 60 kg N/ha/yr as NH <sub>4</sub> NO <sub>3</sub> ; shrubland soil: 60 kg N/ha/yr as NH <sub>4</sub> NO <sub>3</sub>	<b>N Addition:</b> Across biomes, a positive correlation of gross nitrification to soil NO <sub>3</sub> <sup>-</sup> ( $r^2 = 0.34$ ) and a negative correlation to soil C:N ( $r^2 = 0.31$ ) was observed.  No correlation was found between gross N mineralization and nitrification. Deserts had the lowest gross N mineralization rates and exhibited similar nitrification rates to the shrublands and grasslands. Only 15% of NH <sub>4</sub> <sup>+</sup> produced was nitrified in the forests compared to 47 to 86% in the other biomes. This suggests that NH <sub>4</sub> <sup>+</sup> production rates did not limit nitrifiers in the forests, but rather, that another factor limited nitrifier activity.	<a href="#">Yang et al. (2017)</a>

### 4.3.7 Decomposition

Decomposition is a general term that refers to the breakdown of organic matter ([Schlesinger, 1997](#)). Decomposition is an important part of N and C cycling that can be altered by N deposition. Decomposition rates correlate with ratios of C:N, lignin:N, and

lignin:cellulose in litter, all of which may be altered by N deposition. The addition of N can stimulate the decomposition of labile compounds that degrade during the initial stages of decomposition, but added N can suppress the decomposition of more recalcitrant material. Evidence for this is widespread in forests but has not yet been well documented in grasslands and other ecosystems. Since 2008, there are new addition studies and meta-analyses to better understand the mechanisms and response trends.

The 2008 ISA documented that the soil microbial community (bacteria and fungi) are the main decomposers of organic matter. Both the microbial community composition and microbial enzyme activity can dynamically respond to shifts in inorganic nutrient and substrate availability ([Compton et al., 2004](#); [Carreiro et al., 2000](#)); the shift reflects the nutrient and energy limitation of the microbial community. Litter decay rates are also well established to correlate with ratios of C:N, lignin:N, or lignin:cellulose in litter ([Hobbie, 2008](#); [Aerts, 1997](#); [Melillo et al., 1982](#)). These chemical traits are strong predictors of litter decay, accounting for over 73% of the variation in litter decomposition rates worldwide ([Zhang et al., 2008](#)).

Traditionally, carbon dioxide (CO<sub>2</sub>) is measured as an indication of soil respiration and a proxy for decomposition. Since the 2008 ISA, analysis of microbial enzymes and genes in the soil have been used to identify microbial activity and determine how it relates to decomposition. Numerous studies have been published since 2008 describing how N addition affects the decomposition of organic C and N ([Table 4-8](#)).

**Table 4-8 Decomposition.**

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference
Decomposition	Sugar maple hardwood forest	Bear Brook Watershed in eastern Maine		1,800 eq/ha/yr of (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub>	<b>N + S Addition:</b> Caused increased N concentration in leaves and faster short-term decomposition.	<a href="#">Hunt et al. (2008)</a>
Enzyme activity Decomposition	Eight annual herb species	Controlled ecosystem (litter bags placed in annual herb-based microcosm ecosystems)	2.0 and 44.0		<b>Growth chamber:</b> N deposition increased soil enzyme activity known to breakdown cellulose (cellobiosidase, β-glucosidase and β-xylosidase).	<a href="#">Manning et al. (2008)</a>
Enzyme activity Decomposition	Northern hardwood forest	Michigan	6.8 to 11.8	30 NO <sub>3</sub> <sup>-</sup>	<b>N Addition:</b> N addition altered rates of organic matter decomposition by suppressing the soil enzymes responsible for litter degradation when litter has a higher N concentration. This causes an increase in surface soil C storage.	<a href="#">Pregitzer et al. (2008)</a>
Enzyme activity Decomposition	Forests grasslands	Central Minnesota	Not specified	100 (NH <sub>4</sub> NO <sub>3</sub> )	<b>N Addition:</b> Generally stimulated activities of cellulose degrading enzymes in litter and soil, but had no effect on lignin degrading enzyme activity. N addition had a negative or neutral effect on litter and SOM decomposition in the same sites, with no correspondence between effects of N on enzyme activity and decomposition across sites.	<a href="#">Keeler et al. (2009)</a>
Enzyme activity	Northern hardwood forest	Catskill Mountains of New York, U.S.		50 (NH <sub>4</sub> NO <sub>3</sub> )	<b>N Addition:</b> Identified that patterns in microbial community structure and function were more strongly influenced by tree species than by fertilization.	<a href="#">Weand et al. (2010)</a>
Soil respiration Decomposition	Forest	Global		Varied	<b>Meta-analysis:</b> N additions decreased root respiration, heterotrophic respiration, and soil CO <sub>2</sub> but had no effect on litter decomposition.	<a href="#">Janssens et al. (2010)</a>

**Table 4–8 (Continued): Decomposition.**

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference
Soil respiration	Temperate broadleaf and mixed forest, temperate conifer forest, boreal forest, tropical forest, grassland, wetland, tundra, desert, and arctic	Global		Varied	<b>Meta-analysis:</b> N additions decreased heterotrophic respiration but had no effect on total soil respiration.	<a href="#">Liu and Greaver (2010)</a>
Enzyme activity Decomposition	Forest and grasslands	U.S.	None	None	<b>Synthesis:</b> Data from 28 ecosystems show resources to produce the enzymes phenol oxidase and $\beta$ -1,4-glucosidase are uncoupled. This indicates that the increasing recalcitrance of organic matter decreases C and nutrient availability and slows microbial growth.	<a href="#">Sinsabaugh and Shah (2011)</a>
Enzyme activity Decomposition	Mature black spruce forest in upland boreal ecosystem	Central Alaska	Not specified	Years 2009 = 200 (NH <sub>4</sub> NO <sub>3</sub> ) Years 2010 = 100 (NH <sub>4</sub> NO <sub>3</sub> )	<b>N Addition:</b> N fertilization may alter decomposer community structure by favoring a shift toward cellulose- and mineral-N users. Cellulose degrading microbes (decomposers) were competitively dominant under N fertilization.	<a href="#">Talbot and Treseder (2012)</a>
Enzyme activity Decomposition	Sugar maple forests	Michigan	Not specified	30	<b>Meta-analysis:</b> N addition increased cellulose decomposition by 9% and decreases lignin decomposition rates by 30%. Overall, N increases the amount of litter mass entering the humus pool and leads to increases in soil C storage under experimental N deposition.	<a href="#">Whittinghill et al. (2012)</a>
Enzyme activity Decomposition	Northern hardwood forest	Minnesota			<b>N Addition:</b> Accelerated the initial decomposition rate. Faster initial decomposition rates corresponded to higher activity of polysaccharide-degrading enzymes and greater relative abundances of Gram-negative and Gram-positive bacteria. Later in decomposition, externally supplied N slowed decomposition, increasing the fraction of slowly decomposing litter, reducing lignin-degrading enzyme activity, and relative abundances of Gram-negative and Gram-positive bacteria.	<a href="#">Hobbie et al. (2012)</a>

**Table 4–8 (Continued): Decomposition.**

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference
Decomposition	Deciduous forests	Catskill Mountains of southeastern New York, U.S.	9.0	50 mg N/ha/yr N (NH <sub>4</sub> NO <sub>3</sub> )	<b>N Addition:</b> N addition caused decrease in mineralization and nitrification and an increase in forest floor C pools and C:N, indicating that N addition increased C sequestration in the organic horizons of the soil, most significantly in hemlock plots.	<a href="#">Lovett et al. (2013)</a>
Enzymes Decomposition	Northern hardwood forest	Upper Michigan	15 to 20	30	<b>N Addition:</b> Caused slower organic matter decay and altered microbial community composition and function. Observed a decrease in the abundance and richness of key protein-coding genes in archaea and bacteria responsible for N fixation, ammonification, denitrification, and assimilatory NO <sub>3</sub> <sup>-</sup> reduction; the same was true for bacterial genes mediating nitrification and dissimilatory NO <sub>3</sub> <sup>-</sup> reduction.	<a href="#">Freedman et al. (2013)</a>
Enzymes Decomposition	Sugar maple forests	Michigan	5.8 to 7.3	30	<b>N Addition:</b> (1) significantly altered the composition of actinobacterial and fungal genes mediating plant and fungal cell wall depolymerization; (2) significantly decreased the richness and diversity of genes involved in the depolymerization of starch (~12%), hemicellulose (~16%), cellulose (~16%), chitin (~15%), and lignin (~16%); and (3) resulted in small changes in community composition (25% difference in fungi; 18% in actinobacteria).	<a href="#">Eisenlord et al. (2013)</a>
Enzymes Decomposition	Northern hardwood forest	Upper Michigan	15 to 20	30 as six equal applications of NaNO <sub>3</sub> pellets delivered to the forest floor over the growing season	<b>N Addition:</b> Observed that atmospheric N deposition increases saprotrophic bacterial laccase-like multicopper oxidases (LMCOs). These results suggest a plausible mechanism by which anthropogenic N deposition has reduced decomposition, increased soil C storage, and accelerated phenolic DOC production.	<a href="#">Freedman and Zak (2014)</a>
Decomposition fungal residue	Forest	Switzerland	Not specified	7 (NH <sub>4</sub> NO <sub>3</sub> ) 70 (NH <sub>4</sub> NO <sub>3</sub> )	<b>N Addition:</b> Promoted the production of new fungal residues but slowed the decomposition of old residues in forest soil fractions. Preservation of old microbial residues could be due to decreased N limitation of microorganisms and therefore a reduced dependence on organic N sources.	<a href="#">Griepentrog et al. (2014)</a>

**Table 4–8 (Continued): Decomposition.**

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference
Enzyme activity	Northern hardwood and softwood forest	Bear Brook Watershed (BBWM), ME, U.S.		25.5	<b>N Addition:</b> After 22 yr of N addition, N enrichment had little effect on microbial enzyme activity in terrestrial compartments, even across varying degrees of organic matter recalcitrance.	<a href="#">Mineau et al. (2014)</a>
Soil respiration	Multiple biomes	Global		Varied	<b>Meta-analysis:</b> N addition significantly increased soil respiration by 2.0% across all biomes but decreased respiration by 1.44% in forests and increased it by 7.84 and 12.4% in grasslands and croplands, respectively ( $p < 0.05$ ).  The response ratios of soil respiration to N addition were positively correlated with mean annual temperature (MAT), most significant when MAT was less than 15°C. N addition largely altered root and microbial biomass and soil C content, which are likely the mechanisms behind the altered soil respiration.	<a href="#">Zhou et al. (2014a)</a>
Decomposition	Grassland	Minnesota, Nebraska, Iowa, Kansas; Colorado	3.1 to 18	100	<b>N Addition:</b> Decreased microbial respiration of OM by as much as 29% relative to control plots, and consequently, decreased C loss from this pool.	<a href="#">Riggs et al. (2015)</a>
Decomposition	Forest	Great Lakes region	6.8 to 11.8	30 as NaNO <sub>3</sub>	<b>N Addition:</b> Fine root biochemistry was less responsive than leaf litter to long-term simulated N deposition. Fine roots were the dominant source of difficult-to-decompose plant C fractions entering the soil.  When combined with litter production, simulated N deposition increased N flux through leaf litter by an average of 29% but did not affect fine root N flux.	<a href="#">Xia et al. (2015)</a>
Enzyme activity	Subalpine forest	Loch Vale watershed (LVWS) is in Rocky Mountain National Park (RMNP) on the eastern edge of the Colorado Front Range.	3–4 kg N/ha/yr (wet)	25 kg NH <sub>4</sub> NO <sub>3</sub> /ha/yr (1996–present)	<b>N Addition:</b> There were no changes in the C degrading enzyme activity in response to fertilization, while the N degrading enzyme activity was enhanced with elevated activity of leucine aminopeptidase (LAP) and marginally significant increase in N-acetyl-β-glucosaminidase (NAG) with N fertilization.	<a href="#">Boot et al. (2016)</a>

**Table 4–8 (Continued): Decomposition.**

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference
Enzyme activity	Northern hardwood forest	Michigan	5.9–7.4 kg N/ha/yr (not specified if wet, dry, or total)	30 kg NaNO <sub>3</sub> /ha/yr (beginning in 1994)	<b>N Addition:</b> This long-term experiment found N deposition decreased the activity reduced the activity of extracellular enzymes mediating plant cell wall decay.	<a href="#">Freedman et al. (2016)</a>
Soil respiration	Northern hardwood forest	White Mountain National Forest, NH; Bartlett, Hubbard Brook, and Jeffers Brook Forests	8 kg N/ha/yr (wet + dry) (20th century average at HBEF)	30 kg N/ ha/yr (NH <sub>4</sub> NO <sub>3</sub> ), 10 kg P/ha/yr (NaH <sub>2</sub> PO <sub>4</sub> ), or N + P (treatments in year 2011)	<b>N Addition:</b> The greatest reduction in soil respiration on N and N + P fertilized plots occurred on the sites with lowest pretreatment soil N mineralization and litterfall N flux. Nutrient additions did not significantly affect either fine root turnover (minirhizotrons) or microbial respiration (laboratory incubations).	<a href="#">Kang et al. (2016)</a>
Decomposition	Restored tallgrass prairie	Prairie Invasion and Climate Experiment (PRICLE) Loveland, CO	~1/3 of N added	5 g N/m <sup>2</sup> /yr urea. “Seasonal maximum 5-day cumulative rainfall” increased by 33 (2012) and 9% (2013)	<b>N Addition:</b> Increasing rainfall variability and N addition can stimulate litter decomposition in tall grass prairie.	<a href="#">Schuster (2016)</a>
Decomposition	All ecosystems	Global	Not specified	Not specified	<b>Meta-analysis:</b> 198 peer-reviewed journal articles found N addition did not significantly alter litter decomposition, soil respiration (except for wetlands, +28.26%), and microbial respiration (except for forests, +9.08).	<a href="#">Yue et al. (2016)</a>

**Table 4–8 (Continued): Decomposition.**

Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Addition kg/ha/yr	Effect of Deposition	Reference
Decomposition	Mixed hardwood forest dominated by black and red oak ( <i>Quercus velutina</i> and <i>Q. rubra</i> )	Chronic Nitrogen Amendment Study (CNAS) located at the Harvard Forest Long-Term 57 Ecological Research (LTER) site in Petersham, MA, USA		50–150	Changes in litter decay by was generally lower in the N treatment microbes compared to control microbes for the same species, a response not readily reversed when N microbial isolates were grown in low N environments. Changes in fungal behaviors accompany and perhaps drive previously observed N induced shifts in fungal diversity, community composition, and litter decay dynamics.	<a href="#">van Diepen et al. (2017)</a>
Decomposition	Forest	Scotland	14–16 kg N/ha/yr	1.18 g <sup>15</sup> N in 4m plot	Litter decomposition is a larger source of N for trees than simulated N deposition.	<a href="#">Nair et al. (2017)</a>

BBWM = Bear Brook Watershed; C = carbon; DOC = dissolved organic carbon; ha = hectare; kg = kilograms; LMCO = Laccase-like multicopper oxidase; mg = milligrams; N = nitrogen; <sup>15</sup>N = nitrogen-15; NaNO<sub>3</sub> = sodium nitrate; NH<sub>4</sub>NO<sub>3</sub> = ammonium nitrate; (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> = ammonium sulfate; NO<sub>3</sub><sup>-</sup> = nitrate; <sup>15</sup>NO<sub>3</sub><sup>-</sup> = nitrogen-15-labeled nitrate; OM = organic matter; S = sulfur; SOM = soil organic matter; yr = year.

The body of knowledge published since the 2008 ISA indicates the effects of N on decomposition rates are inconsistent among studies. New field work supported the concept that N deposition suppresses decomposition ([Riggs et al., 2015](#); [Zak et al., 2008](#)). Likewise, [Kang et al. \(2016\)](#), in a large-scale N addition study of 13 northern hardwood forests in the U.S., supported the findings that N addition decreases forest respiration and further identified the greatest reduction in soil respiration on N fertilized plots occurred on the sites with lowest pretreatment soil N mineralization and litterfall N flux ([Kang et al., 2016](#)). In contrast, meta-analysis that evaluated the central tendencies of N addition on total soil respiration in forest biomes reported inconsistent results, including an increase ([Yue et al., 2016](#)), decrease ([Zhou et al., 2014a](#)), and no effect ([Liu and Greaver, 2010](#)). Meta-analyses that looked for the central tendencies of terrestrial soil respiration to N addition also have inconsistent results; two meta-analyses found that N did not alter total soil respiration in terrestrial soils ([Yue et al., 2016](#); [Liu and Greaver, 2010](#)), another identified an increase ([Zhou et al., 2014a](#)), and only one identified a decrease ([Janssens et al., 2010](#)). The different results in the meta-analyses reflect slightly different selection criteria the authors used to determine which studies to include in the analyses. Among biomes, differences in soil respiration may result largely from stimulation of autotrophic respiration by N addition to croplands and grasslands compared with no significant change for forests, and a simultaneous decline in heterotrophic/microbial respiration in most biomes [[Liu and Greaver \(2010\)](#); [Zhou et al. \(2014a\)](#), with the exception of croplands, tropical forests, and boreal forests].

One proposed mechanism for reduced microbial decay under increased N deposition is a shift in the species composition of the microbial community with the consequence of decreased lignin decomposition. Lignin is an organic polymer, particularly important in cell wall formation of vascular plants. Under N addition, the microbial community would shift from basidiomycete fungal activity, some of which oxidize lignin in plant detritus and polyphenols in SOM to CO<sub>2</sub>, to more metabolism by bacteria and ascomycete fungi (cellulose degraders), which only partially oxidize these organic substrates ([Freedman and Zak, 2014](#); [Zak et al., 2011](#)). There is new evidence to support this theory in northeastern hardwood forests in the U.S. where N enrichment increases the species richness and diversity of ascomycetes generally [cellulose degraders; [Morrison et al. \(2016\)](#)], with evidence that observed changes in decay abilities were not readily reversed when N isolates were grown in control environments, indicating that the fungal community may not recover quickly following the cessation of N enrichment [[van Diepen et al. \(2017\)](#); see [Appendix 6](#)].

There is new evidence to support that lignolytic enzyme activity decreases under N addition ([Freedman et al., 2016](#); [Keeler et al., 2009](#); [Manning et al., 2008](#)). This trend is also supported by a meta-analysis by [Whittinghill et al. \(2012\)](#), who found that N

addition decreased lignin decomposition rates by 30% and increased cellulose decomposition by 9%. Fine roots are likely the dominant source of difficult-to-decompose plant carbon fractions entering the soil, and this pattern appears to be widespread in boreal and temperate forests ([Xia et al., 2015](#)).

There are cases in which N addition causes no change in enzyme activity of microbes; for example, the hardwood and softwood forests growing in the Bear Brook Watershed in Maine ([Mineau et al., 2014](#)) and C degrading enzymes in a subalpine forest ([Boot et al., 2016](#)). Another study in the Catskill Mountains of New York State found that patterns in microbial community structure and function (detected by enzyme activity) were more strongly influenced by the tree species present than by fertilization ([Weand et al., 2010](#)).

Microbial decomposition response to N addition may also change through time. The 2008 ISA documented an N addition study lasting longer than 2 years that indicated that a shift can occur from stimulation to depression of decomposition over time ([Knorr et al., 2005](#)). In a study looking at changes through time of the organic layer, [Hobbie et al. \(2012\)](#) suggested N deposition in forest ecosystems may decrease mean residence times of active fractions in fresh litter, while increasing those of more slowly decomposing fractions, including more processed litter. In boreal forests, [Talbot and Treseder \(2012\)](#) found a transition over time from competition among decomposers to high cellulase activity and suppressed lignin loss under N fertilization. The trend suggests that, in N limited systems, N fertilization may alter decomposer community structure by favoring a shift toward cellulose- and mineral-N users.

There is also new evidence that experimental N deposition significantly decreased the richness and diversity of microbial genes involved in the depolymerization of starch (12%), hemicellulose (16%), cellulose (16%), chitin (15%), and lignin (16%) ([Eisenlord et al., 2013](#)).

---

#### 4.3.8 Nitrogen Mineralization

Mineralization refers to processes that release carbon as CO<sub>2</sub> and nutrients in inorganic form. Nitrogen mineralization is the process by which organic N is converted to plant-available inorganic forms. The 2008 ISA documented that the rate of mineralization may be influenced by numerous factors including C:N of soil organic matter, soil pH, and the microbial community. N mineralization has been shown to increase with increasing N addition ([Aber et al., 1998](#)), often up to 1.6 times the control ([Gundersen et al., 1998](#)).

New publications ([Table 4-9](#)) support that soil N mineralization increases with N addition across terrestrial ecosystems ([Lu et al., 2011a](#)), specifically in temperate forests ([Nave et](#)

[al., 2009a](#)), likely due to increases in dissolved organic nitrogen (DON), the size of the N pool in the soil, and decreases in C:N ratios. The forest floor responds differently than the deeper mineral soil layer [[Figure 4-7](#); [Nave et al. \(2009a\)](#); [Lovett et al. \(2013\)](#)].

In two forested headwater catchments in Ontario, [Casson et al. \(2014a\)](#) found that N mineralization and nitrification rates were similar, indicating that almost all mineralized N was converted to  $\text{NO}_3^-$  (ranging from 71 to 99%) in catchments they studied. While [Bade et al. \(2015\)](#) found in old-growth spruce forests, lower N mineralization occurred in the more open patches than the closed ones. Possible reasons were reduced litter supply and lower canopy N interception in gaps in this forest under exposure to high N deposition. Further studies in other old-growth forests are needed to better understand the mechanisms causing long-term change in N cycling with forest development.

In desert shrublands, [Rao et al. \(2009\)](#) found that N deposition may increase production and/or alter litter C:N ratios that increase soil C. There was an inverse relationship between the C:N ratio and total N mineralized, yet a positive relationship between organic C and total N with mineralization. These results indicate that microbial activity in low productivity arid land soils is primarily limited by C and secondarily limited by N.

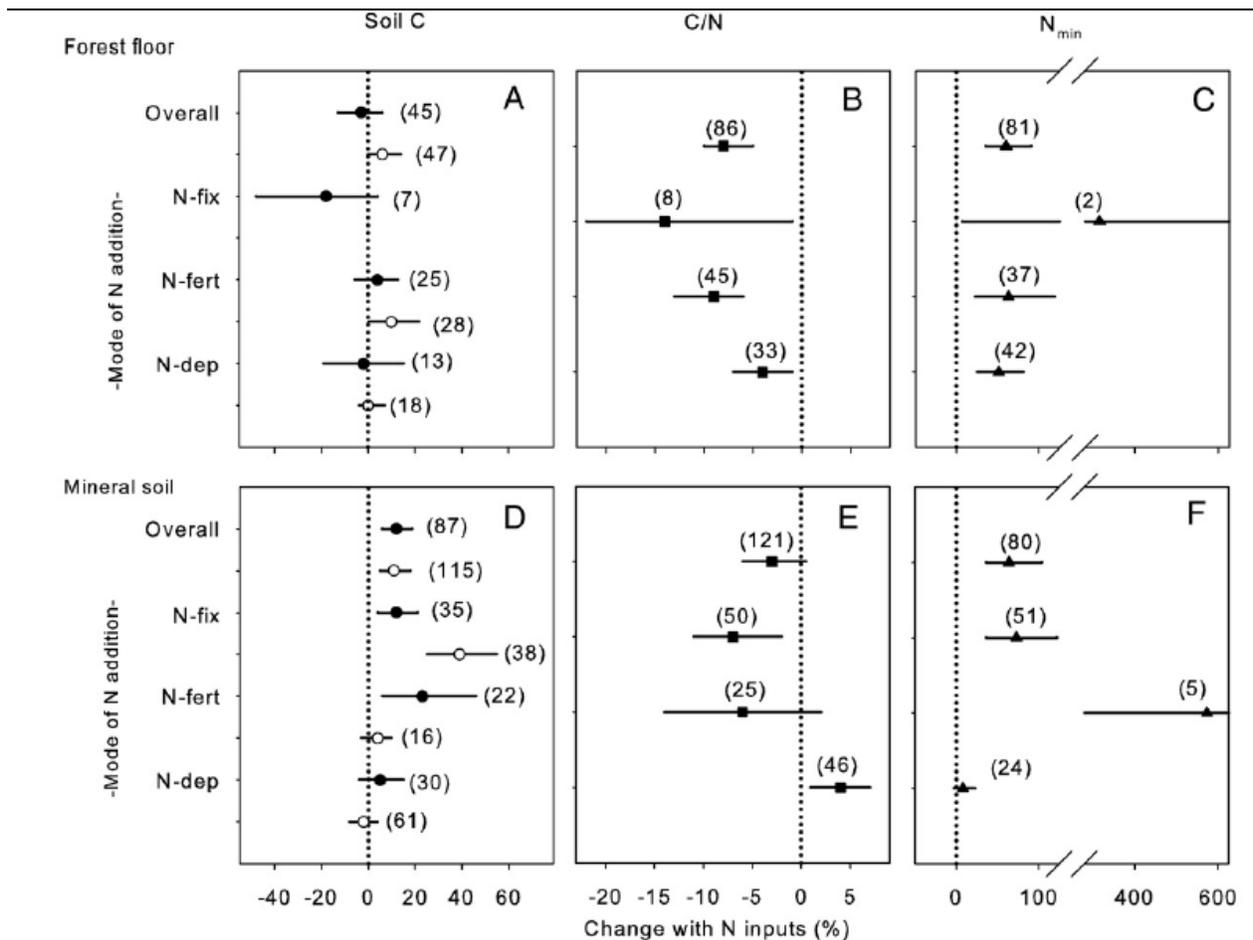

**Table 4-9 Nitrogen mineralization.**

Process Endpoint	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference
Mineralization	Semiarid	Southern California, U.S.	Up to 35–45 for N	Two applications per year of 30 kg N	N is mineralized at a faster rate from grass litter enriched in N as a result of N deposition.	<a href="#">Sirulnik et al. (2007a)</a>
Mineralization	Semiarid	Southern California, U.S.	Up to 35–45 for N	Two applications per year of 30 kg N	When significantly lower microbial N was reported in fertilized plots it corresponded to faster net N mineralization. When higher microbial N was observed in fertilized plots it corresponded to net immobilization (though not significantly faster), thus corroborating evidence that the microbial community was taking up more N in fertilized plots. These rates may have corresponded to C availability, which was not measured.	<a href="#">Sirulnik et al. (2007b)</a>
Mineralization soil [N] soil [Ca]	Mixed hardwood stands	Adirondack Mountains, NY, U.S.	Not specified	None	<b>Ca Gradient:</b> The exchangeable Ca coupled with soil moisture, soil organic matter, and ambient temperature accounted for 61% of the variability in extractable inorganic N across 11 sites. The influence of Ca on soil inorganic N may be through interactions between soil Ca concentrations and species composition, which in turn affect the quality of litter available for N mineralization.	<a href="#">Page and Mitchell (2008)</a>
Decomposition Enzyme activities	Spruce forest	Germany	8.5		<b>N Exclusion:</b> Some N cycling enzymes increased activities, whereas others decreased under reduced N treatment.	<a href="#">Enowashu et al. (2009)</a>
N mineralization	Desert	Joshua Tree National Park	2.7 to 14.4		Calculated soil N from deposition was directly correlated with measured soil C and N and decreasing C:N ratios.	<a href="#">Rao et al. (2009)</a>

### 4.3.9 Dissolved Organic Carbon Leaching

The acid-base characteristics of dissolved organic matter (DOM) are an important part of understanding the recovery potential for soils, lakes, and streams impaired by acid deposition. The composition of DOM includes fulvic and humic acids, carboxylic acids, and amino acids; dissolved organic carbon (DOC) includes these organic acids. Here we focus on the DOC component of DOM. The many carboxylic groups of DOC make it chemically interact like a weak acid; therefore, DOC content may affect pH levels. In addition, [Fakhraei and Driscoll \(2015\)](#) emphasized the importance of predicting accurately the acid-base properties of recovering surface waters because, for example, the acidic components of DOC act as hosts for binding trace metals like toxic  $Al_i$  (for additional discussion on  $Al_i$  and DOM see [Appendix 4.3.5](#)).

In recent years, the DOC of many lakes and streams has risen, with the likely source being the soils in the adjacent terrestrial watershed. However, the mechanism causing the observed increase is unclear. The increase may be due to a combination of soil recovery from acidification, changes in climate (e.g., temperature and precipitation), and N deposition, among other mechanisms [for reviews see [Kalbitz et al. \(2000\)](#); [Evans et al. \(2005\)](#)]. New studies in the literature have investigated soil DOC response to acidification (N + S deposition) and/or looked at the effects of N addition; these studies will be the focus of the following discussion ([Table 4-10](#)). For a discussion of DOC in surface water see [Appendix 7](#).

**Table 4-10 Terrestrial dissolved organic carbon (DOC) leaching.**

Process	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference
DOC	Bog, heathland, grassland, broadleaf and coniferous forest	Synthesis of 17 addition experiments in the northeastern U.S. and northern Europe	Ranged from 5–16 N dep	Ranged from 10 to 150 N (chemical forms for N varied)	<b>Synthesis:</b> N had inconsistent effect on DOC; however, the form of N applied indicates nonacidifying forms of N tend to increase DOC concentrations.	<a href="#">Evans et al. (2008)</a>
DOC	Temperate mixed and conifer forests, boreal forests, grasslands, tropical forests, arctic, wetlands, desert, and tundra	410 observations globally	Not specified	10 to 650	<b>Meta-analysis:</b> N addition increases short-term belowground C storage by increasing C content of the organic layer. N addition; increased DOC concentration (+18%); and increased C content of the organic soil layer (+17%) but not the mineral soil layer.	<a href="#">Liu and Greaver (2010)</a>
DOC	Norway spruce ( <i>Picea abies</i> ) forests	Southern Sweden	Not specified	Not specified	<b>Model:</b> The Stockholm Humic Model was used to model DOC solubility in soil water and predicted that DOC trends could vary between positive and negative depending on changes in pH, ionic strength, and soil Al pools.	<a href="#">Lofgren et al. (2010)</a>

**Table 4-10 (Continued): Terrestrial dissolved organic carbon (DOC) leaching.**

Process	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference
DOC	Beech forest stands on calcareous soils	Swiss Jura mountain range	Not specified	5.5 (NH <sub>4</sub> NO <sub>3</sub> )	<b>N Addition:</b> Leaching of DOC from the litter layer was not affected by N additions, but DOC fluxes from the mineral soils at 5- and 10-cm depth were significantly reduced by 17%. <sup>13</sup> C indicated that litter-derived C contributed less than 15% of the DOC flux from the mineral soil, with N additions not affecting this fraction. Hence, the suppressed DOC fluxes from the mineral soil at higher N inputs can be attributed to reduced mobilization of nonlitter derived “older” DOC.	<a href="#">Hagedorn et al. (2012)</a>
DOC	None— theoretical	None— theoretical	Not specified	Not specified	<b>N Addition:</b> Increases mineralization causing the pool of bioavailable DOC to decrease. Consequently, relatively less bioavailable DOC remains for NH <sub>4</sub> <sup>+</sup> assimilation and immobilization in microbial biomass, leaving more NH <sub>4</sub> <sup>+</sup> for nitrifiers. As a result, internal NO <sub>3</sub> <sup>-</sup> production increased. The higher bacterial demand for DOC under elevated availability of N and electron acceptors comes into conflict with increasing chemical suppression of DOC solubility and bioavailability in the progressively acidifying soils and finally results in the C limitation of microbial metabolism.	<a href="#">Kopáček et al. (2013)</a>
DOC	Northern hardwood forest	Upper Michigan	15 to 20 kg N/ha/yr	30 (as six equal applications of NaNO <sub>3</sub> pellets delivered to the forest floor over the growing season)	<b>N Addition:</b> N addition accelerated phenolic DOC production.	<a href="#">Freedman and Zak (2014)</a>

Process	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference
DOC	Forest and streams	Hubbard Brook Experimental Forest, NH	Variable	None	<b>Field observation:</b> Concentrations of DOC showed statistically significant declines in the Oa soil solutions of all three elevation zones, and a subset of the Bs soil solutions over the period of 1984–2011.	<a href="#">Fuss et al. (2015)</a>
DCO	Lakes	Adirondack Long-Term Monitoring (ATLM) Program lakes at Huntington Forest and Whiteface Mountain, Adirondack Mountains, NY	Variable	None	<b>Field observation:</b> increasing DOC in 29 of 48 lakes as lake pH increased.	<a href="#">Driscoll et al. (2016)</a>
DOC	Forest and grassland	U.K.	Mean 1993 to 2010 gradients of deposition: S: 44 to 86 meq/m <sup>2</sup> /yr; N: 40 to 90 meq/m <sup>2</sup> /yr; Cl: 94 to 306 meq/m <sup>2</sup> /yr	None	<b>Modeling:</b> Using the MADOC model, the acidifying effect of S deposition was the predominant control on the observed soil water DOC trends. The relative importance of S and N loading depended on soil sensitivity to acidification, and on N limitation.	<a href="#">Sawicka et al. (2017)</a>

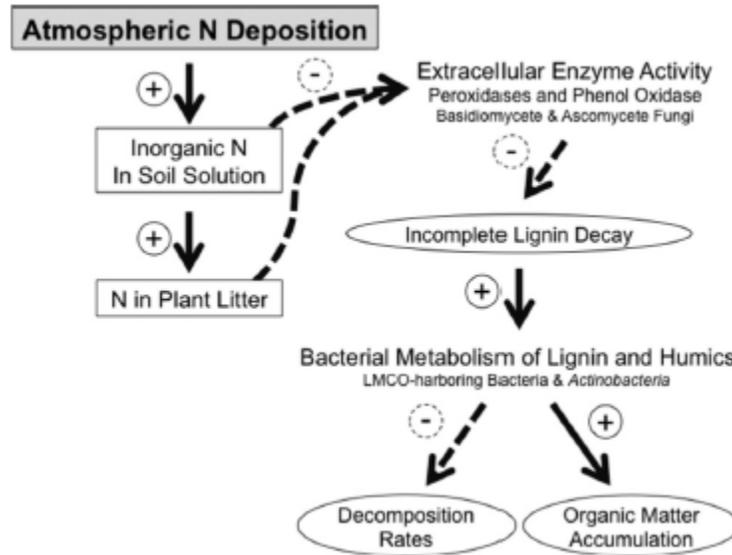

<sup>13</sup>C = carbon-13; C = carbon; DOC = dissolved organic carbon; ha = hectare; kg = kilogram; N = nitrogen; NaNO<sub>3</sub> = sodium nitrate; NH<sub>4</sub><sup>+</sup> = ammonium; NH<sub>4</sub>NO<sub>3</sub> = ammonium nitrate; NO<sub>3</sub><sup>-</sup> = nitrate; S = sulfur; yr = year.

A number of studies suggest that recovery from acidification is driving the elevated levels of DOC. An inverse relationship between mineral and organic acid export to surface waters from soils was first proposed in the 1980s ([Krug and Frink, 1983](#)). Support for this theory is found in a range of laboratory experiments in which increases in both acidity and ionic strength (associated with a high  $\text{SO}_4^{2-}$  loading) have been shown to reduce soil solution DOC ([Kalbitz et al., 2000](#)). [Evans et al. \(2008\)](#) addressed whether elevated N deposition or recovery from acidification associated with decreasing S cause increased DOC loss from upland soil. Their analysis of a large experimental data set including 12 sites in the U.S. and northern Europe showed that although the response to N addition is inconsistent, DOC concentrations responded predictably to the chemical form of N added. DOC concentrations increased with  $\text{NaNO}_3$  additions or gaseous  $\text{NH}_3$  exposure and decreased with most  $\text{NH}_4^+$  salt additions. The authors cite the effect of the chemical form of N on acidity as a plausible mechanism and further conclude that their evaluation does not provide clear support for the role of N deposition as the sole driver of rising DOC, but is consistent with an acidity-change mechanism. [Evans et al. \(2008\)](#) also stated their finding is consistent with findings based on long-term monitoring data, that DOC increases in northern European and North American surface waters are substantially attributable to regional decreases in acidifying, primarily S, deposition ([Monteith et al., 2007](#); [Evans et al., 2005](#)). New studies also report that N addition has caused inconsistent changes to DOC, with N addition causing both increases ([Driscoll et al., 2016](#); [Liu and Greaver, 2010](#)) and decreases ([Fuss et al., 2015](#); [Hagedorn et al., 2012](#)).

In the Adirondack Long-term Monitoring Program, [Driscoll et al. \(2016\)](#) measured increasing DOC in 29 of 48 monitored lakes as lake ANC and pH increased. In contrast, decreases in DOC concentrations were observed in the soil solution from the Oa soil horizon at all sites, the Bs soil horizon soil solution of one site, and the stream water measured at the base of the watershed. These observations were attributed to recovery from acidification in the HBEF, NH ([Fuss et al., 2015](#)). [Fuss et al. \(2015\)](#) considered these results surprising and therefore reviewed European and U.S. research literature, found studies with similar observed trends, and identified a number of potential factors leading to this difference. While surface water DOC generally emanates from soil water DOC (with the possible exception of snowmelt), soil ionic strength and soil Al pools, as well as soil depth, may also influence DOC in soil solution ([Lofgren et al., 2010](#)). Decreasing ionic strength can decrease DOC; higher levels of organic aluminum complexes in soil can increase DOC solubility; and DOC in forest floor soil water may decrease at a faster rate than in mineral soil water. The authors did note that HBEF's rate of decreasing DOC concentrations appeared to be diminishing in the later 15 years of reporting.

Although most studies are on forests, [Sawicka et al. \(2017\)](#) used the MADOC model for three forested and three grassland and heath sites and observed that the acidifying effect of S deposition was the predominant control on the observed soil water DOC trends ([Sawicka et al., 2017](#)). The relative importance of S and N loading depended on soil sensitivity to acidification and on N limitation. In all N limited soils investigated, the modeled DOC increases over the monitoring period were dominated by the effects of recovery from acidification (higher DOC solubility), but the effects of N enrichment driving higher DOC production may have been important in the longer term. In contrast, reductions in nonmarine chloride deposition and the effects of long-term warming appeared to have been relatively unimportant.

Other work has further explored the mechanisms for how N addition (including nutrient as well as acidification effects) affects DOC ([Freedman and Zak, 2014](#); [Kopáček et al., 2013](#)). [Freedman and Zak \(2014\)](#) reported that atmospheric N deposition led to less microbial biodiversity and favored bacterial species in the forest floor that lead to reduced decomposition, increased soil C storage, and accelerated phenolic DOC production ([Figure 4-8](#)). [Kopáček et al. \(2013\)](#) observed that N addition, together with  $\text{SO}_4^{2-}$  deposition, increases the availability of electron acceptors for soil microbial processes. The chemical and microbial responses include an increase in bacterial mineralization creating DOC, increased N mineralization where N availability increases (with an increase in bacterial uptake of DOC), chemical suppression of DOC solubility and bioavailability in the progressively acidifying soils, and finally, the C limitation of microbial metabolism. Bacterial assimilation of  $\text{NO}_3^-$ , which depends on the stoichiometric  $\text{NO}_3^-$  to DOC ratio in the substrate, may initially increase with increasing  $\text{NO}_3^-$  concentrations, but then decrease due to a lower pool of bioavailable DOC.

N = nitrogen; LMCO = Laccase-like multicopper oxidase.

**Figure 4-8** Conceptual diagram of positive (solid arrows) and negative (dashed arrows) fluxes in nitrogen pools (squares) and carbon pools (ovals) and the biological processes (no border) that are affected by experimental nitrogen deposition.

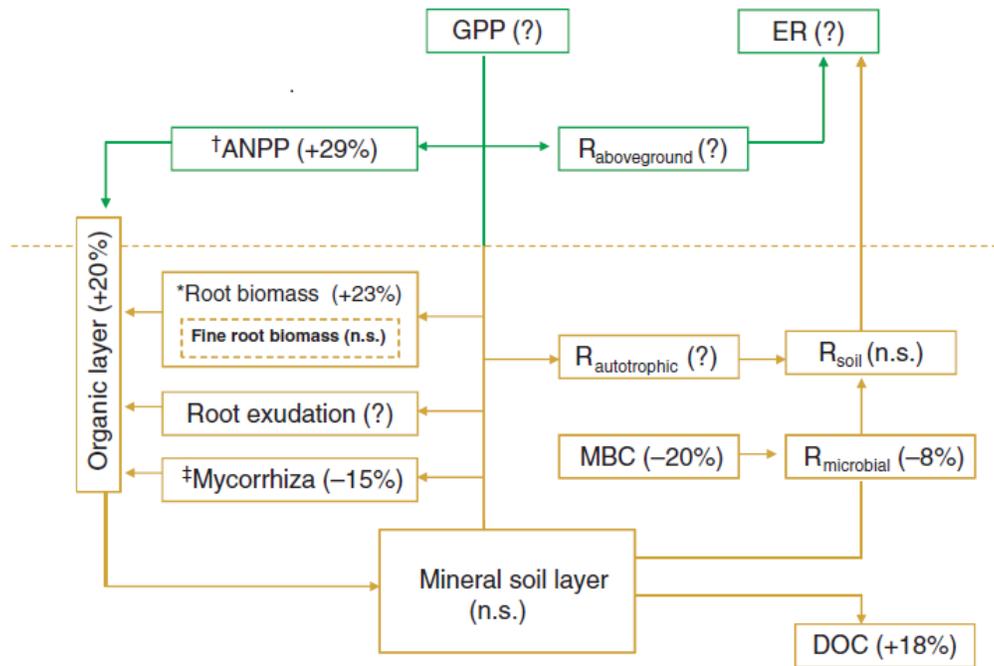

#### 4.3.10 Belowground Carbon Pools

In general, N enrichment influences C flux, C partitioning, and the amount of C sequestered by ecosystems. A number of studies have suggested that C sequestration increases with increasing N supply based on the changes in aboveground net primary production [ANPP; [LeBauer and Treseder \(2008\)](#); [Xia and Wan \(2008\)](#)]. However, about half of the C fixed annually by terrestrial vegetation is allocated to belowground pools. Many studies have shown that the belowground C cycle does not always mirror the aboveground cycle. For example, elevated CO<sub>2</sub> and N both have been shown to increase aboveground biomass production ([LeBauer and Treseder, 2008](#)). However, increases in aboveground plant production and greater aboveground litter inputs do not necessarily increase mineral soil C storage ([Talhelm et al., 2009](#); [Gielen et al., 2005](#); [Lichter et al., 2005](#)), and increases in soil C do not necessarily result from greater aboveground litter inputs ([Pregitzer et al., 2008](#)). This disparity indicates that it is inappropriate to extrapolate from aboveground responses to belowground processes. Aboveground plant biomass, once dropped from the canopy, is one of the major contributors to soil organic

matter accumulation ([Sullivan et al., 2007a](#)). ANPP generally increases with increasing N supply ([LeBauer and Treseder, 2008](#); [Xia and Wan, 2008](#)). However, this increase in C input may not cause an increase in belowground ecosystem C storage. This is because the output of C from the soil may be stimulated by N induced alteration of plant tissue chemistry or the ratio of root:shoot, each of which will change the rate of decomposition (see [Appendix 4.3.7](#)). Since the 2008 ISA was published there have been several new meta-analyses on the effects of N addition on belowground carbon pools ([Janssens et al., 2010](#); [Liu and Greaver, 2010](#)), each integrating information from numerous pools to improve the understanding of how N addition alters the carbon cycle belowground. Additional studies are summarized in [Table 4-11](#).

[Liu and Greaver \(2010\)](#) synthesized data from multiple terrestrial ecosystems to quantify the response of belowground C cycling under N addition ([Figure 4-9](#)). N addition increased aboveground litter inputs (+20%), but fine root litter inputs were unchanged. N addition inhibited microbial activity, as indicated by a reduction in microbial respiration (−8%) and microbial biomass carbon (−20%). Although soil respiration was not altered by N addition, dissolved organic carbon concentration increased (+18%), suggesting C leaching loss may increase. N addition increased the C content of the soil organic horizon (+17%) but not the mineral soil. The increase in organic horizon C was attributed to both increased litter input and decreased decomposition [inferred from the lower microbial respiration rates ([Liu and Greaver, 2010](#))].

Field studies provide additional support for the finding that soil carbon responds differently to N addition depending on the organic (vs. mineral) content of the soil, with organic content tending to decrease with increasing soil depth. In four northern hardwood forests spread across Michigan that received experimental N deposition (additional 30 kg N/ha/yr) for 10 years, [Pregitzer et al. \(2008\)](#) and [Zak et al. \(2008\)](#) reported significant increases in soil C, particularly within the soil organic horizon. These increases occurred despite no increase in aboveground litter production or root turnover. A  $^{15}\text{NO}_3^-$ -labeling experiment revealed that N accumulated in SOM by first flowing through soil microorganisms to plants, which then shed the leaves back to the detrital layer. In a meta-analysis including data from 72 north temperate forests, [Nave et al. \(2009a\)](#) found N addition increased soil C (+7.7%). The forest floor responded differently than the deeper mineral soil layer (5- to 100-cm depth) as increased soil C storage occurred only in the mineral soil (+12.2%), in contrast to the findings of [Liu and Greaver \(2010\)](#) and [Pregitzer et al. \(2008\)](#).

ANPP = aboveground net primary production; DOC = dissolved organic carbon; ER = ecosystem respiration; GPP = gross primary productivity; MBC = microbial biomass carbon; n.s. = nonsignificant;  $R_{\text{aboveground}}$  = aboveground respiration;  $R_{\text{autotrophic}}$  = soil autotrophic respiration;  $R_{\text{microbial}}$  = microbial respiration;  $R_{\text{soil}}$  = total soil respiration.

**Figure 4-9 Estimation of the changes in carbon budget of terrestrial ecosystem under nitrogen addition.**

A new study has evaluated the consistency of N cycling in different ecosystems by synthesizing data across five biomes in California. The results indicated that, across biomes, N concentration in soil has a strong positive correlation to SOC ([Yang et al., 2017](#)). There are also new studies indicating N deposition increases SOM accumulation without altering the biochemical composition ([Zak et al., 2017](#)). New studies on how the response of belowground soil C to N is modified by temperature and precipitation has been published since the 2008 ISA ([Ni et al., 2017](#); [Greaver et al., 2016](#)) and is summarized in [Appendix 4.7](#).

**Table 4-11 Belowground carbon pools.**

Process	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference
SOC	Soil	Great Britain	0–2 g N/m <sup>2</sup> /yr	None	<b>Model:</b> Using model N <sup>14</sup> CP for data from ~2,000 N limited field sites, it was predicted that, N deposition increased NPP between the years 1750 and 2010, increasing via detritus SOC by 1.2 kg C/m <sup>2</sup> (~10%). (The authors assumed ~30% error of estimated values.)	<a href="#">Tipping et al. (2017)</a>
SOC	Five biome classes in California: desert, grassland, shrubland, forest, wetland	California	0.6–18.4 kg N/ha/yr	Grassland soil: 76.4 kg N/ha/yr as NPK (29:3:4); desert soil: 60 kg N/ha/yr as NH <sub>4</sub> NO <sub>3</sub> ; shrubland soil: 60 kg N/ha/yr as NH <sub>4</sub> NO <sub>3</sub>	<b>Synthesis:</b> Across biomes, total N concentration was strongly correlated to SOC ( $R^2 = 0.88$ ; $\log(y) = [0.81 \times \log(x)] - 1.10$ ).	<a href="#">Yang et al. (2017)</a>
SOC	Hardwood forest birch ( <i>Betula platyphylla</i> ) and aspen ( <i>Populus davidiana</i> )	Jilin province, China	23 kg N/ha/yr	0 kg N/ha/yr, 25 kg N/ha/yr, and 50 kg N/ha/yr	<b>N Addition:</b> This was a 6-yr fertilization study. The authors observed that fertilization decreased the fraction of macroaggregates (2–8 mm) and increased the fraction of 0.053–2 mm aggregates. ( $P = 0.01$ ). They concluded that N deposition (as simulated with fertilization) can increase formation of micro- and macroaggregates within macroaggregate soil and thus stabilize C.	<a href="#">Chen et al. (2017)</a>

**Table 4-11 (Continued): Belowground carbon pools.**

Process	Type of Ecosystem	Region	Ambient N/S Deposition kg/ha/yr	N/S Addition kg/ha/yr	Effect of Deposition	Reference
Soil organic matter	Sugar maple ( <i>Acer saccharum</i> )-dominated northern hardwood forests	North-south geographic range of sugar maple-dominated upper Great Lakes and eastern North America	6.8–11.8 kg N/ha/yr (wet + dry) across sites	30 kg NO <sub>3</sub> <sup>-</sup> -N/ha/yr (NaNO <sub>3</sub> )	<b>N Addition:</b> SOM accumulated as soil particulate organic matter occlusion at N addition sites.	<a href="#">Zak et al. (2017)</a>
Abundance of carboxyl, aryl, O/N-alkyl, and alkyl C in mineral soil (biochemical composition of forest floor [Oe/Oi-horizon ~4 cm] and organic matter)	Sugar maple ( <i>Acer saccharum</i> )-dominated northern hardwood forests	North-south geographic range of sugar maple-dominated upper Great Lakes and eastern North America	6.8–11.8 kg N/ha/yr (wet + dry) across sites	30 kg NO <sub>3</sub> <sup>-</sup> -N/ha/yr (NaNO <sub>3</sub> )	<b>N Addition:</b> Abundance of carboxyl and aryl C in forest floor differed across sites but the abundance of O/N-alkyl and alkyl C did not ( <i>P</i> = 0.10–0.80). No difference was observed in the proportion of aryl, O/N-alkyl, or alkyl C in mineral soil between ambient deposition and N addition sites. (Particulate organic matter's increased occlusion of organics may shift fungal and bacterial activity toward partial oxidation of organics without changing biochemistry of organic matter.)	<a href="#">Zak et al. (2017)</a>

#### 4.3.11 New Biogeochemical Indicators

In this section, we report on new biogeochemical indicators reported in the literature since the 2008 ISA. Recent literature offering potential new indicators of biogeochemical change due to N and/or S deposition included fungal-to-bacterial ratio ([Högberg et al., 2013](#)) and syntaxonomic associations [[Wamelink et al. \(2011\)](#); [Table 4-12](#)].

[Högberg et al. \(2013\)](#) proposed soil microbial community indices as predictors of soil solution chemistry and N leaching in *Picea abies* spruce forests in southern Sweden. Stands with low concentrations of  $\text{NO}_3^-$  and  $\text{Al}^{3+}$  had higher fungi:bacteria ratios compared with stands with higher concentrations of  $\text{NO}_3^-$  and Al. They identified three promising microbial community indices as indicators of N leaching from forests; the soil fungi:bacteria ratio was the most important.

In a study in the Netherlands, [Wamelink et al. \(2011\)](#) examined whether the abiotic ranges of syntaxonomic units (associations) in terms of pH and  $\text{NO}_3^-$  concentration can be estimated and then, in principle, used to estimate critical loads for acid and N deposition. They used splines to estimate abiotic ranges of syntaxonomic units based on measured soil pH and  $\text{NO}_3^-$  concentration and vegetation relevés. They acknowledge it is not yet possible to directly estimate ranges for syntaxa for pH and  $\text{NO}_3^-$  on a large scale using this approach; however, indirectly estimated soil pH and  $\text{NO}_3^-$  concentrations are sufficiently available to derive ranges for many associations.

**Table 4-12 New biogeochemistry indicators.**

Endpoint	Nutrient Enrichment Indicator	Acidification Indicator	Deposition kg/ha/yr	Addition kg/ha/yr	Description/Direct Effect of Soil/Water Endpoint on Biological Effect	Reference
N leaching		X	Throughfall N includes wet and dry inputs and ranged from 2.7 to 19	20 (NH <sub>4</sub> NO <sub>3</sub> )	Microbial community composition in the organic layer of spruce forests and soil solution chemistry below the rooting zone was highly correlated. Stands with low concentrations of NO <sub>3</sub> <sup>-</sup> and Al were fungi dominated and had a higher fungi:bacteria ratio compared with stands with high concentrations of these leachates. Leaching stands had higher abundance of Gram-positive bacteria.	<a href="#">Högberg et al. (2013)</a>
Vegetation health	X	X	Not specified	None	Acknowledge the approach is not yet possible to directly estimate ranges for syntaxa for pH and NO <sub>3</sub> <sup>-</sup> on a large scale; however, indirectly estimated soil pH and NO <sub>3</sub> <sup>-</sup> concentrations are sufficiently available to derive ranges for many associations.	<a href="#">Wamelink et al. (2011)</a>

Al = aluminum; ha = hectare; kg = kilogram; N = nitrogen; NH<sub>4</sub>NO<sub>3</sub> = ammonium nitrate; NO<sub>3</sub><sup>-</sup> = nitrate; yr = year.

---

#### 4.3.12 Differential Effects of Reduced and Oxidized Nitrogen

Some biogeochemical process responses to N deposition have the potential to vary depending on whether the dominant form of deposited N was oxidized or reduced. We have focused on presenting meta-analyses as they synthesize the central tendencies of many studies. In some cases, the results for a given endpoint are not consistent among meta-analyses. [Table 4-13](#) summarizes the studies that look at the most common forms of N.

Additional studies include the observation by [Evans et al. \(2008\)](#) that DOC concentrations responded predictably to the chemical form of N used for manipulation, increasing with NaNO<sub>3</sub> additions or gaseous NH<sub>3</sub><sup>+</sup> exposure, and decreasing with most NH<sub>4</sub><sup>+</sup> salt additions ([Appendix 4.3.9](#)). The authors cite the effect of the chemical form of N on acidity as a plausible mechanism. [Ramirez et al. \(2010a\)](#) investigated whether soil microbes in three distinct soils (from aspen, pine, and grassland ecosystems) respond differently to six different reduced and oxidized N species, including NH<sub>4</sub>NO<sub>3</sub>, (NH<sub>2</sub>)<sub>2</sub>CO (urea), KNO<sub>3</sub>, NH<sub>4</sub>Cl, (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>, and Ca(NO<sub>3</sub>)<sub>2</sub> (also discussed in [Appendix 6](#)). The authors found that all inorganic forms of N fertilizer significantly decreased microbial CO<sub>2</sub> production but that organic N (urea) decreased the respiration rate in forest soil only by 27% (aspen) and 11% (pine) and increased the grassland microbial respiration rate by 20%. They added that the soil pH change resulting from N addition did not appear to influence the observed decrease in the soils' microbial respiration rate.

[Jovan et al. \(2012\)](#) monitored tree trunk pH during their research on eutrophic lichen abundance in the Los Angeles air basin, oxidized forms of N (particularly HNO<sub>3</sub>) dominate dry deposition. They noted that NH<sub>3</sub> deposition would normally raise bark pH but in the arid, hot Mediterranean climate of the study area, high trunk pH dust raises bark pH.

**Table 4-13 The effects of different forms of inorganic nitrogen on biogeochemical processes and indicators according to meta-analyses. See [Table 6-1](#) for the effects of different forms of inorganic nitrogen on biological endpoints.**

## 4.4 Soil Monitoring and Databases

There are several new studies using long-term monitoring data sets in the U.S. and Europe ([Table 4-14](#)). New studies in the U.S. include an analysis of 45 years of biogeochemical monitoring data ([Yanai et al., 2013](#)) and sulfur accumulation ([Mitchell and Likens, 2011](#)) at the HBEF, NH. At the Niwot Ridge LTER site, CO ([Lieb et al., 2011](#)), identify the effects of a decade of simulated N deposition in the southern Rocky Mountains.

[Yanai et al. \(2013\)](#) evaluated 45 years of biogeochemical monitoring data at the HBEF, NH. Since 1992, the ecosystem shifted to a net N sink ~8 kg N/ha/yr. There are several possible explanations: (1) gaseous N fluxes from the ecosystem in response to denitrification, (2) a budget discrepancy in the net error of the other measured and estimated stocks and fluxes, and/or (3) N accumulation in an unidentified ecosystem compartment.

As discussed in [Appendix 4.3.3](#), [Mitchell and Likens \(2011\)](#) examined the sulfur accumulation observed in over four decades of continuous long-term records for four watersheds in HBEF, NH and found that as S deposition declined, soil moisture became a more powerful control on S release from soils than did deposition.

At the southern Rocky Mountains Niwot Ridge LTER site, CO, [Lieb et al. \(2011\)](#) found a decade of simulated N deposition to alpine ecosystems caused ongoing changes in diversity and soil biogeochemistry, including lower soil acid buffering capacity, decreased concentrations of exchangeable  $Mg^{2+}$ , and increased concentrations of the potentially toxic cations  $Mn^{2+}$  and  $Al^{3+}$ . Their results suggested an N deposition threshold for the onset of acidification at this site of 28 kg N/ha/yr.

**Table 4-14 Biogeochemistry monitoring and databases.**

Process/ Indicator	Type of Ecosystem	Region	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Effects	Reference
Base cation (Bc) release soil [Al] soil [Mn] soil pH	Alpine soils	Niwot Ridge in the southern Rocky Mountains, CO, U.S.	6 to 8 (10 yr)	8, 28, 48, and 68 (NH <sub>4</sub> NO <sub>3</sub> )	<b>Addition:</b> Changes in diversity, lower soil acid buffering capacity, decreased concentrations of Mg <sup>2+</sup> , and increased concentrations of the potentially toxic cations Mn <sup>2+</sup> and Al <sup>3+</sup> . Results suggested an N deposition threshold of 28 kg N/ha/yr.	<a href="#">Lieb et al. (2011)</a>
Sulfate leaching [SO <sub>4</sub> <sup>2-</sup> ]	Northeastern forest	HBEF, NH, U.S.	Not specified	None	<b>Monitoring:</b> Over four decades of data were used to evaluate S budgets. Current declining inputs of atmospheric S and the higher outputs of SO <sub>4</sub> <sup>2-</sup> in drainage waters relative to precipitation inputs are driven by the S stored in the soil. Climatic change will potentially increase SO <sub>4</sub> <sup>2-</sup> mobilization and hence could slow the resultant recovery from acidification.	<a href="#">Mitchell and Likens (2011)</a>
N accumulation C:N soil [N]	Northern hardwood forest	HBEF, NH, U.S.	~7 (since 1992)	None	<b>Monitoring:</b> Since 1992, the ecosystem shifted to a net N sink, either storing or denitrifying ~8 kg N/ha/yr.	<a href="#">Yanai et al. (2013)</a>

**Table 4-14 (Continued): Biogeochemistry monitoring and databases.**

Process/ Indicator	Type of Ecosystem	Region	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Effects	Reference
NO <sub>3</sub> <sup>-</sup> leaching C:N (lake) C:N (mineral soil layer) TOC:TN	Boreal soils and lakes	Sweden	<3 to 17	None	<b>Gradient:</b> Significant relation found between C:N ratios of the organic soil layer and the ones of lake waters. Evidence found of N deposition having depressed the C:N ratios of lake waters more than the ones of organic soil layers. Clear sudden increase seen in NO <sub>3</sub> <sup>-</sup> leaching in regions where N deposition exceeded 7.5 kg/ha/yr.	<a href="#">Khalili et al. (2010)</a>
Oxidation of organic S in humic soils due to S dep Ratio of reduced to oxidized organic S	Grassland	Rothamsted Park Grass Experiment, Hertfordshire, England	Not specified	None	<b>Monitoring:</b> Analysis of the effects of atmospheric SO <sub>2</sub> emissions since the late 1800s found acidification led to a depletion of exchangeable Ca and Mg and an 8× increase in exchangeable Al.	<a href="#">Lehmann et al. (2008)</a>
Bc, N, and SO <sub>4</sub> <sup>2-</sup> flux soil solution [Al] soil solution Bc soil solution [Inorganic N] soil solution [SO <sub>4</sub> <sup>2-</sup> ] molar Bc:Al in soil solution	Forest, including beech and Norway spruce	Switzerland, Jura Mountains in southern Alps. The forests were not managed during the whole observation period	Between 2000 and 2007, mean (-0.02 to 1.99 kmol/ha/yr)	None	<b>Monitoring:</b> A decade (1995–2007) of monitoring data indicates acidifying deposition significantly decreased at three out of the nine study sites due to a decrease in total N deposition. In the soil solution, no trend in concentrations and fluxes of Bc, SO <sub>4</sub> <sup>2-</sup> , and inorganic N were found at most soil depths at five out of the seven sites, suggesting that the soil solution reacted very little to the changes in atmospheric deposition.	<a href="#">Pannatier et al. (2011)</a>

**Table 4-14 (Continued): Biogeochemistry monitoring and databases.**

Process/ Indicator	Type of Ecosystem	Region	Deposition (kg/ha/yr)	Addition (kg/ha/yr)	Effects	Reference
pH, ANC, base cations, Al <sub>i</sub> , Al <sub>o</sub>	Forest and streams	HBEF, NH	Variable	None	<b>Field observation:</b> Soil solution monitoring 1984–2011 at HBEF showed that: pH and ANC did not change significantly in the Oa-horizon but ANC increased in Bs-horizon. Total base cations decreased in Bs-horizon. Al <sub>o</sub> decreased and. Al <sub>i</sub> decreased in the 2 high-elevation subwatersheds.	<a href="#">Fuss et al. (2015)</a>

Al = aluminum; Al<sub>i</sub> = inorganic aluminum; Al<sub>o</sub> = organic aluminum; Bc = base cation; C = carbon; Ca = calcium; ha = hectare; HBEF = Hubbard Brook Experimental Forest; kg = kilogram; kmol = kilomole; Mg = magnesium; Mn = manganese; N = nitrogen; NH<sub>4</sub>NO<sub>3</sub> = ammonium nitrate; NO<sub>3</sub><sup>-</sup> = nitrate; S = sulfur; SO<sub>2</sub> = sulfur dioxide; SO<sub>4</sub><sup>2-</sup> = sulfate; TN = total nitrogen; TOC = total organic carbon; yr = year.

There are new studies evaluating long-term monitoring in Europe, including those looking at S dynamics in England ([Lehmann et al., 2008](#)) and N and S dynamics in Switzerland ([Pannatier et al., 2011](#)). In Sweden, [Khalili et al. \(2010\)](#) examined N and C interactions between boreal soils and lakes. [Lehmann et al. \(2008\)](#) found that soil acidification from the input of oxidized organic S proceeded much more rapidly than did recovery after reductions of atmospheric emissions and deposition. [Pannatier et al. \(2011\)](#) examined monitoring data at Swiss Long-Term Forest Ecosystem Research sites. The results suggested that the fluxes of  $\text{Bc}$ ,  $\text{SO}_4^{2-}$ , and inorganic N in soil solution reacted very little to the changes in atmospheric deposition. A stronger reduction in base cations compared to  $\text{Al}^{3+}$  was detected at two sites, possibly indicating that acidification of the soil solution was proceeding faster at these sites than the other sites. In Sweden, [Khalili et al. \(2010\)](#) examined samples collected in selected years between 1993 and 2005. Although they found a significant relation between C:N ratios of the organic soil layer and lake waters, the large-scale variations in soil C content were not directly linked to C concentrations in lake waters. Soil N seems to have leached in small amounts from the soils directly into the lakes in the form of  $\text{NO}_3^-$ .  $\text{NO}_3^-$  leaching showed a clear and sudden increase in regions where N deposition exceeded 7.5 kg/ha/yr.

---

## 4.5 Models

The 2008 ISA described the most commonly applied soil biogeochemistry models in the U.S. used to track N and/or S deposition (Section A.3 of the 2008 ISA). The focus of [Appendix 4.5](#) is to update available information on several key models currently being used in the U.S. to assess the effects of S and N deposition on terrestrial ecosystem soil biogeochemistry. Steady-state models include steady-state simple mass-balance (SMB). Dynamic models include the Very Simple Dynamic (VSD) soil acidification model, MAGIC, PnET/BGC, and DayCent-Chem. One important input to these models is estimating base cation weathering (BCw), and there are new updates on two methods to estimate this parameter: Soil Texture Approximations (STA) and PROFILE.

---

## 4.5.1 Updates to Key Previously Identified Models

---

### 4.5.1.1 Soil Texture Approximation (STA) and PROFILE: Estimating Base Cation Weathering

Base cation weathering (BCw) rate is one of the most influential yet difficult to estimate parameters in the calculation of critical acid loads of N and S deposition for terrestrial systems. As discussed in [Appendix 4.3](#), acidifying deposition causes base cation leaching from soil. The supply of base cations is largely replenished by base cation weathering of minerals from rock within the ecosystems. Obtaining accurate estimates of weathering rates is difficult because weathering is a process that occurs over very long periods of time. There are some new studies on estimating BCw, including a study on the clay correlation-substrate method and PROFILE ([Koseva et al., 2010](#)), a new application of PROFILE in the U.S. ([Phelan et al., 2014](#)), and an evaluation of uncertainty in estimating BCw ([Futter et al., 2012](#)).

The clay correlation-substrate method, also called clay-based Soil Texture Approximation (STA), is an empirical steady-state model that has been used to estimate BCw rates for forest ecosystems in the U.S. because it is simple and has low data requirements. The STA method has an empirical function that was first developed for European soils and later adapted to soils in Canada and the U.S. The method estimates total base cation weathering rates (BCw, sum of  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Na}^+$ , and  $\text{K}^+$ ), based on the relationship between established weathering classes and clay content of soils for different acidity classes—acidic, intermediate, and basic. An alternate steady-state model, PROFILE ([Sverdrup and Warfvinge, 1993](#)), may offer an improved method to estimate BCw rates. It is a transferable, process-based model that simulates the weathering rates of groups of minerals. PROFILE was developed in Sweden and is a mechanistic, steady-state kinetics model that calculates the weathering of  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{K}^+$ , and  $\text{Na}^+$  in each horizon within a soil profile based on mineral specific chemical dissolution rates and site and soil conditions. Because PROFILE is a steady-state model, weathering rates calculated by PROFILE can be used with the SMB critical acid load model. One of the main limitations that has discouraged the wider adoption of PROFILE for BCw rate determinations in the U.S. is the large data requirements of the model ([Koseva et al., 2010](#)).

[Koseva et al. \(2010\)](#) reported on their evaluation and revision of the STA model for use in Canadian forests. The authors compared the performance of the STA model to PROFILE weathering estimates for soils at 75 sites in Canada. The relative ability of the STA and PROFILE models to provide reasonable weathering rates was evaluated using

base cation mass balances at a subset of sites in Ontario ( $n = 19$ ). Mineral weathering rates calculated with the STA method at 75 sites in Canada (6–367 eq/ha/yr) were up to 38 times lower (7 times on average) than rates estimated with PROFILE (143–2,119 eq/ha/yr,  $p < 0.0001$ ). Despite deviations from the 1:1 line, weathering estimates obtained using the STA method were significantly correlated using PROFILE weathering estimates ( $p < 0.05$ ). The authors concluded that the “revised” STA model they used may be more widely applicable in Canada, but not necessarily suited to all regions in the U.S. The uncertainty of the model is largely unknown, and the three equations of the clay correlation-substrate method require recalibration or revision when transferred to new locations. In addition, the STA equations were derived for young soils that developed following the Late Wisconsin glaciation ([Koseva et al., 2010](#)); the clay correlation-substrate model, which is based on clay content and parent material acidity, may not be suitable for older, more weathered soils that were not affected by the most recent glaciation and which cover the majority of the U.S. ([U.S. EPA, 2009c](#)).

PROFILE requires over 26 time series or site parameters as model inputs. The U.S. Geological Survey (USGS) recently completed a soil geochemical and mineralogical survey of the U.S. as part of the North American Soil Geochemical Landscapes Project. This project, hereafter referred to as the USGS Landscapes Project, included mineralogy analyses conducted on soil samples collected from 4,871 evenly spaced sites across the U.S. ([Smith et al., 2013](#)). These new data allow the PROFILE model to be applied at a larger scale. [Phelan et al. \(2014\)](#) evaluated PROFILE using national data sets as a method to estimate BCw rates for forests in the U.S., focusing on Pennsylvania as the first test state. The model was successfully applied at 51 forested sites across Pennsylvania. Weathering rates ranged from 11.9 to 924.5 meq/m<sup>2</sup>/yr and were consistent with soil properties and regional geology. The authors suggest that the method be applied to other locations to further evaluate the performance of the model.

A data set of published BCw rates was evaluated by [Futter et al. \(2012\)](#). The data set included 394 individual silicate mineral weathering rate estimates from 82 poorly buffered, silicate-mineral-dominated locations across the world where at least 3 published estimates of BCw were available. The researchers found uncertainty for the input data high relative to the estimated contribution of model parameter uncertainty of BCw weathering rate (meq/m<sup>2</sup>/yr) to overall variability related to PROFILE and MAGIC, ranging from 1.7 to 2.1 for the two models, respectively. The two models have been most widely used to make assessments of weathering rates for environmental decision making, and each represents the landscape differently. PROFILE provides estimates for shallow one-dimensional soil, whereas MAGIC integrates weathering processes for the whole catchment, including deep soil weathering. Therefore, lower weathering rate estimates are shown from PROFILE in comparison to MAGIC, which considers deep soil

weathering to constitute a potentially important source of Bc in catchment weathering ([Futter et al., 2012](#)).

[Whitfield et al. \(2018\)](#) evaluated major sources of uncertainty associated with using PROFILE for upland forests in the continental U.S. Mineral stoichiometry was not an important influence on BCw estimates (uncertainty < 1%). Characterizing B-horizon mineralogy by averaging A- and C-horizons was found to be a minor (< 5%) contributor to uncertainty in some areas, but where mineralogy is known to vary with depth the uncertainty can be large. Estimating mineral-specific surface areas had a strong influence on estimated BCw, however the greatest uncertainty in BCw estimates, was due to the particle size class-based method used to estimate the total specific surface area upon which weathering reactions can take place.

---

#### 4.5.1.2 Steady-State Mass Balance

The 2008 ISA documented a model to assess CLs for acidification in forest soils based on simple mass-balance equations [SMBE; [McNulty et al. \(2007\)](#)]. This study estimated critical acid load and exceedance in soils at a 1-km<sup>2</sup> spatial resolution across the U.S. A second publication discussed the uncertainties associated with this model and national-scale assessment ([Li and McNulty, 2007](#)). The authors quantified uncertainty under natural variability in 17 model parameters and determined the relative contributions of each in predicting critical loads. The results indicated that uncertainty in the CLs came primarily from components of base cation weathering (BCw; 49%) and acid neutralizing capacity (46%), whereas the most critical parameters were BCw base rate (62%), soil depth (20%), and soil temperature (11%). The authors concluded that improvements in estimates of these factors are crucial to reducing uncertainty and successfully scaling up SMBE for national assessments. This work remains the best national-scale estimate of terrestrial soil acidification in the U.S. (see [Appendix 4.6](#)). A new study by [Posch et al. \(2011\)](#) is a regional application of SMB models, while several other studies using SMB have been published to determine acidification critical loads based on critical limits of Bc:Al and ANC ([Phelan et al., 2014](#); [Duarte et al., 2013](#); [Jung et al., 2013](#); [Whitfield and Watmough, 2012](#); [Forsius et al., 2010](#); [McNulty and Boggs, 2010](#); [Nasr et al., 2010](#)). The biological implications of these critical loads are discussed in [Appendix 5](#) and a summary of SMB CLs in the U.S. is presented in [Appendix 4.6](#).

[Posch et al. \(2011\)](#) published an article outlining SMB models for use in N deposition on ecosystem biodiversity. This approach has the well-established benefit of easy regional applicability, while incorporating specified critical chemical criteria to protect specified receptors. Rather than indicating an upper limit for deposition (i.e., critical load), linked

nutrient nitrogen and acidity chemical criteria for plant occurrence produce an “optimal” nitrogen and sulfur deposition envelope. This method is similar to the methods developed in the 2012 Policy Assessment for the Review of the secondary NAAQS for Oxides of N and S.

---

#### **4.5.1.3 ForSAFE and ForSAFE-VEG**

The ForSAFE model ([Wallman et al., 2005](#)) is the biogeochemical simulator platform that simulates the cycles of carbon, nitrogen, base cations (Bc), and water in a forest ecosystem, including simulation of soil chemistry, tree growth, and soil organic matter accumulation or depletion. ForSAFE requires site-specific inputs of the physical properties of the soil (including mineralogy, hydrological parameters, density, depth, and stratification), tree type, and time series of atmospheric deposition and climatic data (temperature, light, and precipitation). The model gives monthly estimates of weathering rates, soil moisture, soil solution concentrations, uptake fluxes of N and Bc, litterfall, decomposition and mineralization, as well as photosynthesis and growth rates. ForSAFE-VEG is a composite model, in which the VEG module ([Sverdrup et al., 2007](#)) reads a set of five drivers (soil solution pH, Bc concentration, N concentration, ground level light, soil moisture) from ForSAFE, including air temperature, and uses them to estimate the relative abundance of a set of indicator plants at the site. The result is a model chain that can link changes in atmospheric deposition, climatic conditions, and land use to responses in the biogeochemistry and plant community composition at the site level, both historically and in the future. A new study by [Belyazid et al. \(2011a\)](#) revealed limitations in the model simulation of N concentrations in soil solution. The authors concluded that the biogeochemical model platform must be improved to simulate N processes more accurately before it is used to calculate CL for N deposition. The model overestimated the actual N concentrations in the soil solution. Several new applications of ForSAFE-VEG have been published ([Sverdrup et al., 2012](#); [Belyazid et al., 2011a](#)), and the results are discussed in [Appendix 5](#) and [Appendix 6](#).

---

#### **4.5.1.4 Model of Acidification of Groundwater in Catchment (MAGIC)**

The Model of Acidification of Groundwater in Catchment [MAGIC; [Cosby et al. \(1985a\)](#); [Cosby et al. \(1985b\)](#); [Cosby et al. \(1985c\)](#)] is one of the most well-known dynamic models of aquatic and terrestrial acidification. It is a lumped-parameter model of soil and surface water acidification in response to atmospheric deposition based on process-level information about acidification. “Lumped-parameter” refers to the extent

that spatially distributed physical and chemical processes in the catchment are averaged or lumped together without affecting the model's reproduction of catchment response. Process-level information refers to how the model characterizes acidification into (1) a section in which the concentrations of major ions are assumed to be governed by simultaneous reactions involving  $\text{SO}_4^{2-}$  adsorption, cation exchange, dissolution-precipitation-speciation of aluminum, and dissolution-speciation of inorganic carbon and (2) a mass balance section in which the flux of major ions to and from the soil is assumed to be controlled by atmospheric inputs, chemical weathering, net uptake and loss in biomass, and losses to runoff. One strength of MAGIC is the size of the pool of exchangeable base cations in the soil. As the fluxes to and from this pool change over time due to changes in atmospheric deposition, the chemical equilibria between soil and soil solution shift to give changes in surface water chemistry. The degree and rate of change of surface water acidity thus depend both on flux factors and the inherent characteristics of the affected soils. The data requirements to run dynamic models like MAGIC are considerable. The equations that characterize the chemical composition of soil water in MAGIC contain 33 variables and 21 parameters. Data required to conduct dynamic modeling are not as available in as many places as the data required to conduct steady-state modeling.

[Oulehle et al. \(2012\)](#) presented a new formulation of the acidification model MAGIC that uses decomposer dynamics to link N cycling to C turnover in soils. In comparisons with earlier versions, the new formulation more accurately simulates observed short-term changes in  $\text{NO}_3^-$  leaching, as well as long-term retention of N in soils. The authors state that the new formulation gives a more realistic simulation of observed changes in N leaching. The new formulation also provides a reasonable simulation of the long-term changes in C and N pools (and C:N ratio) with SOM.

MAGIC has recently been used to calibrate BCw at 140 locations throughout the southern Appalachian Mountains, where input data were sufficient for running the dynamic model ([Povak et al., 2014](#)). Results were then extrapolated to the region. [McDonnell et al. \(2014b\)](#) used these calibrated regionalized BCw values as inputs for regional steady-state CL modeling.

---

#### **4.5.1.5 Photosynthesis and Evapotranspiration—Biogeochemical (PnET-BGC)**

The Photosynthesis and Evapotranspiration—Biogeochemical (PnET-BGC) model is an integrated forest-soil-water model that has been used to assess the effects of air pollution and land disturbances on forest and aquatic ecosystems ([Gbondo-Tugbawa et al., 2001](#)). The model was developed by linking two submodels: PnET-carbon and nitrogen

[PnET-CN; [Aber et al. \(1997\)](#)] and BGC ([Gbondo-Tugbawa et al., 2001](#)). The main processes in the model include tree photosynthesis, growth and productivity, litter production and decay, mineralization of organic matter, immobilization of nitrogen, nitrification ([Aber et al., 1997](#)), vegetation and organic matter interactions of major elements, abiotic soil processes, solution speciation, and surface water processes ([Gbondo-Tugbawa et al., 2001](#)). The hydrologic algorithms used in PnET-BGC are summarized by [Aber and Federer \(1992\)](#) and [Chen and Driscoll \(2005\)](#). PnET-BGC has the capability of using multiple soil layers ([Chen and Driscoll, 2005](#)) to model seasonal variations in soil parameters and chemistry. Applications and conceptual advancements to the model published since 2008 are summarized in [Table 4-15](#).

---

#### **4.5.1.6 DayCent-Chem**

DayCent-Chem links two widely accepted and tested models, one of daily biogeochemistry for forest, grassland, cropland, and savanna systems, DayCent ([Parton et al., 1998](#)), and the other of soil and water geochemical equilibrium, PHREEQC ([Parkhurst and Appelo, 1999](#)). The linked DayCent/PHREEQC model was created to capture the biogeochemical responses to atmospheric deposition and to explicitly consider those biogeochemical influences on soil and surface water chemistry. The linked model expands on DayCent's ability to simulate N, P, S, and C ecosystem dynamics by incorporating the reactions of many other chemical species in surface water.

**Table 4-15 Photosynthesis and Evapotranspiration—Biogeochemical (PnET-BGC) and DayCent.**

Region	Deposition	Model (Dynamic or Steady State)	Approach/Observation	Reference
HBEF, NH	526 eq S/ha/yr; 327 eq NO <sub>3</sub> <sup>-</sup> /ha/yr; ~522 eq NO <sub>3</sub> <sup>-</sup> + NH <sub>3</sub> /ha/yr	PnET-BGC	<b>Application:</b> Combination of multiple deposition scenarios of S, NO <sub>3</sub> <sup>-</sup> , and base cation deposition (0 to 100% decrease in 20% increments after 2008), as well as current climate and climate change scenarios to year 2100.	<a href="#">Wu and Driscoll (2010)</a>
HBEF, NH	Not specified	PnET-BGC	<b>Conceptual advancement:</b> PnET-BGC modified to include CO <sub>2</sub> .	<a href="#">Pourmokhtarian et al. (2012)</a>
San Bernadino Mtns., CA	Two sites: (1) 8.8 kg N/ha/yr; (2) 70 kg N/ha/yr	DayCent	<b>Conceptual advancement:</b> DayCent modified to include O <sub>3</sub> effects.	<a href="#">Bytnerowicz et al. (2013)</a>
Adirondack Long-term Monitoring Program (ALTM; 128 lakes)	Mean wet + dry dep. 2009–2011: S = 20–34 meq/m <sup>2</sup> /yr; N = 24–33 meq/m <sup>2</sup> /yr	PnET-BGC	<b>Application:</b> Controlling S deposition is more effective in promoting acidic lake recovery than controlling S + N deposition.  Reducing S dep. 60% beyond 2011 level is predicted to restore 28% of impaired lakes to ANC 20 µeq/L ≥ by 2050 and 60% of lakes by 2200. An ANC of 11 µeq/L can be achieved to 53% of lakes by 2050.	<a href="#">Fakhraei et al. (2014)</a>
Adirondack Mtns. Region, NY	SO <sub>4</sub> <sup>2-</sup> = 290.3–365.7 eq/ha/yr; NO <sub>3</sub> <sup>-</sup> = 172.5–233.5 eq/ha/yr		<b>Application:</b> PnET-BGC was used to evaluate biophysical factors that affect CLs and TLs of acidity for the Constable Pond watershed, as an example of a chronically acidic drainage lake in the Adirondack region of New York, U.S. These factors included a range of future scenarios of decreases in atmospheric nitrate, ammonium and sulfate deposition from present to 2200.	<a href="#">Zhou et al. (2015c)</a>
Great Smoky Mtns. National Park	6.8–27.8 kg S/ha/yr 6.1–16.6 kg N/ha/yr (2004–2008)	PnET-BGC	<b>Application:</b> Simultaneous reduction in SO <sub>4</sub> <sup>2-</sup> and NO <sub>3</sub> <sup>-</sup> deposition is more effective at increasing stream ANC than SO <sub>4</sub> <sup>2-</sup> alone. NO <sub>3</sub> <sup>-</sup> leaching continues as N deposition decreases. Stream recovery is delayed as NO <sub>3</sub> <sup>-</sup> facilitates desorption of legacy SO <sub>4</sub> <sup>2-</sup> that is adsorbed to acid soils.	<a href="#">Zhou et al. (2015b)</a>

**Table 4-15 (Continued): Photosynthesis and Evapotranspiration—Biogeochemical (PnET-BGC) and DayCent.**

Region	Deposition	Model (Dynamic or Steady State)	Approach/Observation	Reference
Great Smoky Mtns. National Park	3.1 kg S/ha/yr 5.1 kg N/ha/yr	PnET-BGC	<b>Application:</b> Due to soil SO <sub>4</sub> <sup>2-</sup> adsorption capacity, reducing NH <sub>4</sub> <sup>+</sup> deposition would be more effective in stream recovery than reducing NO <sub>x</sub> and SO <sub>2</sub> .	<a href="#">Fakhraei et al. (2016)</a>

---

## 4.5.2 New Models (Published since 2008)

---

### 4.5.2.1 SMARTml

SMARTml is an assemblage of surface complexation models (SCMs), which are used in predicting dynamics in soil chemistry without any site-specific calibration. In the first published application of SMARTml to a spruce forest site in Germany, model results matched observations well overall ([Bonten et al., 2011](#)). Simulations deviated from observations only for soil layers or parameters for which insufficient information was available. These positive results demonstrate the potential to further apply SCMs in dynamic modeling. Current results only refer to a single site, and the testing of SCMs for more cases with differences in soil types, depositions, and environmental conditions are needed to better understand the strengths of this model.

---

### 4.5.2.2 Very Simple Dynamic (VSD) and VSD<sup>+</sup>

The Very Simple Dynamic (VSD) soil acidification model is the simplest extension of the steady-state SMB model into a dynamic model. It does this by including cation exchange and time-dependent N immobilization (accumulation). The VSD model is designed for sites with little available data and for applications on a large regional or continental scale. The model has a short execution time that allows rapid scenario analyses and the calculation of target loads (i.e., deposition targets), which result in a desired chemical condition in the soil (solution) in a specified year. [Posch and Reinds \(2009\)](#) developed a version of the VSD for steady-state critical load applications at the regional scale. Although simpler than other widely used dynamic models (such as MAGIC and SAFE), VSD contains the basic physical and chemical relationships common to all these models. However, the model's simplicity also means that some processes have either been left out altogether (e.g.,  $\text{SO}_4^{2-}$  sorption) and others strongly simplified (e.g., N cycling processes). As a consequence, VSD is not best suited for sites where  $\text{SO}_4^{2-}$  adsorption is important. Furthermore, the simple description of N processes does not allow simulating decreasing soil N pools (and increasing C:N ratios) under reduced N inputs.

[Bonten et al. \(2015\)](#) describe an extension of the VSD model, called VSD<sup>+</sup>, which includes an explicit description of C and N turnover. The VSD<sup>+</sup> model includes an explicit description of organic C and N turnover, whereas in the VSD model, N

immobilization depends on the N availability and C sequestration mostly depends on the N immobilization rate, which is controlled by user-prescribed C:N ratios. The VSD<sup>+</sup> model also includes S adsorption on soils. The authors apply VSD<sup>+</sup> to three forest stands, which differ in N deposition and soil C:N ratios. Results suggest that at some locations VSD<sup>+</sup> can accurately predict trends and absolute values of NO<sub>3</sub><sup>-</sup> and NH<sub>4</sub><sup>+</sup> concentrations in soil and stream waters, soil C:N ratios and pH.

---

#### 4.5.2.3 Soil Organic Matter

The Soil Organic Matter (SOM) model was developed as an alternative to the decomposition module of the PnET model for application in northeastern forests. It relies on empirical representations of litter decomposition and soil C turnover rates, and explicitly represents multiple soil horizons. [Tonitto et al. \(2014\)](#) examined the effect of N addition on SOM dynamics. Their model simulations suggested that ambient atmospheric N deposition at the forest has led to an increase in cumulative O-, A-, and B-horizons C stocks of 211 g C/m<sup>2</sup> (3.9 kg C/kg N) and 114 g C/m<sup>2</sup> (2.1 kg C/kg N) for hardwood and pine standards, respectively. They concluded that the model proved largely able to simulate soil C and N dynamics at their study site under control conditions and that field observations, mechanistic experiments, and model simulations suggest that the addition of N to forest ecosystems could have a substantial effect on forest soil C accumulation via suppression of organic matter decomposition.

---

#### 4.5.2.4 ORCHIDEE—Carbon-Nitrogen

ORCHIDEE—Carbon-Nitrogen (O-CN) is a terrestrial biosphere model which has been developed from the land surface model ORCHIDEE and describes the N and C fluxes and stocks of vegetation and SOM for 10 natural plant functional types, as well as C<sub>3</sub> and C<sub>4</sub> croplands at a half-hourly timescale. [Zaehle \(2013\)](#) determined that the estimate C sequestration from the process-based O-CN model is lower than was found in earlier studies based on simple biogeochemical models and upscaling of field-based measurement, which have estimated C sequestration based on N deposition estimates as 0.4–0.7 Pg C/yr in 1990. The O-CN results were within the range of previous model simulations with the current generation of C-N cycle models (0.2–0.6 Tg N/yr). The authors believe the study provides an advance over previous assessments because it relies on a “process-based ecosystem model that integrates the key C-N cycle interactions and their coupling to biogeophysical processes, while considering the impacts of atmospheric (climate, CO<sub>2</sub>) and land cover changes.” Key uncertainties in the modeling include (1) the response of canopy-level photosynthesis to N additions, (2) changes in the allocation

patterns (root:shoot ratio), and (3) the competition of plants and soil microbes for the added (or reduced) amount of N.

---

#### 4.5.2.5 Dynamic Model N<sup>14</sup>C

Dynamic model N<sup>14</sup>C is a plant-soil N and C cycling model that simulates terrestrial ecosystem responses to atmospheric N deposition ([Tipping et al., 2012](#)). The model includes four plant functional types: broadleaved and coniferous trees, herbs, and dwarf shrubs. It simulates net primary production (NPP); C and N pools; leaching of DOC, DON, and inorganic N; denitrification; and the radiocarbon contents of organic matter on an annual time step. The model simulates annual plant growth and turnover and soil C and N cycling and is reasonably successful at reproducing average results. However, for individual sites, there are no significant correlations for C pools or C:N ratios and only weak relationships for N pools and inorganic N leaching. Inorganic leaching has traditionally been considered one of the main indicators of N saturation (however, see new studies in [Appendix 4.3.2](#)) and therefore an important goal of N<sup>14</sup>C is to simulate its response to N enrichment.

---

#### 4.5.2.6 Dynamic Simulation Model of Ecosystem Nitrogen

[Perakis and Sinkhorn \(2011\)](#) reported  $\delta^{15}\text{N}$  constraints on long-term N balances in temperate forests using a dynamic simulation model of ecosystem N and  $\delta^{15}\text{N}$ . Their model evaluated which combination of N input and loss pathways could produce a range of high ecosystem N contents characteristic of forests in the Oregon Coast Range, U.S. Ecosystem  $\delta^{15}\text{N}$  displayed a curvilinear relationship with ecosystem N content and largely reflected mineral soil, which accounted for 96–98% of total ecosystem N. Model simulations of ecosystem N balances parameterized with field rates of N leaching required long-term average N inputs that exceed atmospheric deposition and asymbiotic and epiphytic N<sub>2</sub>-fixation, and that were consistent with cycles of post-fire N<sub>2</sub>-fixation by early successional red alder. Soil water  $\delta^{15}\text{NO}_3^-$  patterns suggested a shift in relative N losses from denitrification to  $\text{NO}_3^-$  leaching as N accumulated, and simulations identified  $\text{NO}_3^-$  leaching as the primary N loss pathway that constrains maximum N accumulation.

---

### 4.5.3 Comparative Analyses

[Tominaga et al. \(2009\)](#) used HBEF located in NH, as the setting to evaluate the performance of three uncalibrated process-oriented models. They performed a Monte

Carlo multiple-model evaluation framework of the dynamic models MAGIC, SAFE, and VSD. The greatest differences in model outputs were attributed to the cation exchange submodel, with Gapon exchange-based models retaining more base cations on the exchange complex and releasing less into solution, resulting in lower soil solution ANC values. Given the same deposition scenario, the three models (without calibration) simulate changes in soil and soil solution chemistry differently, but the basic patterns were similar.

[Bonten et al. \(2015\)](#) compared common dynamic models used to evaluate soils ([Table 4-16](#)). Comparisons are summarized in [Table 4-17](#).

**Table 4-16 Overview of properties of four dynamic soil chemistry models as characterized in [Bonten et al. \(2015\)](#).**

Features	VSD	MAGIC	ForSAFE	SMARTml
Number of soil layers	1	1–3	1–20	1–15 soil horizons
Temporal resolution	Annual	Annual/monthly	Monthly	Variable (day–yr)
Bc weathering	External input	Calibrated, or external-input	Submodel	External input
Forest nutrient uptake	External input	External input	Submodel	Submodel
Runoff-to-precipitation ratio	External input	External input	Fixed ratio	External input
Sulfate adsorption	Not included	Langmuir isotherm	Yes	At Fe/Al hydroxides using a 2pK-DDL model
N immobilization	Fractional, fixed, or external input	Fractional, fixed, or external input	Submodel	Submodel
Nitrification	100%	Fractional	Submodel	Submodel
Denitrification	Fractional, fixed	Fractional	None or submodel	Submodel
Soil N build-up controlled by C:N ratio	Yes	Yes	No	Submodel
CO <sub>2</sub> degassing in surface water	Yes	Yes	Yes	No surface water
Al(OH) <sub>3</sub> precipitation in stream	Yes	Yes	Yes	No surface water
Lumped base cations (Ca <sup>2+</sup> , Mg <sup>2+</sup> , and K <sup>+</sup> )	Yes	No	Yes	No
DOC dissociation model	Oliver or simple monoprotic	Triprotic	Oliver	NICA-Donnan

**Table 4-16 (Continued): Overview of properties of four dynamic soil chemistry models as characterized in Bonten et al. (2015).**

Features	VSD	MAGIC	ForSAFE	SMARTml
Cation exchange	Gaines-Thomas or Gapon	Gaines-Thomas	Gapon	OM: NICA-Donnan clay: Donnan gel hydroxides: 2pk DDL
Number of cation exchange equations	2	4	1	Not relevant
Ions in soil solution charge balance	12	28	16	Full speciation of ions in the soil solution
First appearance in the literature	2009	1985	1993	2011

**Table 4-17 Model comparison.**

Soil Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Modeled Observation	Reference
Soil S	Forest	Three Swiss forest monitoring sites	Not specified	In a comparison of four models VSD, MAGIC, ForSAFE, and SMARTml, ForSAFE-modeled S concentrations tended to be underestimated by the model.	<a href="#">Bonten et al. (2015)</a>
Soil pH	Forest	Three Swiss forest monitoring sites	Not specified	In a comparison of four models VSD, MAGIC, ForSAFE, and SMARTml, ForSAFE results indicated upper soil layers can have higher modeled pH than observed.	<a href="#">Bonten et al. (2015)</a>
Soil ANC and pH	Scots pine plantation	Long-term forest monitoring site in U.K. (Peak District of northern England)	Not specified	In a comparison of four models VSD, MAGIC, ForSAFE, and SMARTml, MAGIC successfully reproduced the trend in acidity (ANC and pH) in soil solution over the majority of the (ca. 1990s) monitoring period.	<a href="#">Bonten et al. (2015)</a>
Soil SO <sub>4</sub> <sup>2-</sup>	Spruce forest	Gårdsjön, Sweden	Not specified	In a comparison of four models VSD, MAGIC, ForSAFE, and SMARTml, ForSAFE modeling results showed SO <sub>4</sub> <sup>2-</sup> was slightly underestimated compared to measured SO <sub>4</sub> <sup>2-</sup> concentrations in soil solutions at 5-, 10-, and 20-cm depth (1990–2000).	<a href="#">Bonten et al. (2015)</a>
Soil SO <sub>4</sub> <sup>2-</sup>	Spruce forest	Bechtel, Switzerland	Not specified	In a comparison of four models VSD, MAGIC, ForSAFE, and SMARTml, ForSAFE-modeled soil SO <sub>4</sub> <sup>2-</sup> was reasonably well modeled at 20-cm depth but clearly below measured values at 100-cm depth (1990–2005).	<a href="#">Bonten et al. (2015)</a>

**Table 4-17 (Continued): Model comparison.**

Soil Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Modeled Observation	Reference
Ion concentrations, Al	Forest	Three Swiss forest monitoring sites	Not specified	Comparison of four models VSD, MAGIC, ForSAFE, and SMARTml. VSD reproduced the ion concentrations similar to measured values, however the modeled Al concentrations were substantially lower than measured ones. VSD only calculates free Al <sup>3+</sup> , whereas measurements also include other Al-species as Al-hydroxides and Al complexed by dissolved organic matter and fluoride.	<a href="#">Bonten et al. (2015)</a>
Base cations (nutrients Ca + Mg + K; Na; and Ca)	Spruce forest	Gårdsjön, Sweden; Bechtel, Switzerland; and long-term monitoring site in Germany	Not specified	ForSAFE results compared to observations. In Sweden, nutrient base cations were slightly underestimated compared to measured values in soil solution at 5-, 10-, and 20-cm depth (1990–2000), while Na <sup>+</sup> in soil solution was relatively well modeled at 5-, 10-, and 20-cm depth but less well in deeper soil. In Switzerland, base cations modeling results were “within the range of the measured values with a slight underestimation at 20-cm depth” (1990–2005). In Germany, Ca <sup>2+</sup> agreed with measured values in soil solution (1990–2005).	<a href="#">Bonten et al. (2015)</a>
Al	Spruce forest	Bechtel, Switzerland	Not specified	ForSAFE-modeled Al <sup>3+</sup> was “in the range of the measured soil solution values at 20-cm depth” (1990–2005).	<a href="#">Bonten et al. (2015)</a>
Al, Ca, and protons	Norway spruce forest	Long-term monitoring site in Germany	Not specified	SMARTml results showed that modeled Al <sup>3+</sup> , Ca <sup>2+</sup> , and protons agree with measured values observations in soil solution (1990–2005).	<a href="#">Bonten et al. (2015)</a>

**Table 4-17 (Continued): Model comparison.**

Soil Process/ Indicator	Type of Ecosystem	Region	Deposition kg/ha/yr	Modeled Observation	Reference
Base saturation	Forest	Great Smoky Mountains National Park	5.1 kg N/ha/yr (36.5 mmolc/m <sup>2</sup> /yr)	PnET-BGC used to model 30 stream watersheds during 1981–2014 when SO <sub>4</sub> <sup>2-</sup> and NO <sub>3</sub> <sup>-</sup> deposition decreased (81 and 53%, resp.). Hindcast modeling (beginning ca. 1850) showed decreased soil base saturation from 17.8% (preindustrial median) to 12.6% (current median).	<a href="#">Fakhraei et al. (2016)</a>

SO<sub>4</sub><sup>2-</sup> = sulfate; kg = kilogram; HBEF = Hubbard Brook Experimental Forest; S = sulfur; yr = year.

## 4.6 National-Scale Sensitivity

The 2008 ISA documented that by the end of the 1980s, after nearly a decade of intensive research performed under the original National Acid Precipitation Assessment Program (NAPAP) research program, the regions of the U.S. with acid-sensitive waters and ecosystems were well recognized. These acid-sensitive ecosystems are generally located in upland mountainous terrain in the eastern U.S. and are underlain by weathering-resistant bedrock, such as granite or quartzite sandstone. The 2008 ISA documented maps of the U.S. that showed areas sensitive to acidification. However, similar maps for areas sensitive to the eutrophication effects of nitrogen were not available. Strong evidence was documented demonstrating that biogeochemical sensitivity to deposition-driven eutrophication and acidification is the result of historical loading, geologic/soil conditions (e.g., mineral weathering and S adsorption), and nonanthropogenic sources of N and S loading to the system. The 2008 ISA documented that there was no single deposition level applicable to all ecosystems in the U.S. that will describe the onset of eutrophication or acidification. Since the 2008 ISA, there are new publications commenting on recovery of terrestrial ecosystems at either the national scale ([NAPAP, 2011](#)) or in specific regions ([Lawrence et al., 2015a](#); [McDonnell et al., 2013](#); [Elliott et al., 2008](#)). One new paper evaluates national-scale terrestrial critical loads for nitrate leaching ([Pardo et al., 2011b](#)), but work on national-scale soil acidification published in 2007 remains the most recent national assessment of this effect ([McNulty et al., 2007](#)).

---

### 4.6.1 Acidification Recovery

It is important to note that different chemical pools within the soil may recover from declining N and S atmospheric deposition at different rates. For example, soil solution Ca:Al ratio or  $\text{SO}_4^{2-}$  or  $\text{NO}_3^-$  concentration are faster responding indicators than total N. Indicators that are linked to slow pools (such as soil percentage base saturations or soil C-to-N ratios) will have slow response times with regard to changes in atmospheric deposition. An indicator such as ANC which is influenced by both fast (solution) and slow (soil) pools has an intermediate response time. In addition to how indicators convey rates of recovery in different biogeochemical pools, recovery can be documented by empirical evidence and projected by models of recovery trajectories.

The most recent national-scale assessment of recovery from acidifying deposition was the National Acid Precipitation Assessment Program (NAPAP) report to Congress ([NAPAP, 2011](#)). NAPAP is a cooperative federal program first authorized in 1980 to coordinate acid rain research and report the findings to Congress. The NAPAP member agencies are

the U.S. EPA, the U.S. Department of Energy, the U.S. Department of Agriculture, the U.S. Department of Interior, the National Aeronautics and Space Administration, and the National Oceanic and Atmospheric Administration. The report concluded that few studies have evaluated terrestrial ecosystem health relative to acidification effects over time, and soils in the most acid-sensitive regions for which there is more data continue to acidify.

New evidence since the publication of the [NAPAP \(2011\)](#) is summarized in [Table 4-18](#). A new study supports the beginning of recovery from soil acidification in the northeastern U.S. ([Fuss et al., 2015](#); [Lawrence et al., 2015a](#)). [Fuss et al. \(2015\)](#) studied HBEF in NH and found indicators of recovery of acidification in soil solution measurements taken from 1984–2011. At the same site, [Phelan et al. \(2016\)](#) conducted a modeling study that showed current reductions in deposition generally halted further damage to soils and plants and resulted in no or only partial recovery.

In the southern Appalachian Mountains, modeling studies suggest current stress and recovery likely to take decades even under scenarios of large reductions in S deposition ([McDonnell et al., 2013](#); [Elliott et al., 2008](#)). [Rice et al. \(2014\)](#) calculated for many forested, unglaciated watersheds from Pennsylvania to Georgia will begin releasing  $\text{SO}_4^{2-}$  over the next two decades ([Appendix 4.3.3](#)). Unglaciated soils, like those that occur in the southeastern U.S., accumulate S that is slowly released from soil pools into drainage water, a process that temporarily delays ecosystem recovery in response to decreases in S deposition ([Appendix 4.3.3](#)).

The acid-base characteristics of DOC are an important part of understanding the recovery potential for soils, lakes, and streams impaired by acid deposition; these effects are discussed in [Appendix 4.3.9](#).

**Table 4-18 Recovery.**

Region	Type of Ecosystem	Empirical or Model	Approach/Observation	Reference
Southern Appalachian Mountains, NC	Forest soil	NuCM	<b>Model:</b> Modeled three S deposition simulations: current, 50% decrease, and 100% increase, at Joyce Kilmer (JK), Shining Rock (SR), and Linville Gorge (LG) wilderness areas. Low Ca:Al ratios results suggest that forests at SR and LG are significantly stressed under current conditions. The soil SO <sub>4</sub> <sup>2-</sup> retention is low, perhaps contributing to the high degree of acidification. The soils are very acidic and low in weatherable minerals. Even with large reductions in SO <sub>4</sub> <sup>2-</sup> and associated acid deposition, it may take decades before these systems recover from depletion of exchangeable Ca, Mg, and K.	<a href="#">Elliott et al. (2008)</a>
Southern Appalachian Mountains, U.S.	65 streams and their watersheds	MAGIC model	<b>Model:</b> A study used the MAGIC model to evaluate soil Bc status. Future S deposition reduction scenarios (6, 58, 65, and 78% reduction), and various changes in timber harvest, temperature, and precipitation were modeled. Each of the scenario projections indicated that median year 2100 soil exchangeable Ca will be at least 20% lower than preindustrial values. The simulations suggested that substantial mass loss of soil Bc has already occurred since preindustrial times. Soil Bc pools in the study region are expected to remain significantly below preindustrial conditions for more than 100 yr, regardless of changes in climate, S deposition, or timber harvest.	<a href="#">McDonnell et al. (2013)</a>
Great Smoky Mountains National Park, U.S.	Forest soils and streams	PnET-BGC	<b>Application:</b> Simultaneous reduction in SO <sub>4</sub> <sup>2-</sup> and NO <sub>3</sub> <sup>-</sup> deposition is more effective at increasing stream ANC than SO <sub>4</sub> <sup>2-</sup> alone. NO <sub>3</sub> <sup>-</sup> leaching continues as N deposition decreases (this is due to unmanaged forests). Stream recovery is delayed as NO <sub>3</sub> <sup>-</sup> facilitates desorption of legacy SO <sub>4</sub> <sup>2-</sup> that is adsorbed to acid soils.	<a href="#">Zhou et al. (2015b)</a>
Great Smoky Mountains National Park, U.S.	Forest soils and streams	PnET-BGC	<b>Model:</b> Modeling of 30 stream watersheds characterized by decreased SO <sub>4</sub> <sup>2-</sup> and NO <sub>3</sub> <sup>-</sup> deposition during 1981–2014 (81 and 53%) showed that stream recovery has been limited and delayed due to the high sulfate adsorption capacity of soils in the park resulting in a long lag time for recovery of soil chemistry.	<a href="#">Fakhraei et al. (2016)</a>

**Table 4-18 (Continued): Recovery.**

Region	Type of Ecosystem	Empirical or Model	Approach/Observation	Reference
Eastern Canada and the northeastern U.S.	Forest and streams	Recovery	<b>Field observation:</b> 27 sites exposed to reductions in wet $\text{SO}_4^{2-}$ deposition of 5.7–76%, over intervals of 8–24 yr. Results are decreased exchangeable Al in the O-horizon and increases in pH in the O and B-horizons at most sites. Among all sites, reductions in $\text{SO}_4^{2-}$ deposition were positively correlated with ratios of base saturation and negatively correlated with exchangeable Al ratios in the O-horizon. However, base saturation in the B-horizon decreased at one-third of the sites, with no increases.	<a href="#">Lawrence et al. (2015a)</a>
HBEF, NH	Forest and streams	Al <sub>i</sub> Recovery	<b>Field observation:</b> Slowed losses of base cations from soil and decreased mobilization of dissolved inorganic aluminum were observed. Stream water pH at the watershed outlet increased at a rate of 0.01 units/yr and the acid neutralizing capacity (ANC) gained 0.88 $\mu\text{eq/L/yr}$ . Dissolved organic carbon generally decreased in stream water and soil solutions. Both baseline and chronic acidification (measured during snowmelt) are recovering at this site.	<a href="#">Fuss et al. (2015)</a>
HBEF, NH, and Bear Brook Watershed, ME	Forests soils and plants	Model ForSAFE-VEG	<b>Model:</b> Only when future deposition to 2100 was returned to preindustrial levels was recovery of soil and plant community to 1900 conditions projected. Policy-based reductions in deposition generally halted further damage to soils and plants and resulted in no or only partial recovery.	<a href="#">Phelan et al. (2016)</a>
Adirondack Long-term Monitoring Program (ALTM; 128 lakes)	Forests soils and lakes	PnET-BGC	<b>Model:</b> Controlling S deposition is more effective at acidic lake recovery than controlling S + N deposition. Reducing N deposition is less effective because the resulting increase in soil pH leads to soil desorption of $\text{SO}_4^{2-}$ and other anions.  Reducing S dep. 60% beyond 2011 level is predicted to restore 28% of impaired lakes to $\text{ANC } 20 \mu\text{eq/L} \geq$ by 2050 and 60% of lakes by 2200. An ANC of 1 $\mu\text{eq/L}$ can be achieved to 53% of lakes by 2050.	<a href="#">Fakhraei et al. (2014)</a>

**Table 4-18 (Continued): Recovery.**

Region	Type of Ecosystem	Empirical or Model	Approach/Observation	Reference
Adirondack Mtns. Region, NY	Forests soils and lakes	PnET-BGC	<p><b>Model:</b> Decreasing <math>\text{SO}_4^{2-}</math> deposition is 4.6x more effective than <math>\text{NO}_3^-</math> decrease for years 2040–2050.</p> <p>Decreases in <math>\text{NO}_3^-</math> deposition is more effective at increasing lake ANC than an equal decrease in <math>\text{NH}_4^+</math> deposition.</p> <p>Due to the higher mass transfer coefficient for in-lake retention of <math>\text{NO}_3^-</math>, decreasing <math>\text{NO}_3^-</math> deposition decreases <math>\text{NO}_3^-</math> leaching but lowers ANC production.</p> <p>As <math>\text{SO}_4^{2-}</math> and <math>\text{NO}_3^-</math> deposition decrease, a significant lake DOC concentration increase has been observed. However, PnET-BGC does not consider the decrease in soil organic matter partitioning as acid deposition decreases and soil pH increases.</p>	<a href="#">Zhou et al. (2015c)</a>

MAGIC = Model for Acidification of Groundwater in Catchments; NuCM = Nutrient Cycling Model;  $\text{SO}_4^{2-}$  = sulfate; Ca = calcium; Mg = magnesium; K = Potassium; S = sulfur; Bc = base cation.

---

## 4.6.2 Critical Loads

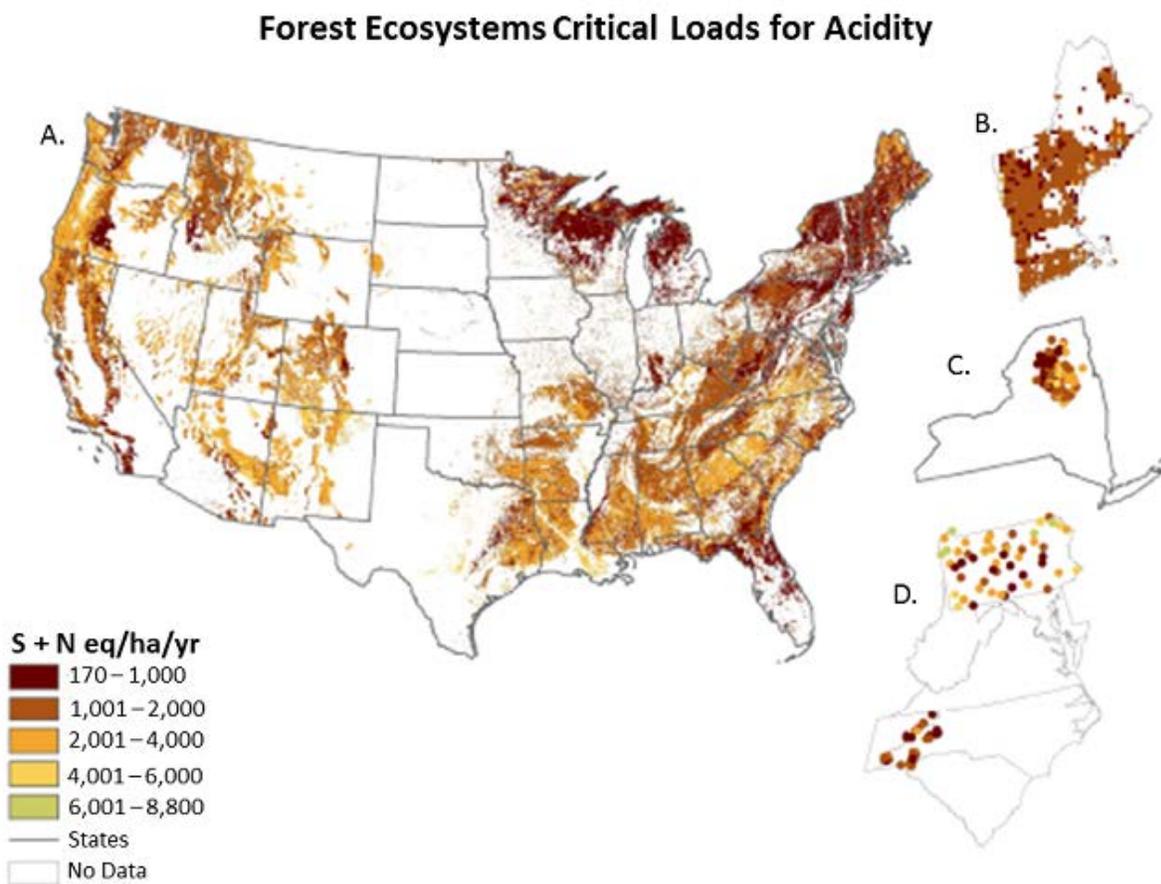

---

### 4.6.2.1 Soil Acidification

The 2008 ISA included [McNulty et al. \(2007\)](#) a national assessment of soil critical loads for acidification calculated by a SMBE technique (see Section 4.5.1.8 of the 2008 ISA). The uncertainty associated with the SMBE technique was discussed in a second publication ([Li and McNulty, 2007](#)). In general, the SMBE predicted that 26% of U.S. forest soils have critical loads less than 1,000 eq/ha/yr. Low critical loads outside of New England, New York, and the Appalachian Mountain region are not necessarily problematic to forest health because acid deposition is much lower across most of the U.S. compared to these areas. Unfortunately, mountainous terrain comprises much of the area with very low forest soil critical loads. Mountain forests receive some of the highest local rates of acidic deposition.

No new publications are identified in this review on the subject of national-scale sensitivity; however, there are new reports on regional sensitivity. [Figure 4-10](#) is a map of soil CLs presented by [McNulty et al. \(2007\)](#) and updated with newer SMB modeling, where available ([McDonnell et al., 2014b](#); [Phelan et al., 2014](#); [Duarte et al., 2013](#); [Sullivan et al., 2011b](#); [Sullivan et al., 2011a](#)). [Duarte et al. \(2013\)](#) is a new evaluation of critical loads for terrestrial acidification in New England, U.S. The steady-state mass balance method is applied at over 4,000 plots. The acceptable ANC leaching rate was calculated based on the critical chemical criteria of no change in base saturation. Over 80% of the critical loads were between 850 and 2,015 eq/ha/yr. [Phelan et al. \(2014\)](#) evaluated PROFILE using national data sets as a method to estimate BCw rates for forests in the U.S., focusing on Pennsylvania as the first test state. The model paired with national data sets was successfully applied at 51 forested sites across Pennsylvania. The soil critical loads were evaluated using a Bc:Al value of 10.0. The CL values ranged from 4 to 10,503 eq/ha/yr. [Sullivan et al. \(2011a\)](#) used the dynamic model MAGIC to model terrestrial soil acidification in the Adirondacks, NY. Simulations were based on one driver of acidic deposition (S) and included evaluation of CLs for soil solution molar Bc:Al and Ca:Al ratio, two critical threshold levels (1 and 10), and two endpoint years of model simulation (2050 and 2100). Statistically selected lakes (n = 44) were modeled to represent a population of 1,320 sites. Nearly all (>93%) had a very low TL (<25 eq/ha/yr for the year 2100) when the protection threshold was set to BC:Al = 10, and the majority (>60%) had a high TL of (>100 eq/ha/yr for the year 2100) to achieve Bc:AL = 1. [Sullivan et al. \(2011b\)](#) calculated surface water CLs for 66 sites in the Blue Ridge

mountains (North Carolina, Tennessee, and South Carolina). CL were reported for surface waters; however, the MAGIC model was parameterized for all 66 sites including terrestrial geochemistry. [McDonnell et al. \(2014b\)](#) studied acidification in the southern Appalachians from northern Georgia to southern Pennsylvania and from eastern Kentucky and Tennessee to central Virginia and western North Carolina. Although soil critical loads were not reported in the publication, soil solution data are reported in [Figure 4-10](#).

eq = equivalent; ha = hectare; yr = year.

(A.) [McNulty et al. \(2007\)](#) critical loads are mapped at 1-km<sup>2</sup> grids (center map). For uncertainty, see [Li and McNulty \(2007\)](#).

(B.) [Duarte et al. \(2013\)](#) critical loads are mapped at 4-km<sup>2</sup> grids; (C. and D.) [Phelan et al. \(2014\)](#) critical loads are mapped for each sampling site (Pennsylvania). [McDonnell et al. \(2014b\)](#); [Sullivan et al. \(2011b\)](#); [Sullivan et al. \(2011a\)](#) critical loads are mapped as a single point at the center point of the watershed (New York and North Carolina).

Source: <http://nadp.slh.wisc.edu/committees/clad>.

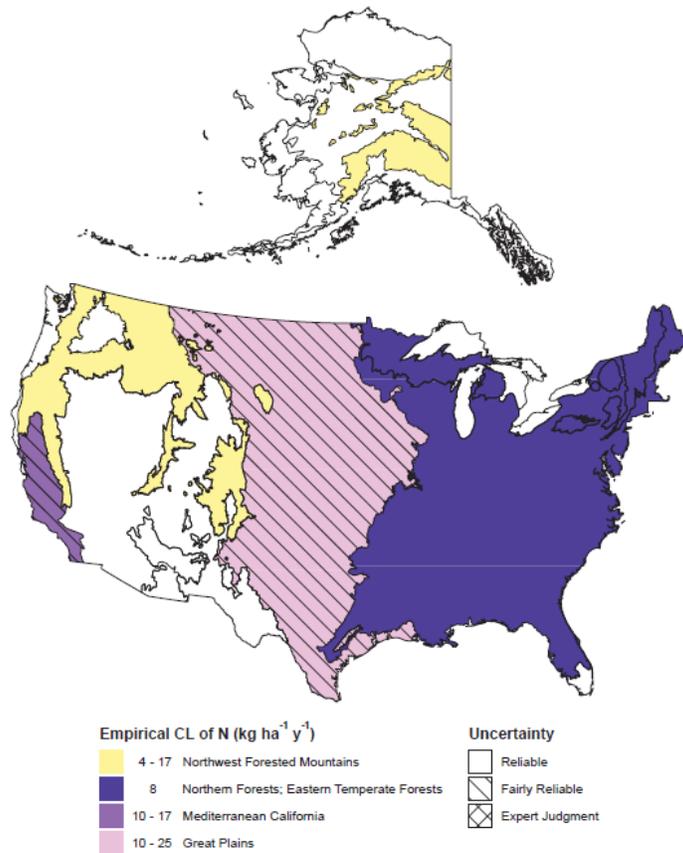

**Figure 4-10 Forest ecosystem critical loads for soil acidity related to base cation soil indicators.**

In the case of semiarid ecosystems of southern California, which are not highly sensitive to acidification, soils in high N deposition areas of chaparral and forested areas in the Los Angeles basin have acidified significantly ([Pardo et al., 2011b](#)).

---

#### 4.6.2.2 Nitrate Leaching

[Pardo et al. \(2011b\)](#) documented the threshold N deposition value which caused increased  $\text{NO}_3^-$  leaching from forest ecosystems into surface water was 8 to 25 kg N/ha/yr. This information is summarized by ecoregion (Omernick Level 1) in [Figure 4-11](#). At 4 kg N/ha/yr, increasing  $\text{NO}_3^-$  was reported in the organic horizon in the Colorado Front Range, which suggests incipient N saturation. In the northeastern U.S., N budgets from 83 forested watersheds show that N retention averages 76% of incoming atmospheric-N deposition and decreases from 90% retention for sites receiving 7 kg N/ha/yr to 60% retention for sites receiving 11 kg N/ha/yr ([Aber et al., 2003](#)). The highest critical loads were reported for Mediterranean California mixed-conifer forests. Since the publication of [Pardo et al. \(2011b\)](#), new studies have been published on nitrate leaching in the U.S. (see [Appendix 4.3.2](#)); one critical load is from [Bowman et al. \(2014\)](#), who identify 10 kg N/ha/yr as the deposition level associated with nitrate leaching in RMNP. New evidence from Europe by [Dise et al. \(2009\)](#) shows approximately 95% of forests receiving less than 8 kg N/ha/yr have leaching of less than 1 kg N/ha/yr. In Sweden, [Khalili et al. \(2010\)](#) showed a clear sudden increase in  $\text{NO}_3^-$  leaching in regions where N deposition exceeded 7.5 kg/ha/yr.

CL = critical load; ha = hectare; kg = kilogram; N = nitrogen; yr = year.

The range of critical loads based on increased nitrate leaching for each ecoregion. The hatch marks indicate increasing levels of uncertainty: no hatch marks for the most certain “reliable” category and single hatching for the “fairly reliable” category. White areas lack data for critical loads determination for nitrate leaching.

Source: [Pardo et al. \(2011b\)](#).

**Figure 4-11 Map of critical loads for nitrate leaching by ecoregion in the U.S.**

## 4.7 Modification of Terrestrial Soil Response to Nitrogen (N)

Biogeochemical responses to N deposition can be modified by many environmental factors including phosphorus, disturbance, stand age and climatic shifts in temperature and precipitation. Here we provide a very brief overview of these topics. [Appendix 13](#) provides an overview of modification of ecosystem response to N driven by climate, whereas this section describes a brief summary of how climate modifies terrestrial soil response to N.

---

#### 4.7.1 Disturbance and Stand Age Effects on Nitrogen Retention

The 2008 ISA reported that varying degrees of N assimilation, leaching, and microbial transformation often reflect differences in N status among treatment sites. These variations have most often been attributed to disturbance history, dating back a century or more ([Goodale and Aber, 2001](#)). Sites that have undergone disturbances that cause loss of soil N, such as logging, fire, and agriculture, tend to be most effective at retaining atmospheric and experimental inputs of N. Fire causes substantial N losses from ecosystems. Timber harvest contributes to nutrient removal from the ecosystem via biomass export and acceleration of leaching losses ([Mann et al., 1988](#); [Bormann et al., 1968](#)). In particular, logging contributes to loss of N and Ca<sup>2+</sup> from the soil ([Latty et al., 2004](#); [Tritton et al., 1987](#)). Fire has been shown to alter N retention by its effects on vegetation, leading to less interception of deposition, and soil characteristics; the effects on these processes may be seen for decades after fire occurs ([Kahl et al., 2007](#)). N retention capability often decreases with stand age, suggesting that older forests are more susceptible than younger forests to becoming N saturated ([Hedin et al., 1995](#)).

One new study has been published since 2008 on how disturbance affects N retention ([Vourlitis and Pasquini, 2008](#)). Fire did little to alter patterns of soil N enrichment from atmospheric N deposition; however, periodic fires have important implications for the structure and function of chaparral shrublands and their propensity to become N saturated under current and future N deposition and fire regimes.

---

#### 4.7.2 Nitrogen and Phosphorus Interactions

Mechanisms driving terrestrial N versus P (phosphorus) limitations differ greatly since their sources and biogeochemical dynamics differ; therefore, there is variability across ecosystems ([Vitousek et al., 2010](#)). Organic N can be decomposed by a variety of enzymes to mineralize N from substrate; however, organic P relies on phosphatase enzymes to mineralize it, an enzymatic process that is independent of C respiration and N mineralization ([Marklein et al., 2016](#)).

Literature on N deposition's effect on N and P dynamics focuses on N and P cycling and the influence of N on phosphatase enzyme activity. Phosphatase is an enzyme released into the soil by organisms. It cleaves or hydrolyzes phosphorous (phosphoric acid) from substrate (soil, roots) to yield available phosphate for uptake ([Marklein et al., 2016](#)). The chemical structure of phosphatase includes N, therefore [Vitousek et al. \(2010\)](#) explained that N fertilization increases P cycling because it enables organisms to increase their extracellular phosphatase and, in turn, release more phosphate from soil organic matter.

There are some conflicting ideas of how N addition effects P in soils. N addition can acidify soil, therefore phosphatase activity may be suppressed by this mechanism, decreasing P release to soil ([Wang et al., 2016b](#)). In contrast, N addition can decrease the adsorption capacity of soil for P ions, thus increasing P availability and uptake by plants for productivity. It is also well known that N addition can increase litter decomposition, which may also increase P release/cycling rates. An increased supply of P can delay the onset of P limitation. It is important though to acknowledge that the type of N applied, application rate, and ecosystem type may influence the phosphatase activity ([Song et al., 2017](#)).

---

### 4.7.3 Climate Modification of Acidification Effects on Soil

For soil acidification, potential future changes in the quantity and temporal distribution of precipitation and temperature (and their interactions) is expected to alter the wet-dry cycles that govern the timing and amount of acidic inputs in precipitation, microbial transformation in the soil, and the flush of acid anions from soils to surface waters.

There are two recent papers on the relationship between precipitation and sulfur in U.S. watersheds. [Rice et al. \(2014\)](#) indicated that hydrology, and specifically runoff, is an important controller of sulfate recovery in watersheds because drainage flushes the accumulated sulfur from the soil. As precipitation and runoff patterns change with a changing climate, this important process will be affected. Changing hydrology in the Northeast is well documented and underway, not just a future effect. Similarly, [Mitchell et al. \(2011\)](#) observed that following decades of changes in stream sulfate concentrations and fluxes that have been driven by atmospheric deposition, variation in stream sulfate is now being controlled by variations in precipitation inputs. Increased variation in precipitation will increase wetting and drying cycles that promote mineralization of sulfate from soil and subsequent methylation.

In general, if acid anions build up in soil during periods of drought, the eventual flushing likely causes a more potent acidification event ([Mosley, 2015](#); [Whitehead et al., 2009](#)). If the acidification event occurs during a time when sensitive biota or lifestages of biota are present, acidification may cause more adversity to these populations ([Kowalik et al., 2007](#)). Increases in storm frequency associated with global climate change ([Collins et al., 2013](#)) could increase the frequency and severity of acidification driven by high levels of sea salt deposition in coastal regions ([Wright and Schindler, 1995](#)). Although the mechanisms of interaction are unclear, increases in DOC concentrations in aquatic ecosystems across Europe and the U.S. have been linked to acidification, N cycling, and

climate change, with important implications for water quality and ecosystem function [[Evans et al. \(2008\)](#); see [Appendix 4.3.9](#)].

Warmer temperatures increase decomposition and nitrification. Nitrification will also increase with increased N supply caused by increased weathering or decomposition ([Booth et al., 2005](#)). The process of nitrification generates protons that increase the rate of nitrate and base cation leaching to drainage waters ([Murdoch et al., 1998](#)). The combined increase of  $\text{NO}_3^-$  leaching and loss of base cations has the potential to magnify acidification in forest soils ([Fernandez et al., 2003](#)). Soil weathering is typically the key buffer to acidic deposition ([Li and McNulty, 2007](#)), and while weathering is increased by both soil temperature and soil moisture ([Gwiazda and Broecker, 1994](#)), it is unclear whether any future change in the magnitude of temperature and precipitation will be enough to alter base cation supply or influence the acid-base balance of sensitive ecosystems. Furthermore, it is unclear whether increased supply of N in soils from either deposition, increased decomposition, or increased nitrogen fixation will negate the ameliorative effect of enhanced weathering. Some studies show that climate change will mitigate acidification through increased weathering ([Kopáček et al., 2017](#); [Belyazid et al., 2011a](#)), while others show that climate change will aggravate acidification although increased nitrification outpacing enhanced weathering ([Wu and Driscoll, 2010](#)). In general, increased temperature and precipitation will likely enhance inputs of buffering agents from weathering and deposition, but also increase inputs of acidifying agents from deposition and enhanced N cycling. The relative sensitivity of these opposing processes to a given change in climate remains unresolved.

Ecological effects of atmospheric nitrogen (N) and sulfur (S) deposition on two hardwood forest sites in the eastern United States were simulated in the context of a changing climate using the dynamic coupled biogeochemical/ecological model chain ForSAFE-VEG. The main driver of ecological effects was soil solution N concentration ([Mcdonnell et al., 2018a](#)).

---

#### **4.7.4 Climate Modification of Nitrogen-Driven Eutrophication in Soil**

The following is a brief summary of how temperature, snow, and precipitation affect soil response to N. In addition, information is summarized on N effects on the flux of three GHGs ( $\text{CO}_2$ ,  $\text{CH}_4$ , and  $\text{N}_2\text{O}$ ) from terrestrial ecosystems.

Snow interacts with soil biogeochemistry in a number of ways, mostly by temperature shifts associated with snowpack and soil moisture flux during snowmelt. The highest flow and lowest ANC periods of the year tend to coincide with times of high snowmelt. This is when acidification is likely to occur. Snowpack insulates soils from frigid winter

air temperatures. With a warming climate, soils are expected to become colder and experience more winter soil freeze-thaw cycles as snow cover continues to decline.

A number of experiments have evaluated snow effects on soil N; these include studies on the timing, frequency, and severity (snow depth). [Contosta et al. \(2017\)](#) found evidence that in winters with more snow, a large pulse of  $\text{NO}_3^-$  may move from soils to streams when temperatures are too low/flows too high to allow for biological uptake. [Groffman et al. \(2001\)](#) conducted a snow manipulation experiment at HBEF and found mild late-season freezing increases soil  $\text{NO}_3^-$  levels by physical disruption (increased fine root mortality) causing reduced plant N uptake and reduced competition for inorganic N, allowing soil  $\text{NO}_3^-$  levels to increase even with no increase in net mineralization or nitrification. Later studies at the same site have shown that soil N mineralization rates were more strongly related to soil volumetric water content than to root biomass, snow or soil frost, or winter soil temperature ([Sorensen et al., 2016](#)), and the more freeze/thaw cycles anticipated with climate warming supported lower rates of N mineralization at HBEF ([Duran et al., 2016](#)). The effects of snow depth on soil N have been synthesized in a meta-analysis by [Li et al. \(2016c\)](#), who evaluated the central tendencies from 41 publications on 12 variables related to soil N. Results are that snow addition (increasing depth) significantly increased foliar N (+4.5%) and microbial N (MBN, +35.9%); however, snow removal did not significantly change under snow removal manipulation. Snow removal manipulation significantly decreased soil  $\text{N}_2\text{O}$  efflux (-34.1%) and nitrification (-24.8%). However, altered snow depth did not significantly affect soil dissolved organic N (DON), total inorganic N, nitrate, and N leaching. Because increasing snowpack depth promoted MBN, the unchanged, net N mineralization and soil ammonium content were probably due to limitation of the soil N availability and other soil abiotic factors rather than soil microbes.

[Greaver et al. \(2016\)](#) created a synthesis of meta-analyses to study the individual effects of either N, temperature, or precipitation on different pools and processes related to ecosystem C pools and fluxes ([Figure 13-2](#)). Nineteen different pools and processes were included in this analysis.

Initial findings are consistent with the biokinetic effects of warming; long-term data and meta-analyses show that soil respiration, including decomposition and microbial respiration, is stimulated by increasing temperature ([Lu et al., 2013](#); [Bond-Lamberty and Thomson, 2010](#); [Rustad et al., 2001](#)). Most empirical studies show rising temperature stimulates N release by mineralization ([Churkina et al., 2010](#)), which may be driven more by temperature effects on moisture ([Emmett et al., 2004](#)). In some dynamic land models, the additional N from mineralization will stimulate C uptake by plants even more than current N deposition ([Burd et al., 2016](#)). At the same time, increased N from

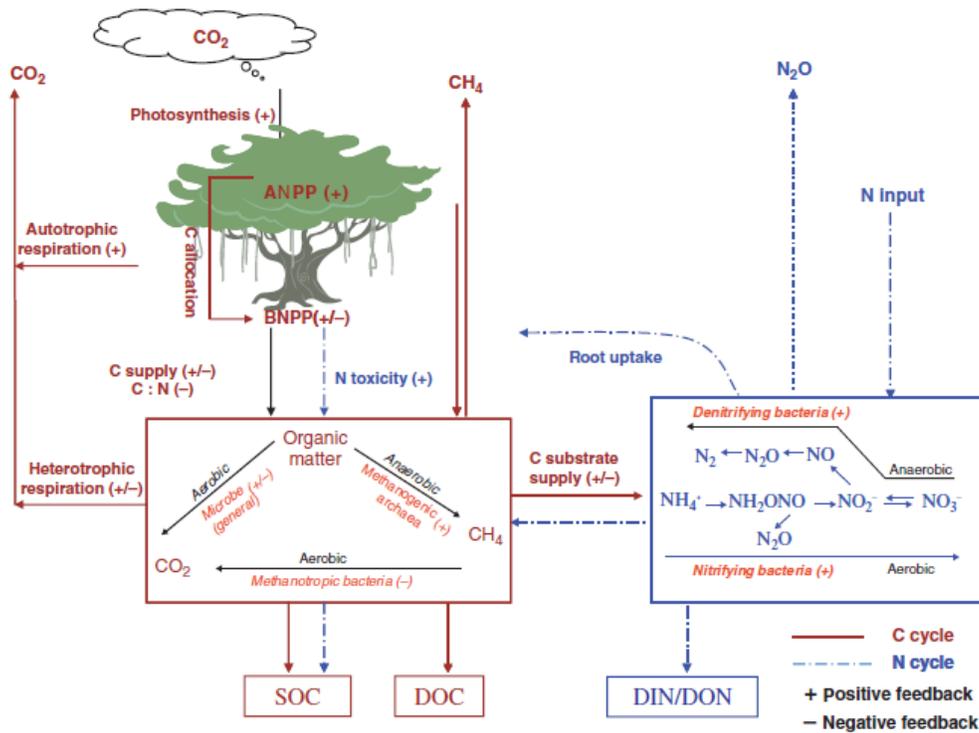

mineralization may cause N induced inhibition of decomposition, a feedback mechanism that might decrease the amount of N released and which is currently considered by a few models ([Gerber et al., 2010](#)). The mechanisms causing N driven reduction in decomposition are not well understood but are thought to result from changes in microbial community composition and the production of decomposition enzymes, as well as possible changes in the character and degradability of soil organic matter ([Conant et al., 2011](#); [Janssens et al., 2010](#)). Climate change could also affect decomposition rates by altering both available soil moisture and microscale connectivity among microorganisms, water, and nutrients within the soil matrix, which, in turn, may alter microbial processes ([Xiang et al., 2008](#)). Although there is no consensus about how dissolved organic carbon (DOC) in surface water is regulated overall, increasing N and temperature increase DOC concentrations ([Laudon et al., 2012](#)). While few meta-analyses have examined precipitation effects on the soil C cycle, precipitation tends to increase the root C pool ([Figure 13-2](#)).

[Ni et al. \(2017\)](#) created a meta-analysis to evaluate the interactions between warming and N deposition and found the interaction greatly increased the soil C input (+49%) compared with the single factor of either warming (+5%) or N deposition (+20%). Soil C loss was not significantly affected by the interaction of N and warming likely because increases in decomposition due to warming are offset by the decreases by N addition.

N addition alters fluxes of GHGs by regulating plant and microbial activities that are directly associated with GHG production and consumption processes ([Figure 4-12](#)). It is important to consider net ecosystem flux because consumption may be offset by production. For example, N addition stimulates plant growth in most ecosystems ([LeBauer and Treseder, 2008](#)), and may in turn increase C sequestration in plant biomass. On the other hand, maintenance respiration is positively correlated with tissue N content ([Reich et al., 2008](#)), and litter with higher N content also decomposes faster. Therefore, increased leaf N content under elevated N may result in higher C loss by increasing both autotrophic and heterotrophic respiration. Like CO<sub>2</sub>, ecosystems may consume and produce CH<sub>4</sub> and N<sub>2</sub>O, and the balance determines their net release.

[Liu and Greaver \(2009\)](#) conducted a meta-analysis of 313 observations across 109 studies to evaluate the effect of N addition on the flux of three GHGs: CO<sub>2</sub>, CH<sub>4</sub>, and N<sub>2</sub>O. The results indicated that N addition increased ecosystem carbon content of forests by 6%, marginally increased soil organic carbon of agricultural systems by 2% but had no significant effect on net ecosystem CO<sub>2</sub> exchange for nonforest natural ecosystems. Across all ecosystems, N addition increased CH<sub>4</sub> emission by 97%, reduced CH<sub>4</sub> uptake by 38%, and increased N<sub>2</sub>O emission by 216%. Most often, N addition is considered to increase forest C sequestration without consideration of N stimulation of GHG

production in other ecosystems. However, this study indicated that although N addition increased the global terrestrial C sink, the GHG benefits of an atmospheric CO<sub>2</sub> reduction could be largely offset (53–76%) by N stimulation of global CH<sub>4</sub> and N<sub>2</sub>O emission from multiple ecosystems.

ANPP = aboveground net primary productivity; BNPP = belowground net primary productivity; SOC = soil organic carbon; DOC = dissolved organic carbon; DIN = dissolved inorganic nitrogen; DON = dissolved organic nitrogen.

---

## 4.8 Summary

---

### 4.8.1 Sources

The effects of N and S deposition on soil biogeochemistry cause cascading effects on biological species. The biological effects are discussed in [Appendix 5](#) and [Appendix 6](#).

Since 2008, there have been a number of estimates of sulfate, oxidized nitrogen, and reduced nitrogen from atmospheric deposition. The most recent estimates are summarized in [Appendix 2](#), and maps showing the geographic distribution of deposition are presented for total acidifying deposition ([Figure 2-12](#)), total N deposition ([Figure 2-13](#)), and total S deposition ([Figure 2-31](#)). Maps depicting how the relative contribution of oxidized and reduced N species varies across the U.S. are presented in [Figure 2-14](#).

In the 2008 ISA, atmospheric deposition was identified as the main source of anthropogenic N, relative to other N sources, to nonmanaged terrestrial ecosystems. This has been confirmed by new studies on N sources to U.S. lands and waterways, which find human-mediated N inputs are spatially heterogeneous across the country, ranging from <1.0 to 34.6-fold the rate of background N input across the conterminous U.S. Synthetic N fertilizer and atmospheric N deposition are the largest and second-largest overall human-mediated N sources (the single largest sources in 41 and 33% of HUC-8s, respectively). There is no new information published on nondeposition sources of S in terrestrial ecosystems. S inputs from emissions to the atmosphere are discussed in [Appendix 2](#).

---

### 4.8.2 Soil Processes and Indicators

Soil N enrichment and soil acidification are occurring in sensitive ecosystems across the U.S. at recent levels of deposition. Soil acidification is a natural process that can be accelerated by N and/or S deposition. A number of soil geochemical processes are associated with acidification ([Appendix 4.3](#) and [Table 4-19](#)). Base cations counterbalance acid anions. Base cations are added to a watershed by weathering and atmospheric deposition and are removed by leaching and (perhaps temporarily) by uptake into growing vegetation. Acidifying deposition can deplete exchangeable base cation pools in soils where acid deposition is high relative to base cation input. The limited mobility of anions associated with naturally derived acidity (organic acids and carbonic acid)

controls the rate of base cation leaching from soil where rates of atmospheric deposition of S and N are low. In addition to increasing ion concentration in soil, inputs of S and N in acidifying deposition provide anions that are highly mobile, further accelerating the rates of base cation leaching. In addition, the deposition of reduced forms of N (e.g.,  $\text{NH}_x$ ) can stimulate nitrification, which is the microbial oxidation of  $\text{NH}_4^+$  to  $\text{NO}_3^-$ . This oxidation process acidifies soils because 2 moles of hydrogen ion ( $\text{H}^+$ ) are released per mole of  $\text{NH}_4^+$  converted to  $\text{NO}_3^-$ . Therefore, both chemically reduced and oxidized forms of N and S deposition contribute to terrestrial acidification. Several useful indicators of soil acidification ([Table 4-19](#)) include indicator thresholds related to biological responses, the biological basis of which are discussed in [Appendix 5](#).

It is clear from [Table 4-19](#) that some of the same processes and indicators associated with acidification are also associated with N enrichment. The N enrichment of terrestrial soils occurs in response to the input of exogenous N. The new studies on N deposition contribution to total N loading in terrestrial U.S. ecosystems are discussed in [Appendix 4.2](#).

The 2008 ISA documented that most N, often more than 85% of the total ecosystem N, is stored in the soil in temperate forest ecosystems. There is new evidence that soil litter is the largest N pool in grasslands, shrublands, and wetlands ([Appendix 4.3.1](#)). The ability of atmospheric deposition to increase soil N is indicated by a positive correlation between atmospheric deposition levels and total N concentration in the organic and mineral soil horizon. Soil N accumulation is linked to increased N leaching and decreased N retention ([Appendix 4.3.2](#)). Thresholds of N deposition that are associated with the onset of elevated  $\text{NO}_3^-$  leaching are discussed in [Appendix 4.6.2.2](#).

Recent work suggests that N leaching from soil can precede the complete saturation of the biotic and abiotic processes that retain N ([Appendix 4.3.2](#)). [Lovett and Goodale \(2011\)](#) proposed a model of N saturation in which  $\text{NO}_3^-$  leaching can occur even if the ecosystem N retention capacity has not yet been saturated, as is observed at many sites and supported by several new studies. Although N leaching may occur prior to saturation, N budgets from 83 forested watersheds in the northeastern U.S. show that N retention averages 76% of incoming N deposition. Nitrogen retention decreases from 90% retention for sites receiving 7 kg N/ha/yr to 60% retention for sites receiving 11 kg N/ha/yr, suggesting a range of response in which leaching is exacerbated in this region ([Aber et al., 2003](#)).

The 2008 ISA documented that N enrichment alters rates of microbial transformation of chemicals in the soil, such as increased rates of nitrification and denitrification, and altered rates of decomposition. The addition of N to terrestrial ecosystems can increase nitrification, an important process for soil acidification and the production of  $\text{NO}_3^-$ .

Nitrification is often stimulated in soils with a C:N ratio below approximately 20 to 25, and N deposition often causes the ratio to fall below this threshold. The  $\text{NO}_3^-$  created by nitrification may be leached or denitrified. In terrestrial ecosystems, denitrification of  $\text{NO}_3^-$  mainly occurs in saturated zones. Several syntheses have been published since 2008 evaluating N addition effects on denitrification and nitrification in terrestrial ecosystems ([Appendix 4.3.6](#)). A new meta-analysis shows N addition significantly increases denitrification from many types of ecosystems (coniferous forest, deciduous forest, tropical forest, wetland, grassland), except heathlands.

**Table 4-19 Summary of key soil geochemical processes and indicators associated with eutrophication and acidification.**

Endpoint	N-Driven Nutrient Enrichment	Acidification	The Effect of Deposition
<b>PROCESS</b>			
N saturation	X	X	New empirical evidence suggests revising the N saturation concept, because observed NO <sub>3</sub> <sup>-</sup> leaching can occur even if the ecosystem N retention capacity has not yet been saturated.
Soil N accumulation	X	X	New meta-analysis across ecosystem types confirms inorganic soil NO <sub>3</sub> <sup>-</sup> concentration increases with N addition. New gradient study confirms that N concentration increases with N deposition. New addition study confirms increased soil accumulation.
NO <sub>3</sub> <sup>-</sup> leaching	X	X	New meta-analysis confirms leaching increases with N addition. New regional-scale gradient analyses: <8 kg N/ha/yr onset of leaching <1 kg N/ha/yr in European forests. Second study suggests <7.5 kg N/ha/yr increases leaching in Swedish forests. New addition study: 9 to 14 kg N/ha/yr increase in inorganic N concentrations. New USFS critical loads for the onset of leaching: 8 to 10 kg N/ha/yr in eastern and western U.S., 17 kg N/ha/yr in the Sierra Nevada and San Bernardino Mountains.
S accumulation and adsorption		X	Some soils (notably in many watersheds in the SE U.S.) have the capacity to adsorb substantial quantities of S, with essentially no acidification of drainage water. Nevertheless, S adsorption capacity is finite and under continual high S deposition loading, the adsorptive capacity of soil will eventually be depleted. New studies of 27 watersheds in the SE indicates most will begin releasing SO <sub>4</sub> <sup>2-</sup> in the next two decades, and northeastern watersheds show a net loss of S from soils now in response to decreased levels of atmospheric S deposition.
SO <sub>4</sub> <sup>2-</sup> leaching		X	Atmospheric S deposition generally increases leaching of SO <sub>4</sub> <sup>2-</sup> to surface waters. The amount of deposition that causes the onset of leaching varies across the landscape.

**Table 4-19 (Continued): Summary of key soil geochemical processes and indicators associated with eutrophication and acidification.**

Endpoint	N-Driven Nutrient Enrichment	Acidification	The Effect of Deposition
Base cation release/depletion		X	<p>Base cation (Ca, Mg, K, Na) release occurs in response to the input of acid anions (<math>\text{SO}_4^{2-}</math> and <math>\text{NO}_3^-</math>) from deposition. This proportional change in base cations relative to acid anions from N and S deposition is called the F-factor.</p> <p>New studies confirm base cation depletion continues to occur in the Rocky Mountains (threshold 28 kg N/ha/yr) and in U.K. grasslands, while in a northeastern forest, 17 yr of N addition did not cause further depletion. A meta-analysis indicates cation depletion occurs early after increased deposition of acid anions, which tapers off with time.</p>
Al mobilization		X	<p>&lt;15 to 20% soil base saturation is the threshold for inorganic Al mobilization from soil. This is an extremely important effect of acidifying deposition because inorganic monomeric Al, including <math>\text{Al}^{3+}</math> and various hydroxide species, is toxic to biota (<a href="#">Appendix 5</a>). Inorganic Al is minimally soluble at pH about 6.0, but solubility increases steeply at pH values below about 5.5.</p> <p>There have been no new studies on Al mobilization.</p>
Nitrification	X	X	<p>Nitrification releases 2 mol hydrogen ion (<math>\text{H}^+</math>) per mol <math>\text{NH}_4^+</math> converted to <math>\text{NO}_3^-</math>, acidifying soils. As soil inorganic N accumulates, net nitrification rates often increase, and <math>\text{NO}_3^-</math> can leach from the ecosystem.</p> <p>New N gradient and meta-analysis studies confirm N addition increases nitrification.</p>
Denitrification	X		<p>Denitrification is the microbial reduction of <math>\text{NO}_3^-</math> to nitrite (<math>\text{NO}_2^-</math>), nitric oxide (NO), the greenhouse gas nitrous oxide (<math>\text{N}_2\text{O}</math>), and <math>\text{N}_2</math>. It occurs under anaerobic conditions. In Europe, soil switched from a source to a sink after two decades of N deposition exclusion.</p> <p>New meta-analysis confirms N addition increases denitrification rates.</p>
DOC leaching	X	X	<p>Acidity of some surface waters is partly regulated by DOC concentrations. Soil acidification can suppress the natural production of DOC. In recent years, the DOC concentration of some lakes and streams has risen, with adjacent terrestrial ecosystems as the DOC source. However, the mechanism for this increase is unclear. It may be due to soil recovery from acidification or N deposition effects on decomposition.</p> <p>New studies include a meta-analysis and field addition studies.</p>

**Table 4-19 (Continued): Summary of key soil geochemical processes and indicators associated with eutrophication and acidification.**

Endpoint	N-Driven Nutrient Enrichment	Acidification	The Effect of Deposition
Decomposition/mineralization	X	X	Decomposition rates correlate with ratios of C:N, lignin:N, or lignin:cellulose in litter. The addition of N can stimulate the decomposition of labile compounds that degrade during the initial stages of decomposition, but added N can suppress the decomposition of more recalcitrant material. Evidence for this is widespread in forests but has not yet been well documented in grasslands and other ecosystems.  There are new addition studies and meta-analysis to better understand the mechanisms and response trends.
<b>INDICATOR</b>			
Soil [N]	X	X	Increasing N deposition increases concentration of N in soil and reflects soil N accumulation that may be assimilated by organisms or mobilized via leaching.
Soil C:N ratio	X	X	Increasing N deposition decreases the C:N in plant tissue, causing cascading effects during decomposition on microbial transformation, especially nitrification, leading to increased NO <sub>3</sub> <sup>-</sup> leaching.  THRESHOLD: <20 to 25 associated with elevated rates of nitrification and elevated risk of nitrate leaching in the U.S. and <25 to 30 for increased NO <sub>3</sub> <sup>-</sup> leaching in Europe.
Soil base saturation		X	Increasing N + S deposition decreases the soil pool of exchangeable base cations.  THRESHOLD: <15 to 20% is the value at which exchange ion chemistry is dominated by inorganic Al and may cause injury to vegetation (see <a href="#">Appendix 5</a> ).
Soil Bc:Al ratio		X	Increasing N + S deposition decreases the soil pool of exchangeable base cations, often decreasing the Ca:Al ratio.  THRESHOLD: Ca:Al <1.0 to 10 causes physiological stress and decreased growth and survival of sensitive plant species (see <a href="#">Appendix 5</a> ).
Fungi:bacteria ratio	X		New indicator since 2008 ISA: Increasing N deposition decreases the fungi-to-bacteria ratio and causes a transition from N to C limitation among soil food webs.

Al = aluminum; Bc = base cation; C = carbon; Ca = calcium; DOC = dissolved organic carbon; H<sup>+</sup> = hydrogen ion; ha = hectare; K = potassium; kg = kilogram; Mg = magnesium; N = nitrogen; N<sub>2</sub> = molecular nitrogen; N<sub>2</sub>O = nitrous oxide; NE = northeast; NH<sub>4</sub><sup>+</sup> = ammonium; NO = nitric oxide; NO<sub>2</sub><sup>-</sup> = nitrite; NO<sub>3</sub><sup>-</sup> = nitrate; S = sulfur; SE = southeast; yr = year.

The effects of N on decomposition, which is the breakdown of organic matter, is an active area of research ([Appendix 4.3.7](#)). Within the soil microbial community, bacteria and fungi are the primary decomposers of organic matter. Both microbial community composition (see [Appendix 6](#)) and microbial enzyme activity can respond dynamically to shifts in inorganic nutrient and substrate availability, reflecting the nutrient and energy limitation of the microbial community. Litter decay rates are also well established to correlate with ratios of C:N, lignin:N, or lignin:cellulose in litter. These chemical traits have been shown to account for over 73% of the variation in litter decomposition rates worldwide. Based on these observations, it could be assumed that added N would stimulate decomposition and the loss of C from soil pools. There is now widespread evidence, however, that the stimulatory effects of N on decomposition are limited to the early stages of mass loss, when more labile compounds are degraded. During the later stages of decomposition when the rates of mass loss are slow and controlled by the degradation of recalcitrant compounds, the addition of N slows decomposition. This slowing of decomposition appears to be a consequence of decreases in the production of some extracellular enzymes by fungi. It is clear that N additions generally decrease respiration from soil heterotrophs, but this may not decrease total soil respiration because heterotrophic respiration accounts for only a portion of soil CO<sub>2</sub> efflux.

Several new meta-analyses have been published since 2008 on N addition effects on belowground carbon cycling ([Appendix 4.3.10](#)). About half of C fixed annually by terrestrial vegetation is allocated to belowground C pools; therefore, it is important to understand how N affects belowground C to better understand changes in plant physiology, plant growth, and ecosystem C cycling ([Appendix 6](#)). Many studies have shown that changes in the belowground C cycle do not always match the aboveground C cycle. Therefore, it is inappropriate to extrapolate from aboveground responses to belowground processes.

---

### 4.8.3 Monitoring

Several new studies use long-term monitoring data sets. [Yanai et al. \(2013\)](#) evaluated 45 years of biogeochemical monitoring data at the HBEF, NH. From 1966 to 1977, more N was accumulating in living biomass than was input by atmospheric deposition; the missing N source was attributed to N fixation. Since 1992, biomass accumulation has been negligible, and the ecosystem shifted to a net missing N sink of ~8 kg N/ha/yr, which the authors hypothesized may not be the result of N retention, but may be due to gaseous N fluxes in response to N deposition or uncertainty the amount of N in the mineral soil. [Mitchell and Likens \(2011\)](#) examined sulfur accumulation observed in over four decades of continuous long-term record for four watersheds, showing that the

biogeochemical control of annual  $\text{SO}_4^{2-}$  export in stream water draining from forested watersheds has shifted from control by atmospheric S deposition to soil moisture driven by climate (reported in [Appendix 4.3.3](#)). At the Niwot Ridge LTER, CO, [Lieb et al. \(2011\)](#) found that a decade of simulated N deposition to alpine ecosystems caused ongoing changes in diversity and soil biogeochemistry, including lower soil acid buffering capacity, decreased concentrations of  $\text{Mg}^{2+}$ , and increased concentrations of the potentially toxic cations  $\text{Mn}^{2+}$  and  $\text{Al}^{3+}$ . Their results suggested an N deposition threshold of 28 kg N/ha/yr.

There are new studies on long-term monitoring in Europe, including investigations of S dynamics in England ([Lehmann et al., 2008](#)), N and S dynamics in Switzerland ([Pannatier et al., 2011](#)), and N and C interactions between boreal soils and lakes in Sweden ([Khalili et al., 2010](#)). Notably, [Khalili et al. \(2010\)](#) found a significant relationship between C:N ratios of the organic soil layer and C in lake waters, and a clear sudden increase in  $\text{NO}_3^-$  leaching in regions where N deposition exceeded 7.5 kg N/ha/yr.

---

#### 4.8.4 Models

The most commonly used ecosystem models in the U.S. were described in the 2008 ISA. Here we focus on the several primary models that are currently being used in the U.S. to assess the effects of S and N deposition on terrestrial ecosystems. One important input to these models are estimates of base cation weathering (BCw). There are new updates on two methods to estimate this parameter: Soil Texture Approximations (STA) and PROFILE. Steady-state models include steady-state mass balance equations (SMBE), while dynamic models include the VSD and  $\text{VSD}^+$ , MAGIC, NuCM, PnET/BGC, and DayCent-Chem.

Base cation weathering rate is one of the most influential yet difficult to estimate parameters in the calculation of critical acid loads of nitrogen (N) and sulfur (S) deposition for terrestrial systems. Commonly used models include STA, a simple empirical steady-state model with low data requirements, and PROFILE, a mechanistic, steady-state kinetics model that requires 26 input parameters. There is a new study on estimating BCw. [Koseva et al. \(2010\)](#) confirmed that the STA equations were derived for young soils that developed following the Late Wisconsin glaciation and may not be suitable for older, more weathered soils that were not affected by the most recent glaciation and which cover the majority of the U.S. ([U.S. EPA, 2009c](#)). The larger data set required to run PROFILE prohibits applying the model to many parts of the U.S. However, a recent soil geochemical data set compiled by the USGS has made it possible to apply PROFILE in the U.S. The initial application in 51 forested sites across

Pennsylvania indicates this technique may be appropriate for applications nationwide ([Phelan et al., 2014](#)). The uncertainty associated with the calculation of BCw has recently been evaluated by [Futter et al. \(2012\)](#), who estimated that the contribution of model parameter uncertainty to overall variability related to PROFILE and MAGIC (a dynamic model that typically uses PROFILE for initial estimates of BCw) was relatively small.

Estimates of BCw are input parameters in soil acidification models. The simplest acidification models are the steady-state mass balance models. The 2008 ISA documented a model based on simple mass-balance equations (SMBE) to assess critical loads for acidification in U.S. forest soils ([McNulty et al., 2007](#)). A second publication discussed the uncertainties associated with this model and national-scale assessment ([Li and McNulty, 2007](#)). The results indicated that uncertainty in the critical load came primarily from components of BCw (49%) and acid neutralizing capacity (46%), whereas the most critical parameters were BCw base rate (62%), soil depth (20%), and soil temperature (11%). The authors concluded that improvements in estimates of these factors are crucial to reducing uncertainty and successfully scaling up SMBE for national assessments. [Posch et al. \(2011\)](#) discussed a regional application of SMB models.

Dynamic models are typically applied to much smaller spatial areas than steady-state models because they require more data and parameterization. The VSD model is the simplest extension of the steady-state SMB model into a dynamic model that is designed for sites with few data available and applications on a large regional or continental scale. [Posch and Reinds \(2009\)](#) developed a version of the VSD for steady-state critical load applications at the regional scale. The ForSAFE model [Wallman et al. \(2005\)](#) simulates the cycles of carbon, nitrogen, base cations (Bc), and water in a forest ecosystem, while simultaneously simulating soil chemistry, tree growth, and soil organic matter accumulation or depletion. ForSAFE-VEG ([Sverdrup et al., 2007](#)) is a composite model that can link changes in atmospheric deposition, climatic conditions, and land use to responses in the biogeochemistry and plant community composition at the site level, both historically and into the future. [Belyazid et al. \(2011a\)](#) stated that the biogeochemical model platform must be improved to simulate N processes more accurately before being applied to calculate critical loads. The model overestimated the actual N concentrations in the soil solution. Several new applications of ForSAFE-VEG were published [[Belyazid et al. \(2011a\)](#); [Sverdrup et al. \(2012\)](#); [McDonnell et al. \(2013\)](#)], and the results are discussed in [Appendix 5](#) and [Appendix 6](#)].

MAGIC ([Cosby et al., 1985a](#); [Cosby et al., 1985c](#); [Cosby et al., 1985b](#)) is one of the most well-known dynamic models of aquatic acidification. An update to MAGIC by [Oulehle et al. \(2012\)](#) gives a more realistic simulation of observed changes in N leaching. The new formulation also provides a reasonable simulation of the long-term changes in C and N

pools (and C:N ratio) with SOM. PnET-BGC is an integrated forest-soil-water model that has been used to assess the effects of air pollution and land disturbances on forest and aquatic ecosystems; it uses a new conceptual advancement that incorporates CO<sub>2</sub> dynamics into the model. DayCent-Chem links two widely accepted and tested models, one of daily biogeochemistry for forest, grassland, cropland, and savanna systems, DayCent ([Parton et al., 1998](#)), and the other of soil and water geochemical equilibrium, PHREEQC ([Parkhurst and Appelo, 1999](#)). There is a new conceptual advancement for DayCent which now includes O<sub>3</sub> ([Bytnerowicz et al., 2013](#)). The Nutrient Cycling Model (NuCM) was developed to synthesize current understanding of nutrient cycling in forests and to predict how forests respond to changing S and N atmospheric deposition rates. No revisions to these models have been identified.

---

#### 4.8.5 National-Scale Sensitivity

The 2008 ISA documented that by the end of the 1980s, after nearly a decade of intensive research performed under the original NAPAP, the regions of the U.S. with many acid-sensitive waters and ecosystems were well recognized. These acid-sensitive ecosystems are generally located in upland mountainous terrain in the eastern U.S. and are underlain by weathering-resistant bedrock like granite or quartzite sandstone. However, similar work characterizing areas sensitive to the eutrophication effects of nitrogen is not available. Typically, all terrestrial ecosystems are sensitive to N deposition.

There is strong evidence to show that biogeochemical sensitivity to N-driven eutrophication and acidification from atmospheric deposition is the result of historical loading, geologic/soil conditions (e.g., mineral weathering and S adsorption), and nonanthropogenic sources of N and S loading to the system. No single deposition level is applicable to all ecosystems in the U.S. that will describe the onset of eutrophication or acidification. Ecosystem sensitivity is heterogeneous.

New publications have commented on recovery of terrestrial ecosystems from acidification at the national scale ([NAPAP, 2011](#)), specifically in the Northeast ([Phelan et al., 2016](#); [Fuss et al., 2015](#); [Lawrence et al., 2015a](#)), and the lack of recovery in the southern Appalachian Mountains ([Fakhraei et al., 2016](#); [Zhou et al., 2015b](#); [McDonnell et al., 2013](#); [Elliott et al., 2008](#)). Work on national-scale soil acidification published in 2007 remains the most recent national assessment of this effect ([McNulty et al., 2007](#)); however, [Figure 4-10](#) is a map of soil CLs that updates ([McNulty et al., 2007](#)) with newly available modeling ([McDonnell et al., 2014b](#); [Phelan et al., 2014](#); [Duarte et al., 2013](#); [Sullivan et al., 2011b](#); [Sullivan et al., 2011a](#)).

New critical loads for nitrate leaching in forest ecosystems reported by [Pardo et al. \(2011b\)](#) ranges from 8 to 25 kg N/ha/yr across ecoregions (Omernick Level 1) in the U.S. ([Figure 4-11](#)). At 4 kg N/ha/yr, increasing  $\text{NO}_3^-$  was reported in the organic horizon in the Colorado Front Range, which suggests incipient N saturation. In the northeastern U.S., N budgets from 83 forested watersheds show that N retention averages 76% of incoming atmospheric-N deposition and decreases from 90% retention for sites receiving 7 kg N/ha/yr to 60% retention for sites receiving 11 kg N/ha/yr ([Aber et al., 2003](#)). The highest critical loads were reported for Mediterranean California mixed-conifer forests. Since the publication of [Pardo et al. \(2011b\)](#), new studies have been published on nitrate leaching (see [Appendix 4.3.2](#)). Evidence from Europe by [Dise et al. \(2009\)](#) showed approximately 95% of forests receiving less than 8 kg N/ha/yr have leaching of less than 1 kg N/ha/yr. In Sweden, [Khalili et al. \(2010\)](#) showed a clear sudden increase in  $\text{NO}_3^-$  leaching in regions where N deposition exceeded 7.5 kg/ha/yr.

---

#### 4.8.6 Climate Modification of Soil Response to Nitrogen Addition

Soil biogeochemistry response to N deposition can be modified by climatic shifts in temperature and precipitation. For soil acidification, potential future changes in the quantity and temporal distribution of precipitation and temperature (and their interactions) is expected to alter the wet-dry cycles that govern the timing and amount of acidic inputs in precipitation, microbial transformation in the soil, and the flush of acid anions from soils to surface waters. In general, increased temperature and precipitation will likely enhance inputs of buffering agents from weathering and deposition, but also increase inputs of acidifying agents from deposition and enhanced N cycling. The relative sensitivity of these opposing processes to a given change in climate remains unresolved.

Snow interacts with soil biogeochemistry in a number of ways, mostly by temperature shifts associated with snowpack and soil moisture flux during snowmelt ([Duran et al., 2016](#); [Sorensen et al., 2016](#); [Groffman et al., 2001](#)). The highest flow and lowest ANC periods of the year tend to coincide with times of high snowmelt. This is when acidification is likely to occur. Snowpack insulates soils from frigid winter air temperatures. With a warming climate, soils are expected to become colder and experience more winter soil freeze-thaw cycles as snow cover continues to decline. There have been a number of experiments evaluating how snow effects soil N; these include studies on the timing, frequency, and severity [snow depth; [Li et al. \(2016c\)](#)].

[Greaver et al. \(2016\)](#) created a synthesis of meta-analyses to study the effects of either N, temperature, or precipitation on different pools and processes related to ecosystem C responses to these variables and to gain some insight as to the direction and magnitude of

the change observed ([Figure 13-2](#)). Nineteen different pools and processes were included in this analysis. [Liu and Greaver \(2009\)](#) conducted a meta-analysis of 313 observations across 109 studies of terrestrial and wetland ecosystems to evaluate the effect of N addition on the flux of three GHGs (CO<sub>2</sub>, CH<sub>4</sub>, and N<sub>2</sub>O). This study indicated that although N addition increased the global terrestrial C sink, the GHG benefits of an atmospheric CO<sub>2</sub> reduction could be largely offset (53–76%) by N stimulation of global CH<sub>4</sub> and N<sub>2</sub>O emission from multiple ecosystems. The authors noted that N addition alters fluxes of GHGs by regulating plant and microbial activities that are directly associated with GHG production and consumption processes. It is therefore extremely important to consider total ecosystem flux of GHGs because consumption may be offset by production, even within the same ecosystem

---

## APPENDIX 5 BIOLOGICAL EFFECTS OF TERRESTRIAL ACIDIFICATION

This appendix characterizes the biological effects of acidifying deposition of nitrogen (N) and sulfur (S) to terrestrial ecosystems. [Appendix 5.2](#) discusses effects on trees and forests ([Appendix 5.2.1](#)), understory plants and grasslands ([Appendix 5.2.2](#)), lichens ([Appendix 5.2.3](#)), soil biota ([Appendix 5.2.4](#)), and fauna ([Appendix 5.2.5](#)). The characteristics, distribution and extent of sensitive ecosystems is presented in [Appendix 5.3](#). Next, [Appendix 5.4](#) presents the application of terrestrial acidification models. Finally, levels of deposition at which effects are manifested is discussed in [Appendix 5.5](#), including a discussion of critical loads ([Appendix 5.5.3](#)). Climate modification of acidifying deposition effects is discussed in [Appendix 5.6](#). A summary section with causal determinations based on a synthesis of new information and previous evidence of biological effects of terrestrial acidification is presented in [Appendix 5.7](#).

---

### 5.1 Introduction

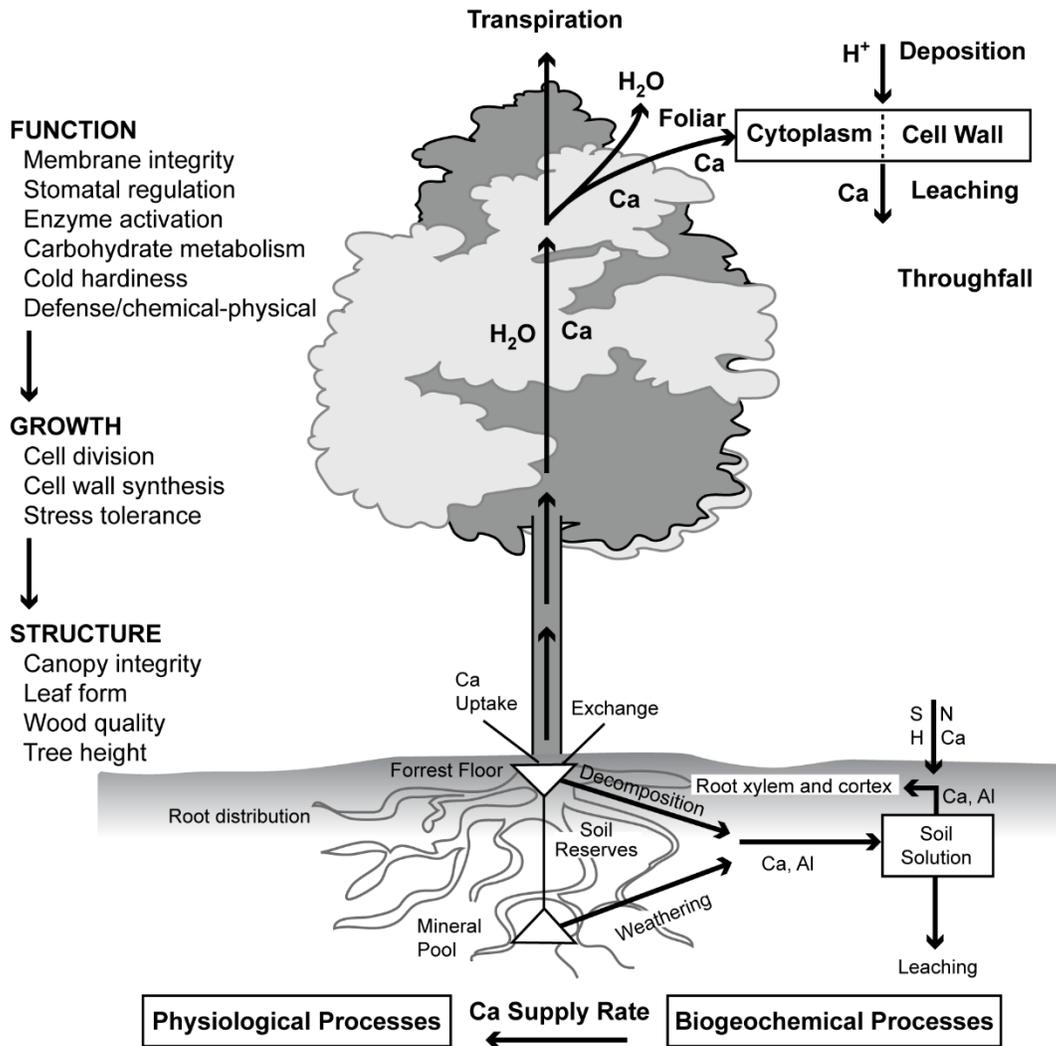

Changes in biogeochemical processes caused by acidifying deposition of N and S to terrestrial systems ([Appendix 4](#)) are linked to changes in terrestrial biota and have significant ramifications for biological functioning of these ecosystems. In the *2008 ISA for Oxides of Nitrogen and Oxides of Sulfur—Ecological Criteria* (hereafter referred to as the 2008 ISA), the evidence was sufficient to infer a causal relationship between acidifying N and S deposition and changes in terrestrial biota. The strongest evidence for a causal relationship comes from studies of terrestrial systems exposed to elevated levels of acidifying deposition that show decreased plant health, reduced plant vigor, and/or loss of terrestrial biodiversity. In multiple studies, consistent and coherent evidence has shown that acidifying deposition can affect terrestrial ecosystems by causing direct effects on plant foliage and indirect effects associated with changes in soil chemistry (Section 3.2.2.3 of 2008 ISA). Biological indicators with reported responses to acidifying deposition and conditions created by acidifying deposition include forest trees, shrubs, lichens, grasslands, and Arctic and alpine tundra.

Acidifying deposition can affect terrestrial ecosystems via direct effects on plant foliage and indirect effects associated with changes in soil chemistry ([Figure 5-1](#)). Biological effects of acidification on terrestrial ecosystems are generally attributable to aluminum (Al) toxicity and decreased ability of plant roots to take up base cations (especially calcium [Ca]) and water from the soil ([Cronan and Grigal, 1995](#)). Acidifying deposition to acid-sensitive soils can cause soil acidification, increased mobilization of Al from soil

to drainage water, and depletion of the pool of exchangeable base cations in the soil (see [Appendix 4.3.4](#) and [Appendix 4.3.5](#) for descriptions of these processes). Effects on the soil and direct effects of acidifying deposition on foliage can influence the response of plants to climatic stresses such as drought and cold temperature. The effects of acidifying deposition can also influence the sensitivity of plants to other stresses, including insect pests and disease ([Joslin et al., 1992](#)).

Since publication of the 2008 ISA, the overarching understanding of terrestrial acidification has not appreciably changed. More recent research has confirmed and strengthened this understanding and provided more quantitative information, especially across the regional landscape. This appendix highlights findings from the literature after the completion of the 2008 ISA. A number of studies have evaluated the relationships between soil chemistry indicators of acidification and ecosystem biological endpoints ([Table 5-6](#)). Much of the new literature reviewed in [Table 5-6](#) concerns natural variability in soil pH, Ca concentrations and studies that have used elevated N and S have been noted in that table under the “N and S Deposition/Additions” column. Soil chemistry indicators examined in recent literature include exchangeable base cations, soil pH, exchangeable acidity (hydrogen ions [H<sup>+</sup>] and Al), exchangeable Ca:Al ratio, base saturation, and Al concentrations. Biological endpoints evaluated included physiological responses of trees and other vegetation, lichens, soil biota, and fauna. Trees and other vegetation included sugar maple (*Acer saccharum*), red spruce (*Picea rubens*), yellow birch (*Betula alleghaniensis*), American beech (*Fagus grandifolia*), American basswood (*Tilia americana*), black cherry (*Prunus serotina*), eastern hophornbeam (*Ostrya virginiana*), white ash (*Fraxinus americana*), hickories (*Carya* spp.), northern red oak (*Quercus rubra*), and forest understory, grassland, and alpine plant species. [Table 5-1](#) provides a summary of the soil chemistry indicator-biological endpoint relationships that have been evaluated in the literature since the 2008 ISA. The 2008 ISA only considered changes in vegetation in the analysis of how acid deposition affected terrestrial ecosystems. More recent research has quantified effects on fauna (e.g., birds, snails) and soil biota ([Appendix 5.2.4](#); [Appendix 5.2.5](#)).

Together with the information available in the 2008 ISA, **this body of evidence is sufficient to infer a causal relationship between acidifying N and S deposition and the alteration of the physiology and growth of terrestrial organisms and the productivity of terrestrial ecosystems.** Further, **the body of evidence is sufficient to infer a causal relationship between acidifying N and S deposition and the alteration of species richness, community composition, and biodiversity in terrestrial ecosystems.**

Al = aluminum; Ca = calcium; H = hydrogen; H<sub>2</sub>O = water; S = sulfur.

Source: [Fenn et al. \(2006\)](#).

**Figure 5-1** Diagram based on [Fenn et al. \(2006\)](#) showing indicators of forest physiological function, growth, and structure that are linked to biogeochemical cycles through processes that control rates of calcium supply. Calcium affects plant physiological processes that influence growth rates and the capacity of plants to resist environmental stresses, such as extremes of temperature, drought, insects, and diseases. Therefore, acidifying deposition, which can deplete soil calcium or interfere with calcium uptake through mobilization of soil aluminum, can affect forest health.

Note: Only soil chemistry indicators with a reported significant relationship (positive or negative) with a biological endpoint are indicated in this table. See [Table 5-6](#) for a listing of soil chemical indicators included in each study.

---

## 5.2 Effects on Terrestrial Organisms and Ecosystems

---

### 5.2.1 Trees and Forests

Both coniferous and deciduous forests throughout the eastern U.S. have been experiencing gradual losses of base cation nutrients from the soil due to accelerated leaching from acidifying deposition. This change in base cation nutrient availability can reduce the quality of forest nutrition over the long term in sensitive areas of low base cation soils. Evidence suggests that red spruce and sugar maple in some areas in the eastern U.S. have experienced declining health as a consequence of acidifying deposition.

The 2008 ISA reported several indicators of stress to forest trees (Table 3-3 in the 2008 ISA), including the percentage of dieback of canopy trees, dead tree basal area (as a percentage), crown vigor index, and fine twig dieback. Biological effects of acidification on terrestrial ecosystems were generally attributed to Al toxicity, decreased ability of plant roots to take up nutrient cations (due to leaching of base cations from soil and interference with uptake), and elevated leaching of  $\text{Ca}^{2+}$  from conifer needles. The Ca:Al ratio in soil solution is a chemical indicator of the negative impacts of soil acidification on terrestrial vegetation ([Cronan and Grigal, 1995](#)). As tree species have shown similar sensitivities to Ca:Al and the molar ratio of base cation (Bc):Al in soil solution (with Bc representing  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ , and  $\text{K}^+$ ), the Bc:Al ratio was used to represent the Ca:Al ratio, and it is the most commonly used indicator in the simple mass balance (SMB) model to estimate critical acid loads in the European Union, Canada, and the U.S. ([McNulty et al., 2007](#); [Ouimet et al., 2006](#); [Spranger et al., 2004](#)).

[Sverdrup and Warfvinge \(1993\)](#), in a meta-analysis of laboratory, greenhouse, and field studies, reported that the critical soil solution Bc:Al ratios for a large variety of tree species ranged from 0.09 to 20.0, although the Bc:Al ratio range reported for tree species native to North America was more restricted at 0.09 to 2.0. This range is similar to that described by [Cronan and Grigal \(1995\)](#) for Ca:Al. In their meta-analysis of studies examining sensitivities to the soil solution Ca:Al ratio, plant toxicity or nutrient antagonism was reported to occur at Ca:Al ratios ranging from 0.2 to 2.5. The meta-analyses conducted by [Sverdrup and Warfvinge \(1993\)](#) explored the relationships between Bc:Al ratios in soil solution and the growth of different tree species. They reported the Bc:Al ratios at which growth was reduced by 20% relative to controls. A Bc:Al ratio of 1.0 is often applied to protect forested systems of Europe, particularly conifers ([Spranger et al., 2004](#)), and a Bc:Al ratio of 10.0 has been identified for forests

in North America, to protect deciduous forests ([McNulty et al., 2007](#); [Quimet et al., 2006](#)). The higher ratio (i.e., 10.0 vs. 1.0) provides a greater level of protection for a wider range of species and various biotic and abiotic conditions.

However, when using soil solution Bc:Al or Ca:Al ratios as the chemical indicators or criterion in the estimation of terrestrial acidification critical loads, several uncertainties must be considered. Many of these considerations have been addressed in the reviews conducted by [Cronan and Grigal \(1995\)](#) and [Vanguelova et al. \(2007\)](#). Although recognized as one of the best indicators of soil acidity risk in forest ecosystems, soil Ca:Al and Bc:Al ratios are variable and can change with soil conditions temporarily and spatially. Estimates of soil base cations and Al concentrations are also influenced by sampling and laboratory analysis methods, and there is still uncertainty regarding which forms of Al are phytotoxic. Soil solution Al occurs in many different ionic and complexed forms, depending on the soil pH and concentrations of soil ligands. In addition, uncertainties regarding the sensitivity of the biological receptor should also be considered. Critical Bc:Al and Ca:Al ratios are often based on seedling studies in controlled environments, and the relationships are less consistent for trees growing in the forest. Environmental and biological conditions, such as differences in tree age, soil horizon chemistry experienced by the roots, and root mycorrhizae are important to consider when comparing laboratory and field-based research studies. Recognizing these different sources of variability, [Cronan and Grigal \(1995\)](#) recommended applying a  $\pm 50\%$  uncertainty to their critical soil Ca:Al ratio of 1.0. Critical fine root Ca:Al ratios have also been suggested as indicators of stress in acidic forest soils ([Vanguelova et al., 2007](#); [Cronan and Grigal, 1995](#)). Fine root Ca and Al indicate what is absorbed by the tree, and there are often strong correlations between fine root and soil solution Ca:Al ratios. Similarly, studies have shown relationships between fine root Ca:Al ratio and metrics of root and above-ground tree health and productivity. However, similar to critical soil solution Ca:Al and Bc:Al ratios, fine root Ca:Al ratios also have sources of uncertainty that can be attributed to factors including soil water and chemistry variability, analysis methods and timing, fine root age, and differences in tree physiology. In addition, U.S. EPA is unaware of a method that uses fine root Ca:Al ratio as the chemical indicator within SMB calculations of critical loads.

The tree species most commonly studied in North America and used in the 2008 ISA to assess the impacts of acidification due to total nitrogen and sulfur deposition include red spruce and sugar maple, although other tree species like flowering dogwood (*Cornus florida*) can also be sensitive to conditions created by acidifying deposition. New information regarding the effects of acidifying deposition on the commonly studied sugar maple and red spruce, as well as other tree, understory, and grassland species is summarized below.

---

### 5.2.1.1 Sugar Maple

Among broadleaf tree species in the northeastern U.S., sugar maple is the species most commonly associated with adverse acidification-related effects resulting from S and N deposition, although other base cation accumulating hardwoods may also be at risk ([Driscoll et al., 2001b](#)). Sugar maple is distributed from Missouri and Minnesota in the northcentral U.S. eastward to Maine and the central Appalachian Mountain region, and the species is a dominant component of the northern hardwood forest type ([Braun, 2001](#)). Within this range, soil acidification is widespread throughout the northeastern U.S. and within many portions of the Appalachian Mountains ([Warby et al., 2009](#)).

The 2008 ISA reported that acidifying deposition, in combination with other stressors, is a likely contributor to the decline of sugar maple trees (Section 3.2.2.3 of 2008 ISA). Sugar maple decline has been noted to occur in some portions of the eastern U.S., on base cation-poor soils developed from parent material dominated by sandstone or other base cation-poor substrates. Sugar maple appears to be particularly sensitive to reduced Ca and magnesium (Mg) availability caused by acidifying deposition. Based on the results from a compilation of laboratory studies, sugar maple growth can be reduced by approximately 20% at a Bc:Al soil solution ratio of 0.6 ([Sverdrup and Warfvinge, 1993](#)).

The more recent literature on sugar maple is consistent with the 2008 ISA. In these studies, sugar maple was sensitive to soil conditions and chemistries associated with acidifying deposition ([Appendix 5.2.1.1.1](#)). Soil chemical indicators that were evaluated included exchangeable base cations, soil pH, exchangeable acidity ( $H^+$  and Al), exchangeable Ca:Al ratios, base saturation, and Al concentrations (Al form unspecified). Measured sugar maple responses included changes in basal area, growth, regeneration success, and foliar nutrient concentrations and chemistry ([Table 5-6](#)). In addition, several studies evaluated physiological mechanisms through Ca and Al addition that could explain the response of sugar maple to changes in soil chemistry induced by acidifying deposition ([Table 5-2](#)).

**Table 5-2 Summary of calcium addition studies in North America.**

Reference	Region	Species	Additions (Ca and/or Al)	Description
<a href="#">Battles et al. (2014)</a>	New Hampshire	Sugar maple, American beech, yellow birch, red spruce, and balsam fir	Approximately 1,000 kg Ca/ha (applied in 1999)	Ca additions resulted in the recovery of tree biomass increments, higher aboveground NPP, and increased photosynthetic surface area. Sugar maple exhibited the largest cumulative change in biomass, while American beech showed a negative cumulative change in biomass.
<a href="#">Boyce et al. (2013)</a>	New Hampshire, Vermont	Red spruce and balsam fir	Total of 38 g Ca/m <sup>2</sup> and/or 10.8 g Al/m <sup>2</sup>	Trends toward greater foliar Ca and Ca:Al ratios and lower Al concentrations across the treatment gradient. Ca availability appeared to enhance the ability of red spruce and balsam fir to repair oxidative stress damage.
<a href="#">Cleavitt et al. (2011b)</a>	New Hampshire	Sugar maple	Approximately 1,000 kg Ca/ha (applied in 1999)	Masting events were not influenced by the Ca treatment. Seeds from the Ca treated sites had lower concentrations of Al, K, and Mg and significantly higher concentrations of Si (but no differences in Ca concentrations). Seeds from the Ca treated sites had higher percentage of seedling emergence and higher seedling survival for the first 3 yr.
<a href="#">Halman et al. (2008)</a>	New Hampshire	Red spruce	Approximately 1,000 kg Ca/ha (applied in 1999)	Foliar Ca and total sugar concentrations were significantly higher in trees in the Ca addition watershed. Cold tolerance of foliage was significantly greater in trees in the Ca addition watershed.
<a href="#">Halman et al. (2013)</a>	New Hampshire	Sugar maple	Total of 38 g Ca/m <sup>2</sup> and/or 10.8 g Al/m <sup>2</sup>	Ca additions were found to increase C allocation to sugar maple growth. Al additions increased root Al concentrations, root cell membrane disturbance, and ascorbate peroxidase and glutathione reductase activity, and reduced foliar reflush following frost injury and the number of viable seeds.
<a href="#">Halman et al. (2015)</a>	New Hampshire	Sugar maple and American beech	Annual application of CaCl <sub>2</sub> (2.5 g/m <sup>2</sup> ) and AlCl <sub>3</sub> (0.9 g/m <sup>2</sup> ) from 1995–1999; Wollastonite (38 g/m <sup>2</sup> ) was applied in 1999 a single dose	The Al and Ca treatments did not affect beech foliar chemistry. Ca additions resulted in significantly higher Ca concentrations in both dominant and nondominant sugar maple trees. By 2008, the growth of American beech was higher than that of sugar maple on the control plots and Al treated plots, and nondominant sugar maple growth was greater than that of American beech and dominant sugar maple on the Ca treated plots. Increases in tree mortality on the Al treated plots may have released surviving American beech and increased their growth.

**Table 5-2 (Continued): Summary of calcium addition studies in North America.**

Reference	Region	Species	Additions (Ca and/or Al)	Description
<a href="#">Minocha et al. (2010)</a>	New Hampshire	Sugar maple, yellow birch, and American beech	Approximately 1,000 kg Ca/ha (applied in 1999)	Foliar soluble Ca increased significantly in all species at mid and high elevations at Ca supplemented watershed. Sensitivity to Ca limitation increased with elevation.
<a href="#">Moore et al. (2012)</a>	Quebec, Canada	Sugar maple	8 dolomite lime addition rates—0, 0.5, 1, 2, 5, 10, 20, and 50 megatonnes/ha (applied in 1994)	Foliar Ca and Mg concentrations were found to be higher for treated trees relative to the control trees. Mean crown dieback of trees decreased and seedling density increased with the lime rate. The stem basal area increment for maple trees and proportion of the sugar maple seedlings was increased with lime treatment.
<a href="#">Schaberg et al. (2011)</a>	New Hampshire	Red spruce	Approximately 1,000 kg Ca/ha (applied in 1999)	Trees from the Ca addition watershed had higher estimated levels of foliar biomass. Ca addition increased the stress tolerance of red spruce foliage during the cold season, resulting in greater crown mass.
<a href="#">Smith et al. (2009)</a>	New York, Vermont	Red spruce	Total of 160 kg Ca/yr (1992–1995)	Greater amounts of Ca were found in the wood from the high-Ca location than from the low-Ca location. Ca concentration was greater in wood formed in the 1970s than for wood formed in the 1980s, and Ca treatments resulted in increased concentration of Ca in both the 1970s and 1980s decadal bands of wood. Foliar concentrations of Ca oxalate were also higher on the high-Ca site.
<a href="#">Sridevi et al. (2012)</a>	New Hampshire	Soil microbes (bacteria)	Approximately 1,000 kg Ca/ha (applied in 1999)	Bacterial community structure in the Ca treated and nontreated reference soils was found to be significantly different, with differences among communities being more pronounced in the mineral soils.

Al = aluminum; AlCl<sub>3</sub> = aluminum chloride; C = carbon; Ca = calcium; CaCl<sub>2</sub> = calcium chloride; g = gram; ha = hectare; K = potassium; kg = kilograms; m = meter; Mg = magnesium; NPP = net primary production; Si = silicon; yr = year.

#### 5.2.1.1.1 Soil Chemical Indicators for Sugar Maple

##### Soil Exchangeable Base Cations

Sugar maple basal area and growth were responsive to soil exchangeable base cation concentrations in several studies in the northeastern U.S. In the Adirondack Mountains of New York, [Beier et al. \(2012\)](#) reported sugar maple basal area was positively correlated to forest floor and mineral soil (B-horizon) exchangeable soil Ca on sites that ranged in soil Ca from 1.83 to 53.89 cmol<sub>c</sub>/kg (in Oa-horizon) and 0.28 to 7.73 cmol<sub>c</sub>/kg in the B-horizon (see Figure 3-2 in the 2008 ISA for a description of soil horizons). Similar results were reported in Quebec, Canada by [Bilodeau-Gauthier et al. \(2011\)](#) who found that sugar maple basal area growth was positively correlated to concentrations of base cations (Ca, potassium [K], and Mg) in wood and mineral soil (B-horizon), and [Long et al. \(2009\)](#) who reported that sugar maple basal area increment (BAI) was positively correlated with exchangeable Ca and Mg in the upper B-horizon in the northeastern U.S. [Page and Mitchell \(2008\)](#) also found that the relative basal area of sugar maple was positively correlated with mineral soil (0–10 cm) exchangeable Ca in the Adirondack Mountains. In the same region, [Sullivan et al. \(2013\)](#) determined that sugar maple canopy vigor was positively correlated with soil exchangeable Ca and Mg, and mean growth rates (measured as BAI) were positively correlated with exchangeable Ca at the watershed level.

Relationships between soil exchangeable base cations and sugar maple regeneration (the growth and abundance of seedlings and saplings) have also been demonstrated. [Cleavitt et al. \(2014\)](#) evaluated sugar maple seedling survival and cause of death across 22 sites in New Hampshire that varied in soil Ca and topographic position. Soil Ca concentration exhibited a ninefold change across the study sites and was positively correlated to increases in sugar maple abundance and initial seedling densities. However, soil Ca concentration was not a significant predictor of 1st-year mortality, nor was it a factor that distinguished among the three main site types. In a study in Quebec, Canada, [Duchesne and Ouimet \(2009\)](#) explored relationships between soil chemistry and sugar maple in the sapling stratum and found that the basal area of sugar maple was positively correlated with soil exchangeable Ca and Mg.

[Pitel and Yanai \(2014\)](#) evaluated the abiotic and biotic factors influencing the mortality of dominant and codominant sugar maple trees in 47 stands in Massachusetts, Vermont, and New York that had experienced defoliation by native forest tent caterpillars (*Malacosoma disstria*) between 2002 and 2007. A total of 54 predictive variables (defoliation year, stand and site characteristics, and soil chemistry variables) were

evaluated through multiple linear regression followed by stepwise regression to produce the best predictive models of sugar maple mortality from 2006 to 2008. Mortality was highest in stands with the greatest amount of crown dieback the previous year, and drought, cold winter temperatures, concave micro-relief, and soil base cation availability were significant predictors of mortality. Concentrations of exchangeable Ca, Mg, and K in the upper B soil horizon were inversely correlated with sugar maple mortality, with exchangeable K showing the strongest relationship. Sites with above average sugar maple mortality (>3 or 4%) were found to occur on soils with low concentrations of exchangeable Ca (0.31–0.46 cmol<sub>e</sub>/kg), Mg (0.06–0.10 cmol<sub>e</sub>/kg), and K (0.03–0.05 cmol<sub>e</sub>/kg). There was also an interaction between defoliation and soil base cation availability: stands defoliated in 2005 that had low soil (A-horizon) Mg saturation suffered higher rates of mortality.

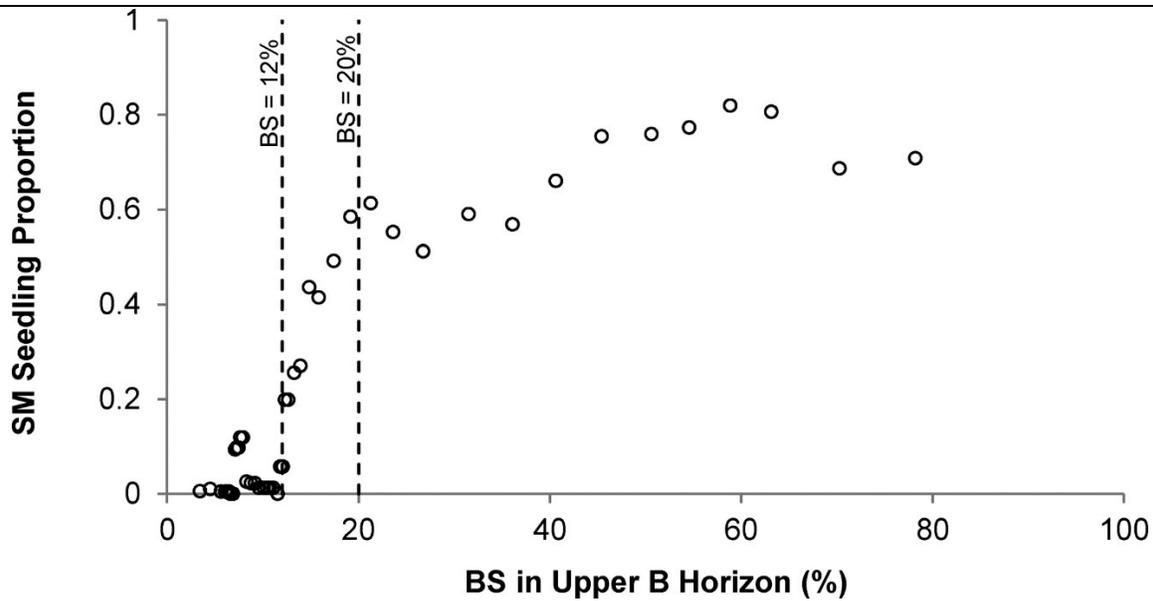

### **Soil Exchangeable Acidity and pH**

[Bilodeau-Gauthier et al. \(2011\)](#) found that sugar maple tree growth was negatively correlated to soil exchangeable acidity (H<sup>+</sup> and exchangeable Al), and through a multifactor analysis, showed that tree age and soil exchangeable Al accounted for 51% of the variation in sugar maple BAI. Positive correlations between mineral soil pH and sugar maple basal area growth have also been reported by [Long et al. \(2009\)](#) and [McEathron et al. \(2013\)](#). [Sullivan et al. \(2013\)](#) found that sugar maple canopy vigor was positively correlated with soil pH.

One study reported a relationship between sugar maple foliar chemistry and exchangeable soil chemistry. [Miller and Watmough \(2009\)](#), in their evaluation of hardwood plots along air-pollution (N, S, and ozone), soil-acidity, and climate gradients in Ontario, Canada, showed that foliar Ca and Mg content was positively correlated and foliar manganese (Mn) content was negatively correlated with soil A-horizon pH.

### **Soil Base Saturation**

An investigation of every relationship between sugar maple BAI and soil variables revealed that base saturation was the best predictor of BAI (nonlinear) and explained 43% of variance ([Bilodeau-Gauthier et al., 2011](#)). Similarly, [Sullivan et al. \(2013\)](#) found that soil base saturation was related to sugar maple regeneration and growth. Plots with lower soil base saturation did not have sugar maple regeneration; the proportion of sugar maple seedlings dropped substantially at base saturation levels less than 20% ([Figure 5-2](#)). Mean growth rates were positively correlated with soil base saturation at the watershed level.

BS = base saturation; SM = sugar maple.

Note: Plots were rank ordered based on soil base saturation, and a 5-plot rolling average was applied to both the soil base saturation and the seedling proportion data. Reference lines are added at base saturation values of 12 and 20%, indicating break points in the sugar maple seedling proportion-response function.

**Figure 5-2 Relationship between the proportion of seedlings that were sugar maple and soil base saturation in the upper B-horizon.**

### Soil Exchangeable Calcium:Aluminum Ratio

The relationship between sugar maple BAI and a soil exchangeable Ca:Al threshold of <0.03 was evaluated by [Long et al. \(2009\)](#) through an analysis of a regional network of 76 forest sites that spanned Pennsylvania, New Hampshire, New York, and Vermont. However, a repeated-measures analysis did not reveal statistically significant effects of the Ca:Al soil ratio threshold of <0.03 on BAI.

#### 5.2.1.1.2 Physiological Mechanisms for Sugar Maple

A number of studies were also conducted to determine the potential mechanisms underlying the sensitivity of sugar maple to the soil conditions created by acidifying deposition. These studies evaluated the influence of Ca additions on sugar maple physiology, growth, seeds, and seedlings ([Table 5-2](#)). In Hubbard Brook Experimental

Forest (HBEF), NH, one study involved the addition of a total of approximately 1,000 kg Ca/ha as pelletized wollastonite ( $\text{CaSiO}_3$ ) in October 1999 to a watershed ([Battles et al., 2014](#)). This treatment resulted in increases in: soil pH (in Oie-horizon) from 4.29 to 5.45; base saturation from 9.6 to 78.6% (in Oie layer), 56% (in Oa-horizon), and 14.3% (in upper mineral soil); and soil solution Ca:Al (inorganic monomeric Al) from 1.6 to 6.4 (in Oa-horizon) and from 0.97 to 3.8 (in the mineral soil). As part of this study, [Battles et al. \(2014\)](#) evaluated the effects of the Ca additions on tree growth and found that sugar maple in the treated watershed exhibited the largest increase in cumulative biomass relative to other species. Another study at the same experiment reported that sugar maple seedlings were 50% larger in the treated watershed and mycorrhizal colonization of seedlings was much higher in the treated watershed (22.47% of root length) as compared with the reference watershed [4.4%; [Juice et al. \(2006\)](#)]. Mycorrhizal colonization also increased in mature sugar maple in the treated watershed (56%) compared to the reference watershed [35%; [Juice et al. \(2006\)](#)]. In contrast to sugar maple, American beech showed a negative cumulative change in biomass. [Minocha et al. \(2010\)](#) examined the effects of the Ca addition treatment on foliar chemistry and found that sugar maple had increased foliar concentrations of Ca, which were accompanied by increases in soluble phosphorous (P), chlorophyll, and two amino acids (i.e., glutamate and glycine). The authors also reported decreases in known metabolic indicators of physiological stress (i.e., arginine and  $\gamma$ -aminobutyric acid, as well as putrescine, a diamine). Sugar maple also exhibited a decrease in foliar putrescine at higher elevations in the watershed, indicating possible remediation from Ca deficiency. [Cleavitt et al. \(2011b\)](#) evaluated sugar maple seed production, seed chemistry, seedling growth (lifestage), and seedling survival on the Ca treated watershed and found that seeds from the Ca treated sites had lower concentrations of Al, K, and Mg and significantly higher concentrations of silicon (Si) than seeds from the reference watershed. The percentage of seedling emergence was also higher, average lifestage was more significantly advanced, and seedling survival was greater on the Ca treated watershed.

In a second study (NuPert Study) conducted at HBEF, [Halman et al. \(2013\)](#) evaluated the impacts of Ca (380 kg/ha) and Al (108 kg/ha) additions on sugar maple physiology. The Ca additions increased the proportion of carbon allocated to sugar maple growth. In contrast, Al additions increased root Al concentrations and root cell membrane disturbance, increased ascorbate peroxidase (APX) and glutathione reductase (GR) activity, reduced foliar reflush following frost injury, and reduced the number of viable seeds. Ascorbate peroxidase and GR are antioxidant enzymes that target reactive oxygen species generated by environmental stresses, such as photo-oxidative stress damage at low temperatures. Elevated APX and GR activity are indicators of increased oxidative stress. Several years later, [Halman et al. \(2015\)](#) re-evaluated the NuPert study to determine the long-term and contrasting responses of sugar maple and American beech to

the Ca and Al treatments following a major ice storm in 1998. The Al and Ca treatments did not affect beech foliar chemistry. However, Ca additions significantly increased Ca concentrations in both dominant and nondominant sugar maple trees, relative to the trees treated with Al. Interestingly, for all treatments, foliar Al concentrations were higher in the nondominant than dominant sugar maple trees, and the opposite was found for foliar Ca concentrations. By 2008 (11 years after the ice storm), the growth of American beech was higher than that of sugar maple on the control plots and Al treated plots, and nondominant sugar maple growth was greater than that of American beech and dominant sugar maple on the Ca treated plots. These differential growth responses emerged within 2 to 11 years following the ice storm, depending on the treatment and species. Although plots were mainly composed of sugar maple, American beech experienced the greatest growth on Al treated plots. Increases in overstory tree mortality on the Al treated plots may have increased light availability, released surviving American beech, and increased beech growth.

[Moore et al. \(2012\)](#) evaluated soil chemistry and sugar maple status 15 years after treatment with dolomite lime (0 to 50 megatonnes/ha) to a hardwood forest in Quebec, Canada, and found results similar to those in HBEF. Foliar Ca and Mg concentrations were higher for treated trees relative to the control trees, and mean crown dieback of trees decreased quadratically with the lime addition rate, from 39% for the control trees to a value of 1 to 3% for the lime rates of 5 megatonnes/ha and higher. In addition, sugar maple BAI for the limed trees was nearly double that of the nonlimed trees. The lime application was also beneficial to the sugar maple regeneration. The overall sugar maple seedling density increased with the lime rate, doubling in the 50 megatonnes/ha (32 seedlings/m<sup>2</sup>) compared with the controls (16 seedlings/m<sup>2</sup>). The proportion of the sugar maple seedlings to all of the other species increased quadratically from 22% in controls to more than 55% in the 5 to 50 megatonnes/ha treatments. In contrast, the proportion of competitive species decreased quadratically with the lime rate, including American beech, for which the proportion in the treated plots (24%) was nearly half the proportion observed in the controls (46%).

---

### **5.2.1.2 Red Spruce**

Red spruce is a conifer that occurs mainly in the northeastern U.S. and at scattered high-elevation sites (e.g., mountain and ridge tops) in the Appalachian Mountains. Red spruce dieback or decline has been observed across high elevation landscapes of the northeastern, and to a lesser extent, southeastern U.S. At high elevations in the Adirondack Mountains in New York and the Green Mountains in Vermont, more than 50% of the canopy red spruce trees died during the 1970s and 1980s. In the White

Mountains in New Hampshire, about 25% of the canopy spruce died during that same period ([DeHayes et al., 1999](#)). Dieback of red spruce has also been observed in mixed hardwood-conifer stands at relatively low elevations in the western Adirondack Mountains, an area that receives high inputs of acidifying deposition ([Shortle et al., 1997](#)); acidifying deposition has been implicated as a causal factor ([DeHayes et al., 1999](#)).

The 2008 ISA reported that changes in soil chemistry (e.g., depletion of soil base cations, Al toxicity to tree roots, leaching of base cations into drainage water; see [Appendix 4.3.4](#) and [Appendix 4.3.5](#)) have contributed to high mortality rates and decreased growth of red spruce trees in some areas of the eastern U.S. over the past three decades. Studies evaluating the physiologic basis behind the responses of red spruce to acidifying deposition have attributed the reduced vigor of the species to increased sensitivity to frost injury and cold temperatures. The frequency of freezing injury to red spruce needles had increased during a period in the latter half of the 20th century that coincided with increased emissions of S and N oxides and increased acidifying deposition ([DeHayes et al., 1999](#)).

Since the 2008 ISA, research evaluating the sensitivity of red spruce to soil indicators of acidifying deposition have mainly focused on the potential mechanisms underlying the sensitivity of the species to acidic soil conditions. These studies have examined the physiological response of red spruce to Ca additions ([Table 5-2](#)).

In the HBEF study that involved the addition of approximately 1,000 kg Ca/ha, [Halman et al. \(2008\)](#) and [Schaberg et al. \(2011\)](#) evaluated the response of red spruce foliar chemistry. [Halman et al. \(2008\)](#) reported significantly higher foliar Ca and total sugar (fructose and glucose) in the Ca addition watershed than in trees in the reference watershed. Foliar APX activity was also higher in trees in the Ca addition watershed during winter. Cold tolerance of foliage was significantly greater in trees in the Ca addition watershed than in trees in the reference watershed. [Schaberg et al. \(2011\)](#) measured concentrations of foliar polyamines and free amino acids, foliar chlorophyll, and sapwood area (as a proxy for foliar biomass) in Ca treated and nontreated trees. Foliar polyamines (putrescine and spermidine) and free amino acids (alanine, gamma aminobutyric acid [GABA]) are putative stress protection compounds that may directly protect or provide other benefits to foliage that increase stress tolerance. The Ca additions increased November concentrations of alanine, GABA, putrescine, and spermidine relative to foliage from the reference watershed. Consistent with increased stress protection indicated by the elevated polyamine and free amino acids, foliage from the Ca addition watershed had higher total chlorophyll concentrations than foliage from the reference watershed. In contrast, foliage from the reference watershed had significantly

higher alanine:glutamic acid ratios, which have been attributed to cold sensitivity or damage in other species. In addition to concentration-based differences in foliar compounds, trees from the Ca addition watershed had higher estimated levels of foliar biomass than trees from the reference watershed. These findings suggested that Ca addition increased the stress tolerance and productive capacity of red spruce foliage during the cold season and resulted in greater crown mass compared to trees growing on nontreated soils.

Similar findings were reported by [Boyce et al. \(2013\)](#), who examined the influence of Ca and Al on the physiology of red spruce and balsam fir (*Abies balsamea*) in three different locations that varied in soil nutritional status. Processes known to be Ca sensitive (root and foliar cation concentrations, chlorophyll fluorescence, soluble sugar concentrations, and the activities of APX and GR in current-year foliage) were measured, and the results from the study suggest that Ca availability enhanced the ability of red spruce and balsam fir to repair oxidative stress damage, including photo-oxidation.

Concentrations of Ca in sapwood and accumulations of Ca oxalate in foliage have been used as markers of environmental change due to acidic deposition or forest management practices. [Smith et al. \(2009\)](#) compared the effects of different Ca fertilization treatments (approximately 178 kg Ca/ha/yr during 1992–1995) on Ca concentrations in wood and Ca and oxalate (Ox) concentrations in red spruce foliage at two locations with different initial concentrations of Ca in the soil (6.4 cmol/kg vs. 13.7 cmol/kg). Greater amounts of Ca were found in the wood from the high-Ca location than from the low-Ca location. Foliar concentrations of Ca oxalate were higher on the high-Ca site than on the low-Ca site and increased in response to Ca additions.

---

### 5.2.1.3 Other Tree Species

In the 2008 ISA, there was some information regarding the effects of acidification on dogwood (*Cornus*) species. Loss of base cations, specifically Ca<sup>2+</sup>, had been implicated in increased susceptibility of flowering dogwood to dogwood anthracnose, its most destructive disease. Susceptibility to the disease and disease severity in stands appeared dependent on several factors, including acid deposition and various edaphic characteristics and meteorological conditions. Studies pointed to greater vulnerability of dogwoods to anthracnose under simulated acid rain treatments ([Britton et al., 1996](#)) and under Ca<sup>2+</sup> deficiency [[Holzmueller et al. \(2007\)](#); Section 3.2.2.3 of 2008 ISA].

Since the 2008 ISA, no further research on dogwood has been published. However, other tree species have been evaluated in studies relating soil chemistry to tree physiology, including red maple, white oak, yellow birch, white ash, American beech, black cherry,

northern red oak, hickories, American basswood, and eastern hophornbeam. These species were reported to vary in their sensitivities to soil conditions associated with acidifying deposition ([Table 5-6](#)).

In a recent study in West Virginia, [Thomas et al. \(2013\)](#) used dendroisotopic techniques to show the recovery of eastern redcedar (*Juniperus virginiana*) trees from decades of S pollution using an analysis of a tree ring chronology from 1909 to 2008. Growth, measured as BAI, in eastern redcedar old-growth stands (118–480 years old) increased significantly since 1970. A multivariate correlation analysis using historical climate variables, atmospheric CO<sub>2</sub> concentrations, and U.S. SO<sub>2</sub> and NO<sub>x</sub> emissions estimates showed that the growth of cedar trees over the 100-year chronology is explained best by increases in atmospheric CO<sub>2</sub> and NO<sub>x</sub> emissions, and decreases in SO<sub>2</sub> emissions. Through carbon isotope (<sup>13</sup>C) analyses, the researchers were able to show that the stomata of cedar may be more sensitive to SO<sub>2</sub> emissions than to increasing atmospheric CO<sub>2</sub>. A breakpoint in the 100-year δ<sup>13</sup>C tree ring chronology occurred around 1980, as SO<sub>2</sub> emissions declined, indicating a gradual increase in stomatal conductance and a concurrent increase in photosynthesis related to decreasing SO<sub>2</sub> emissions and increasing atmospheric CO<sub>2</sub>. After 1990, calculated stomatal conductance increased more than photosynthesis. These patterns in physiology led to changing trends in intrinsic water use efficiency (*i*WUE; the ratio of photosynthesis to water loss through stomatal conductance). The calculated *i*WUE generally increased from the 1940s to 1990 mainly because of SO<sub>2</sub> emission effects on stomatal conductance, and then *i*WUE began to decrease after 1990 because SO<sub>2</sub> emissions no longer constrained stomatal function. Through S isotope analysis (tree ring δ<sup>34</sup>S), the study showed a synchronous change in the sources of S used at the whole-tree level that indicated a reduced anthropogenic influence. The increase in growth and the δ<sup>13</sup>C and δ<sup>34</sup>S trends in the tree ring chronology of these *Juniperus* trees provide evidence for a distinct physiological response to changes in atmospheric SO<sub>2</sub> emissions since 1980. The authors attributed the changes since 1980 to an indirect effect of decreases in acid deposition. However, the exact mechanism is unclear because the 100-year chronology could only be correlated to estimated SO<sub>2</sub> emissions because acidifying deposition measurements were not available. Other researchers have pointed out that the trees in the [Thomas et al. \(2013\)](#) study were growing on a limestone outcrop that could be well buffered from soil acidification ([Schaberg et al., 2014](#)). Further, the rapid recovery of tree growth could also point to a direct effect of gaseous SO<sub>2</sub> rather than an indirect effect of soil acidification, which would have a longer response time to decreases in emissions. See [Appendix 3.2](#) for further discussion of direct gaseous SO<sub>2</sub> effects on vegetation.

**Soil Exchangeable Base Cations**

Several studies reported on the relationships between species-specific basal area and growth and soil exchangeable base cations. In the Adirondack Mountains, [McEathron et al. \(2013\)](#) evaluated the relationships between basal area and soil chemistry and reported that yellow birch basal area was positively correlated with mineral soil exchangeable Ca. Similarly, [Page and Mitchell \(2008\)](#) compared the basal areas of American basswood, American beech, and white ash with mineral soil (0–10 cm in depth) exchangeable Ca concentrations and found exchangeable Ca had a positive correlation with relative basal area of American basswood, a negative correlation with the relative basal area of American beech, and no correlation with relative basal area of white ash. The positive relationship between American basswood and soil exchangeable Ca is consistent with other studies. [Beier et al. \(2012\)](#), in their evaluation of vegetation communities across northern hardwood sites that ranged in exchangeable Ca concentrations from 1.83 to 53.89 cmol<sub>c</sub>/ha (in Oa-horizon) and 0.28 to 7.73 cmol<sub>c</sub>/ha (in B-horizon), reported that American basswood and eastern hophornbeam were only found on the sites with the highest exchangeable Ca concentrations. Similarly, negative relationships between American beech and soil exchangeable Ca have been reported elsewhere. [Duchesne and Ouimet \(2009\)](#) found that basal area of American beech in the sapling stratum in sugar maple-dominated forests was negatively correlated with exchangeable Ca and Mg. Soil concentrations of Ca and Mg on sites colonized by American beech were, on average, roughly half those on sites where American beech was absent, thereby suggesting that beech effectively colonizes sites with low base status. These findings are also consistent with the responses of American beech to the Ca addition studies described earlier ([Battles et al., 2014](#); [Moore et al., 2012](#)).

**Soil Base Saturation**

One study of 30 forest plots within Monongahela National Forest, WV reported on the relationship between soil base saturation and tree abundance. [Elias et al. \(2009\)](#) evaluated relationships between tree growth parameters and soil indicators of acidifying deposition and found that hickories were the only species (out of four within-species comparisons) to have significantly lower numbers on sites with base saturation below 20% (A-horizon) and 2.5% (B-horizon). They also found that the percentage of dead northern red oak was highest on sites with Al concentrations (A-horizon) above 43 cmol<sub>c</sub>/kg. The authors reported that sites in the year 2000 with subsurface base saturation above 10% had more unique species.

## Soil Exchangeable Calcium:Aluminum Ratio

A study of 76 hardwood stands across the northeastern U.S. noted the relationship between exchangeable Ca:Al ratios and BAI. [Long et al. \(2009\)](#) found that, unlike sugar maple, black cherry BAI was greater in stands with exchangeable Ca:Al ratios (B-horizon) below the <0.03 threshold adopted by the study.

---

## 5.2.2 Forest Understory and Grassland Species

The 2008 ISA did not specifically assess the effect of acidification on forest understory species due to the lack of studies. Also, the 2008 ISA reported that grasslands were thought to be less sensitive to acidification than woodlands ([Köchy and Wilson, 2001](#); [Blake et al., 1999](#)), and grasslands with calcareous soils will be less sensitive than those with acidic soils ([Bobbink et al., 1998](#)).

Since the 2008 ISA, several studies have evaluated the relationships between soil chemistry indicators of acidification and forest understory and grassland species ([Table 5-6](#)).

---

### 5.2.2.1 Soil Chemical Indicators for Forest Understory and Grassland Species

#### Soil pH, Exchangeable Base Cations, and Exchangeable Acidity

One study examined the relationship between soil chemistry indicators of acidification and forest understory species. [Horsley et al. \(2008\)](#) evaluated 35 soil chemistry, stand, and climatic variables as predictors of understory plant species composition in northern hardwood stands, and found that a base cation-acid cation nutrient gradient accounted for 71.9% (in New Hampshire and Vermont) and 63% (in Pennsylvania and New York) of the variation in the nonmetric multidimensional scaling ordination analyses of plant community composition. Soil Ca, Mg, and pH formed the base end and Al, Mn, K, soil acidity, and organic matter represented the acid end of the gradient. Based on results from McNemars' exact test, a total of 50 of the 234 understory species were associated with the base end of the base cation-acid cation nutrient gradient. These species have value as indicators of sites at the high end of the base cation nutrient gradient in northern hardwoods, sites that would be suitable for acid-sensitive species such as sugar maple.

In the U.K., [Stevens et al. \(2010b\)](#) used data from a national survey to evaluate the species richness of 68 grasslands along an N deposition gradient. Ellenberg R

(reaction-soil pH) and N (soil nutrient) scores and an index of soil acidity preference were used as the metrics to characterize the plant diversity responses to the soil chemistry conditions created by N deposition. Although the study did not find any significant relationships between the Ellenberg and soil acidity index values and N deposition, there was evidence that soil acidification was contributing to changes in species diversity and community composition. Soil acidification may have led to decreased nutrient availability and increased Al solubility, thus, masking the effects of increased soil N availability (see also [Appendix 6.3.5](#) for N discussion).

A similar analysis along an N deposition gradient (2.4 to 43.5 kg N/ha/yr) was conducted by [Pannek et al. \(2015\)](#) using a vegetation data set from 153 seminatural acidic grasslands in northwestern Europe. Species frequency in response to N and other factors including soil (0–10 cm) P, pH,  $\text{NH}_4^+$ , and  $\text{NO}_3^-$  and geographical, climatic, and management factors were evaluated. A second set of data from acidic grasslands in Germany (392 plots) and the Netherlands (144 plots) containing plots from different time periods were also included in the analyses to determine whether the results of the spatial gradient approach coincided with temporal changes in the abundance of species. Out of 44 species included in the study, 16 were found to be affected by N deposition, with 12 of them exhibiting a decreased abundance response. Increasing soil pH and P influenced 24 and 14 species, respectively, predominantly increasing abundance. Change of species over time was unrelated to their responses to pH. However, species were found to significantly decline over time in both Germany and the Netherlands in response to N deposition, soil P, and  $\text{NO}_3^-$ . These results show the influence of N deposition in a decline for many plant species in seminatural acidic grasslands, although impacts of N deposition on pH did not appear to be the mechanism of plant responses (see also [Appendix 6.2.5](#) for N discussion).

---

### 5.2.3 Lichens

In the 2008 ISA it appeared that lichen populations were affected in areas with acidifying deposition ([Davies et al., 2007](#)). However, it was not clear whether effects were due to direct effects of  $\text{SO}_2$ , N effects, or acidifying deposition. See [Appendix 6.3.7](#) for a discussion of N deposition on lichens.

We have not identified any new studies published since the 2008 ISA that evaluated the relationships between conditions created by acidifying deposition and lichen physiology. However, in Acadia National Park, [Cleavitt et al. \(2011a\)](#) evaluated the interactions among N and S deposition, tree type, and epiphytic lichen and bryophyte diversity, biomass, and abundance to (1) document any differences in the depositional

environments (throughfall and cloud water) of red spruce and red maple (*Acer rubrum*) trees, (2) relate deposition differences to both chemistry of the bark and corresponding epiphyte biomass and composition on the bark, and (3) describe any species-specific relationships that emerged between the epiphytes and bark chemistry ([Table 5-6](#)). Throughfall N and S deposition were higher under spruce trees than under maple trees, and average S concentrations in cloud water were negatively correlated with bark Ca and bark Mg. Epiphytic lichen richness was higher on maple trees than spruce trees, and tree species differed in the number of rare epiphytic species. Several pollution-sensitive epiphytes were restricted to the maples: the cyanolichens *Leptogium cyanescens* (bipartite) and *Lobaria pulmonaria* (tripartite), the large ruffle lichen *Parmotrema crinitum*, and the moss *Zygodon viridissimus* var. *rupestris*. Cyanolichens only occurred on maple bark and did not occur on any bark with a pH below 5.02. Apparent overlap between the bark chemistry of spruce and maple, particularly for samples from higher on maple boles, suggest a reduction in the area of chemically suitable substratum for epiphytes.

---

## 5.2.4 Soil Biota

Soil biota were not specifically addressed in the 2008 ISA. Since the 2008 ISA, several studies have evaluated the relationships between soil chemistry indicators of acidification and soil biota ([Table 5-6](#)). The effects of elevated N on soil biota is addressed throughout [Appendix 6](#) (see [Appendix 6.2.3](#), [Appendix 6.2.4](#), [Appendix 6.2.5](#), and [Appendix 6.3.5](#)).

---

### 5.2.4.1 Soil Chemical Indicators for Soil Biota

#### Soil pH and Exchangeable Calcium:Aluminum Ratio

[Bardhan et al. \(2012\)](#) evaluated the relationships between soil chemistry and bacterial diversity in 30 plots along a soil chemistry and deposition gradient in high-elevation spruce-fir forests in the Great Smoky Mountain National Park (GSMNP). Modeled S deposition ranged from 6 to 41 kg S/ha/yr, measured soil pH ranged from 3.0 to 4.6, and measured CEC ranged from 1.3 to 23.1 cmol/kg (soil samples pooled from the O-, A-, and B-horizons). However, bacterial diversity and community composition did not change along the gradients of S deposition, soil pH, or exchangeable Ca:Al ratio.

## Soil pH and Aluminum Concentrations

[Chen et al. \(2013\)](#) evaluated the impacts of S additions on soil microbial and nematode communities in a grassland system of Inner Mongolia. Seven treatments of 28 to 166 mol H<sup>+</sup>/ha were applied in three doses in the form of sulfuric acid (H<sub>2</sub>SO<sub>4</sub>) from 2009 to 2010. The authors found that the proportions of soil bacteria, fungi, and nematodes were altered by the treatments, and the responses were related to soil pH and Al concentrations. Increases in fungal fatty acids (49% increase) and fungi:bacteria ratio (120% increase) and decreases in total and bacterial fatty acids (40–47% decrease) relative to the controls were attributed to soil pH and Al concentrations. High Al concentrations (51 to 83 mg/kg) were associated with decreases in total fatty acids and bacterial fatty acids and increases in fungal fatty acids. These results are consistent with a study of an agricultural soil gradient that showed that at soil pH below 4.5, microbes (bacteria and fungi) are decreased due to increased Al solubility ([Rousk et al., 2009](#)), and that fungi are often more dominant in acidic soils. [Chen et al. \(2013\)](#) also reported that acid additions also impacted the soil nematode community by initially increasing the total number of soil nematodes and then altering nematode community composition: bacterivorous and fungivorous nematodes increased, but plant-feeding and omnivorous and carnivorous nematodes decreased. The shifts in the nematode community were attributed to decreased soil pH and changes in soil moisture.

## Soil pH and Exchangeable Calcium

One study also investigated the influence of Ca addition (~1,000 kg Ca/ha/yr in 1999) on the soil bacterial community in a northeastern hardwood forest ([Sridevi et al., 2012](#)). The study detected 1,756 taxa spanning 42 phyla, 53 classes, 127 orders, and 154 families in the Ca treated and reference watersheds. Bacterial community structure was significantly different between the Ca treated and nontreated reference soils, with differences among communities being more pronounced in the mineral soils. Calcium additions resulted in significant changes in bacterial community composition in the organic and in the mineral soil horizons. The numbers of detectable taxa in families such as Acidobacteriaceae, Comamonadaceae, and Pseudomonadaceae were lower in the Ca amended soils, while Flavobacteriaceae and Geobacteraceae were higher. Analyses of relationships between soil chemistry and the bacterial communities indicated that only exchangeable Ca, pH, and P were significantly correlated with bacterial community structure.

## Soil pH

[Gilliam et al. \(2011b\)](#) evaluated the microbial community across a soil weathering gradient in a northern hardwood forest in West Virginia. Microbial community composition, characterized through phospholipid fatty acid (PLFA) analysis, varied among sites. Fungi were dominant at the most weathered, low  $\text{NO}_3^-$ -production site, while Gram-negative bacteria were significantly higher at the less weathered, moderate and high  $\text{NO}_3^-$ -production sites. Accordingly, the fungi:bacteria ratio increased in the direction of the low  $\text{NO}_3^-$ -production plots in ordination space. Correlations between the soil parameters and PLFA results suggest that low soil pH and  $\text{NO}_3^-$  concentrations supported fungal dominance, although other important factors including differences in plant community and clay and organic matter content may have also influenced the soil microbial community.

## Soil Exchangeable Calcium

A study in Japan evaluated the relationship between forest type and soil invertebrate communities in evergreen broad-leaved forests versus Japanese cedar (*Cryptomeria japonica*) plantation forests ([Ohta et al., 2014](#)). Exchangeable Ca was found to be significantly higher in soil from the Japanese cedar plantations than the evergreen forest. The invertebrate community composition also differed significantly between the two forest types and was best explained by exchangeable Ca concentrations. Two major taxa of soil crustaceans, Talitridae and *Ligidium japonicum*, were only found in the Japanese cedar plantations. In contrast, millipedes (Paradoxosomatidae) and beetles were relatively abundant in the evergreen plots.

---

## 5.2.5 Fauna

Fauna were not specifically assessed in the 2008 ISA. Since the 2008 ISA, two studies were found that evaluated the relationships between soil chemistry indicators of acidifying deposition and fauna ([Table 5-6](#)).

---

### 5.2.5.1 Soil Chemical Indicators for Fauna

## Soil Exchangeable Calcium

[Beier et al. \(2012\)](#) characterized the variation in gastropod, salamander, and vegetation communities among northern hardwood forests attributable to soil exchangeable Ca. The

sites represented the variability in soil Ca in the Adirondack Mountains, ranging from 1.83 to 53.89 cmol<sub>c</sub>/kg (Oa-horizon) and 0.28 to 7.73 cmol<sub>c</sub>/kg (B-horizon). Snail community richness and the abundance and live biomass of red-backed salamanders (*Plethodon cinereus*) were all positively correlated with soil Ca. Land snail species richness and abundance were positively correlated with Oa-horizon Ca and negatively correlated to SO<sub>4</sub><sup>2-</sup> deposition and site elevation (and NO<sub>3</sub><sup>-</sup> deposition for snail abundance). Salamander communities were dominated by mountain dusky salamanders (*Desmognathus ochrophaeus*) at Ca poor sites, with composition continuously shifting toward dominance by red-backed salamanders as Ca availability increased. Several known calciphilic species of snails (*Paravitrea multidentata*, *Gastrocopta pentodon*, and *Euconulus polygyrus*) were found only at the highest Ca sites. Some of the observations (e.g., decreasing snail abundance) were confounded by a strong positive correlation between elevation and estimated acid deposition. However, although the underlying mechanisms require further study, these findings indicate that Ca availability, which is shaped by geology and acidic deposition inputs, influences northern hardwood forest ecosystems at multiple trophic levels.

### **Soil Exchangeable Calcium and pH**

[Pabian and Brittingham \(2012\)](#) determined the relationships between soil (Oa-horizon) chemistry and forest bird community composition, abundance, and diversity, and evaluated potential mechanisms responsible for the relationships in oak and red maple-dominated forests in Pennsylvania. Mean soil (Oa-horizon) exchangeable Ca for the 14 forest sites ranged from 5.28 to 23.5 meq/100 g and pH ranged from 3.6 to 5.1. Bird community composition (species richness and species abundances) varied with soil Ca and pH, with 10 bird species having the highest abundances in forests with high-Ca soils, and 5 species having the highest abundances with low-Ca soils. Five species were classified as “generalists” because they had high abundances and were present at all forest sites. Bird species associated with low-Ca soils were associated with high densities of mountain laurel (*Kalmia latifolia*) and five tree species whose basal areas were explained by low soil pH and Ca. Bird species associated with high-Ca soils were associated with high densities of saplings and high basal areas of acid-sensitive tree species (17 species whose basal areas were, in part, explained by high Ca and soil pH). All environmental and soil variables explained 37.8% of the variation in bird species abundance data, with environmental variables explaining 36.0%, soils explaining 0.5%, and 1.3% being explained by both. Most (67%) of the variation in the bird abundance data explained by soils was also explained by the vegetation and invertebrate variables, thereby supporting the hypothesis that the environmental variables were responsible for the soil-bird relationships.

---

## 5.3 Characteristics, Distribution, and Extent of Sensitive Ecosystems

In the 2008 ISA, it was known that geology (particularly surficial geology) is the principal factor governing the sensitivity of terrestrial and aquatic ecosystems to acidification from S and N deposition. Geologic formations with low base cation supply (e.g., sandstone, quartzite), due mainly to low weathering, generally underlie the watersheds of acid-sensitive lakes and streams. Bedrock geology has been considered in numerous acidification studies ([Sullivan et al., 2007b](#); [Vertucci and Eilers, 1993](#); [Stauffer and Wittchen, 1991](#); [Stauffer, 1990](#); [Bricker and Rice, 1989](#)). Other factors contribute to the sensitivity of soils and surface waters to acidifying deposition, including topography, soil chemistry, land use, and hydrologic flowpath.

Forests of the Adirondack Mountains of New York, Green Mountains of Vermont, White Mountains of New Hampshire, the Allegheny Plateau of Pennsylvania, and mountain top and ridge forest ecosystems in the southern Appalachians are the region's most sensitive to terrestrial acidification from atmospheric deposition (Section 3.2.4.2 of 2008 ISA). Recent decreases in acid deposition had been linked to improvements in surface water chemistry ([Appendix 7](#)). However, there remains widespread measurements of ongoing depletion of exchangeable base cations in forest soils in the northeastern U.S. ([Appendix 4.3.4](#)).

At the time of the 2008 ISA, there had been no systematic national survey to determine the extent and distribution of terrestrial ecosystem sensitivity to the effects of acidifying deposition. However, one preliminary national evaluation by [McNulty et al. \(2007\)](#) used a simple mass balance model and available national databases to estimate forest soil critical acidifying deposition loads (for wet and dry deposition of S and N) and exceedances. They found that approximately 15% of forest soils in the U.S. receive acidifying deposition that exceeds the estimated critical load of wet and dry deposition of S and N by more than 250 eq/ha/yr ([McNulty et al., 2007](#)). The areas where exceedances reach this level could be considered to represent those areas that are likely most sensitive to continued high levels of acidifying deposition.

Since the 2008 ISA, a series of studies have evaluated the characteristics, distribution, and/or sensitivity of ecosystems to acidifying N and S deposition. For descriptions of studies that characterized ecosystem sensitivity through critical load and critical load exceedance determinations, see [Appendix 5.5](#).

---

## 5.4 Application of Terrestrial Acidification Models

The models that were used in recent studies to evaluate terrestrial acidification and its components included the simple mass balance [SMB; [Forsius et al. \(2010\)](#); [McNulty and Boggs \(2010\)](#); [Nasr et al. \(2010\)](#); [Whitfield and Watmough \(2012\)](#); [Duarte et al. \(2013\)](#); [Jung et al. \(2013\)](#); [Phelan et al. \(2014\)](#)], soil texture approximation [STA; [Whitfield et al. \(2010b\)](#)], MAGIC ([Sullivan et al., 2011a](#); [Whitfield et al., 2010a](#); [Whitfield et al., 2009](#)), ForSAFE-VEG ([McDonnell et al., 2014a](#); [Sverdrup et al., 2012](#)), and empirical models outlined by [Spranger et al. \(2004\)](#) and [Krzyzanowski \(2011\)](#). See [Appendix 4.5](#) for a review of models.

[Phelan et al. \(2014\)](#) applied the PROFILE model (see [Appendix 4.5.1.1](#)) to estimate BC<sub>w</sub> to support SMB critical load estimates for 51 hardwood forest sites in Pennsylvania. The rates of BC<sub>w</sub> ranged from 119 to 9,245 eq/ha/yr and were consistent with soil properties and regional geology. Critical loads ranged from 4 to 10,503 eq/ha/yr. The PROFILE model estimates by [Phelan et al. \(2014\)](#) were three times larger than those reported for the same sites by [McNulty et al. \(2007\)](#) who used the clay correlation-substrate method and SMB models to estimate BC<sub>w</sub> rates and critical loads, respectively. These PROFILE model results suggest that the hardwood sites in Pennsylvania may not be as sensitive to acidifying deposition as previously estimated by [McNulty et al. \(2007\)](#). It should be noted that BC<sub>w</sub> rates were not measured for these areas and may be a result of the different (empirical vs. mechanistic) approaches of each model. As the [Phelan et al. \(2014\)](#) study only tested and compared the PROFILE model in Pennsylvania, the researchers recommended applying PROFILE in different regions and ecosystems in the U.S. to gain a better understanding of the model performance and the degree to which BC<sub>w</sub> rates estimated by PROFILE differ from those estimated using the clay correlation-substrate model.

---

## 5.5 Levels of Deposition at Which Effects Are Manifested

Since the 2008 ISA, several studies have evaluated the relationships between N and S deposition and the growth and physiology of terrestrial organisms and ecosystem function. In addition, numerous studies have used estimates of critical load exceedances caused by historic, current, and future N and S deposition levels to characterize the impacts of acidifying deposition. In this section, these relationships are described as (1) impacts of elevated N and S deposition, (2) impacts of ambient levels of N and S deposition, and (3) critical loads and exceedances.

---

### 5.5.1 Impacts of Elevated Nitrogen and Sulfur Deposition

A number of studies published since the 2008 ISA have evaluated the impacts of elevated N and S deposition on trees, herbaceous species, and soil biota ([Table 5-3](#)). “Elevated” N and S deposition in this section refers to additions of N and S above ambient atmospheric deposition during the time of the specified study. As detailed in [Appendix 6](#), N deposition may lead to enrichment effects as well as acidification.

In Bear Brook Watershed, ME, [Bethers et al. \(2009\)](#) investigated the effects of chronically elevated N and S deposition (i.e., 25.2 kg N/ha/yr and 28.8 kg S/ha/yr additions since 1989) on growth, foliar nutrients, and photosynthetic capacity of sugar maple saplings. Sugar maple saplings in the treated watershed had higher foliar Al (+56%), N (+15%), P (+10%), and K (+15%) and lower foliar Ca (−25%) compared to the nontreated watershed, presumably through influences on soil chemistry. The treated saplings also had lower photosynthetic capacity, higher N:P ratios, negative correlations between leaf N and electron transport capacity, and reduced carboxylation capacity, which suggest nutrient imbalances induced by the elevated N and S deposition. However, sapling growth was unaffected by the treatments. In another study conducted in Quebec, Canada, [Moore and Houle \(2013\)](#) observed similar results in their evaluation of the effects of 8 years of NH<sub>4</sub>NO<sub>3</sub> additions (26 and 85 kg N/ha/yr applied from 2001–2008) on sugar maple physiology and soil chemistry. Foliar Ca in the high N treatment decreased by 79% compared to the control and reached 0.24%, the lowest foliar Ca concentration ever reported for sugar maple. The treatments did not significantly alter dieback rate or basal area growth. These results corresponded to changes in soil chemistry; the treatments significantly decreased exchangeable Ca, Mg, Mn, and K in at least one of the top organic soil layers. The largest differences were observed for exchangeable Ca between the control and the high N treatment, with the L and the H layers of the soil organic horizon showing exchangeable Ca decreases of 29 and 72%, respectively. These results suggest that increased N deposition can strongly affect Ca nutrition of sugar maple at sites with low base cation saturation; however, effects on tree growth have not been documented.

In West Virginia, [Jensen et al. \(2014\)](#) examined long-term impacts of relatively high N and S additions (22 years of 169 kg/ha/yr (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>) on black cherry and yellow poplar (*Liriodendron tulipifera*) bole wood Ca, Mg, and Mn concentrations; tree growth; and basal area. Bole wood Ca concentrations were lower and Mn concentrations higher in both species on the treated versus nontreated watershed. Growth responses, measured through relative growth rates of cored trees and changes in basal area, were not conclusively affected by the treatment.

[Jung and Chang \(2012\)](#) evaluated the impacts of 4 years of elevated N and S deposition (30 kg N/ha/yr, 30 kg S/ha/yr, and 30 kg N/yr + 30 kg S/ha/yr additions from 2006 to 2009) on a forest composed of trembling aspen (*Populus tremuloides*), white spruce (*Picea glauca*), balsam fir, black spruce (*Picea mariana*), and paper birch (*Betula papyrifera*) in the Athabasca oil sands region of Alberta, Canada. None of the treatments influenced the growth of the understory plants or soil microbial biomass; understory and microbial community composition were not measured. However, N increased tree growth in the N and N + S treatments, indicating N limitation. Nitrogen and S additions decreased soil exchangeable  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ , and these decreases were attributed to a combination of increased tree uptake to support greater growth and increased leaching with  $\text{SO}_4^{2-}$ .

[Guy et al. \(2013\)](#) conducted a greenhouse experiment to assess the potential effects of acidic deposition on the root system morphology of three endemic species that grow on sand dunes in the Athabasca oil sands region of Alberta, Canada: *Armeria maritima*, *Deschampsia mackenzieana*, and *Stellaria arenicola*. Plants were exposed to three pH treatments (pH 5.6, 5.0, and 4.2) together with additions of 2.61 to 4.67 mg/L of  $\text{SO}_4^{2-}$  and 1.95 to 3.51 mg/L  $\text{NO}_3^-$  for 55–60 days. There were no statistically significant differences in plant survival, root length, root surface area, or root tip numbers between acid treatments. Therefore, current rates of acidifying N and S deposition are not likely a threat to these species.

Since the 2008 ISA, three studies were identified on the impacts of N and/or S deposition on soil biota. [Payne et al. \(2010\)](#) examined the impacts of elevated  $\text{SO}_4^{2-}$  deposition on the microbial community in a Scottish peatland and showed that additions of 95 kg  $\text{SO}_4^{2-}$ /ha/yr applied over 18 months decreased the concentrations and percentages of live amoebae. Abundances of *Trinema lineare*, *Corythion dubium*, and *Euglypha rotunda* were also significantly reduced. These results suggest the potential importance of  $\text{SO}_4^{2-}$  deposition in influencing testate amoebae communities in the peatland soils. In another study, [Chen et al. \(2013\)](#) evaluated the impacts of S additions on soil microbial and nematode community composition in an Inner Mongolian grassland in China. Seven treatments of 28 to 166 mol  $\text{H}^+$ /ha were applied in three doses in the form of sulfuric acid ( $\text{H}_2\text{SO}_4$ ) from 2009 to 2010. Fungal fatty acids were increased by 49% and fungi:bacteria ratio increased by up to 120% by the acid additions. Total and bacterial fatty acids were decreased by the S treatments by up to 47 and 40%, respectively. Acid additions also impacted the soil nematode community by initially increasing the total number of soil nematodes, then altering community composition; bacterivorous and fungivorous nematodes increased, while plant-feeding and omnivorous and carnivorous nematodes decreased. [Hu et al. \(2013\)](#) examined the impacts of N and S additions on soil microbial biomass and function in a boreal mixed-wood forest in the Athabasca oil sands region of

Alberta, Canada. Five years of N and S additions (30 kg N/ha/yr and/or 30 kg S/ha/yr) did not influence soil microbial biomass C and N. However, activities of some extracellular enzymes in the soil were decreased by the treatments, with greater  $\beta$ -glucosidase activity in the N + S treatment than in the S treatment and decreased soil arylsulfatase activity in the S addition treatment. Thus, the additions of N and/or S strongly affected soil microbial community functions and enzymatic activities without changing soil microbial biomass in this boreal forest.

**Table 5-3 Impacts of acidifying nitrogen and sulfur deposition.**

Reference	Ecosystem Type/Region	Species	Nitrogen and Sulfur Deposition/Additions	Description
<a href="#">Bardhan et al. (2012)</a>	Forest Great Smoky Mountain National Park, TN, NC	Soil microbes (bacteria)	6 to 41 kg S/ha/yr (modeled)	Soil analyses indicated only minor differences in bacterial diversity among sites; the bacterial community did not change along the gradients of S deposition.
<a href="#">Bethers et al. (2009)</a>	Forest Bear Brook watershed, ME	Sugar maple	Ambient: 8.4 kg N/ha/yr and 14.4 kg S/ha/yr; elevated: 25.2 kg N/ha/yr and 28.8 kg S/ha/yr	Treated watershed had a 56% increase in foliar Al, a 25% reduction in foliar Ca, N (+15%), P (+10%), and K (+15%). The treated saplings had lower photosynthetic capacity, high N:P ratios, and negative correlations between leaf N and electron transport capacity, which may indicate nutrient imbalance.
<a href="#">Boot et al. (2016)</a>	Loch Vale watershed in Rocky Mountain National Park, CO	Soil microbes	17 yr of 25 kg N/ha/yr (as NH <sub>4</sub> NO <sub>3</sub> ) addition	Long-term fertilization resulted in increased soil acidity and reduced soil C. Soil microbial biomass in the fertilized soils was also lower (22%), the microbial community was altered through reductions in vesicular arbuscular mycorrhizae and saprotrophic fungi, and activity of N degrading microbial enzymes was decreased.
<a href="#">Chen et al. (2013)</a>	Grassland Mongolia, China	Soil microbes, bacteria, fungi, and nematodes	Sulfuric acid (0, 2.76, 5.52, 8.28, 11.04, 13.8, and 16.56 mol H <sup>+</sup> /m <sup>2</sup> )	Fungal fatty acids were increased by 49% and fungi:bacteria ratio increased by up to 120% by the acid additions relative to the controls. Total and bacterial fatty acids were decreased by the S treatments by up to 47 and 40%, respectively. In the treatments, bacterivorous and fungivorous nematodes increased, while herbivorous and omnivorous + carnivorous nematodes decreased.

**Table 5-3 (Continued): Impacts of acidifying nitrogen and sulfur deposition.**

Reference	Ecosystem Type/Region	Species	Nitrogen and Sulfur Deposition/Additions	Description
<a href="#">Cleavitt et al. (2011a)</a>	Forest Acadia National Park, ME	Epiphytic lichens	12 to 18 kg S/ha/yr	Throughfall chemistry influenced bark pH and the suitability of tree boles as habitat for lichen; epiphytic lichen species richness and presence of pollution-sensitive epiphytes were greater on red maple trees, which have a higher pH in the bark relative to red spruce trees.
<a href="#">Dietze and Moorcroft (2011)</a>	Forest Eastern and central portions of the U.S.	267 tree species organized into 10 PFTs	6 to 16 kg/ha/yr as NO <sub>3</sub> <sup>-</sup> ; 4 to 30 kg/ha/yr as SO <sub>4</sub> <sup>2-</sup> (NADP wet)	Mean sensitivity by covariate and PFTs showed that overall tree mortality was most sensitive to atmospheric pollutants, with acid deposition (SO <sub>4</sub> <sup>2-</sup> ) showing the highest sensitivity and N deposition the third highest sensitivity. Stand DBH showed the second highest sensitivity.
<a href="#">Duarte et al. (2013)</a>	Forest Northeastern U.S.	21 tree species	256 to 920 eq/ha/yr of N; 242 to 1,154 eq/ha/yr of S (modeled)	Statistically significant negative correlations between critical load exceedance and growth (17 species), and crown density (4 species) were determined. Positive correlations between critical load exceedance and declining vigor (4 species), crown dieback (4 species), and crown transparency (7 species) were determined. Species that were most negatively affected by N and S deposition included balsam fir, red spruce, quaking aspen, and paper birch.
<a href="#">Jensen et al. (2014)</a>	Forest Fernow Experimental Forest, WV	Yellow poplar and black cherry	35.5 kg N/ha/yr; 40.5 kg S/ha/yr as (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub> (addition)	Bole wood Ca concentrations were lower and Mn concentrations were higher in both species on the treated watershed. Growth responses were not conclusive and appeared to differ by species.

**Table 5-3 (Continued): Impacts of acidifying nitrogen and sulfur deposition.**

Reference	Ecosystem Type/Region	Species	Nitrogen and Sulfur Deposition/Additions	Description
<a href="#">Jung and Chang (2012)</a>	Forest Alberta, Canada	Trembling aspen, white spruce, balsam fir, black spruce, and paper birch	30 kg N/ha/yr, 30 kg S/ha/yr, and 30 kg N/yr + 30 kg S/ha/yr (additions)	Nitrogen addition increased tree growth in the N and N + S treatments. None of the treatments affected understory growth or soil microbial biomass. Annual leaching losses of SO <sub>4</sub> <sup>2-</sup> were increased by S and S + N additions. Leaching of base cations showed a similar trend to SO <sub>4</sub> <sup>2-</sup> leaching.
<a href="#">Miller and Watmough (2009)</a>	Forest Southern Ontario, Canada	Sugar maple	9 to 12.8 kg N/ha/yr; 7.6 to 14.8 kg S/ha/yr (ambient)	Sugar maple foliar S and N contents were positively correlated with modeled N and S deposition. Foliose lichen species richness was negatively correlated with modeled air pollution levels (S deposition, N deposition, and atmospheric ozone).
<a href="#">Pannek et al. (2015)</a>	Acidic grassland Atlantic biogeographic region of Europe	44 grassland species within the <i>Violion caninae</i> alliance	2.4 to 43.5 kg N/ha/yr (ambient)	Out of 44 species studied, 16 were affected by N deposition, with 12 of them exhibiting a negative response. Increasing soil pH and P influenced 24 and 14 species, respectively, predominantly positively. Species that were negatively affected by high N deposition and/or high soil P also showed a negative temporal trend characterized by short stature and slow growth.
<a href="#">Payne et al. (2010)</a>	Peatland Scotland	Soil microbes (testate amoebae)	Ambient: 5 kg SO <sub>4</sub> <sup>2-</sup> /ha/yr; elevated: 95 kg SO <sub>4</sub> <sup>2-</sup> /ha/yr	Analysis showed that the SO <sub>4</sub> <sup>2-</sup> treatment reduced the concentrations and percentages of live amoebae, suggesting a less active community as a result of the treatment. In addition, abundances of <i>Trinema lineare</i> , <i>Corythion dubium</i> , and <i>Euglypha rotunda</i> were significantly reduced.

**Table 5-3 (Continued): Impacts of acidifying nitrogen and sulfur deposition.**

Reference	Ecosystem Type/Region	Species	Nitrogen and Sulfur Deposition/Additions	Description
<a href="#">Quesnel and Cote (2009)</a>	Forest Boreal region of Canada	White spruce	NA	Meta-analysis of foliar results (nutrient concentrations) from 23 white spruce forests (natural and nonfertilized plantation forests) revealed that N deficiencies occurred in less than 10% of the sites. Base cation deficiencies identified were attributed to removals with harvest, higher requirements of white spruces for K and Ca, and nutrient deficiencies/imbbalances induced by N additions/deposition.
<a href="#">Rose et al. (2016)</a>	Open uplands, open lowlands, and woodlands U.K.	Vascular plants	NA	Changes in vegetation from 1993–2012 at a network of plots (504) within 12 Environmental Change Network (ECN) sites. Significant increases in species richness were detected at the network level. Increases in acid-sensitive species and comparatively little change in acid-tolerant species were noted. Changes are consistent with increases in pH observed and attributed to the large reductions in acid deposition. Increases in species diversity were also attributed to wetter summers and a reduction in soil N availability at some of the upland locations.
<a href="#">Soulé (2011)</a>	Forest Grandfather Mountain, NC	Red spruce	NA	Radial growth rates of red spruce increased through time, and growth rates were significantly correlated to temperature (positively), days with precipitation (negatively), atmospheric CO <sub>2</sub> (positively), and emissions of SO <sub>x</sub> and NO <sub>x</sub> (negatively).
<a href="#">Sullivan et al. (2013)</a>	Forest/Adirondack Mountains, NY	Sugar maple	750 to 1,120 eq/ha/yr as N + S (NADP wet, CASTNET dry)	Found that plots without sugar maple seedlings had higher rates of atmospheric N + S deposition.

**Table 5-3 (Continued): Impacts of acidifying nitrogen and sulfur deposition.**

Reference	Ecosystem Type/Region	Species	Nitrogen and Sulfur Deposition/Additions	Description
<a href="#">Thomas et al. (2013)</a>	Forest Appalachian Mountains, WV	Eastern redcedar	NA	Dendroisotopic techniques showed the recovery of eastern redcedar trees from decades of S pollution. Analysis provided evidence for a distinct physiological response to changes in atmospheric SO <sub>2</sub> emissions since 1980.
<a href="#">Cleavitt et al. (2015)</a>	Forest VT, NH, ME	Lichens	3 to 8 kg N/ha/yr and 4.5 to 5.2 kg S/ha/yr	Annual mean and cumulative N deposition were strongly correlated with decreases in lichen species richness, decreases in N sensitive species, and poorer thallus condition. Cumulative dry deposition of S had the best fit to decreases in thallus condition, poorer community-based S index values, and the absence of many S sensitive species.

---

## 5.5.2 Impacts of Ambient Deposition

Five studies that were published since the 2008 ISA have been identified that documented the impacts of ambient N and S deposition on terrestrial biological endpoints, including tree species, tree species grouped into plant functional types (PFTs), lichens, and soil biota ([Table 5-3](#)). “Ambient” N and S deposition in this section refers to the levels of atmospheric N and S deposition experienced during the time of the specified study.

[Dietze and Moorcroft \(2011\)](#) conducted a large-scale analysis of central and eastern U.S. that investigated 13 covariates (including climate, air pollutants [N deposition, acid deposition, and ozone averaged 1994–2005], topography, and stand characteristics) as predictors of individual tree mortality. Tree species (267 species) were grouped into 10 PFTs based on hardwoods/softwoods, latitude, successional phase (early, mid, and late successional), and hydrological soil status (i.e., hydric). The researchers found that tree mortality was most sensitive to stand characteristics and air pollutants. Nine PFTs had decreased mortality with increased N deposition, and only the northern mid successional hardwoods showing the opposite pattern (i.e., increased mortality with increased N deposition). Seven PFTs showed large increases in mortality with acid deposition (as  $\text{SO}_4^{2-}$ ), with only late successional conifers showing the inverse (i.e., a weak decline in mortality with increased acid deposition). Mean sensitivity by covariate and PFT showed that overall tree mortality was most sensitive to atmospheric pollutants, with acid deposition ( $\text{SO}_4^{2-}$ ) showing the highest sensitivity and N deposition the third highest sensitivity. Individual tree DBH showed the second highest sensitivity.

[Duarte et al. \(2013\)](#) evaluated the responses of tree species in 4,057 forest plots in the northeastern U.S. to the exceedance of critical loads of N and S deposition. Modeled S and N deposition ranged from 242 to 1,154 eq/ha/yr and 256 to 920 eq/ha/yr, respectively. Critical loads were exceeded in 45% (calculated using midpoint weathering rates) of the plots. See [Appendix 5.5.3](#) for a greater description of critical loads and exceedances from this study. Results from Spearman’s rank correlation analyses showed that the growth of 17 species and crown density of 4 species were negatively correlated with critical load exceedance ([Table 5-4](#)). Positive correlations between critical load exceedance and declining vigor (three species), crown dieback (four species), and crown transparency (seven species) were also found ([Table 5-5](#)). Crown dieback was considered the most reliable indicator of forest health. Based on this metric, balsam fir, red spruce, quaking aspen, red maple, and paper birch were identified as the species most negatively impacted by N and S deposition.

**Table 5-4 Results of Spearman’s rank correlation analysis comparing growth versus critical load exceedance by species for the forested plots in the northeastern U.S. [from [Duarte et al. \(2013\)](#)]. Modeled sulfur and nitrogen deposition on the plots ranged from 242 to 1,154 eq/ha/yr and 256 to 920 eq/ha/yr, respectively. Correlations shown here are significant at  $\alpha = 0.05$ .**

eq = equivalents; ha = hectare; yr = year.

Source: [Duarte et al. \(2013\)](#).

[Sullivan et al. \(2013\)](#) evaluated relationships between deposition and sugar maple regeneration in the Adirondack Mountains. Total N and S deposition ranged between 750 and 1,120 eq/ha/yr, and plots that received higher rates of N (median of approximately 560 eq/ha/yr), S (median of approximately 480 eq/ha/yr), and N + S (median of approximately 1,040 eq/ha/yr) deposition had no sugar maple seedlings.

[Soulé \(2011\)](#) sampled red spruce trees within a high elevation red spruce-Fraser fir (*Abies fraseri*) forest on Grandfather Mountain, NC between 2006 and 2008, and used dendrochronology to evaluate the influences of climate (precipitation, temperature, and CO<sub>2</sub> concentrations) and emissions of SO<sub>x</sub> and NO<sub>x</sub> on growth. Radial growth rates of red spruce increased through time and were positively correlated to temperature and atmospheric CO<sub>2</sub> but were negatively correlated to emissions of SO<sub>x</sub> and NO<sub>x</sub> and number of days with precipitation in a year.

[Miller and Watmough \(2009\)](#) evaluated hardwood plots along air pollution (N, S, and ozone), soil acidity, and climate gradients in Ontario, Canada, and found that foliose lichen species richness was negatively correlated with modeled air pollution levels (S deposition, N deposition, and atmospheric ozone). In the same study, however, no relationship was seen in canopy condition and ground vegetation richness and diversity.

[Bardhan et al. \(2012\)](#) evaluated bacterial diversity along a soil and S deposition gradient in high elevation spruce-fir forests in GSMNP. Modeled S deposition ranged from 6 to 41 kg S/ha/yr. However, neither bacterial diversity nor community composition changed along the gradient of S deposition. The bacterial community on all sites was dominated by members of the phyla Actinobacteria, Acidobacteria, Planctomycetes, Proteobacteria, and Chloroflexi. Species from these phyla are often found in highly acidic environments such as acid-mine drainage and sphagnum bogs. Therefore, these analyses suggested that despite reductions in acid deposition, the soil conditions in these GSMNP sites were still acidic and had not yet reached a threshold suitable for nonacidophilic bacterial communities.

[Pannek et al. \(2015\)](#) used a data set from seminatural grasslands found on acidic soils along an N deposition gradient (2.4 to 43.5 kg N/ha/yr) in northwestern Europe to examine the response of species frequency to N and other factors including soil (0–10 cm) P, pH, NH<sub>4</sub><sup>+</sup>, and NO<sub>3</sub><sup>-</sup> and geographical, climatic, and management factors. Out of 44 studied species, 16 were affected by N deposition, with 12 of them exhibiting a negative response (see also [Appendix 6.2.5](#) and [Appendix 6.3.5](#)).

---

### 5.5.3 Critical Loads and Exceedances

Since the 2008 ISA, critical load evaluations have been conducted in the northeastern forests of the U.S., hardwood forests in Pennsylvania, forests in western Canada, and arctic, subarctic, alpine, subalpine, and boreal systems. Studies also simulated target loads and critical loads and exceedances into the future under different deposition and climate scenarios and evaluated the sensitivity of critical load estimates to varying environmental conditions and forest management and uncertainties in critical load estimates. See [Appendix 4.6.2.1](#) for more information on critical loads based on soil acidification and [Appendix 6.5](#) for information on N critical loads in terrestrial systems.

[Duarte et al. \(2013\)](#) calculated critical loads of N and S for 4,057 forested plots in the northeastern U.S. using the steady-state SMB model (see also [Appendix 4.5.1.2](#)) and soil solution Bc:Al of 10.0 as the chemical indicator and threshold. In addition, the study evaluated the influence of three different BCw rates on critical loads: minimum, midpoint, and maximum. These BCw rates were determined using the clay correlation-substrate method and the range of U.S. Department of Agriculture (USDA) Natural Resources Conservation Service (NRCS) Soil Survey Geographic Database (SSURGO) values for each soil series. Critical loads using the midpoint weathering rates were found to range from 11 to 6,540 eq/ha/yr (over 80% within the range of 850–2,050 eq/ha/yr), and in comparisons with deposition estimated using the ClimCalc model, were exceeded in 98% (calculated using minimum weathering rates), 45% (calculated using midpoint weathering rates), and 15% (calculated using maximum weathering rates) of plots. Similarly, [Phelan et al. \(2014\)](#) calculated critical loads of N and S deposition for 51 hardwood forests in Pennsylvania using the SMB model, soil solution Bc:Al of 10.0 as the chemical indicator, and the PROFILE model to estimate BCw rates. They found that critical loads ranged from 4 to 10,503 eq/ha/yr, and that critical loads at 53% of the sites were exceeded by the 2002 N and S deposition.

[Krzyzanowski \(2011\)](#) modeled deposition and soil acidification critical loads in northeastern British Columbia, Canada using empirical methods described in [Spranger et al. \(2004\)](#). Slow weathering of shale- and mudstone-derived feldspars, micas, and quartz placed the soils of the study area in the “high-sensitivity” class of critical loads. Soil acidification critical load was estimated to be 200 eq/ha/yr. Neither S nor N deposition exceeded this critical load. The combined S and N deposition at the dominant point of reception (i.e., near Blueberry River First Nation) was estimated to be 73.5 eq/ha/yr.

Estimates of S and N critical loads and exceedances for upland soils were generated for the Georgia Basin in British Columbia, Canada using the SMB model and zero base cation depletion as the chemical criterion and threshold ([Nasr et al., 2010](#)). The objective of the study was to evaluate critical load and exceedance calculations in the context of

sustainable forest and soil management policies by using “no further changes in soil base saturation” as the critical load criterion. Critical loads were found to range between 140 and 4,000 eq/ha/yr and were generally lowest on ridge tops and increased towards the valleys. Critical load exceedance ranged from 13% of the basin based on wet deposition fluxes to 32% under modeled total (wet and dry) deposition. With continued N and S deposition, significant portions of the basin were predicted to experience exceedance-enhanced base cation depletion rates greater than 200 eq/ha/yr.

[Forsius et al. \(2010\)](#) determined critical loads and exceedances for terrestrial ecosystems in the arctic and subarctic regions (with latitudes north of 60°) for 1990, 2000, 2010, and 2020 using the SMB model and two different chemical indicators (soil solution Al:Bc of 1.0 and ANCle of 0.0). The Al:Bc indicator was hypothesized to protect against fine root damage, and the ANCle indicator was hypothesized to preserve existing soil base cation pools. The 2020 deposition scenario was based on the maximum feasible reduction (MFR) emissions for 2020. Critical load estimates were generally comparable among the three main regions (northern Europe, Russia, and North America) and were influenced by the chemical indicator and associated threshold. The Al:Bc of 1.0 was less stringent than ANCle of 0.0, with the median critical loads for the two indicators being 700 and 300 eq/ha/yr, respectively. In North America, the lowest critical loads occurred in eastern Canada above latitudes of 60°. In general, low critical loads were found in areas with low weathering rates associated with coarse soils on acidic parent material. Critical loads in North America (above latitudes of 60°) were not exceeded by any of the deposition levels for any of the years: The lowest critical load was 130 eq/ha/yr, while the maximum rates of N and S deposition in North America were estimated to be 30 to 40 eq/ha/yr.

[Simkin et al. \(2016\)](#) quantified the effect of N deposition on species richness in the continental U.S. using data from over 15,000 plots. N deposition had a strong effect on species richness, but this effect differed between closed canopy and open ecosystems (i.e., forests and nonforest). In nonforested ecosystems (grasslands, deserts, shrublands, subalpine ecosystems), there was a positive relationship between N deposition and herbaceous species richness at low rates of N deposition, then a decrease in species richness with higher rates of N deposition over a threshold of 8.7 kg N/ha/yr. This study focused N enrichment, but highlighted interactions with soil acidification. Vegetation on acidic soils was more susceptible to species loss under elevated N. See [Appendix 6.2](#) and [Appendix 6.5.3](#) for more information on this study.

---

### 5.5.3.1 Target and Future Critical Loads/Critical Load Exceedances

Target loads are generally defined as the deposition that is determined to provide a selected level of protection for or recovery of an ecosystem in a given future year. Target loads of S deposition were calculated for 44 watersheds and extrapolated to 1,320 acid-sensitive watersheds in the Adirondacks using MAGIC (see also [Appendix 4.5.1.4](#)) and different soil chemical indicator and thresholds of base saturation (5 and 10%), soil solution Bc:Al, and Ca:Al [1.0 and 10.0; [Sullivan et al. \(2011a\)](#)]. In a comparison of target loads (out to years 2050 and 2100) and the 2002 deposition, only 11.6 to 13.5% of the watersheds were simulated to be in exceedance of target loads to protect soil base saturation to 5%. For target loads to protect soils to a base saturation of 10%, 79.7 to 87.5% of the watersheds were in exceedance. For soil solution Bc:Al, 7.8 and 98.1% of watersheds were exceeded by the 2002 deposition for target loads to protect soil solution ratios of 1.0 and 10.0, respectively. For soil solution Ca:Al, 44.1 to 58.2% of watersheds experienced exceedances of target loads associated with a soil solution ratio of 1.0, and 98.1% of watersheds with target loads to protect Ca:Al ratios of 10.0 were exceeded. Further investigations revealed that 58.2, 85.7, and 93.6% of watersheds could not obtain threshold values of 10% base saturation, Bc:Al = 10, or Ca:Al = 10, respectively, even if acidic deposition was held at zero, thereby demonstrating that these chemical indicator threshold values were not useful for target load calculations using MAGIC in the Adirondack Mountains.

[Sverdrup et al. \(2012\)](#) and [McDonnell et al. \(2014a\)](#) used the ForSAFE-VEG model (see also [Appendix 4.5.1.3](#)) to evaluate potential long-term effects of climate change and atmospheric N deposition on alpine/subalpine ecosystems. Critical loads in both studies were defined as the amount of N deposition to protect against a change in plant biodiversity of 5 to 10 Mondrian (M) units (i.e., 5–10% change in plant species cover). [Sverdrup et al. \(2012\)](#) focused on a “generalized” alpine/subalpine site in the Rocky Mountain National Park, and simulated plant responses to a future climate (IPCC scenario A2) and four levels of N and S deposition (preindustrial background, Clean Air Act [CAA] controls, no CAA controls, and no CAA controls + high deposition). Soil base saturation decrease to less than 1% and soil solution Bc:Al were predicted to be less than 10.0 after year 2100, with the futures of no CAA emission controls and no CAA controls + high deposition (indicating soil acidification). Future plant species coverages were predicted to change in successively greater amounts in response to the altered climate, CAA emission controls, no CAA emission controls, and no CAA emission controls + high deposition. Critical loads of N deposition were calculated (based on a change of 5 M) to be 1 kg N/ha/yr. Critical loads related to S deposition were not discussed. All future N deposition scenarios (except preindustrial background N) were

simulated to result in critical load exceedance. [McDonnell et al. \(2014a\)](#) found similar results in their study that evaluated the response of plants on a site in the Loch Vale watershed, CO to 100 different scenario combinations of N deposition, precipitation, and temperature. The estimated critical load of N to protect against future (average of years 2010–2100) change in biodiversity (10 M) was estimated to be between 1.9 and 3.5 kg N/ha/yr, depending on the temperature increase scenario. Current deposition levels were found to exceed the critical load. Future increases in temperature were forecasted to substantially impact plant community composition beyond the predicted changes in response to N alone; N deposition was forecasted to result in approximately a 10- to 25-M change by 2100, whereas a +4.6°C increase in temperature was forecasted to result in approximately a 38- to 48-M change by 2100. In both studies, plant community response appeared to be attributed to N enrichment or eutrophication, as [McDonnell et al. \(2014a\)](#) stated that the critical load adopted in their study was much lower than critical loads to protect against  $\text{NO}_3^-$  leaching and soil acidification determined by other studies.

---

### **5.5.3.2 Sensitivity of Critical Load Estimates to Forest Management and Environmental Stresses**

#### **Influences of Forest Management**

Removal of N and base cations with tree harvesting can be included in the calculation of critical loads. Several recent studies evaluated the amounts of base cations removed through different harvesting practices and determined that base cation removal can be substantial and contribute to site acidification.

[Duchesne and Houle \(2008\)](#) determined base cation budgets in a managed boreal balsam fir forest in Quebec, Canada according to six different scenarios, including two harvesting scenarios (whole-tree and stem-only harvesting), and three scenarios of mineral weathering. Whole-tree harvesting was found to remove twice as much Ca (1,358 vs. 664 mol/ha) and K (483 vs. 200 mol/ha) as stem only. In contrast to Ca and Mg, immobilization of K within tree biomass (69 mol/ha/yr) was the main pathway of K losses from the soil exchangeable reservoir, being five times higher than losses via soil leaching (14 mol/ha/yr). The amounts of K contained within the aboveground biomass and the exchangeable soil reservoir were 3.3 and 4.2 kmol/ha, respectively. Whole-tree harvesting was estimated to remove 44% of the K that was readily available for cycling in the short term.

Similar results were found by [Iwald et al. \(2013\)](#) in their evaluation of the removal of base cations with the harvesting of tree stumps and logging residues for biofuels in

Sweden. Their study evaluated three levels of harvesting intensity that varied in the amounts of stump and logging residues left on site (0–40%). Results from the study indicated that harvesting of stumps and logging residues constituted 13 to 24% and 27 to 45% of total (stumps + stem wood + logging residues) base cation extraction, respectively, depending on harvest intensity and tree species. The higher acidifying effect of logging residue removal was explained by the higher contents of base cations in needles and branches compared to stem wood. In a comparison between total net cation extraction by tree harvesting and maximum levels of current acid deposition, the acidifying effect of pine harvesting was found to be 57 to 108% of that of acid deposition, the acidifying effect of spruce harvesting was 114 to 263%, and the acidifying effect of birch harvesting was 60 to 171%.

In the northeastern U.S., [Lucas et al. \(2014\)](#) evaluated base cation extractions under three different management scenarios that varied in management intensity and conservation focus. The MaxGrowth management option, which involved site scarification, intensive fertilization (ammonium nitrate), and short rotation lengths (60–100 years), resulted in roughly 50 to 100% greater base cation removal than that associated with the other three management scenarios. Additionally, removal of treetops, branches, and stumps consistently resulted in removal rates of Ca, Mg, and K three to four times greater than conventional stem-only harvests.

[Johnson et al. \(2015a\)](#) used mass balance calculations to evaluate the impact of harvesting on ecosystem balances of Ca, Mg, K, and acidification of forest soils at 40 sites in Ireland. Three harvesting scenarios were evaluated: stem-only harvest (SOH), stem plus branch harvest (SBH), and whole-tree harvest (WTH). Mass balances for Ca, Mg, and K were determined based on the difference between long-term inputs (atmospheric deposition plus mineral weathering) and outputs (biomass removal plus leaching losses). Soil acidification was calculated using a simplified acidity balance of inputs (base cation and Na deposition and base cation weathering) and outputs (base cation uptake, S deposition, and Cl<sup>-</sup> deposition). Under the SOH and SBH management, inputs of Ca, Mg, and K were predicted to be sufficient to meet outputs. Atmospheric deposition was the most important source of Ca and Mg input. For K, inputs from soil weathering were as important as deposition. Under the WTH scenario, Ca output exceeded input at 19 of the 40 study sites. However, the differences were small relative to the sizes of the Ca pools; at the 19 sites, exchangeable pools could support Ca removal with WTH for a median of 220 years. Mg and K removal with WTH was balanced by inputs through deposition and soil weathering. In contrast, for soil acidification budgets, base cation removal with all scenarios of harvesting was much greater than that generated by soil weathering, suggesting that soils will become acidified over the long term. However, there was considerable uncertainty around the calculation of base cation fluxes.

For Ca balances, confidence intervals spanned positive and negative values at so many sites that it was not possible to predict the balance of Ca budgets. In addition, uncertainty in flux calculations was particularly important for K, as soil exchangeable pools were small and could be depleted within one or two rotations.

[Zetterberg et al. \(2014\)](#) evaluated the long-term effects of whole-tree harvest (WTH) on soil and stream water acidity in three forested catchments dominated by Norway spruce in Sweden. Potential influences of varying the amounts of logging residues, Ca concentrations in tree biomass, and site productivity on the model predictions were also evaluated through a sensitivity analysis. The MAGIC model was used to simulate changes in forest soil exchangeable Ca pools and stream water ANC from 1850 to 2100, with WTH occurring in 2020. Large depletions in soil Ca supply and a reversal of the positive trend in stream ANC were predicted for all three catchments sites after WTH. However, the magnitude of impact on stream ANC varied depending on site and the concentrations of mobile strong acid anions. Varying the tree biomass Ca concentrations was found to have the largest impacts on modeled soil and stream chemistry. Site productivity was the second most influential variable, and changing the amount of harvest residues left on site only marginally affected soil exchangeable Ca and stream water ANC. The results from this study suggest that future research should concentrate on minimizing uncertainties in tree biomass Ca concentrations and performing studies on biological feedback mechanisms that can increase Ca availability in the soils.

### **Influences of Environmental Stresses**

Climate and other environmental stresses may also directly or indirectly alter ecosystem parameters that are used in the SMB model to determine critical loads. The potential influences of climate were examined by [McNulty and Boggs \(2010\)](#) in their case-study evaluation of red spruce stands in western North Carolina that were experiencing low versus high rates of mortality associated with a pine beetle outbreak. There were positive relationships between site fertility (forest floor and soil measurements, foliar N concentrations, and Mg:N ratios) and red spruce mortality. Annual basal area growth of red spruce on more fertile plots was more sensitive to drought than on less fertile sites. Based on these observations, critical loads of acidity could change as a result of episodic stress (e.g., drought, insect infestations, frost injury, cold tolerance, etc.), and increased growth due to higher fertility and/or nutrient imbalances caused by acidifying deposition may make red spruce more susceptible to environmental stresses. Critical loads of N and S, therefore, might be lower when environmental stresses are present.

---

### 5.5.3.3 Uncertainties in Critical Load Estimates

[Reinds and de Vries \(2010\)](#) evaluated the uncertainties in critical and target loads of S and N for 182 European forest soil plots using the Very Simple Dynamic (VSD) model (see also [Appendix 4.5.2.2](#)). Target loads were defined as the deposition that leads to a desired chemical state of the ecosystem in a given future year. The VSD model was calibrated using Bayesian prior probability functions for model parameters based on literature data, data from 200 Dutch forest sites and from simulated denitrification rates from a detailed ecosystem model, which improved the model fit to observed soil measurements. Critical loads determined by the calibrated model varied by chemical criterion. Minimum critical loads of N ranged between 181 (5th percentile) and 1,606 eq/ha/yr (95th percentile), maximum critical loads of N ranged between 502 (5th percentile) and 31,247 eq/ha/yr (95th percentile), and maximum critical loads of S ranged between 4 (5th percentile) and 9,670 eq/ha/yr (95th percentile), with the critical loads based on Al:Bc = 1 being higher than those determined using the ANC = 0 eq/ha/yr criterion. Uncertainty analysis also showed that the main drivers of uncertainty were largely dependent on the chemical criterion used in the critical and target load calculations. Base cation weathering, deposition, and the parameters describing the H-Al equilibrium in the soil solution were the main sources of uncertainty in the estimates of maximum critical loads for S ( $Cl_{max}[S]$ ) based on the Al:Bc criterion of 1.0, and uncertainty in  $Cl_{max}(S)$  based on ANC was completely determined by base cation inputs. The denitrification fraction was the most important source of uncertainty for the maximum critical loads of N ( $Cl_{max}[N]$ ). Calibration of VSD reduced the levels of uncertainty for all critical loads and criteria. After calibration, the coefficient of variation (CV) for  $Cl_{max}(S)$  was below 0.4 for almost all plots, and target loads were not needed in any of the simulations for 40% of the plots. According to the noncalibrated model, there was a positive probability for the need of a target load for almost all plots.

---

## 5.6 Climate Modification of Ecosystem Response

The effect of acidifying deposition on terrestrial ecosystems can be modified by climate shifts in temperature and precipitation. [Appendix 13](#) provides an overview on this topic and [Appendix 4.7.1](#) provides information on climate modification of soil acidification.

Warmer temperatures increase decomposition and nitrification. Nitrification will also increase with increased N supply caused by increased weathering or decomposition ([Booth et al., 2005](#)). The process of nitrification generates protons that increase the rate of nitrate and base cation leaching to drainage waters ([Murdoch et al., 1998](#)). The combined increase of  $NO_3^-$  leaching and loss of base cations has the potential to magnify

acidification in forest soils ([Fernandez et al., 2003](#)). Soil weathering is typically the key buffer to acidic deposition ([Li and McNulty, 2007](#)), and while weathering is increased by both soil temperature and soil moisture ([Gwiazda and Broecker, 1994](#)), it is unclear whether any future change in the magnitude of temperature and precipitation will be enough to alter base cation supply or influence the acid-base balance of sensitive ecosystems. Furthermore, it is unclear whether increased supply of N in soils from either deposition, increased decomposition, or increased nitrogen fixation may negate the ameliorative effect of enhanced weathering. Some studies show that climate change will mitigate acidification with increased weathering ([Belyazid et al., 2011a](#)), while others show that climate change will aggravate acidification although increased nitrification outpaces enhanced weathering ([Wu and Driscoll, 2010](#)). In general, increased temperature and precipitation will likely enhance inputs of buffering agents from weathering and deposition, but also increase inputs of acidifying agents from deposition and enhanced N cycling. The relative sensitivity of these opposing processes to a given change in climate remains unresolved.

The mountainous regions of the Eastern U.S. are especially interesting to study because acidifying deposition and climate change interact in these areas. Recently, [Wason et al. \(2017\)](#) studied the responses of red spruce and balsam fir to acidic deposition and trends in climate on Whiteface Mountain in New York using tree ring analysis in forests plots along an elevational gradient. They found that both species increased growth with increased precipitation and pH. Red spruce growth appeared to increase growth with a warming climate and balsam fir did not. Despite the changes in growth due to precipitation chemistry and climate, the authors did not detect changes in the distribution in the spruce-fir forest and perhaps this is a longer-term process. The study demonstrated the complexity of forest response as multiple environmental factors change as these forests recover from acidifying deposition.

[Koo et al. \(2014\)](#) used the Annual Radial Model (ARIUM) to investigate projected climate change effects and changing air pollution on red spruce growth in the Great Smoky Mountain national park. The model estimated that high elevation (<1,700 m) red spruce growth would decline 10.8% when a climate change interacted with a 10% increase in air pollution. However, growth increased by 8.4% when air pollution decreased 10% in air pollution with climate change. In contrast, low elevation red spruce growth decreased with future climate change with decreased, increased and no change in air pollution.

---

## 5.7 Summary

Since publication of the 2008 ISA, the overarching understanding of terrestrial acidification has not appreciably changed. More recent research has confirmed and strengthened this understanding and provided more quantitative information, especially across the regional landscape. A number of studies have evaluated the relationships between soil chemistry indicators of acidification and ecosystem biological endpoints (see [Table 5-6](#)). Soil chemistry indicators examined in recent literature include exchangeable base cations, soil pH, exchangeable acidity ( $H^+$  and Al), exchangeable Bc:Al ratio, base saturation, and Al concentrations. Biological endpoints included in the evaluations consisted of physiological and community responses of trees and other vegetation, lichens, soil biota, and fauna.

---

### 5.7.1 Physiology and Growth

The physiological effects of acidification on terrestrial ecosystems in the U.S. were well characterized at the time of the 2008 ISA. Consistent and coherent evidence from multiple species and studies in 2008 showed that the biological effects of acidification on terrestrial ecosystems were generally attributable to physiological impairment caused by Al toxicity and decreased ability of plant roots to take up base cations (Section 3.2.2.3 of the 2008 ISA). Acid deposition can also leach membrane-associated stores of Ca from young red spruce needles, which affects membrane stability and freezing tolerance. New information since the 2008 ISA has supported these conclusions ([Appendix 5.2](#)), including further studies on the impact of acidifying deposition on sensitive tree species, such as sugar maple and red spruce. Much of the new evidence for the negative effects of acidifying deposition on these species comes from Ca addition experiments, in which the addition of Ca has alleviated many of the negative plant physiological and growth effects. Consistent with the findings of the 2008 ISA, **the body of evidence is sufficient to infer a causal relationship between acidifying N and S deposition and the alteration of the physiology and growth of terrestrial organisms and the productivity of terrestrial ecosystems.**

In the 2008 ISA, acidifying deposition, in combination with other stressors, was found to be a likely contributor to physiological effects that led to the decline of sugar maple trees living at higher elevation in some portions of the eastern U.S. that have geologies dominated by sandstone or other base-poor substrate, and that have base-poor soils. Studies since the 2008 ISA support these findings (see [Appendix 5.2.1.1](#)). For example, recent field studies demonstrated relationships between soil chemical indicator threshold values and tree responses. Substantial declines in sugar maple regeneration were found at

soil base saturation levels <20%, which is consistent the range reported in the 2008 ISA. In new studies, sugar maple showed positive growth and regeneration responses to increasing exchangeable base cations, base saturation and soil pH, and negative relationships with increasing exchangeable Al. Additional studies indicated that growth, regeneration and physiological responses of sugar maple to soil conditions created by acidifying N and S deposition were reversed or ameliorated by Ca additions. The responses to Ca additions included increased growth and regeneration, decreased crown dieback, increased foliar chlorophyll, and decreases in foliar metabolic indicators of physiological stress.

The 2008 ISA reported that changes in soil chemistry, such as depletion of soil base cations, increasing Al concentration, and leaching of base cations into drainage water, have contributed to physiological stress, high mortality rates, and decreasing growth trends of red spruce trees. New information since the 2008 ISA from Ca addition studies supports the conclusion that depletion of base cations contributed to these effects in trees ([Appendix 5.2.1.2](#)). Foliar biomass and physiological responses of red spruce to soil conditions created by acidifying N and S deposition were reversed or ameliorated by Ca additions. The responses included higher foliar antioxidant activity in the winter, significantly greater foliar cold tolerance, and higher levels of foliar metabolic compounds that indicate an increased tolerance of environmental stresses. ([Schaberg et al., 2011](#); [Halman et al., 2008](#)).

In the 2008 ISA, there was a limited amount of information on acidification effects on flowering dogwood. Since the 2008 ISA, no additional information on dogwood has been published; however, other tree species that have been evaluated in studies relating soil chemistry to tree physiology include yellow birch, white ash, American beech, black cherry, northern red oak, hickories, American basswood, and eastern hophornbeam. These species were reported to vary in their sensitivities to soil conditions associated with acidifying deposition. Data are insufficient to draw general conclusions for other species. New information was also published on the recovery of eastern redcedar since the 1980s as SO<sub>2</sub> emissions declined. However, it is unclear whether this recovery was from acid deposition, direct SO<sub>2</sub> effects, or a combination of each ([Appendix 5.2.1.3](#)).

New studies since the 2008 ISA have also added new information about acidifying deposition on forest understory vegetation, grasslands, lichen communities, and higher trophic-level organisms (snails and salamanders). These studies are not as numerous as those from the decades of tree research; however, results of these studies support the conclusions of the 2008 ISA regarding the effects of acid deposition on terrestrial ecosystems.

---

## 5.7.2 Biodiversity

Consistent with the findings of the 2008 ISA, **the body of evidence is sufficient to infer a causal relationship between acidifying N and S deposition and the alteration of species richness, community composition, and biodiversity in terrestrial ecosystems.** The physiological effects of acidifying deposition can result in changes in species composition and biodiversity whereby sensitive species are replaced by more tolerant species. For example, sugar maple was found to have greater growth and seedling colonization with increasing soil cation availability, and American beech was more prevalent on soils with lower levels of base cations—locations where sugar maple does less well ([Appendix 5.2.1.3.1](#)). As noted above, studies have found increased regeneration of sugar maple with Ca additions and less regeneration with increasing exchangeable Al. Soil acid-base chemistry was found to be a predictor of understory species composition. Fifty understory species were associated with the basic end of a soil pH gradient, and these species could have value as indicators of sites with high base cation status and potentially suitable habitat for acid-sensitive species like sugar maple. In another set of studies, soil acid-base chemistry predicted and was correlated with soil biota diversity and community composition. Proportions of soil bacteria, fungi, and nematodes were found to be correlated to soil pH and Al concentrations. Fungi and nematodes were more abundant in acidic soils. Ca additions resulted in a change in soil bacterial community composition, and the bacterial community structure was found to be significantly correlated with soil exchangeable Ca, pH, and P ([Appendix 5.2.4](#)).

---

## 5.7.3 National-Scale Sensitivity and Critical Loads

Sensitivity of soils to acidifying deposition is discussed in detail in [Appendix 4](#) and summarized in [Section IS.5.1](#). In general, surficial geology is the principal factor governing the sensitivity of terrestrial ecosystems soil to acidification from S and N deposition. Other factors contribute to the sensitivity of soils to acidifying deposition, including topography, soil chemistry, and land use. Forests of the Adirondack Mountains of New York, Green Mountains of Vermont, White Mountains of New Hampshire, the Allegheny Plateau of Pennsylvania, and mountain top and ridge forest ecosystems in the southern Appalachians are the regions most sensitive to terrestrial acidification from atmospheric deposition (Section 3.2.4.2 of the 2008 ISA). Sensitive ecosystems can also be characterized by presence of acid-sensitive soils and plant species ([Appendix 5.3](#)).

Models used to determine critical loads of acidifying deposition included: SMB, STA, MAGIC, ForSAFE-VEG, and empirical models. Several models and extrapolation methods to estimate BCw rates were also investigated. The PROFILE model was

evaluated as a model to estimate soil BCw rates to support estimates of SMB critical loads in the U.S. In general, recently published models used soil solution Bc:Al of 10.0 as an indicator to estimate critical loads in North America. These models are described in more detail in [Appendix 4.5](#).

Sensitivities of ecosystems to ambient N and S deposition were also characterized through critical loads and exceedances ([Appendix 5.5](#)). Calculated critical loads for forest sites based on the soil solution Bc:Al of 10.0 in the northeastern U.S. ranged from 11 to 6,540 eq/ha/yr (eq quantifies the supply of H<sup>+</sup> ions available for acid-base reaction, allowing the acidifying effects of N and S deposition to be combined into the same unit), and 15–98% of these critical loads were exceeded by N and S deposition. In this region, correlation analyses showed that the growth of 17 species and crown density of 4 species were negatively correlated with critical load exceedance. In Pennsylvania, critical loads based on the soil solution Bc:Al of 10.0 for hardwood forests ranged from 4 to 10,503 eq/ha/yr and were exceeded by the 2002 N and S deposition in 53% of the plots. In comparison, critical loads for terrestrial ecosystems in the arctic and subarctic regions of North America were not exceeded by estimated deposition in the years 1900, 2000, 2010, and 2020. For these high latitude ecosystems, the lowest critical load was 130 eq/ha/yr, while the maximum N and S deposition was 30 to 40 eq/ha/yr.

In western Canada, critical loads ranged from 40 to 4,000 eq/ha/yr depending on the study and location. Several studies evaluated the influence of BCw rates, soil chemical indicators and thresholds, N retention, tree species-specific base cation uptake, and/or bulk (i.e., wet) versus total deposition on critical load estimates. All of these parameters were found to influence critical load and exceedance determinations, thereby demonstrating the uncertainties and sensitivities associated with critical load estimates.

**Table 5-6 Mode of action for acidifying nitrogen and sulfur deposition.**

Reference	Ecosystem Type/Region	Species	N and S Deposition/ Additions	Soil Indicator	Description
<a href="#">Bardhan et al. (2012)</a>	Forest Great Smoky Mountain National Park, TN, NC	Soil microbes (bacteria)	6 to 41 kg S/ha/yr modeled deposition classes ( <a href="#">Weathers et al., 2006</a> )	Soil pH and exchangeable Ca and Al, CEC and base saturation (O-, A-, and B-horizons)	Only minor differences in bacterial diversity among sites; the bacterial community did not change along the gradients of S deposition, soil pH, or exchangeable Ca:Al ratio. High elevation sites remain acidic and have not yet reached a threshold suitable for nonacidophilic bacterial communities.
<a href="#">Beier et al. (2012)</a>	Forest Adirondack Mountains, NY (12 upland hardwood forests)	NA	14.57 to 19.7 kg/ha/yr as wet NO <sub>3</sub> <sup>-</sup> ; 17.44 to 29.09 kg/ha/yr as wet SO <sub>4</sub> <sup>2-</sup> ; modeled ( <a href="#">Ito et al., 2002</a> ) 1990–1999	Exchangeable Ca and pH (Oa- and B-horizons)	Increasing trends in snail community richness and abundance, live biomass of red-backed salamanders, and canopy tree basal area with increasing soil Ca. Land snail species richness and abundance were positively correlated with Oa-horizon Ca and negatively correlated to SO <sub>4</sub> <sup>2-</sup> deposition. Salamander communities changed continuously along the Ca gradient. Several known calciphilic species of snails and plants were found only at the highest Ca sites. The proportion of basal area attributed to standing dead trees decreased significantly with Oa-horizon Ca.
<a href="#">Bilodeau-Gauthier et al. (2011)</a>	Forest Quebec lakes network, Quebec, Canada (6 watersheds)	Sugar maple	NA	Soil pH, base saturation, exchangeable Ca:Al ratio, exchangeable Al, Ca, Mg, Mn, and K (forest floor and 0 to 15 cm of B-horizon)	Tree growth was positively correlated to concentrations of base cations (Ca, K, and Mg) in wood and soil, and negatively correlated to concentrations of acidic metals in wood (Al, Mn, and Cd) and soil (H <sup>+</sup> and exchangeable Al). Percentage base saturation was the best predictor of BAI (nonlinear) and explained 43% of variance. Multifactorial relationships indicated that tree age and soil exchangeable Al accounted for 51% and tree age and log of the ratio of base cations (Ca + Mg + K):Al in the soluble (water and acid soluble wood extracts) fractions accounted for 46% of the variation in sugar maple BAI.

**Table 5-6 (Continued): Mode of action for acidifying nitrogen and sulfur deposition.**

Reference	Ecosystem Type/Region	Species	N and S Deposition/ Additions	Soil Indicator	Description
<a href="#">Bondi et al. (2016)</a>	White, Green, and Adirondack Mountains (34 forest sites)	Red-backed salamander ( <i>Plethodon cinereus</i> )	NA	Soil pH (Oa-horizon—on 16 sites A-horizon). Soil pH range was 2.73–5.54.	Studied the relationships between soil pH (organic horizon) and the abundance and health of red-backed salamanders. No associations between soil pH and salamander metrics (abundance, body size, and body condition) were found, and the salamanders did not appear to select habitats based on soil pH. The strongest driver of the abundance of red-backed salamanders was the presence of dusky salamanders ( <i>Desmognathus</i> spp.).
<a href="#">Cai et al. (2017a)</a>	Semiarid grassland Inner Mongolia, China	Grasses ( <i>Agropyron cristatum</i> , <i>Stipa krylovii</i> ), forbs ( <i>Artemisia frigida</i> , <i>Potentilla tanacetifolia</i> , <i>Potentilla bifurca</i> )	0, 5, 10, and 15 g N/m <sup>2</sup> /yr and two water addition treatments	Soil pH and Al plant tissue Zn, Cu, Mn, and Fe concentrations	N additions resulted in decreased pH and increased soil available Fe, Mn, and Cu concentrations, with water additions partially counteracting the impacts of N. Nitrogen additions caused higher foliar Mn, Cu, and Zn and lower Fe concentrations, resulting in micronutrient imbalances. Similar to the soils, water additions partially offset the impacts of the N additions on foliar chemistry.
<a href="#">Chen et al. (2013)</a>	Grassland Mongolian steppe, China	Soil microbes (bacteria, fungi, and nematodes)	Seven treatments of S additions as sulfuric acid (0, 2.76, 5.52, 8.28, 11.04, 13.8, and 16.56 mol H <sup>+</sup> /m <sup>2</sup> ) as three additions (2009–2010)	Soil pH and extractable cations (Al, Ca, Mg, and NA; 0 to 15 cm)	Fungal fatty acids were increased by 49% and fungi:bacteria ratio increased by up to 120% by the H <sub>2</sub> SO <sub>4</sub> additions, relative to the controls. The H <sub>2</sub> SO <sub>4</sub> treatments decreased total and bacterial fatty acids by up to 47 and 40%, respectively. These responses were attributed to soil pH and Al <sup>3+</sup> concentrations. High Al <sup>3+</sup> concentrations (51 to 83 mg/kg) were associated with decreased total fatty acids and decreases in bacterial and increases in fungal fatty acids. Soil nematode numbers were initially increased by the H <sub>2</sub> SO <sub>4</sub> treatments followed by changes in the nematode community. The shifts in the nematode community were attributed to decreased soil pH and changes in soil moisture.

**Table 5-6 (Continued): Mode of action for acidifying nitrogen and sulfur deposition.**

Reference	Ecosystem Type/Region	Species	N and S Deposition/ Additions	Soil Indicator	Description
<a href="#">Chen et al. (2016)</a>	Alpine grasslands and global terrestrial biomes	Soil microbes (bacteria, fungi)	NA	Soil pH	Studied the relative importance of site, biotic, and climatic factors on soil microbial communities in two alpine grasslands in the Tibetan Plateau and across global terrestrial biomes. Microbial communities were characterized by phospholipid fatty acid (PFLA) and grouped as total microbial biomass, fungal biomass, arbuscular mycorrhizal fungi biomass, actinomycete biomass, and fungal:bacterial ratio. In the Tibetan grasslands, all measures of soil microbial communities were found to be negatively related to soil pH (soil pH ranged from ~6–10) and positively correlated with soil C:N ratio (C:N ratio range of 4–15). The fungal:bacterial ratio showed a positive relationship with pH at soil pHs that ranged from 7.5–10, and negative relationship with soil C:N. Across the global biomes, total microbial biomass was also found to be positively correlated with soil C:N and negatively correlated with soil pH. Soil variables (alone) accounted for 43.4% of the variation in total microbial biomass, while climatic and biotic variables (alone) only accounted for 4.5 and 0.2% of variation, respectively.
<a href="#">Cleavitt et al. (2014)</a>	Forest Hubbard Brook Experimental Forest, NH	Sugar maple	NA	Exchangeable Ca (top 5 cm of B-horizon)	Soil Ca concentration exhibited a 9x change across the study sites and was positively correlated to sugar maple abundance and initial seedling densities. However, soil Ca concentration was not a significant predictor of 1st-year mortality, nor was it a factor that distinguished among the three main site types.
<a href="#">Duchesne and Ouimet (2009)</a>	Forest Southern Quebec, Canada (426 monitoring plots)	Sugar maple and American beech	NA	Soil pH, exchangeable K, Ca, Mg, H, and Al (upper B-horizon)	The basal area of sugar maple in the sapling stratum was positively correlated with soil exchangeable Ca and Mg. Basal area of American beech in the sapling stratum was negatively correlated with exchangeable Ca and Mg. However, the basal area of sugar maple in the sapling stratum was positively correlated with both the relative basal area of dead sugar maple and sugar maple in the tree stratum. The basal area of American beech was also positively correlated with the relative basal area of American beech in the tree stratum.

**Table 5-6 (Continued): Mode of action for acidifying nitrogen and sulfur deposition.**

Reference	Ecosystem Type/Region	Species	N and S Deposition/ Additions	Soil Indicator	Description
<a href="#">Elias et al. (2009)</a>	Forest Monongahela National Forest, WV (FIA plots)	Hardwood and conifer tree species	NA	Soil pH, base saturation, exchangeable Ca:Al (A- and B-horizons)	The study authors found that hickories were the only species to be in significantly lower numbers on sites with base saturation below 20 (A-horizon) and 2.5% (B-horizon). Percentage of dead northern red oak was highest on sites with A-horizon Al concentrations above 43 cmol <sub>e</sub> /kg of soil. Soil exchangeable Ca:Al and sum of base cations in the B-horizon were highest in stands that experienced the lowest species turnover rates (1989–2000). Periodic mean annual volume increment (whole stand) was positively correlated with A-horizon base saturation (range of 5 to 77%), Ca concentrations, and exchangeable Ca:Al (range of 0.17 to 10.2) and B-horizon pH. The exchangeable Ca:Al of the A-horizon accounted for over 30% of the variation in the periodic mean annual volume increment.
<a href="#">Gilliam et al. (2011b)</a>	Forest Fernow Experimental Forest, WV	Soil microbes (bacteria and fungi)	NA	Soil pH (5 cm)	Fungi were dominant at the most weathered, low NO <sub>3</sub> <sup>-</sup> site, while Gram-negative bacteria were significantly higher at the less weathered, moderate and high NO <sub>3</sub> <sup>-</sup> sites. Accordingly, the fungi:bacteria ratio increased in the direction of the low NO <sub>3</sub> <sup>-</sup> plots in ordination space. Correlations between the soil parameters and PLFA results suggest that low soil pH and NO <sub>3</sub> <sup>-</sup> concentrations supported fungal dominance, although other factors including differences in plant community and clay and organic matter content may have also influenced the soil microbial community.
<a href="#">Horsley et al. (2008)</a>	Forest Pennsylvania, New York, New Hampshire, and Vermont (86 northern hardwood stands)	234 forest understory species	NA		The study authors found that a base cation-acid cation nutrient gradient accounted for 71.9% (in NH and VT) and 63% (in PA and NY) of the variation in the nonmetric multidimensional scaling ordination analyses of plant community composition. Sugar maple foliar Mg and Ca had the strongest association with the base end of the gradient. Exchangeable Al (in NH and VT) and foliar Mn (in PA and NY) were strongly associated with the acid end of the gradient. A total of 50 of the 234 understory species were associated with the base end of the base cation-acid cation nutrient gradient.

**Table 5-6 (Continued): Mode of action for acidifying nitrogen and sulfur deposition.**

Reference	Ecosystem Type/Region	Species	N and S Deposition/ Additions	Soil Indicator	Description
<a href="#">Huang et al. (2017)</a>	Forest Eastern China	Soil microbes (Archaeal diversity)	NA	Soil pH and Al concentrations	Studied influence of Al additions on the archaeal diversity in red soils. Three Al treatments of 0, 100, or 200 mg Al/kg soil (as AlCl <sub>3</sub> ·6H <sub>2</sub> O); pH maintained at pretreatment level. Al additions were found to increase the abundance but decrease the evenness of the Archaea. Abundances of Crenarchaeota increased while those of Euryarchaeota decreased in response to higher Al concentrations, suggesting that Crenarchaeota is more tolerant of Al than is Euryarchaeota
<a href="#">Kunito et al. (2016)</a>	Forest Japan (27 sites)	Soil microbes	NA	pH and Al (soluble and exchangeable) concentrations in 0–15 cm of soil	Evaluated the relationship between soil chemistry (Al concentrations and pH) and soil microbial biomass and enzymes involved with C, N, and P cycling ( $\beta$ -D-glucosidase, polyphenol oxidase, L-asparaginase, acid phosphatase). The researchers found that $\beta$ -D-glucosidase and polyphenol oxidase were reduced with higher amounts of soluble and exchangeable Al, acid phosphatase shared an inverse relationship with soil pH, and L-asparaginase increased as pH increased. Microbial biomass was also found to decrease as organically bound Al and Fe increased.
<a href="#">Li et al. (2016a)</a>	Natural steppe ecosystem Inner Mongolia, China	Soil microbes (bacteria)	<u>Elevated N</u> 5–15 g N/m <sup>2</sup> /yr as urea applied in May and June since 2005	Soil pH (0–15 cm)	Evaluated: (1) the impacts of N and water additions on soil microbial community (0–15 cm of soil), (2) the linkages between the variation in belowground bacterial community and aboveground vegetation community, and (3) relationships between soil/plant factors and soil microbial community. In general, bacterial alpha diversity was positively correlated with total N and pH and negatively correlated with soil C:N ratio and concentrations of NH <sub>4</sub> and NO <sub>3</sub> . Beta diversity of the bacterial community was significantly correlated with C/N ratio, inorganic N, and pH. The relative abundances of Proteobacteria, Firmicutes, TM7, and OD1 increased with N addition gradient. The relative abundances of Proteobacteria Firmicutes, TM7, and OD1 were positively correlated with inorganic N and negatively correlated with soil pH.

**Table 5-6 (Continued): Mode of action for acidifying nitrogen and sulfur deposition.**

Reference	Ecosystem Type/Region	Species	N and S Deposition/ Additions	Soil Indicator	Description
<a href="#">Long et al. (2009)</a>	Forest Pennsylvania, New York, New Hampshire, and Vermont (76 sites)	Sugar maple and black cherry	NA	Soil Ca:Al (threshold of 0.03; upper B-horizon)	Exchangeable Ca, Mg, and pH in upper B-horizon were positively correlated with sugar maple BAI growth in 1987–1996. Generally, in long-term trends (1937–1996), sugar maple in stands with below-threshold amounts of foliar Ca or Mg and above-threshold amounts of Mn had decreasing BAI trends, while stands with above-threshold Ca and Mg and below-threshold Mn showed a leveling off of the BAI. Black cherry consistently showed greater growth on stands with below-threshold foliar Ca and Mg compared with above-threshold stands. Black cherry BAI was also greater in stands with below-threshold Ca:Al molar ratios in the upper B-horizon.
<a href="#">Lucash et al. (2012)</a>	Forest 19 sites in northeastern U.S. (New York and New Hampshire)	Hardwood and conifer tree species	NA	Exchangeable Ca, Mg, and Al (Oie, Oa 0 to 10 cm, 10 to 30 cm, and 30 cm to top of C-horizon)	Concentrations of Ca and Mg in foliage were correlated with exchangeable Ca and Mg concentrations in the upper mineral soil; for most tree species they were also correlated to acid-extractable Ca and Mg in the parent material (C-horizon). Foliar Al was insensitive to soil Al concentrations.
<a href="#">Medeiros et al. (2016)</a>	Greenhouse study	Red maple and white oak	N and P treatments (control and low N/P—90% of control N/P levels), pH (4.5 and 6)	pH	Studied the influence of pH (simulated acid rain) on leaf, xylem, and hydraulic trait coordination responses of 1-yr-old red maple and white oak seedlings in a greenhouse study. The researchers found interactions between nutrient levels and pH; low pH reduced the ability of both species to adjust xylem traits and leaf water relations (i.e., hydraulic acclimation) in response to changes in nutrient availability.
<a href="#">McEathron et al. (2013)</a>	Forest Ha-De-Ron-Dah Wilderness Area in Adirondack Mountains, NY (seven subwatersheds)	Sugar maple, black cherry, American beech, red maple, and yellow birch	NA	Soil pH and exchangeable Ca and Al (0 to 10 cm mineral soil horizon)	Evaluated the relationships between species-specific basal area and soil and stream water chemistry. Sugar maple basal area was positively correlated with mineral soil pH, and yellow birch basal area was positively correlated with mineral soil exchangeable Ca. Sugar maple basal area was also negatively correlated with stream water DOC.

**Table 5-6 (Continued): Mode of action for acidifying nitrogen and sulfur deposition.**

Reference	Ecosystem Type/Region	Species	N and S Deposition/ Additions	Soil Indicator	Description
<a href="#">Mueller et al. (2016)</a>	Sugar maple dominated forests Michigan	Soil microbes	NA	Soil pH	Studied the relationships between soil bacterial and fungal community activity and soil pH and C:N gradients in the litter from sugar maple stands in Michigan. The proportion of active bacteria were found to increase along the soil pH gradient, but decreased along the soil C:N gradient. In contrast, no significant correlations were detected for the fungal community. Similarly, no significant correlations were between temperature and the fungal or bacterial communities.
<a href="#">Pabian and Brittingham (2012)</a>	Forest Pennsylvania (14 forest sites)	NA	NA	Exchangeable Ca and pH (Oa-horizon). Mean soil exchangeable Ca and pH for the 14 study sites ranged from 5.28 to 23.5 meq/100 g and 3.6 to 5.1, respectively.	Bird community composition (species richness and species abundances) varied with soil Ca and pH, with 10 bird species having the highest abundances in forests with high-Ca soils, and 5 species having the highest abundances with low-Ca soils. Bird species associated with low-Ca soils were associated with high densities of acid-loving mountain laurel ( <i>Kalmia latifolia</i> ) and five tree species with basal area explained by low soil pH and Ca, whereas bird species associated with high-Ca soils were associated with high densities of saplings and high basal area of acid-sensitive tree species.
<a href="#">Page and Mitchell (2008)</a>	Forest Adirondack Mountains, NY (11 sites)	Sugar maple, American beech, American basswood, and white ash	NA	Exchangeable Ca, exchangeable Ca:Al (forest floor and upper [0 to 10 cm] mineral soil)	Evaluated the relationships between exchangeable soil Ca concentrations and tree basal area. There were no observed trends relating total basal area to mineral soil (0 to 10 cm) exchangeable Ca concentrations; however, the relative basal areas of sugar maple and American basswood were positively correlated with mineral soil exchangeable Ca, and relative basal area of American beech was negatively correlated. Relative basal area of white ash was not correlated to soil exchangeable Ca.
<a href="#">Perakis et al. (2013)</a>	Forest Oregon (coastal range)	Douglas fir (plantations)	NA	None	Nitrate leaching (at 20 and 100 cm) increased, soil pH declined (from 5.8 to 4.2), and exchangeable soil Ca, Mg, and K decreased (10x declines) along the soil N gradient. Exchangeable Ca and Mg (in both 0 to 20 cm and 0 to 100 cm) and K (0 to 20 cm) declined with increasing nitrate leaching. Mean soil profile pH declined logarithmically with nitrate leaching at 20 and 100 cm. The sum of exchangeable Ca, Mg, and K was positively correlated with soil pH at 20 and 100 cm. Aboveground tree biomass contained an increasing percentage of total ecosystem Ca, Mg, and K as soil N increased.

**Table 5-6 (Continued): Mode of action for acidifying nitrogen and sulfur deposition.**

Reference	Ecosystem Type/Region	Species	N and S Deposition/ Additions	Soil Indicator	Description
<a href="#">Pitel and Yanai (2014)</a>	Forest Massachusetts, Vermont, and New York	Sugar maple	NA	Soil pH, exchangeable Ca:Al, Al, and cations (Ca, Mg, K), cation (Ca, Mg, K, and total) saturation, and effective CEC (A- and upper B-horizons)	Evaluated the mortality of dominant and codominant sugar maple in 47 stands that had experienced defoliation by native forest tent caterpillar ( <i>Malacosoma disstria</i> ). Mortality was found to be highest in stands with the greatest amount of crown dieback the previous year. Drought, cold winter temperatures, concave microrelief and soil base cation availability were also significant predictors of mortality. Concentrations of exchangeable Ca, Mg, and K in the upper B soil horizon were inversely correlated with sugar maple mortality, with exchangeable K having the strongest relationship with mortality. Site with above-average sugar maple mortality (>3 or 4%) occurred on soils with low concentrations of exchangeable Ca (0.31 to 0.46 cmol <sub>e</sub> /kg), Mg (0.06 to 0.10 cmol <sub>e</sub> /kg), and K (0.03 to 0.05 cmol <sub>e</sub> /kg). Stands defoliated in 2005 that had low Mg saturation (A-horizon) suffered higher rates of mortality, suggesting an interaction between low base cations and defoliation events.
<a href="#">Sridevi et al. (2012)</a>	Forest Hubbard Brook Experimental Forest, NH	Soil microbes (bacteria)	NA	Soil pH, exchangeable cations, Al, Fe, P, Mn, Zn, exchangeable acidity, and CEC (0 to 15 cm)	Ca additions of 1,000 kg Ca/ha applied in 1999. The bacterial community structure in the Ca treated and nontreated reference soils was found to be significantly different, with differences among communities being more pronounced in the mineral soils. Calcium additions resulted in a change in bacterial community composition of 23% in the organic and 22% in the mineral soil horizons. Numbers of detectable taxa in some families were lower in the Ca amended soils, while some families were higher. Analyses of relationships between soil chemistry and the bacterial communities indicated that only Ca, pH, and P were significantly correlated with bacterial community structure.
<a href="#">Stevens et al. (2010b)</a>	Grassland U.K. (68 sites)	Grassland species	6.2 to 36.3 kg N/ha/yr Centre for Ecology and Hydrology (CEH) National Atmospheric Deposition Model	Ellenberg R (reaction-soil pH) and N (soil nutrient) scores	Data from a national survey were used to evaluate species richness of 68 U.K. grasslands along an N deposition gradient. The results suggest that soil acidification (instead of eutrophication) was contributing to changes in species diversity and composition. Soil acidification may have led to reduced nutrient availability and increased Al solubility preventing the “fertilizing” effects of N addition from being apparent.

**Table 5-6 (Continued): Mode of action for acidifying nitrogen and sulfur deposition.**

Reference	Ecosystem Type/Region	Species	N and S Deposition/ Additions	Soil Indicator	Description
<a href="#">Sullivan et al. (2013)</a>	Forest Adirondack Mountains, NY (50 plots in 20 small watersheds with sugar maple overstory)	Sugar maple	75 to 112 meq/m <sup>2</sup> /yr as N + S NADP (wet deposition); CASTNET (dry deposition) 2000–2004 (average)	Soil pH, exchangeable Ca, exchangeable Mg, and base saturation (forest floor, A- and upper B- (0 to 10 cm) horizons)	The study found that plots with lower soil base saturation did not have sugar maple regeneration (these same plots also received higher N and S deposition levels); proportion of sugar maple seedlings dropped substantially at base saturation levels less than 20%. Canopy vigor was positively correlated with soil pH and exchangeable Ca and Mg. Mean growth rates (BAI) were positively correlated with exchangeable Ca and base saturation at the watershed level.
<a href="#">Tian et al. (2016b)</a>	Temperate steppe Inner Mongolia, China	Grassland species; <i>Stipa krylovii</i> and <i>Artemisia frigida</i>	<u>Elevated N</u> 9 yr of urea additions at 0, 1, 2, 4, 8, 16, 32, and 64 g N/m <sup>2</sup> /yr	Soil pH, exchangeable Mn and Al (three soil depths: 0–10, 10–20, 20–30 cm)	Long-term N additions increased total above-ground plant biomass but decreased species richness; N additions significantly reduced forb species richness, while the diversity of grass species was not affected. Soil chemistry was influenced by the N additions; soil pH was reduced and concentrations of exchangeable Mn, ferric Fe, and Al were increased. Foliar concentrations of Mn in both <i>A. frigida</i> and <i>S. krylovii</i> were increased by N additions. A greenhouse study showed that the biomass of <i>A. frigida</i> seedling shoots and roots were significantly reduced with MnCl <sub>2</sub> additions, but the treatments had no effect on <i>S. krylovii</i> seedlings.
<a href="#">Tu et al. (2016)</a>	Forest types across North America	Soil diazotrophs (N <sup>2</sup> fixing microbes)	NA	Soil pH (0–10 cm)	The soil diazotrophic community structure was found to differ significantly across the six forests; lower microbial spatial turnover and greater community diversity were found in rainforests relative to temperate forests. In addition, community diversity was strongly correlated with latitude, mean annual temperature, plant species richness, and total annual precipitation. Diazotrophic community diversity was weakly correlated with soil pH and moisture.
<a href="#">Ying et al. (2017)</a>	Grassland Inner Mongolia, China	Soil microbes (ammonia-oxidizing bacteria and Archaea)	<u>Elevated S</u> H <sub>2</sub> SO <sub>4</sub> additions started in 2009; 0, 2.76, 5.52, 8.28, 11.04, 13.80, 16.56 mol H/m <sup>2</sup>	Soil pH and NH <sub>4</sub> <sup>+</sup> -N and NO <sub>3</sub> <sup>-</sup> -N	Study evaluated the impacts of soil pH on the abundance and structure of soil ammonia-oxidizing bacteria (AOB) and Archaea (AOA) communities. Decreasing soil pH was found to be correlated with decreases in AOB abundance (pH range of 5.0–7.3) and increases in AOA (pH range of 5.3–7.3) abundance, except at the lowest pH (pH 5.0), which negatively influenced AOA abundance. Soil acidification did not significantly influence AOA or AOB community composition.

**Table 5-6 (Continued): Mode of action for acidifying nitrogen and sulfur deposition.**

Reference	Ecosystem Type/Region	Species	N and S Deposition/ Additions	Soil Indicator	Description
<a href="#">Yuan et al. (2016)</a>	Alpine tundra Niwoot Ridge, Colorado Rocky Mountain National Park	Soil bacteria	<u>Elevated N</u> 20 yr of N and P additions—0 and 20 g N/m <sup>2</sup> /yr and 0 and 2 g P/m <sup>2</sup> /yr (1993–1995), 0 and 10 g N/m <sup>2</sup> /yr and 2 g P/m <sup>2</sup> /yr (1996–1997), same application rates every 2 yr (1998–2009), 10 g N/m <sup>2</sup> /yr was added as Ca(NO <sub>3</sub> ) <sub>2</sub> to address soil acidification	Soil pH (0–10 cm)	Soil bacterial communities differed by plant community type, with bacterial alpha diversity being significantly correlated with plant richness and production of forbs. N additions also influenced soil bacteria, with bacterial communities treated with N (and N + P) being significantly different than those in the control and P treatments. Chloroflexi and Bacteroidetes responded positively to the additions of N, while Acidobacteria and Verrucomicrobia responded negatively to N. The N additions resulted in reduced soil pH; from wet to dry systems, the relative importance of N additions on soil pH increased. Of the soil variables, pH shared the strongest correlations with plant and bacterial diversity metrics. Structural equation modeling showed that the indirect effects (as opposed to direct effects) of N additions—changes in soil pH and plant communities—were the strongest determinants of soil bacterial community responses.
<a href="#">Zeng et al. (2016)</a>	Temperate steppe Inner Mongolia, China	Soil microbial communities	<u>Elevated N</u> 6 yr of NH <sub>4</sub> NO <sub>3</sub> additions at 0, 60, 120 and 240 kg N/ha/yr	Soil pH (0–10 cm and 10–20 cm)	Plant community biomass was found to significantly increase, species richness decrease, and N concentrations increase with N additions. Seven bacterial phyla (mainly rare phyla) in the 0–10-cm soil depth were significantly changed with N additions, while only 1 phylum in the 10–20-cm depth was affected by the additions of N. Hierarchical structural equation modeling revealed that changes in bacterial community composition were due to changes in soil pH and plant composition, while shifts in bacterial richness were attributed to NH <sub>4</sub> <sup>+</sup> concentrations.

**Table 5-6 (Continued): Mode of action for acidifying nitrogen and sulfur deposition.**

Reference	Ecosystem Type/Region	Species	N and S Deposition/ Additions	Soil Indicator	Description
<a href="#">Zhang et al. (2016b)</a>	Temperate steppe Inner Mongolia, China	57 vascular plant species	<u>Elevated N</u> 6 yr of NH <sub>4</sub> NO <sub>3</sub> additions at 0, 1, 2, 3, 5, 10, 15, 20, and 50 g N/m <sup>2</sup> /yr (2x and 12x per year)	Soil pH (0–10 cm)	N additions, at both frequencies, significantly decreased the number of new species gained and increased the number of old species lost. However, the number of new species gained was lower on the low frequency of N addition plots compared to the high frequency, while the number of old species lost was not affected by N addition frequencies. There was a negative correlation between the cumulative gain of new species and soil pH, NH <sub>4</sub> concentrations and community biomass accumulation, while cumulative loss of old species was positively correlated with these variables.
<a href="#">Basto et al. (2015b)</a>	Grassland Peak District National Park, U.K.	261 grassland species; seed bank	NA	Soil pH (gradient with soil pH range of 3.5 to 6.5)	Studied seed bank and seed germination, viability, and damage (through seed burial experiment conducted with <i>Scabiosa columbaria</i> , <i>Hypericum pulchrum</i> , and <i>Campanula rotundifolia</i> ) along a natural pH gradient from acidic to calcareous grasslands. Increasing soil pH was found to be correlated with decreases in total and grass seed abundance, declines in the persistence of <i>H. pulchrum</i> seed, and declines in damage to <i>C. rotundifolia</i> seed. Seed germination was not influenced by pH. In soil with pH higher than 5.6, indirect effects of pH (through increased fungal pathogens) appeared to decrease the persistence of the seed of all three grassland species. This study suggested that: acidic soils are associated with increased seed persistence; the longevity and size of grassland seed banks decline as soil pH increases; and that pH indirectly influences seed persistence.

## APPENDIX 6 TERRESTRIAL ECOSYSTEMS: NITROGEN ENRICHMENT EFFECTS ON ECOLOGICAL PROCESSES

[Appendix 5](#) examined the biological effects of terrestrial acidification from nitrogen (N) and sulfur (S) deposition. This appendix characterizes the biological effects of terrestrial N enrichment that can be caused by atmospheric N deposition. Following an introduction ([Appendix 6.1](#)), this appendix is composed of five major sections: effects on physiology, growth, and productivity ([Appendix 6.2](#)); changes in biodiversity and community composition ([Appendix 6.3](#)); climate modifications of N enrichment effects ([Appendix 6.4](#)); critical loads ([Appendix 6.5](#)); and a summary ([Appendix 6.6](#)). The first two sections begin with an introduction ([Appendix 6.2.1](#) and [Appendix 6.3.1](#)) reviewing the previous causal determination and presenting the current causal determination. Following this introduction, an overview is presented of the mechanisms operating across ecosystems to link N enrichment to biological change ([Appendix 6.2.2](#) and [Appendix 6.3.2](#)). [Appendix 6.2](#), [Appendix 6.3](#), and [Appendix 6.5](#) are further divided into subsections based on ecosystem type (e.g., forests, grasslands, etc.) or functional group (e.g., lichens, trees, herbaceous plants). Finally, [Appendix 6.6](#) provides a summary of the new information generated since the *2008 ISA for Oxides of Nitrogen and Sulfur—Ecological Criteria* (hereafter referred to as the “2008 ISA”).

---

### 6.1 Introduction

Nitrogen (N) is a key element required by all organisms in order to build amino acids and nucleic acids, the basic biochemical subunits needed to synthesize the proteins, enzymes, RNA, and DNA sustaining all biological processes. By the second half of the 19th century, before these biochemical pathways had been identified, it was already understood that N was a component of plant and animal tissues and a supply of N was essential for plant growth ([Galloway et al., 2004](#)). Indeed, the ability of added N to stimulate plant growth had been recognized by science (and commerce) for over a century ([Galloway et al., 2004](#); [Galloway and Cowling, 2002](#)) prior to the 2008 ISA. By 2008, it was already clear that N availability broadly limited productivity in terrestrial ecosystems.

By 2008, it was also clear N availability could alter the biodiversity of terrestrial ecosystems. Broadly, the effects of N deposition on the diversity of terrestrial ecosystems stem from four mechanisms [*sensu* [Bobbink et al. \(2010\)](#)]: (1) eutrophication, (2) acidification, (3) direct toxicity and damage, and (4) increased susceptibility to

secondary stress. Multiple mechanisms likely operate simultaneously to alter diversity within a particular community or ecosystem. As described in [Appendix 5](#), N deposition may lead to soil acidification, which can have negative effects on plants and microorganisms. Direct toxicity and damage from N deposition often come from an accumulation of  $\text{NH}_4^+$  in soils and plant tissues. Increased susceptibility to secondary stressors includes greater impacts of pathogens ([Bobbink et al., 2010](#)) and shifts in herbivory as a result of altered tissue chemistry ([Throop and Lerdau, 2004](#)). Among these four major mechanisms, eutrophication is perhaps the most complex because it can change the physiology of individual organisms, alter the relative growth and abundance of species, transform relationships between species, and indirectly affect the availability of other essential resources such as light, water, and nutrients [[Suding et al. \(2005\)](#); [Clark et al. \(2007\)](#); [Hautier et al. \(2009\)](#); see also [Appendix 4](#)]. These can lead to biodiversity shifts, including community compositional changes, the loss of species, and decline in species richness.

Since the 2008 ISA, the effects of N deposition on terrestrial ecological processes and biodiversity have continued to be widely studied. With the increasing volume of research, a number of new studies have been conducted using meta-analysis to synthesize published observations or using continental or global data sets to understand broad-scale patterns. New studies have provided a more detailed understanding of how N influences terrestrial ecosystem growth and productivity; community composition and biodiversity; and sensitive organisms and ecosystems. Further, a large body of work has been published on critical loads (CLs) for N since 2008. Together with the information available in the 2008 ISA, **this body of evidence is sufficient to infer a causal relationship between N deposition and (1) the alteration of the physiology and growth of terrestrial organisms and the productivity of terrestrial ecosystems; and (2) the alteration of species richness, community composition, and biodiversity in terrestrial ecosystems.**

---

## 6.2 Linking Nitrogen Deposition to Changes in Physiology, Growth, and Productivity in Terrestrial Ecosystems

---

### 6.2.1 Introduction

In the 2008 ISA, evidence was sufficient to infer a causal relationship between N deposition and the alteration of the terrestrial carbon (C) and N biogeochemical cycles. These effects included not only changes in soil C and N pools and fluxes (described in

[Appendix 4](#)), but also significant alterations of plant and microbial growth and physiology. The 2008 ISA built upon the conclusions of the 1993 Oxides of Nitrogen Air Quality Criteria Document. By 1993, a series of hypotheses regarding the effects of chronic N deposition on northern temperate forests had already been developed from early field observations ([Aber et al., 1989](#)). Briefly, N deposition was expected to increase tree growth in most forests, but once plant demand for N had been satisfied (biological and physical sinks had reached “N saturation”), further N deposition could lead to nitrification, soil cation leaching, acidification, nutrient deficiencies, and decreased tree growth [[Aber et al. \(1989\)](#)]; described in [Appendix 4](#) and [Appendix 5](#)]. A revised form of these N saturation hypotheses ([Aber et al., 1998](#)) provided much of the conceptual foundation in the 2008 ISA for understanding how N deposition influenced plant physiology, growth, and ecosystem productivity.

The effects of N deposition on terrestrial ecological processes have been widely studied since 2008. Research on N deposition has continued in North America and Europe, with other areas receiving less attention [e.g., temperate forests in Asia and the Southern Hemisphere ([Gilliam, 2016](#))]. A significant new body of research has developed in the boreal, arid, and subtropical ecosystems of Asia, particularly in China [e.g., [Du and Fang \(2014\)](#); [Du et al. \(2014b\)](#); [Du et al. \(2014a\)](#); [Sun et al. \(2014\)](#); [Zhang et al. \(2015e\)](#)]. New meta-analyses have provided a more detailed understanding of how added N affects productivity responses in different biomes ([LeBauer and Treseder, 2008](#)), growth among plant functional types ([Xia and Wan, 2008](#)), growth of individual plant parts ([Xia and Wan, 2008](#)), root growth ([Li et al., 2015](#)), and ecosystem C storage ([Liu and Greaver, 2009](#)), while other broad-scale analyses have examined changes in plant N concentrations ([Xia and Wan, 2008](#)), microbial biomass ([Treseder, 2008](#)), and belowground C cycling ([Liu and Greaver, 2010](#)). This expanded body of research has created a better understanding of how N influences processes at molecular to global scales. Together with the information available in the 2008 ISA, this body of evidence is sufficient to infer a causal relationship between N deposition and the alteration of the physiology and growth of terrestrial organisms and the productivity of terrestrial ecosystems.

---

## 6.2.2 Mechanisms Operating across Terrestrial Ecosystems

The 2008 ISA evaluated a large number of studies assessing how N deposition has changed terrestrial C cycling and found an array of ecological responses. The most extensive evidence of the effect of N deposition on C cycling was available for forests in North America and Europe. In experimental N addition studies, moderate to high additions of N led to either no significant change in tree growth rates or transient growth increases (generally at deposition rates lower than 10 kg N/ha/yr), followed by increased

mortality, especially at higher rates of N addition. This group of studies showed coherence in effects and indicated the presence of a biological gradient in responses with increasing N deposition.

Some of the broad-scale changes caused by N additions to terrestrial ecosystems have been quantified by meta-analysis, a data synthesis tool that started to become common in ecological research beginning in the late 1990s ([Gurevitch et al., 2001](#)). Using this tool to understand the effects of N additions on herbaceous plant communities, ([Gough et al., 2000](#)) found that N additions stimulated aboveground plant productivity by an average of 53%. In a broader synthesis, [Elser et al. \(2007\)](#) conducted a meta-analysis of N addition effects on plant community productivity and observed average increases in productivity of 20–30% in grasslands, forests, tundra, and wetlands. In addition to changes in plant growth, [Koricheva et al. \(1998\)](#) identified via meta-analysis that added N could alter the chemistry of plant tissues, including increasing tissue concentrations of N and free amino acids, while decreasing concentrations of starch and C based secondary compounds (important for defense against herbivores), including phenylpropanoid compounds. In a meta-analysis of the belowground effects of N, [Treseder \(2004\)](#) found N additions decreased both the abundance of mycorrhizal fungi and the percentage of plant roots colonized by mycorrhizal fungi. In addition, multiple lines of evidence showed that N deposition increases the performance of insect herbivores, and potentially, insect populations ([Throop and Lerdau, 2004](#)). In a synthesis of 500 observations of the effect of N on litter decomposition rates, [Knorr et al. \(2005\)](#) found that added N stimulated decomposition at sites with low rates of ambient N deposition (<5 kg N/ha/yr), but slowed decomposition at sites with moderate rates of N deposition [5–10 kg N/ha/yr; [Knorr et al. \(2005\)](#)] and that N additions at rates from 2 to 20 times ambient N deposition inhibited decomposition by 8 to 16%.

These changes can cause a cascade of ecological consequences. For instance, the inhibition of decomposition can increase soil C content, but the accumulation of plant litter on the soil surface can inhibit the establishment of some plant species ([Patterson et al., 2012](#); [Cleavitt et al., 2011b](#); [Xiong and Nilsson, 1999](#); [Facelli and Pickett, 1991](#)). In the western U.S., [Fenn et al. \(2003a\)](#) suggested greater plant growth caused by N deposition could increase plant litter accumulation, in turn increasing the susceptibility of forests and other wildlands to severe wildfires. Nitrogen deposition also affects the patterns of C allocation because most of the additional plant growth occurs aboveground. This increases the shoot-to-root ratio, which can be detrimental to plants because of decreased resistance to environmental stressors, such as drought and wind ([Braun et al., 2003](#); [Krupa, 2003](#); [Minnich et al., 1995](#); [Fangmeier et al., 1994](#)). Thus, it was recognized in the 2008 ISA that the effects of N deposition on biological and ecological processes in

terrestrial ecosystems were pervasive, complex, and difficult to fully understand and predict.

Although evidence showed plant productivity responses to N deposition as of the 2008 ISA, the extent to which N increased forest C content in C budget measurements (quantified input and output of C to the ecosystem) was uncertain. A prominently reported estimate of >600 kg C sequestered per kg of N deposited to forests, which was based on a regional gradient technique ([Magnani et al., 2007](#)), was widely criticized. Subsequent reassessments of these data suggested that forest C sequestration was an order of magnitude lower ([Sutton et al., 2008](#)). [Liu and Greaver \(2009\)](#) found in a meta-analysis that N additions ranging from 25.5 to 200 kg N/ha/yr increased forest ecosystem C content (+6%).

In addition, fewer studies had examined the effects of N deposition on the eutrophication of nonforested ecosystems. [Mack et al. \(2004\)](#) examined C and N pools in a long-term N addition experiment at the Arctic Long-Term Ecological Research site near Toolik Lake, AK. Plant growth increased as a result of N additions, but the N additions enhanced decomposition of belowground C pools in deep soil layers more than it increased primary production, leading to a substantial net loss of C from this ecosystem. More broadly, [Liu and Greaver \(2009\)](#) conducted a meta-analysis of 16 observations from nine publications to evaluate the relationship between N addition (16 to 320 kg N/ha/yr) and C sequestration in nonforest ecosystems and did not find a significant effect on net ecosystem exchange (NEE, kg C/ha/yr).

[Xia and Wan \(2008\)](#) identified nearly 1,600 observations of plant biomass growth in response to N additions, excluding agricultural and horticultural species ([Figure 6-1A](#)). Overall, plant biomass increased by 54%, with a larger gain in seeded plants (+55%) than spore plants (+21%; not shown). Among the seeded plants, grasses showed the largest biomass response, followed by trees, forbs, and shrubs. Annual herbs (+92%) showed a stronger response than perennial herbs (+56%). Overall, biomass responses to N increased linearly with mean annual precipitation (MAP). The studies included in the analysis had addition rates ranging from 10 kg N/ha/yr to 1,000 kg N/ha/yr. When the N additions were divided into low (<100 kg N/ha/yr) and high (>100 kg N/ha/yr) groups, there were only a few differences among functional groups. The response of woody species was lower than for herbaceous species at the low addition rate (+25 vs. +51%), but the groups had similar responses at the high N addition rate. Among herbaceous plants, both legumes and nonlegumes had positive responses to low rates of N additions (19 and 23%, respectively), while the high rate of N additions increased nonlegume biomass (+43%) but did not significantly affect legume growth. The authors also examined how these responses varied in response to the rate of N additions. The N

addition studies were divided into 50 kg N/ha/yr increments from 0 to 300 kg N/ha/yr, but aside from increasingly positive growth responses for trees and woody plants with greater N additions, there were few apparent trends, and sample sizes were inconsistent.

In their analysis, [Xia and Wan \(2008\)](#) separated plant growth data into aboveground (887 observations) and belowground (340 observations) components. Across almost all functional groups, there were greater increases in biomass in aboveground than belowground components ([Figure 6-1A](#); see also [Appendix 4](#)). In a subsequent meta-analysis of plant C pools, [Lu et al. \(2011b\)](#) also found that N additions to plants in nonagricultural systems stimulated shoot C by 28.5% (n = 146) and root C by 20% (n = 77). These results indirectly suggest that plant C allocation changes in response to N addition. These changes were also shown by a more direct analysis of a much smaller meta-analysis data set (n = 15) in which [Li et al. \(2015\)](#) observed a significant 11% decrease in the root:shoot biomass ratio. Together, these results provide further support to the conclusion in the 2008 ISA that N additions can alter plant C allocation and result in elevated shoot:root ratios. Further, [Lu et al. \(2011b\)](#) analyzed the response of some individual plant parts to added N and observed a 1.6% increase in leaf C mass.

Belowground processes are important components of terrestrial ecosystems. As detailed in [Appendix 5](#), soils are often the largest ecosystem pools of both C and N; soil respiration can be the largest ecosystem efflux of CO<sub>2</sub>; and soils can be important sources and sinks for the greenhouse gases N<sub>2</sub>O and CH<sub>4</sub>. Biologically, the large C fluxes plants allocate belowground for root exudation, the growth and maintenance of roots, and the support of mycorrhizal fungi help support complex belowground food webs. Less information is available about belowground responses to N additions than aboveground responses. However, [Li et al. \(2015\)](#) recently conducted a meta-analysis of how root traits respond to N additions. Notably, [Li et al. \(2015\)](#) found that although total root biomass increased (+20%; n = 74), fine root biomass declined (-13%; [Figure 6-2B](#)). This discrepancy is apparently accounted for by an increase in the biomass of coarse roots (+57%; n = 7), which are typically structural and conductive tissues. Morphological traits of fine roots, such as length (n = 25), diameter (n = 10), and specific root length (n = 22), were unaffected by N additions. Fine root turnover rate was 21% higher (n = 12), but fine root production was not significantly affected by the N additions [n = 22; [Li et al. \(2015\)](#)].

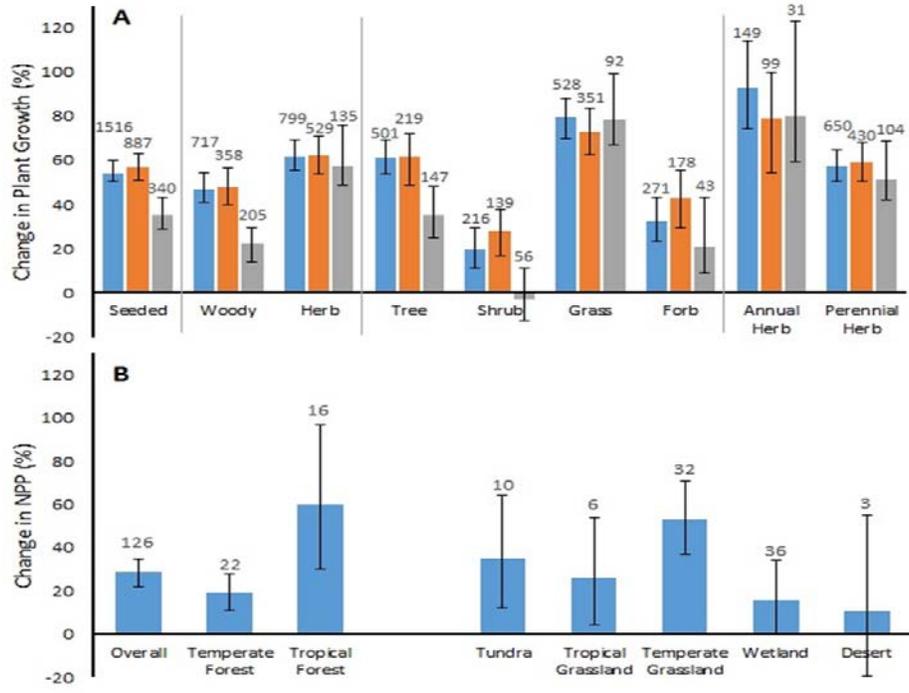

Aboveground net primary productivity (NPP), which measures aboveground plant growth at the community scale, was less responsive on average (+29%) than individual plant growth to N additions [[LeBauer and Treseder \(2008\)](#); [Figure 6-1B](#) and [Figure 6-2A](#)]. Consistent with the plant functional group analysis conducted by [Xia and Wan \(2008\)](#), [LeBauer and Treseder \(2008\)](#) observed a large stimulation of aboveground NPP in

grass-dominated ecosystems such as temperate grasslands (+53%), tropical grasslands (+26%), and tundra (+35%), whereas NPP increased only 19% in temperate forests. There were also significant NPP increases in tropical forests and wetlands. Added N did not significantly increase NPP in deserts, but the analysis only included three observations.

More recently, [Tian et al. \(2016a\)](#) synthesized aboveground NPP data from studies that had experimentally added N at more than one rate in order to examine how plant growth responses per unit N changed with increasing levels of N. Their metric, termed “N response efficiency” [ $100 \times (\text{ANPP}_{\text{treatment}} - \text{ANPP}_{\text{control}}) / \text{ANPP}_{\text{control}} / \text{N addition rate}$ ] did not significantly differ across the three ecosystem types (wetlands, forests, grasslands), with an average increase of 3 to 4% in NPP per g of added N. The N response efficiency decreased with N addition rates above 50 kg N/ha/yr, consistent with a saturating response to N.

[Liu and Greaver \(2009\)](#) had smaller data sets, with 16 observations of net ecosystem exchange (NEE; all in nonforested systems) and 17 observations of ecosystem C content ([Figure 6-2](#)). There were no significant effects of added N on NEE overall or within the individual biomes included in the analysis (grasslands, wetlands, tundra). However, added N did increase forest ecosystem C content by 6%. Belowground NPP responses have not been synthesized, at least in part, because data are lacking ([LeBauer and Treseder, 2008](#)).

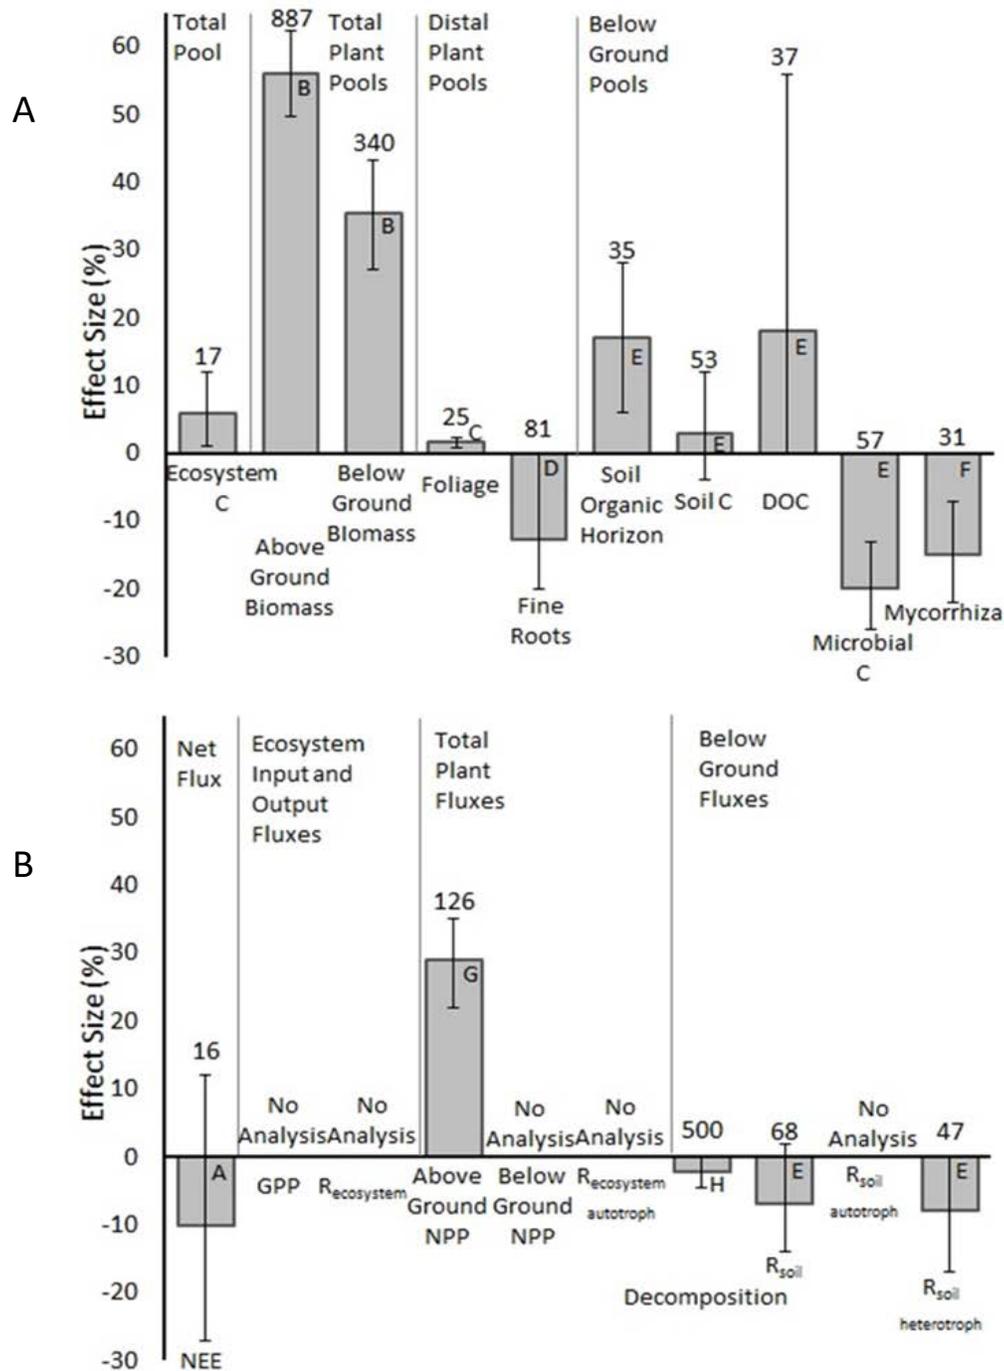

In terms of altered physiology, there is also widespread evidence that N additions increase plant tissue N concentrations. The meta-analysis by [Xia and Wan \(2008\)](#) included changes in plant N concentrations overall, aboveground, and belowground. Overall, N additions increased plant N concentrations by an average of 28.5% ([Xia and Wan, 2008](#)). Although there was significant variation among plant functional groups, the average increase in tissue N concentration among seeded plants was much more similar across functional groups than the biomass growth response, ranging only from +24 to +35% once legumes (+7%) and the two broader functional groups containing legumes (forbs, +14%; perennial herbs: +22%) were excluded. Likewise, belowground and aboveground plant tissues had a similar change in N concentration, in contrast to the varying biomass growth responses to N ([Xia and Wan, 2008](#)). [Li et al. \(2015\)](#) also observed that N additions significantly increased root N concentrations in a root trait meta-analysis (+18%;  $n = 84$ ). Because of these increased N concentrations, N additions can significantly decrease plant C:N ratios ([Yue et al., 2017](#)).

NPP = net primary productivity.

Notes: (A) Mean change in plant biomass growth in response to N additions redrawn from [Xia and Wan \(2008\)](#), with blue bars representing the overall response, orange bars representing aboveground growth, and grey bars representing belowground growth. Vertical grey lines identify different ways the data were parsed (i.e., all seeded plants; woody vs. herbaceous plants, etc.). (B) Mean change in aboveground net primary productivity data from [LeBauer and Treseder \(2008\)](#). Error bars represent the 95% confidence interval. Numbers above the error bars indicate the number of observations included in the analysis.

**Figure 6-1 Effects of nitrogen additions on plant growth and net primary productivity.**

DOC = dissolved organic carbon; NEE = net ecosystem exchange; NPP = net primary production; GPP = gross primary production; R<sub>ecosystem</sub> = ecosystem respiration; R<sub>ecosystem autotroph</sub> = plant respiration; R<sub>soil</sub> = soil respiration; R<sub>soil heterotroph</sub> = heterotroph soil respiration.

Notes: mean effect sizes from meta-analyses of N addition experiments on ecosystem, plant, and soil pools ([a] top panel) and fluxes ([b] bottom panel). Error bars represent 95% confidence intervals. Numbers above the bars are the sample sizes for each analysis. Letter with each bar denote the data source. No Analysis denotes a pool or flux that has not yet been meta-analyzed.

Data sources: (A) [Liu and Greaver \(2009\)](#); (B) [Xia and Wan \(2008\)](#); (C) [Lu et al. \(2011b\)](#); (D) [Li et al. \(2015\)](#); (E) [Liu and Greaver \(2010\)](#); (F) [Treseder \(2004\)](#); (G) [LeBauer and Treseder \(2008\)](#); (H) [Knorr et al. \(2005\)](#).

**Figure 6-2 Effects of added nitrogen on ecosystem carbon pools and fluxes.**

The 2008 ISA linked enhanced terrestrial productivity to increases in photosynthesis and gross primary productivity. Gross primary productivity (GPP) can increase as a result of either a greater amount of photosynthetic tissue (more light absorption) or a higher rate of photosynthesis per leaf. There is a strong mechanistic and conceptual link between greater foliar N concentrations, higher leaf concentrations of the C assimilating enzyme rubisco ([Evans, 1989](#)), and greater maximum rates of leaf-level photosynthesis in vascular plants ([Wright et al., 2004](#)). Consequently, the increase in foliar N caused by N additions has been linked to increases in the leaf-level rate of photosynthesis for decades [e.g., [Teskey et al. \(1994\)](#) and references therein]. Alternately, evidence cited in the 2008 ISA suggests that much of the increased foliar N observed when N is added may be physiologically inactive because it manifests as an increase in storage compounds such as free amino acids ([Bauer et al., 2004](#)). While increases in photosynthesis in response to N additions have been observed in trees, grasses, and shrubs, these increases have not been consistent [e.g., [Gulmon and Chu \(1981\)](#); [Lajtha and Whitford \(1989\)](#); [Newman et al. \(2003\)](#); [Chen et al. \(2005b\)](#); [Elvir et al. \(2006\)](#); [Talhelm et al. \(2011\)](#); [Pivovarov et al. \(2016\)](#)] and there does not appear to be a meta-analysis or other synthesis on the response of leaf-level photosynthesis or GPP ([Figure 6-2B](#)) to N additions. Similarly, there is a strong fundamental relationship between tissue N concentration and respiration rates in plants ([Reich et al., 2008](#); [Reich et al., 2006](#); [Ryan et al., 1996](#)), such that this relationship is used to model respiration rates [e.g., [Amthor \(2000\)](#); [Hanson et al. \(2004\)](#)]. However, there is evidence that this relationship can breakdown in N addition studies [e.g., [Schaberg et al. \(1997\)](#); [Drake et al. \(2008\)](#); [Burton et al. \(2012\)](#)], and there are currently no broad analyses on the effects of N additions on ecosystem or plant-scale autotrophic respiration ([Figure 6-2B](#)).

The 2008 ISA noted some observations of decreased microbial biomass as a result of added N, particularly for mycorrhizal fungi [[Treseder \(2004\)](#); [Figure 6-2B](#)]. Since 2008, however, it has become increasingly clear that N deposition can greatly impact microbial communities, often including a decrease in microbial biomass. Meta-analyses conducted across all ecosystem types have found that N additions can decrease microbial biomass ([Treseder, 2008](#)), microbial biomass C ([Liu and Greaver, 2010](#)), and microbial biomass N ([Lu et al., 2011b](#)) and that the effects of added N on microbial biomass increase with the duration of N additions and the total amount of N added ([Treseder, 2008](#)). These changes are noteworthy given the diverse role of microorganisms in nutrient cycling, greenhouse gas fluxes, and other ecosystem services. Although N additions frequently decrease microbial biomass, the results are not always consistent ([Liu and Greaver, 2010](#); [Treseder, 2008](#)). The effects of N were not significant at the level of individual microbial domains (bacteria, fungi), although there were trends toward increasing negative effects of N additions on fungal biomass as duration and cumulative N load increased ([Treseder, 2008](#)). In a meta-analysis, [Carey et al. \(2016\)](#) observed that N additions increased the

abundance of ammonia-oxidizing bacteria across nonagricultural ecosystems, but did not affect the abundance of ammonia-oxidizing archaea. Recently, [Li et al. \(2015\)](#) provided a new meta-analysis of N addition effects on mycorrhizal colonization of fine root tips and observed an overall 17% decline (n = 21). While this reinforces the conclusions of an earlier meta-analysis by [Treseder \(2004\)](#), there are important qualifiers to this finding: the sample only included observations from forests and grasslands in temperate and subtropical climates; significant decreases were only observed in temperate and forested ecosystems, after more than 3 years of N additions, or at N addition rates >100 kg N/ha/yr ([Li et al., 2015](#)).

Changes in mycorrhizae in turn can affect plant productivity. Mycorrhizal fungi provide benefits to plants, yet also carry costs. In exchange for nutrients and water from the fungus, the plant provides C from photosynthesis ([Högberg et al., 2010](#); [Rillig, 2004](#)). In many cases, this tradeoff works to the plant's advantage. For instance, [Van der Heijden et al. \(1998\)](#) observed higher biomass for most of the individual plant species in their study when inoculated with arbuscular mycorrhizae versus when mycorrhizae were absent. They suggested the mycorrhizal acquisition of a limiting nutrient, in this case phosphorus (P), for the plant in exchange for C explained this finding. However, under conditions in which the nutrient limitation of the plant is relieved (e.g., high N availability), mycorrhizae may no longer be as needed by the plant for nutrient acquisition, yet concomitantly still impose a C cost. In this case, the tradeoff is no longer as beneficial to the plant. With increased N availability, plants that make fewer mycorrhizal associations can benefit both from the physiological advantages accompanying an alleviation of N limitation (e.g., increases in photosynthesis, changes in plant chemistry) and from incurring a lower C cost for mycorrhizae ([Johnson et al., 2008](#)). Indeed, shifts in C allocation away from mycorrhizae may be a mechanism to support increased plant productivity in situations where plants do not show gains in photosynthesis [e.g., [Talhelm et al. \(2011\)](#)].

There are numerous mechanisms through which N deposition could impact microbial biomass, including changes in soil chemistry, changes in the rates of aboveground and belowground plant C inputs (including litter production, root exudates, and C supplied to mycorrhizal fungi), and changes in plant tissue chemistry ([Treseder, 2008](#)). Nitrogen additions can change the chemistry of litter inputs by altering the tissue composition of plant species ([Throop and Lerdau, 2004](#)) or by changing the composition of plant communities contributing to the ecosystem flux of plant litter [e.g., [Manning et al. \(2008\)](#)]. Within a particular species, N additions can cause changes in both of the dominant forms of plant litter: leaf litter and fine roots [e.g., [Xia et al. \(2015\)](#)]. These changes can be relatively direct, such as increases in tissue concentrations of inorganic and organic forms of N [e.g., [Koricheva et al. \(1998\)](#); [Bauer et al. \(2004\)](#)]. While leaf

litter N concentrations are not as widely measured as green leaf N, increases in leaf litter N concentrations due to added N are also likely to be widespread because increased N availability often either decreases or has no effect on the fraction of N plants absorb from leaves during senescence ([Aerts, 1996](#)). Other changes in litter chemistry, such as increases in condensed tannins, soluble phenolics, and nonstructural carbohydrates ([Xia et al., 2015](#)), likely involve more complex biological mechanisms. In a meta-analysis of plant biochemistry data, [Liu et al. \(2016a\)](#) observed different effects of added N on trees and herbs. For the live tissues of trees, N additions decreased concentrations of lignin, cellulose, and nonstructural carbohydrates, and increased the concentration of protein. In the live tissues of herbs, added N decreased the concentrations of nonstructural carbohydrates and hemicellulose, but increased lignin, cellulose, and protein concentrations. These changes have implications for herbivores and detritivores, as well plant growth dynamics.

In a litter decomposition meta-analysis, [Knorr et al. \(2005\)](#) observed that the effects of added N also differed based on the length of the study and the initial litter lignin content. Added N stimulated decomposition in studies lasting less than 2 years, but reduced decomposition in studies lasting more than 2 years. High-lignin litter decomposed more slowly than low-lignin litter. Because lignin concentrations tend to increase during litter decomposition, both of these results were considered to be consistent with earlier evidence that increased N supplies stimulate microbial activity responsible for the decomposition of labile litter constituents, while suppressing the microbial production of extracellular enzymes responsible for the degradation of lignin [[Knorr et al. \(2005\)](#); see also [Appendix 4](#)]. In a meta-analysis of biochemistry data for decomposing litter, [Liu et al. \(2016a\)](#) observed that N additions increased the concentration of lignin in decomposing litter for herbs and shrubs, but did not have a significant effect on decomposing tree litter. In comparison, N additions decreased cellulose concentrations in decomposing tree litter, but did not significantly affect cellulose concentrations in decomposing herb litter. In another meta-analysis, [Liu and Greaver \(2010\)](#) found that although N additions increased aboveground litter production (+20%; n = 37; not shown) across all biomes and N addition rates, there were no significant overall changes in either total soil respiration ([Figure 6-2B](#)) or heterotrophic soil respiration ([Figure 6-2B](#)). In fact, both forms of soil respiration tended to decline. Currently, no similar cross-biome analysis has been conducted for changes in autotrophic soil respiration (respiration from roots and mycorrhizal fungi), but [Janssens et al. \(2010\)](#) noted in a meta-analysis that autotrophic respiration was suppressed by N additions in forests.

Because some biogeochemical processes involve specific chemical forms of N (e.g., denitrification, ammonium toxicity; see [Appendix 4](#)), there is the potential that biological responses to N deposition (or N addition) could depend on whether the

dominant form of deposited N is oxidized ( $\text{NO}_y$ ) or reduced ( $\text{NH}_x$ ). A number of studies have specifically addressed this issue, either by conducting experiments directly testing additions of different forms of N or indirectly through syntheses comparing the effects of  $\text{NO}_y$  and  $\text{NH}_x$  in different experiments. Different responses to individual forms of N have been observed for some endpoints, such as increases in dissolved organic C, decreases in ecosystem N retention, increases in soil  $\text{N}_2\text{O}$  emissions, plant growth, and defense against pathogens [[Liu and Greaver \(2009\)](#); [Liu and Greaver \(2010\)](#); [Templer et al. \(2012\)](#); [Verhoeven et al. \(2011\)](#); [Yue et al. \(2016\)](#); [Mur et al. \(2016\)](#); see also [Table 4-13](#)]. By contrast, other studies have failed to observe a difference between the effects of N forms. One direct test occurred in the Front Range of the Rocky Mountains in Colorado, where [Ramirez et al. \(2010a\)](#) investigated whether soil microbes respond differently to additions of  $\text{NH}_4^+$  versus  $\text{NO}_3^-$  and found that the total amount of N added was correlated with a decrease in soil respiration, not the form of the N ( $\text{NH}_4^+$  vs.  $\text{NO}_3^-$ ). A more comprehensive understanding is available by reviewing the results of meta-analyses comparing the responses of N addition experiments conducted with different forms of N ([Table 6-1](#)). With notable exceptions, most often differences in the effect of the form of N were not observed in these meta-analyses. Moreover, studies finding differences tended to occur where sample sizes were small [e.g., belowground C pools in [Yue et al. \(2016\)](#)].

**Table 6-1 The effects of different forms of inorganic nitrogen on biological endpoints according to meta-analyses.**

See [Table 4-13](#) for the effects of different forms of inorganic nitrogen on biogeochemical processes and indicators.

Before the 2008 ISA, neither terrestrial N cycling nor anthropogenic N deposition had been widely incorporated into Earth systems models (ESMs) used to understand and forecast global climate and biogeochemical cycling. [Thornton et al. \(2007\)](#) made the first effort to understand how both coupled C and N cycling and anthropogenic N deposition would impact ESM predictions for terrestrial C uptake by inserting a new land biogeochemistry model into a coupled climate system model. In the resulting model

output, N limitation greatly decreased the amount of terrestrial C uptake predicted from future increases in atmospheric CO<sub>2</sub> and decreased the sensitivity of terrestrial C sequestration to increases in temperature and precipitation ([Thornton et al., 2007](#)). Including N deposition within the model directly increased terrestrial C uptake and also indirectly increased terrestrial C uptake by removing some of the N limitation predicted to occur under increased atmospheric CO<sub>2</sub> ([Thornton et al., 2007](#)). Subsequently, efforts to model biogeochemical processes at regional and global scales have expanded ([Thomas et al., 2015](#); [Zaehle and Dalmonech, 2011](#)). Although the integration of terrestrial N cycling into ESMs remains relatively weak, more ESMs are incorporating the coupling of terrestrial C and N cycling as overall model development and sophistication advances ([Thomas et al., 2015](#); [Arora et al., 2013](#); [Zaehle and Dalmonech, 2011](#); [Bonan and Levis, 2010](#); [Gerber et al., 2010](#)). Consistent with the findings of [Thornton et al. \(2007\)](#), inclusion of coupled C-N cycling in ESMs has two primary effects: decreasing the stimulatory effects of elevated atmospheric CO<sub>2</sub> on terrestrial productivity and decreasing the sensitivity of terrestrial C sequestration to climate warming because increased soil N mineralization stimulates plant productivity ([Arora et al., 2013](#); [Zaehle and Dalmonech, 2011](#); [Zhang et al., 2011b](#); [Arneeth et al., 2010](#); [Bonan and Levis, 2010](#); [Gerber et al., 2010](#); [Yang et al., 2010](#); [Zaehle et al., 2010](#); [Thornton et al., 2009](#)). However, the ESMs that do include basic terrestrial C-N coupling lack more recently identified interactions such as plant organic N uptake, soil priming (root exudation), and the suppression of litter decomposition at high soil N availability, all of which could increase terrestrial C uptake to varying extents ([Thomas et al., 2015](#); [Zaehle and Dalmonech, 2011](#)). In addition, the interactions between and the net effects of N, precipitation, and temperature on ecosystem C response in soils are unknown in many cases (see [Appendix 13.1.2.1](#)).

In the few ESMs that have directly included the effects of N deposition, the additional N increased terrestrial C uptake and increased the extent to which elevated atmospheric CO<sub>2</sub> stimulates terrestrial C uptake ([Devaraju et al., 2016](#); [Bonan and Levis, 2010](#); [Yang et al., 2010](#)). In addition, N deposition in the Northern Hemisphere (particularly in the U.S.) apparently compounded the increase in C sequestration caused by the regrowth of secondary forests during the late 20th century following agricultural abandonment and timber harvest ([Gerber et al., 2013](#); [Yang et al., 2010](#)). However, ESMs that do not include potential N saturation may overestimate the effect of N deposition on terrestrial C uptake in regions experiencing high N deposition rates ([Lu et al., 2016](#)). In addition, it should be noted that although N deposition and the overall anthropogenic production of reactive N increases terrestrial C sequestration, they are not the only influence of anthropogenic N on global climate. It is difficult to quantify the overall climate impact of anthropogenic N [e.g., [Pinder et al. \(2013\)](#)] because reactive N can change the planetary albedo by enhancing aerosol formation, stimulate the production of biogenic greenhouse gases, alter the production and destruction of methane and tropospheric ozone in the

atmosphere, and indirectly decrease terrestrial productivity due to the phytotoxic effects of ozone ([Lu and Tian, 2013](#); [Pinder et al., 2013](#); [Pinder et al., 2012](#); [Arneeth et al., 2010](#); [Zaehle et al., 2010](#)). Many of these effects are discussed further in the atmospheric chemistry and terrestrial biogeochemistry portions of this ISA (see [Appendix 2](#) and [Appendix 4](#)).

In addition to the global-scale analyses conducted using ESMs, biogeochemical process models have been used to assess the impact of N deposition on terrestrial productivity and C sequestration at national and regional scales. [Tian et al. \(2012\)](#) used the Dynamic Land Ecosystem Model (DLEM) to model the influence of climate, tropospheric ozone, fertilizer use, land use/land cover change, atmospheric CO<sub>2</sub>, and N deposition on terrestrial C storage over the 20th century in the southeastern U.S. (encompassing Texas and Oklahoma to Florida and Virginia). Terrestrial C storage increased from 1951–2007, with the model identifying atmospheric CO<sub>2</sub> and N deposition as the environmental factors responsible for the increase in C sequestration ([Tian et al., 2012](#)). In China, a series of papers has been published using biogeochemical process models to identify how this same set of environmental factors influenced terrestrial C cycling in that country. Rates of N deposition in China grew rapidly during the late 20th century and were considerably higher than in the U.S. by the early 21st century, with nationwide average rates of approximately 20 kg N/ha/yr and rates in southeast China averaging 35–40 kg N/ha/yr ([Lu and Tian, 2013](#); [Lu et al., 2012](#)). [Tian et al. \(2011\)](#) applied the Terrestrial Ecosystem Model and the DLEM model to China using data from 1961–2005. In both models, China was a C sink during this time period, with the combination of N deposition and agricultural fertilizer use accounting for 61% of the increase in C sequestration. Notably, the responsiveness of terrestrial C sequestration to N deposition has declined since the 1980s as N deposition in China increased, providing evidence that terrestrial ecosystems are becoming less N limited in China ([Tian et al., 2011](#)). [Lu et al. \(2012\)](#) conducted a similar analysis, using DLEM to understand how multifactor environmental change influenced terrestrial C sequestration in China from 1901–2005. Like [Tian et al. \(2011\)](#), [Lu et al. \(2012\)](#) observed that N deposition increased terrestrial C sequestration in China throughout much of the late 20th century, but that the responsiveness of terrestrial C sequestration to N deposition has declined since the 1980s. Moreover, [Lu et al. \(2012\)](#) reported that all areas of China, aside from some shrublands and portions of western China, are becoming N saturated.

## 6.2.3 Forests

---

### 6.2.3.1 Aboveground Processes

The 2008 ISA noted a wide range of forest productivity responses to added N. Responses to low levels of N were often positive because N availability tends to limit growth in terrestrial ecosystems ([LeBauer and Treseder, 2008](#)). However, forest productivity responses to higher rates of N addition were neutral or negative [e.g., [Magill et al. \(2004\)](#)]. The effects of N deposition were variable across species. Conifer species, particularly at high elevations, were more likely to exhibit negative growth responses or mortality in response to added N. Conifer species were less likely to demonstrate increased growth in response to additional N and more often exhibited decreased growth and increased mortality [e.g., [McNulty et al. \(2005\)](#); [Beier et al. \(1998\)](#); [Boxman et al. \(1998a\)](#)]. Differences between broadleaf and conifer species were especially clear in long-term N addition experiments: [Elvir et al. \(2003\)](#) observed increased sugar maple (*Acer saccharum*) basal area growth in response to long-term (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> (25 kg N/ha/yr for 10 years) additions, but red spruce (*Picea rubens*) growth was unchanged. At Harvard Forest, oak (*Quercus velutina*, *Q. rubra*) increased growth in response to chronic N additions (50 or 150 kg N/ha/yr for 15 years), while red pine (*Pinus resinosa*) growth slowed and mortality increased ([Magill et al., 2004](#)). Most empirical observations of the effects on atmospheric N deposition on forest productivity came from chronic N addition experiments in temperate forests in the U.S. [e.g., [Aber et al. \(1995\)](#); [McNulty et al. \(1996\)](#); [Elvir et al. \(2003\)](#); [Magill et al. \(2004\)](#); [Pregitzer et al. \(2008\)](#)] and temperate and boreal forests in Europe ([Hyvönen et al., 2008](#); [Högberg et al., 2006](#); [Beier et al., 1998](#); [Boxman et al., 1998a](#)). Empirical analyses of the effects of atmospheric N deposition on forest productivity in the U.S. were lacking.

Research published since 2008 has reinforced many of the ideas in the 2008 ISA. There is considerable evidence from deposition gradient studies, forest modeling, and long-term N addition experiments that N deposition broadly stimulates tree growth and the productivity of forested ecosystems, but that effects vary by species. Using forest inventory data collected between 2000 and 2016, [Horn et al. \(2018\)](#) found N deposition coincided with a small overall increase in tree growth and mortality. The particular response though varied greatly between species. The study analyzed results for 94 tree species, but ultimately focused on a subset of 71. Of the 71 species, 39 exhibited a significant relationship between growth and N deposition. Twenty of the 39 had increasing growth with greater N deposition across the full depositional range experienced by that species. Seventeen displayed increasing growth at lower levels of N

deposition but decreasing growth at higher levels. Two species (yellow birch [*Betula alleghaniensis*] and eastern hemlock [*Tsuga canadensis*]) declined in growth consistently with increasing N deposition. Mortality also varied between species, with 3 species increasing in survival, 25 species increasing in survival at lower N deposition before decreasing in survival at higher levels, and 6 species consistently declining in survival ([Horn et al., 2018](#)).

Similarly, other studies have shown variation in tree growth and mortality with N deposition. [Thomas et al. \(2010\)](#) assessed tree species response to N deposition using forest inventory data from the early 1980s through the mid-1990s. Of the 23 species surveyed, N deposition accelerated growth in 11 species, including 3 of the 4 most abundant species (red maple [*Acer rubrum*], sugar maple, and northern red oak [*Quercus rubra*]). Negative effects on growth were seen in three species, all of which were evergreen conifers (red pine [*Pinus resinosa*], red spruce, northern white cedar [*Thuja occidentalis*]). All five of the arbuscular mycorrhizal tree species included in the analysis exhibited increased growth. Eight species exhibited higher mortality rates with increasing N deposition in the [Thomas et al. \(2010\)](#) analysis, notably several oak species, including northern red oak. Only three species showed increased survival. Additionally, [Xia and Wan \(2008\)](#) observed positive effects of added N on growth for both broadleaf and coniferous trees in a meta-analysis, with broadleaf trees (+73%) more responsive than conifers (+37%).

Examining forest stand-level responses, [Hember et al. \(2017\)](#) concluded N deposition had increased forest stand growth in one of the five Canadian ecozones (Montane Cordillera), decreased it in another (Boreal Plain), and did not significantly affect stand growth in the remaining three (Pacific Maritime, Boreal Shield, and Atlantic Maritime). They similarly found differences in forest stand mortality, with N deposition decreasing mortality in three of the five ecozones (Pacific Maritime, Montane Cordillera, and Boreal Plain) and no significant effect in the remaining two. In an analysis of forest inventory data from across the entire eastern U.S. from the 1970s through early 2000s, [Dietze and Moorcroft \(2011\)](#), as noted in [Appendix 5](#), found N deposition was linked to decreased tree mortality in 9 of 10 plant functional types and increased mortality only in the northern midsuccessional hardwoods functional type. Across a smaller gradient within the Adirondacks, [Bedison and McNeil \(2009\)](#) found a significant positive overall effect of N deposition on tree growth from 1984–2004, but positive growth effects only for red maple, balsam fir (*Abies balsamea*), and red spruce at the species level. Thus, it appears from these inventory analyses that while tree growth has generally been enhanced by N deposition over the last several decades, individual species have exhibited variable responses to N deposition in mortality and growth.

Variation has also been shown in tree responses to experimental N additions. Overstory sugar maple trees increased growth in response to added N in Michigan [Pregitzer et al. (2008); N added at 30 kg N/ha/yr] and Maine [Elvir et al. (2003); 25 kg N/ha/yr], but mature sugar maple and red maple did not respond in the Catskills [Lovett et al. (2013); 50 kg N/ha/yr]. Northern red oak increased growth at Harvard Forest [Frey et al. (2014); 50 and 150 kg N/ha/yr] but showed no growth response at two sites in New York state [Wallace et al. (2007); 75 kg N/ha/yr, Lovett et al. (2013); 50 kg N/ha/yr], with increased mortality at one of the New York sites (Wallace et al., 2007). Red pine at Harvard Forest exhibited decreased growth and higher mortality in response to chronic N additions [Frey et al. (2014); 50 and 150 kg N/ha/yr], while red spruce showed no growth response in Maine [Elvir et al. (2003); 25 kg N/ha/yr]. A 13-year study in a young forest in West Virginia included the two species with the most positive growth responses in the Thomas et al. (2010) analysis and found that N addition (35 kg N/ha/yr of  $[\text{NH}_4]_2\text{SO}_4$ ) generally decreased growth of black cherry (*Prunus serotina*) and tulip poplar (*Liriodendron tulipifera*), although these changes were not statistically significant (May et al., 2005).

Notably, N additions in these studies often exceeded levels observed in forest inventory studies (Horn et al., 2018; Thomas et al., 2010). For instance, Horn et al. (2018) found growth in black cherry increased with N deposition up to just over 15 kgN/ha/yr, before declining with increases in deposition beyond that. Thus, the N addition of 35 kg N/ha/yr in (May et al., 2005) far exceeded the point of maximum growth for black cherry. Tulip poplar consistently increased in growth with N deposition according to Horn et al. (2018), but, even in this case, the 35 kg N/ha/yr added by May et al. (2005) exceeded the maximum amount of deposition (almost 34 kg N/ha/yr) experienced by tulip poplar in the Horn et al. (2018) study. This could help explain some of the differences in tree growth and mortality responses between experimental N addition and forest inventory studies.

Other studies have also observed similarly mixed results on tree growth and mortality in U.S. forests. At the same sites in Michigan where long-term N additions increased growth of mature sugar maple (Pregitzer et al., 2008), N additions decreased the growth and survival of sugar maple saplings (Talhelm et al., 2013; Patterson et al., 2012). Notably, this negative effect occurred without increase in overstory leaf area that would reduce light availability or a decrease in soil pH (Talhelm et al., 2013). More recently, Ibanez et al. (2016) observed that although small overstory trees (5–10 cm diameter at breast height) at these sites were growing faster, they were also experiencing increased mortality. As with sugar maple saplings in Michigan, N deposition appears to be decreasing growth among northern red oak saplings in the Chicago area, potentially contributing to the inability of this species to regenerate in that region (Bassirrad et al., 2015). In Vermont, 2 years of N addition at 150 kg N/ha/yr increased growth in four hardwood species (including sugar maple and northern red oak), decreased growth in one

conifer, and had no effect on two other hardwoods ([Finzi, 2009](#)). [Allen et al. \(2010\)](#) reported higher mortality and a decrease in ectomycorrhizal root tips ([Table 6-2](#)), with N addition (100 kg N/ha/yr) in ectomycorrhizal piñon pine in New Mexico, while no change in the mortality of arbuscular mycorrhizal juniper. [Allison et al. \(2010\)](#) observed a 2.5-fold increase in aboveground net primary productivity in response to several years of N additions (100 kg N/ha/yr) in central Alaska in a recently burned boreal forest. At two mixed conifer forests in the Sierra Nevada, 2 years of N additions (12 or 24 kg N/ha/yr) had a positive effect on herb community biomass at one site (24 kg N/ha/yr) and a negative effect at the other site (12 kg N/ha/yr); shrub biomass was unaffected ([Hurteau and North, 2008](#)). Modeling 50 years into the future based on these results, a lower rate of N deposition (12 kg N/ha/yr) was expected to increase herb biomass, while the high rate of N deposition (24 kg N/ha/yr) led only to a small increase in shrub biomass. In combination with a wetter precipitation regime, both N deposition rates were predicted to increase shrub and herb biomass ([Hurteau et al., 2009](#)). In a greenhouse study, N additions of up to 120 kg N/ha/yr had no effect on the N fixing tree black locust (*Robinia pseudoacacia*) when grown in a monoculture or in competition with the sawtooth oak (*Quercus acutissima*), but N additions increased the height and total biomass of the sawtooth oak when grown in competition with black locust ([Luo et al., 2014](#)).

Notes: single studies are reported more than once if multiple endpoints were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

A number of studies on the effects on N deposition or chronic N additions have been conducted in temperate and boreal forests in Europe, and these studies have more consistently found positive effects of N on tree growth [e.g., [Solberg et al. \(2009\)](#); [Ferretti et al. \(2014\)](#); [Nair et al. \(2016\)](#)]. [Ferretti et al. \(2014\)](#) observed a positive relationship between N deposition and tree growth across 26 forest plots in Italy. A positive effect of N deposition on tree growth was also found on 135 Swiss long-term observation plots for mature beech and spruce from the mid-1980s through late 2000s ([Braun et al., 2010](#)). Further N additions decreased tree growth at three of seven experimental sites, yet these changes were linked to P deficiencies ([Braun et al., 2010](#)). [Eastaugh et al. \(2011\)](#) took a more complex approach to understand growth trends of Norway spruce (*Picea abies*) in the Austrian National Forest Inventory from 1960–2008. Using the Biome-BGC model to isolate growth trends from variation in climate, the authors found a positive relationship between tree growth and N deposition. Using data from long-term N addition experiments in Norway spruce and Scots pine (*Pinus sylvestris*) forests throughout Sweden and Finland, [Hyvönen et al. \(2008\)](#) found increased tree growth at 11 of 12 sites. The effects of added N on forest productivity appear to persist for decades and carry over through major ecosystem disturbances. [From et al. \(2015\)](#) studied young Norway spruce and Scots pine forests planted in the late 1990s after the original forests were clear-cut. The original forests had received N additions of 150 kg N/ha/yr (as  $\text{NH}_4\text{NO}_3$ ) either twice (in 1977 and 1985), once (1985), or never. Tree height growth of the young forests was positively related to the amount of previous N additions, with significantly greater height growth in the forests that had received two N additions. Foliar N concentrations were also significantly higher in the forests that had received N additions ([From et al., 2015](#)). Biomass of understory shrubs and bryophytes decreased in response to N additions (100 kg N/ha/yr for 6 years) on boreal forest islands in Sweden, although one of three shrub species increased in growth ([Wardle et al., 2016](#)).

The 2008 ISA tied greater tree growth and forest productivity to increases in foliar N, photosynthesis, and gross primary productivity. In addition, foliar N was identified as a sensitive indicator of changes in forest N availability ([Aber et al., 1989](#)). Since the 2008 ISA, increases in foliar N continue to have been linked to N deposition in forests in the U.S., Europe, and Asia in pollution gradient studies ([Sardans et al., 2016](#); [Talhelm et al., 2012](#); [Jones et al., 2011](#); [Cox et al., 2010](#); [Thimonier et al., 2010](#); [Fenn et al., 2008](#)) and N addition experiments ([Du, 2017](#); [Fusaro et al., 2017](#); [Gilliam et al., 2016a](#); [Wardle et al., 2016](#); [Fowler et al., 2015](#); [Du and Fang, 2014](#); [Lovett et al., 2013](#); [Talhelm et al., 2013](#); [Lovett and Goodale, 2011](#); [Talhelm et al., 2011](#); [Allen et al., 2010](#); [Braun et al., 2010](#)). For instance, [Cox et al. \(2010\)](#) observed a 40% increase in foliar N (from 15 mg/g to 21 mg/g) in Scots pine forests in Germany and the U.K. along an N deposition gradient of 4.6 to 28 kg N/ha/yr. In addition to trees, forest bryophytes and lichens also show increased tissue N concentrations when exposed to additional N ([Maaroufi et al., 2016](#);

[McMurray et al., 2015](#); [McMurray et al., 2013](#); [Gundale et al., 2011](#); [Fenn et al., 2008](#); [Glavich and Geiser, 2008](#)). Increased foliar N is not universally observed in N addition studies [e.g., [Lovett et al. \(2013\)](#); [Zhang et al. \(2015c\)](#); [Zhang et al. \(2017\)](#)] or along N deposition gradients ([Watmough and Meadows, 2014](#)), but a meta-analysis found that N additions generally increase foliar N in trees ([Lu et al., 2011b](#)).

Although there are clear links between N deposition and increased foliar N and between higher foliar N and increased photosynthesis, there is only limited evidence that chronic N deposition directly increases leaf-level photosynthesis in forests. For instance, in long-term simulated N deposition experiments in Massachusetts and Maine, only one of four species exhibited increased photosynthesis with N additions ([Elvir et al., 2006](#); [Bauer et al., 2004](#)). Research on photosynthesis since the 2008 ISA has been similarly mixed. [Talhelm et al. \(2011\)](#) did not observe a significant increase in either photosynthesis or canopy leaf area in mature sugar maple trees at four sites in Michigan in response to N additions (30 kg N/ha/yr as NaNO<sub>3</sub> for 14 years). Using a canopy-applied N treatment at two Swiss forests, [Wortman et al. \(2012\)](#) found that N additions improved photosynthetic processes in oak at one site, but did not significantly influence photosynthetic parameters in spruce or beech at the other site. In Swedish boreal forests, higher tissue N concentrations resulting from N additions (20 or 100 kg N/ha/yr for 4 years) increased the amount of <sup>13</sup>CO<sub>2</sub> assimilated into shrub (*Vaccinium*) foliage but decreased the amount of C assimilated by bryophytes ([Hasselquist et al., 2016](#)). At a broader scale, [Fleischer et al. \(2013\)](#) analyzed the effect of N deposition on photosynthesis using observations from 80 forest eddy covariance C flux measurement sites predominantly located in the eastern U.S. and western Europe. In this data set, canopy photosynthetic capacity was positively correlated to N deposition for conifer forests when N deposition was below an observed critical load of approximately 8 kg N/ha/yr ([Fleischer et al., 2013](#)). Most of the stimulus provided by N deposition occurred in boreal forests, with little to no influence of N deposition in broadleaf forests or forests in the temperate climate zones ([Fleischer et al., 2013](#)). [Leonardi et al. \(2012\)](#) compiled a global data set of published tree ring <sup>13</sup>C chronologies and found that the rate of N deposition had a significant linear effect on intrinsic water-use efficiency (iWUE) and <sup>13</sup>C discrimination ( $\Delta^{13}\text{C}$ ) in conifers and a quadratic effect in angiosperms. This change in <sup>13</sup>C discrimination suggests that the additional N either stimulated photosynthesis or stimulated growth to the extent that the trees became more water limited.

The apparent contradiction between the wide observations that N deposition can increase both tree growth and foliar N concentrations and the inconsistent effects of N deposition on leaf-level photosynthesis could be explained by two other physiological responses to N. First, plants can store excess N in foliage as free amino acids and other

physiologically inactive forms of N ([Bauer et al., 2004](#)). Increases in foliar amino acid concentrations, particularly arginine, have been observed in forests in chronic N addition experiments ([Bauer et al., 2004](#)) and along N deposition gradients ([Braun et al., 2010](#)). In these cases, the added foliar N would have no impact on photosynthesis. Second, plants can respond to added N by altering C allocation. As noted in the 2008 ISA, higher N availability often causes trees to allocate less photosynthate to roots and belowground processes and more toward aboveground growth ([Vicca et al., 2012](#); [Högberg et al., 2010](#); [Janssens et al., 2010](#); [Litton et al., 2007](#); [Aerts and Chapin, 1999](#); [Minnich et al., 1995](#)). Research since the 2008 ISA has provided further evidence that N deposition is likely capable of causing such a shift in forests. In a greenhouse experiment, N additions (2, 5, and 10 kg N/ha/yr) resulted in more biomass allocated to leaves than to roots at all four N addition levels for oak and black locust trees. At the same Michigan sites where [Talhelm et al. \(2011\)](#) observed that chronic N additions had no effect on leaf-level photosynthesis or stand leaf area, the combination of increased aboveground growth, no change in root production or respiration, and decreased mycorrhizal abundance led the authors to conclude that a change in C allocation away from mycorrhizae was the likely cause for enhanced tree growth. More broadly, [Vicca et al. \(2012\)](#) found that across 49 forest sites, higher site fertility increased both the fraction of biomass that was allocated aboveground and the fraction of photosynthate that was allocated toward biomass production. The increase in C allocated to biomass production was thought to most likely result from less C being allocated to root symbionts such as mycorrhizae ([Vicca et al., 2012](#)). Likewise, [Janssens et al. \(2010\)](#) conducted a meta-analysis of 20 forest N addition experiments and found that N additions decreased the fraction of C allocated to belowground processes but did not affect root biomass. As an example of this, [Högberg et al. \(2010\)](#) conducted a short-term (~2 hour)  $^{13}\text{CO}_2$  canopy labeling experiment in a young Scots pine forest in northern Sweden to determine how N additions (two 100 kg N/ha additions over 2 years) altered the allocation of recent photosynthate belowground. In the 3 weeks following the canopy labeling, the total soil respiratory efflux of the  $^{13}\text{C}$  label was 62% lower in the plots that had received the N additions. Other observed physiological responses to N include delayed bud burst ([De Barba et al., 2016](#)), decreased tree ring width, and increased xylem conduit density ([Borghetti et al., 2017](#)).

The effects of N addition on forest productivity have the potential to be moderated by increases in herbivory, particularly among insects ([Throop and Lerdau, 2004](#)). For instance, [Andersen et al. \(2010\)](#) observed that N additions increased foliar N and photosynthetic rates within a tropical forest in Panama, but that tree growth rates were unaffected because of increased herbivory. At Harvard Forest in Massachusetts, northern red oak regeneration declined with N additions [50 and 100 kg N/ha/yr; [Bogdziewicz et al. \(2017\)](#)]. Acorn production increased, but so did weevil infestation of the acorns, and

germination rates declined. In a Pennsylvania common garden experiment with northern red oak, saplings receiving N additions (200 kg N/ha/yr) tended to have greater herbivore damage, but the effects of N addition on herbivory and the link between herbivory and decreased growth both varied by the type of herbivore, the tree lineage (breeding family), and the study location ([Cha et al., 2010](#)). Similarly, [Jones et al. \(2008\)](#) and [Jones et al. \(2011\)](#) observed that the most abundant herbivore of bracken fern (*Pteridium aquilinum*) and a beetle herbivore of California black oak (*Quercus kelloggii*) were increased by N addition at a heavily polluted site, but not at a drier, less polluted site. However, there was a positive correlation between leaf NO<sub>3</sub><sup>-</sup> concentrations and the abundance of several groups of black oak herbivores.

---

### 6.2.3.2 Belowground Processes

The 2008 ISA analysis of how belowground processes in forests reacted to N deposition focused on fine root dynamics, aboveground litter inputs, decomposition, soil respiration, and soil C. [Johnson \(2001\)](#) had found a significant increase in forest soil C in response to N additions as part of a meta-analysis, but only a single long-term N addition field study had observed a significant increase in forest soil C [[Pregitzer et al. \(2008\)](#); see [Appendix 4](#)]. For fine roots, [Nadelhoffer \(2000\)](#) hypothesized that N deposition would decrease biomass, but stimulate turnover and production. The 2008 ISA found little evidence with which to evaluate this hypothesis. There was more available research on N effects on decomposition and soil respiration. As noted earlier, [Knorr et al. \(2005\)](#) observed in a meta-analysis that N additions increased decomposition at sites receiving low rates of ambient N deposition (<5 kg N/ha/yr), but N additions suppressed decomposition at sites receiving moderate rates of N deposition (5–10 kg N/ha/yr).

Research completed since the 2008 ISA has advanced our understanding of how N affects belowground processes in forests. In two meta-analyses, [Liu and Greaver \(2010\)](#) did not find a consistent effect of N additions on forest fine root production, while [Li et al. \(2015\)](#) observed a decrease (–13.5%) in forest fine root biomass. Broadly, some of the results discussed in the 2008 ISA that appeared inconsistent at the time were likely a reflection of how N additions interacted with other ecological processes. In young, rapidly expanding forests, N addition may increase root biomass as a consequence of an overall enhancement of plant growth ([Janssens et al., 2010](#)). For instance, N additions (150 kg N/ha/yr for 3 years) to a young bamboo forest increased fine root growth by >30%, even though this forest already received high rates of atmospheric N deposition [95 kg N/ha/yr of wet deposition; [Tu et al. \(2015\)](#)]. However, as noted in the “Aboveground Processes” section ([Appendix 6.2.3.1](#)), increases in N deposition tend to decrease the proportion of C allocated to roots relative to aboveground growth ([Li et al.,](#)

[2015](#); [Vicca et al., 2012](#); [Janssens et al., 2010](#); [Litton et al., 2007](#); [Minnich et al., 1995](#)). Thus, in more mature forests, root biomass and production are not consistently affected by N deposition. For instance, there were no effects of chronic N additions on fine root biomass in four mature hardwood forests in Michigan [30 kg N/ha/yr for over 15 years; [Burton et al. \(2012\)](#)], and in two mature mixed oak (*Quercus*) stands at Harvard Forest [50 or 150 kg N/ha/yr for over 20 years; [Frey et al. \(2014\)](#)]. Likewise, N addition (50 kg N/ha/yr) did not cause significant changes in root biomass in a tropical forest in Puerto Rico ([Cusack et al., 2010](#)). Root turnover did not respond to N addition (30 kg N/ha/yr for 3 years) across 13 successional (20–40 years old) and mature (>90 years old) hardwood stands in central New Hampshire ([Kang et al., 2016](#)). In contrast with the mixed oak stands, fine root biomass decreased in two red pine stands at Harvard Forest [50 or 150 kg N/ha/yr for over 10 years; [Frey et al. \(2014\)](#)], and root biomass also decreased with N additions (50 or 150 kg N/ha/yr for 3 years) in a subtropical, broadleaf forest in China ([Peng et al., 2017](#)).

Observations of how other belowground processes respond to N additions provide further evidence of an increase in the ratio of tree C allocated to aboveground growth and productivity versus the C allocated belowground. In a meta-analysis of forest soil respiration responses to N addition, [Janssens et al. \(2010\)](#) noted that N additions decreased soil respiration overall, with a portion of this effect caused by a decrease in autotrophic respiration. Within forests, autotrophic respiration may make up more than 50% of total soil respiration ([Hasselquist et al., 2012](#)). Much of this autotrophic respiration is mycorrhizal respiration, with the C allocated to and respired by mycorrhizae estimated to account for 9 to 34% of forest soil respiration ([Hasselquist et al., 2012](#); [Heinemeyer et al., 2007](#)).

Mycorrhizal fungi have long been observed to be sensitive to increased forest N availability, particularly ectomycorrhizae because these fungi have direct roles in plant N acquisition, and their production of aboveground fruiting bodies (sporocarps) makes it easier to observe changes in abundance ([Treseder, 2004](#); [Lilleskov et al., 2002](#); [Wallenda and Kottke, 1998](#)). As noted in [Appendix 4](#), when N supply increases, C allocation to ectomycorrhizal fungi decreases, and their abundance and activity decline. In a meta-analysis, [Li et al. \(2015\)](#) found that N additions decreased mycorrhizal colonization of fine root tips by 19% (n = 12). In contrast to the widespread increases in aboveground tree growth, studies of ectomycorrhizal growth and productivity responses to added N have documented nearly universally negative or neutral effects on metrics such as mycorrhizal root colonization, sporocarp abundance, and the abundance of the fungal lipid biomarker 18:2 $\omega$ 6,9 in the soil ([Table 6-2](#)). Although this research is consistent, these studies have limitations because nearly all of this research has been conducted on conifer species and most of the negative effects occur in studies using unrealistically high

rates of N addition (>100 kg N/ha/yr). However, two studies of ectomycorrhizae in Norway spruce forests in Europe have documented significant declines along gradients of ambient N deposition ([Bahr et al., 2013](#); [Kjøller et al., 2012](#)). In particular, ([Kjøller et al., 2012](#)) observed an 80 and 90% decrease in ectomycorrhizal root tip abundance and mycelial production, respectively, across a canopy throughfall N deposition gradient of 27 to 43 kg N/ha/yr in Denmark. [Morrison et al. \(2016\)](#) also observed a decline in the relative abundance of ectomycorrhizal fungal DNA within the soil of the N addition (50 or 150 kg N/ha/yr for 25 years) plots at the oak (*Quercus*)-dominated Harvard Forest in Massachusetts.

Given these decreases in ectomycorrhizal growth and productivity in response to added N, it is not surprising that the amount of C allocated belowground by plants to mycorrhizae can be sensitive to N availability. [Högberg \(2012\)](#) twice added N (100 kg N/ha) over a period of two growing seasons to boreal Scots pine forests in Sweden as part of a short (~2 hour) <sup>13</sup>C canopy labeling experiment. In the 5 weeks following the labeling, 48% less of the <sup>13</sup>C label was found in an ectomycorrhizal fungal lipid biomarker in the soil of the N amended plots. [Hasselquist et al. \(2012\)](#) found that in Scots pine forests in northern Sweden, 6 years of N additions at a rate of 100 kg N/ha/yr decreased respiration from ectomycorrhizae by 40%, but N additions at a rate of 20 kg N/ha/yr increased this respiration by 120%. However, the low N addition did not change the fractional contribution of ectomycorrhizae to total soil respiration. The low N addition treatment also had no effect on ectomycorrhizal sporocarp production, but the high N addition treatment nearly eliminated sporocarp production [99% decrease; [Hasselquist et al. \(2012\)](#)]. The availability of N also appears to influence the transfer of N from mycorrhizal fungi to plants. In a boreal Scots pine forest in Sweden, [Näsholm et al. \(2013\)](#) observed that a single N dose (100 kg N/ha) shifted the dominant sink for a <sup>15</sup>N tracer added 2 weeks later from the cytoplasm of ectomycorrhizal fungi and other soil microorganisms to the pine foliage.

Although ectomycorrhizae are important in many high latitude and temperate ecosystems, particularly forests, most species of terrestrial plants form arbuscular mycorrhizae ([Rillig, 2004](#)). The impact of N deposition on arbuscular mycorrhizae has received less research attention, perhaps partly because these fungi are best known for their role in plant P acquisition ([Rillig, 2004](#)). Arbuscular mycorrhizae community composition and production can be sensitive to added N [[Egerton-Warburton and Allen \(2000\)](#); [van Diepen et al. \(2010\)](#); [Table 6-3](#)], but these effects may not be consistent. [van Diepen et al. \(2010\)](#) reviewed eight previous studies of how intraradical (within root) and extraradical arbuscular mycorrhizal biomass responded to N additions, predominantly in forests, and found inconsistent effects. Intraradical biomass significantly declined in response to N in three studies and increased in two studies, including in the work of

[Garcia et al. \(2008\)](#). In comparison, extraradical biomass was either unresponsive or declined ([van Diepen et al., 2010](#)). Aside from the work of [Garcia et al. \(2008\)](#), other researchers since 2008 have found either neutral or negative effects on metrics of arbuscular mycorrhizal biomass and abundance ([Table 6-3](#)). Observations of decreased arbuscular mycorrhizal biomass span from a subtropical broadleaf evergreen forest in China that experienced a single year of N additions [25 or 50 kg N/ha/yr; [Shi et al. \(2016a\)](#)] to a subalpine Englemann spruce (*Picea engelmannii*) forest in Rocky Mountain National Park that had received more than 15 years of N additions [25 kg N/ha/yr; [Boot et al. \(2016\)](#)].

Notably, the arbuscular mycorrhizal species studied by [Garcia et al. \(2008\)](#) were all understory or subdominant canopy species growing beneath ectomycorrhizal loblolly pines. The increased growth of these larger trees in response to added N may have imposed other resource limitations on the arbuscular mycorrhizal plant species. In general, the response of arbuscular mycorrhizae to N additions may depend upon the relative availability of P or other nutrients. [Johnson et al. \(2003\)](#) found N additions decreased arbuscular mycorrhizae when the soil N:P ratio was low (i.e., P-rich soils), while increasing arbuscular mycorrhizae under high soil N:P (i.e., P-poor soils). Where P is more limiting, plants may allocate more carbon to arbuscular mycorrhizae in order to acquire it ([Egerton-Warburton et al., 2007](#); [Johnson et al., 2003](#)). Thus, the varying availability of soil P may explain in part the seemingly inconsistent response of arbuscular mycorrhizae to N additions.

**Table 6-3 Growth, productivity, and carbon cycle responses of arbuscular mycorrhizal fungi to nitrogen added via atmospheric deposition or experimental treatments.**

ha = hectare; kg = kilogram; N = nitrogen; yr = year.

Notes: single studies are reported more than once if multiple endpoints were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

Aside from mycorrhizal respiration, the other dominant component of autotrophic soil respiration is root respiration. Although [Janssens et al. \(2010\)](#) observed a decrease in autotrophic soil respiration in the presence of N, this decrease was not apparently related to changes in root respiration. In a long-term N addition experiment (30 kg N/ha/yr for +15 years) in four northern hardwoods forests, [Burton et al. \(2012\)](#) found that although root N concentration was a strong predictor of the root respiration rate and N additions had increased root N concentrations, N additions had not increased root respiration because the added N changed the relationship between root N and respiration. [Drake et al. \(2008\)](#) made a similar observation in loblolly pine forests in North Carolina: N additions (100 kg N/ha/yr for 2 years) increased fine root N concentrations but did not impact fine root respiration rates, resulting in an altered tissue N respiration relationship. [Frey et al. \(2014\)](#) also reported that root respiration was unresponsive to long-term N additions (50 or 150 kg N/ha/yr) in oak forests and pine forests in Massachusetts. However, [Hasselquist et al. \(2012\)](#) found that a relatively modest N addition rate (20 kg N/ha/yr for 6 years) increased both root and mycorrhizal respiration in a boreal forest in Sweden that received relatively low rates of ambient N deposition (<5 kg N/ha/yr). Thus, it appears that C allocation to mycorrhizae is more sensitive to N availability than C allocation to root respiration.

In a meta-analysis of the effects of N additions on microbial biomass, [Treseder \(2008\)](#) found that changes in soil respiration were significantly and positively correlated with the response of microbial biomass. Mycorrhizal fungi are major components of forest soil microbial communities, with [Högberg et al. \(2010\)](#) estimating that ectomycorrhizal mycelium made up 39% of total soil microbial biomass in a Swedish boreal forest. At Harvard Forest, [Morrison et al. \(2016\)](#) observed that 59–72% of all fungal operational taxonomic units (OTUs) belonged to ectomycorrhizal fungi. Given the widespread negative effects of added N on mycorrhizal fungi, the results of Treseder's meta-analysis and the broadly negative or neutral effects of N additions on microbial biomass in the studies published since 2008 are unsurprising ([Table 6-4](#)).

Notes: single studies are reported more than once if multiple endpoints were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

However, forest soil microbial communities are taxonomically and functionally diverse (see [Appendix 6.3.3.3](#)) and have exhibited varying responses to added N ([Zhang et al., 2015c](#); [Treseder, 2008](#)). For instance, [Wang et al. \(2015b\)](#) added N (50, 100, or 150 kg N/ha/yr for 9 years) to pine, broadleaf, and mixed pine-broadleaf forests in southern China; the 50 kg N treatment increased microbial biomass C in the pine forests and the 150 kg N treatment decreased microbial biomass C in the broadleaf forests, but there were no other significant treatment effects. Elsewhere in China, a single year of N additions (25 or 50 kg N/ha/yr) in a subtropical broadleaf evergreen and temperate broadleaf deciduous forest had no effect on total microbial biomass in either forest, but decreased the abundance of Gram-negative bacteria, actinomycetes, and saprotrophic fungi in the subtropical evergreen forest ([Shi et al., 2016a](#)). The addition of 100 kg N/ha/yr to a regenerating Alaskan boreal forest decreased the microbial biomass and the C:N ratio of microbial biomass ([Allison et al., 2010](#); [Allison et al., 2008](#)), while N additions (50 kg N/ha/yr) in Indiana mixed hardwood forests decreased microbial biomass without affecting the microbial C:N ratio ([Midgley and Phillips, 2016](#)). In Sweden, the addition of 100 kg N/ha/yr to boreal forests for 6 years decreased bacterial biomass, but did not significantly affect fungal biomass ([Wardle et al., 2016](#)). The opposite result was observed in pine and hardwood stands at Harvard Forest and in subalpine spruce-fir forests in Rocky Mountain National Park (RMNP). There, N additions decreased fungal biomass, but bacterial biomass was unaffected [50 and 150 kg N/ha/yr for 14 years at Harvard Forest; 25 kg N/ha/yr for 17 years in RMNP; [Boot et al. \(2016\)](#)]. In Michigan, long-term (+15 years) N additions (30 kg N/ha/yr) to northern hardwood forests decreased the abundance of actinobacteria in the surface mineral soil, but not in the soil organic horizon ([Eisenlord and Zak, 2010](#)). Relative to mycorrhizal

fungi, there is less information available regarding the growth and biomass responses of individual domains and other taxonomic groupings within microbial communities ([Table 6-4](#)). Of this finer scale information, most observations are for fungi (sometimes including mycorrhizal fungi), with positive, neutral, and negative effects of added N.

Atmospheric N deposition may affect forest microbial communities and litter decomposition by altering litter chemistry through shifts in forest community composition, increasing litter N concentrations, or changing the secondary chemistry of litter. The two dominant forms of forest plant litter, leaves and fine roots, can each be altered by N additions ([Xia et al., 2015](#)). As noted in the aboveground processes section of this appendix, there is abundant evidence that N deposition can increase foliar N concentrations in trees and there is also a large body of research that the increase in foliar N concentrations will result in increased leaf litter N concentrations ([Aerts, 1996](#)). Since the 2008 ISA, there have been new observations of increased leaf litter N concentrations both in long-term N addition experiments ([van Diepen et al., 2015](#); [Xia et al., 2015](#); [Zak et al., 2008](#)) and along an N deposition gradient [6.8–11.8 kg N/ha/yr; [Talhelm et al. \(2012\)](#)]. Increases in leaf litter N concentrations with greater N deposition are not universal [e.g., [Watmough and Meadows \(2014\)](#)], but in a meta-analysis, [van Diepen et al. \(2015\)](#) observed a >20% increase in tree leaf litter N concentrations in response to N additions. Other changes in forest litter chemistry likely involve changes in more complex physiological and biogeochemical mechanisms ([Du and Fang, 2014](#)). In an old growth boreal forest in China, N additions (20, 50, or 100 kg N/ha/yr for 3 years) decreased leaf litter P concentrations, an effect that could have been caused by changes in either physiological or biogeochemical processes ([Du and Fang, 2014](#)). In a meta-analysis, [van Diepen et al. \(2015\)](#) found that simulated N deposition significantly decreased leaf litter concentrations of P, calcium, manganese, aluminum, and zinc, but did not find significant changes in concentrations of potassium (K), magnesium, boron, iron, or copper. It is not entirely understood how all of these changes in elemental composition impact the composition and function of soil microbial communities, but manganese and calcium are needed for the production of extracellular enzymes that degrade lignin ([van Diepen et al., 2015](#)).

There is a large volume of research about how major biochemical constituents of plant litter such as lignin, cellulose, condensed tannins, and phenolics impact leaf litter decomposition, but less information about how N additions change the abundance of these compounds. [Xia et al. \(2015\)](#) researched the effects of long-term N additions (30 kg N/ha/yr for +15 years) on sugar maple leaf litter and fine root chemistry in four mature northern hardwood forests in Michigan. The N additions increased concentrations of condensed tannins in leaf litter and in fine roots. At three of the four sites, N additions increased the fraction of nonstructural cell wall material and decreased both cellulose and

lignin in leaf litter. On an ecosystem basis, N additions decreased total annual litter (leaf + fine root) fluxes of condensed tannins and soluble protein and increased the fluxes of nonstructural carbohydrates (sugars + starch) and N (Xia et al., 2015). Based on broad decomposition chemistry patterns observed elsewhere, these changes in litter chemistry were expected to increase initial rates of litter decomposition, which contrasts with the decrease in litter turnover rates observed at these sites (Xia et al., 2015). However, changes in tissue chemistry are not ubiquitous; for example, Griepentrog et al. (2015) observed that the abundance and composition of fatty acids in leaf and root tissues in spruce and beech trees in Switzerland were not influenced by added N (70 kg N/ha/yr). Further, while N additions can change plant tissue chemistry, links between litter chemistry and microbial abundance and microbial function are complex [e.g., Baumann et al. (2009)].

### 6.2.3.3 Forest Lichens

Lichens are widely used as indicators of N deposition impacts on ecosystems, particularly in forests. However, lichens also are important for ecosystem function. For insects, birds, and mammals, lichens represent camouflage, building materials for nests, and a source of food (Brodo et al., 2001). Lichens absorb N, sulfur (S), and other elements from atmospheric deposition and throughfall, and lichens that host cyanobacteria can add significantly to ecosystem N inputs, providing N to other plants (Kobylinski and Fredeen, 2015). In addition, lichens also have a role in hydrologic cycling, have many traditional human uses, and have high potential for pharmaceutical use (McCune and Geiser, 1997). Lichens are symbioses comprised of fungi (mycobiont) and a green alga and/or cyanobacterium [photobiont; Palmqvist (2000); Sundberg et al. (2001)]. Much of the lichen biomass is comprised of fungal (mycobiont) tissue, but the photobiont synthesizes organic compounds, supplying the energy and structural C needed for growth of the lichen. Both the photobiont and the mycobiont require N for growth (Palmqvist, 2000), but the supply of C and N must be coordinated for the development of lichen thalli (Sundberg et al., 2001). Lichens with a cyanobacterial photobiont are N fixing, but those with a green algal photobiont depend on atmospheric deposition for N.

Lichens can be classified based on their response to N pollution. Lichens occurring in areas that receive high N deposition are considered nitrophytic or eutrophic; lichens common in areas receiving low N input are designated acidophytic or oligotrophic (Gai-Oliveira et al., 2005; van Herk, 2001). Atmospheric N deposition can impact lichens through changes in physiological function caused by an increased supply of N or by altering the pH of tree bark hosting the lichen (Jovan, 2008). Although lichens with a green algal photobiont depend on atmospheric deposition as a source of N, these lichens

can also be negatively impacted by N deposition via the accumulation of toxic concentrations of  $\text{NH}_4^+$  within the thallus. Cyanobacteria can grow on either  $\text{NO}_3^-$  or  $\text{NH}_4^+$  sources when administered at nontoxic concentrations, but more rapid growth has been observed with  $\text{NH}_4^+$  than  $\text{NO}_3^-$  (Von Rückert and Giani, 2004). Ammonium is more easily assimilated by lichens; both  $\text{NO}_3^-$  and nitrite must first be reduced to  $\text{NH}_4^+$  before assimilation can occur (Von Rückert and Giani, 2004). The 2008 ISA noted that lichens with a cyanobacterial photobiont appear to be more sensitive to adverse effects from atmospheric N deposition than most other lichens (Dahlman et al., 2002; Hallingbäck and Kellner, 1992; Hallingbäck, 1991). In part, the sensitivity of lichens to increasing N deposition is a function of the mechanisms with which that lichen can respond to high N supply, such as decreasing N uptake or assimilating N into nontoxic forms such as arginine (Gaio-Oliveira et al., 2005; Dahlman et al., 2002).

Since the 2008 ISA, new research on the impact of N deposition on the growth and physiology of forest lichens has both confirmed that lichen abundance is sensitive to N deposition and provided further insight on the growth and physiological changes that occur when lichens are exposed to exogenous N (Table 6-5). For example, previous research had suggested that lichens were most sensitive to N as ammonia (Sheppard et al., 2011; Jovan, 2008). However, a study of lichen communities on California black oak (*Quercus kelloggii*) forests at 22 sites in the Los Angeles Basin in California, Jovan et al. (2012) found that the abundance of eutrophic lichen species was only weakly related to gaseous  $\text{NH}_3$  concentrations. Instead, the strongest N pollution-related predictor of eutrophic lichen abundance was total N deposition (as canopy throughfall). Further, at the relatively neutral bark pH levels in the Los Angeles Basin, there was no influence of pH on the abundance of eutrophic lichen species. The abundance of eutrophic lichens was also best correlated with total throughfall N deposition in southeastern Alaska (Schirokauer et al., 2014a). This research provides strong evidence that total N deposition, not the deposition of a particular form of N, is the primary driver of changes in the growth, physiology, and composition of epiphytic lichens.

Increases in lichen thalli N concentrations in response to added N have been widely observed in the U.S. and Europe (Table 6-5), even at relatively low rates of atmospheric N deposition. For instance, McMurray et al. (2013) measured throughfall N deposition and sampled lichen thalli N concentrations at sites near the Bridger-Teton National Forest Wilderness that were at increasing distances downwind of a major oil and natural gas production field. Although the observed rates of N deposition were only 0.8 to 4.1 kg N/ha/yr along this gradient, thalli N concentrations in *Usnea lapponica* approximately doubled from ~1.2 to 2.4%. In southeastern Alaska, Schirokauer et al. (2014a) found increases in thalli N concentrations along an even smaller range of N

deposition (0.05 to 1.05 kg N/ha/yr), a pollution gradient attributed to cruise ship emissions.

In southern California, [Riddell et al. \(2008\)](#) transplanted thalli from the oligotrophic lichen *Ramalina menziesii* from relatively unpolluted sites into fumigation chambers under moderate and high HNO<sub>3</sub> concentrations (19.9–25 µg/m<sup>3</sup> and 26.4–35.3 µg/m<sup>3</sup>, respectively). The HNO<sub>3</sub> fumigation caused significant declines in chlorophyll content and C exchange capacity compared to thalli in control chambers. This research was later expanded to six species known to vary in sensitivity to N pollution ([Riddell et al., 2012](#)). Fumigation with HNO<sub>3</sub> (daily peaks near 50 ppb) decreased chlorophyll content, chlorophyll fluorescence, gross photosynthesis, and dark respiration in three of the five N sensitive species; while only photosynthesis declined in the other two N sensitive species. Four of the N sensitive species were tested for fumigation effects on cell membrane ion leakage; overall ion leakage, and specifically K<sup>+</sup> ion leakage, were increased by HNO<sub>3</sub> fumigation in all species.

Johansson and colleagues conducted a series of experiments in Sweden intended to understand the physiological responses of epiphytic lichens to added N ([Johansson et al., 2012](#); [Johansson et al., 2011](#); [Johansson et al., 2010](#)). In a whole-tree N addition experiment in a spruce forest in boreal Sweden, low rates of N addition (6, 12.5 kg N/ha/yr for 3 years) increased total lichen abundance, but higher N addition rates (25, 50 kg N/ha/yr) decreased total lichen abundance ([Johansson et al., 2012](#)). However, there was considerable variation among lichen species in the N addition treatment rate that resulted in optimal growth. For two of the lichen species in that experiment, *Alectoria sarmentosa* and *Platismatia glauca*, [Johansson et al. \(2010\)](#) quantified physiological responses to N additions. Thalli N concentrations increased in both species at the two highest N addition rates (25, 50 kg N/ha/yr). There was a significant positive relationship between cumulative N dose and chlorophyll content, but the N additions did not affect thalli P concentrations. In a separate experiment with a single much higher N addition rate (300 kg N/ha/yr for one season), [Johansson et al. \(2011\)](#) examined the physiological and growth responses of three lichen species. All three lichen species exhibited increased tissue N concentrations, increased chlorophyll concentrations, increased photosynthesis, and increased growth of the photobiont. However, mycobiont growth decreased in two species and was unchanged in the third. Total biomass changes among the three species were positive, neutral, and negative.

In another experiment in Scandinavia, lichens collected from Sweden and Norway were exposed to added N (50 kg N/ha/yr for one season) to understand whether this addition altered the concentrations of the C based secondary compounds (CBSCs) thought to protect lichens from herbivores and whether it affected feeding preferences of gastropod herbivores ([Asplund et al., 2010](#); [Nybakken et al., 2009](#)). The N additions decreased the concentrations of CBSCs in one species, but had no effect on the other three lichen species ([Nybakken et al., 2009](#)). The gastropod herbivores preferred to feed on lichens from the control treatment for three of the four species, while preferring the thalli from the N addition treatment for the fourth lichen species ([Asplund et al., 2010](#)). Notably, the species exhibiting the decrease in CBSCs was not the species that was preferable to herbivores in the N addition treatment. Together, these results suggest that N deposition may alter lichen community composition by shifting herbivore feeding preferences.

---

#### 6.2.3.4 Net Ecosystem Production and Carbon Sequestration Response

The 2008 ISA concluded that N deposited onto terrestrial ecosystems increased net primary productivity (NPP) and ecosystem C storage (kg C/ha). However, the extent to which this additional N stimulates forest C sequestration was a topic of debate [e.g., [Nadelhoffer et al. \(1999b\)](#); [Magnani et al. \(2007\)](#); [De Schrijver et al. \(2008\)](#); [de Vries et al. \(2008\)](#); [Sutton et al. \(2008\)](#)]. [Magnani et al. \(2007\)](#) correlated net ecosystem production (NEP; kg C/ha/yr) with estimated rates of N deposition for 20 forested sites in North America and Europe, which resulted in an estimate of 725 kg C sequestered per kg of added N (i.e., kg C/kg N). However, this estimate was widely criticized and a reanalysis of these data produced an estimate of C sequestration more than an order of magnitude lower [68 kg C/kg N; [Sutton et al. \(2008\)](#)].

Since the 2008 ISA, several new syntheses and a number of field experiments and modeling studies have provided further evidence that N deposition increases NPP, NEP, and ecosystem C content, and that have more tightly constrained estimates of the response of plant, soil, and ecosystem C content to N deposition. [Nave et al. \(2009b\)](#) estimated that up to 15% of the N needed to support NPP in a northern Michigan aspen forest was supplied by atmospheric N deposition. In China, N additions of 20, 50, or 100 kg N/ha/yr to an old growth boreal forest stimulated aboveground tree productivity by 5, 7, and 23% during the second and third years of the experiment ([Du and Fang, 2014](#)). [Chen et al. \(2011\)](#) found that a Douglas fir stand in the Pacific Northwest increased NEP by 2,500 kg/ha (+83%) in the first year after receiving 200 kg N/ha of urea, both from decreased respiration (930 kg/ha) and increased gross primary production (157 kg/ha). Increases in ecosystem C content have been noted in long-term N addition experiments in Massachusetts ([Frey et al., 2014](#)), Michigan ([Pregitzer et al., 2008](#)), and New York ([Lovett et al., 2013](#)). Using a process model that neglected changes in stand ontogeny, disturbances, and shifts in forest management, [de Vries and Posch \(2011\)](#) concluded that N deposition was a dominant determinant of European forest productivity throughout the 20th century.

Since the 2008 ISA, a variety of techniques have been used to quantify the C sequestration response of forests to N deposition, particularly in Europe ([Frey et al., 2014](#)). Using a <sup>15</sup>N-labeling technique, [Gundale et al. \(2014\)](#) observed a linear relationship between C sequestration and N additions of up to 50 kg N/ha/yr that had a slope of 16 kg C/kg N in a Swedish boreal forest. [Hyvönen et al. \(2008\)](#) synthesized soil and plant C sequestration data from 15 long-term (14–30 year) N addition experiments in boreal (*Picea abies*, *Pinus sylvestris*) forests in Sweden and Finland and estimated that C sequestration averaged 23 kg C/kg N for *Picea* and 30 kg C/kg N for *Pinus*, with an

additional 11 kg C/kg N within the soil. Also in Sweden, [Eliasson and Ågren \(2011\)](#) applied an ecosystem model to Scots pine (*Pinus sylvestris*) forests and estimated that ecosystem C stocks increased by 24,123 kg/ha in response to a cumulative 224 kg N/ha added over a century (108 kg C/kg N). Based on the stimulation of photosynthesis and assumptions about the fraction of photosynthate that is ultimately transformed into tree biomass, [Fleischer et al. \(2013\)](#) estimated that N deposition stimulates C sequestration by 25 kg C/kg N.

Forest inventory studies typically make use of one or more decades of tree growth data from national or continental monitoring networks and relate the variation in this growth to differences in N deposition and other environmental factors. Across western and northern Europe, [Solberg et al. \(2009\)](#) found that variation in tree volume increment was positively related to N deposition and summer temperature, particularly for pine (*Pinus*) and spruce (*Picea*), with similar, but weaker, relationships for beech (*Fagus*) and oak (*Quercus*). The overall model estimated C sequestration was 19 kg C/kg N. [Eastaugh et al. \(2011\)](#) analyzed Norway spruce (*Picea abies*) growth data from the Austrian National Forest Inventory and estimated that N deposition sequestered 21.6 kg C/kg N in aboveground tree biomass during the latter half of the 21st century. [Etzold et al. \(2014\)](#) and [Ferretti et al. \(2014\)](#) took similar approaches with 18 inventory plots in Switzerland and 25 inventory plots in Italy, respectively. Both studies found a positive relationship between N deposition and NPP, but the authors were unable to isolate NPP effects from other environmental factors.

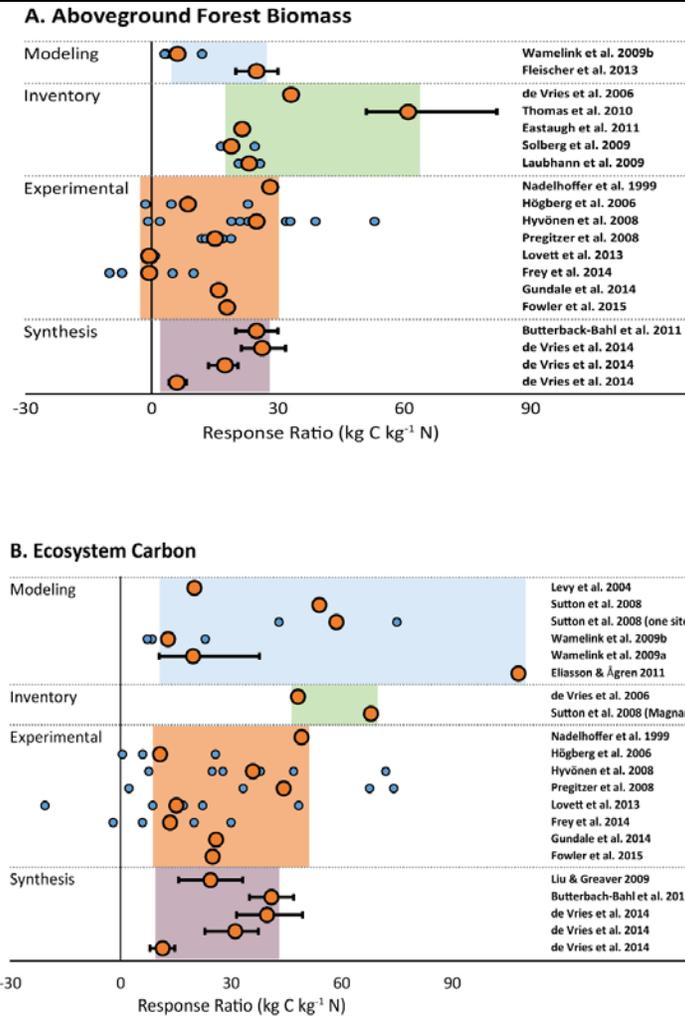

Within the U.S., the analysis of forest inventory data in the northeastern U.S. by [Thomas et al. \(2010\)](#) estimated that N deposition increased aboveground tree biomass at 61 kg C/kg N; a rough estimate including belowground C increased this to 73 kg C/kg N. [Pinder et al. \(2012\)](#) modified the estimates of [Thomas et al. \(2010\)](#), using alternate values for N deposition, more complex belowground biomass estimates, and changes in soil C pools, to produce an enhancement of 65 kg C/kg N. One criticism of the inventory and modeling studies is that they match variation in growth only to current levels of N deposition and neglect the potential effects of previous N deposition at that site. Thus, the influence of current N deposition may be exaggerated ([Högberg, 2012](#)). In addition, estimates of tree growth and biomass production typically rely on the application of equations that predict tree biomass based on measurements of tree stem diameter, either alone or in combination with tree height measurements. [Ibanez et al. \(2016\)](#) observed that at the sites in Michigan where N additions had increased tree growth ([Pregitzer et al., 2008](#)), the N additions had also altered the allometric patterns of sugar maple tree growth so that at a given tree stem diameter at breast height (1.4 m), the trees receiving N additions were taller than those in the control plots. This meant that stemwood biomass equations underestimated tree size for trees receiving N additions ([Ibanez et al., 2016](#)). If

these results apply in other environments and with other tree species, this implies that allometric biomass equations may be underestimating tree biomass in regions experiencing high rates of atmospheric N deposition and that estimates of C sequestration due to tree growth increases [e.g., [Thomas et al. \(2010\)](#)] may be too low.

In the long-term N addition experiment at Harvard Forest ([Frey et al., 2014](#)), the C response to N deposition ranged from  $-2$  to  $30$  kg C/kg N among the four treatment types ( $50$  or  $150$  kg N/ha/yr; *Pinus* or *Quercus* forests) and the amount of C sequestered in the soil was equal to or greater than the amount of C sequestered in trees. Similar results showing more C sequestration in the soil than in trees were found in N addition experiments at four Michigan forests [ $23$  kg C/kg N soil vs.  $17$  kg C/kg N tree; [Pregitzer et al. \(2008\)](#)] and in the Catskills ([Lovett et al., 2013](#)). Several syntheses of forest C sequestration changes in response to N deposition have been conducted ([Tian et al., 2016a](#); [Frey et al., 2014](#); [Pinder et al., 2013](#); [Pinder et al., 2012](#); [Butterbach-Bahl et al., 2011](#); [Janssens et al., 2010](#); [Liu and Greaver, 2009](#)), producing estimates of  $12$ – $41$  kg C/kg N. Often these synthesis studies are meta-analyses; however, [de Vries et al. \(2014a\)](#) took a novel approach of combining estimates of ecosystem N retention with N allocation and C:N ratios to develop stoichiometric estimates of N deposition for tropical, temperate, and boreal ecosystems. Although this approach involves a number of important assumptions about biogeochemistry and tree physiology, estimates for tree and soil C sequestration response rates were similar to values from other syntheses ([Figure 6-3](#)). In their study of aboveground NPP responses per unit of added N, [Tian et al. \(2016a\)](#) found that the average forest response was a  $3.75\%$  increase in NPP per g of N.

Variation in these estimates is likely influenced by the research approach. For instance, the model used by [Eliasson and Ågren \(2011\)](#) predicted almost no N losses from the forests due to leaching or denitrification, which are both widely reported at high rates of N deposition. However, environmental and ontological factors also appear to influence the sensitivity of forest C sequestration to N deposition. Using the G'DAY model, [Dezi et al. \(2010\)](#) found recent forest harvests, shifts in plant C allocation away from roots, and canopy N uptake all increased the C sequestration response to N deposition. Among the 15 experiments synthesized by [Hyvönen et al. \(2008\)](#), the amount of C sequestered ranged from  $-0.8$  to  $61$  kg C/kg N, with greater increases in kg C/kg N at lower N doses. The amount of additional tree C sequestered was small in plots that had low soil O-horizon C:N ratios (near 25) and the amount of C sequestered by added N increased with O-horizon C:N until C:N reached 35. Among *Picea* forests, young stands were more responsive than old stands, but no such effect was apparent for *Pinus*. In addition, C sequestration increased more in plots simultaneously supplied with K and P ([Hyvönen et al., 2008](#)). [Janssens et al. \(2010\)](#) acknowledged the role of stand age in altering the

dynamic of C cycling, explicitly removing young, rapidly expanding forests from some portions of the meta-analysis.

C = carbon; kg = kilogram; N = nitrogen.

Notes: Studies are grouped by research approaches, including process modeling, forest inventory analyses, long-term N addition experiments, or data syntheses. The citations to the right represent studies that quantified at least one of three aspects of forest C sequestration responses to N (forest biomass, soil C, or ecosystem C). The large orange circles represent the mean response for each study and the smaller blue circles represent individual estimates (replicate plots, study sites, or model simulations). The colored boxes bound the range of mean responses.

Data sources: [Nadelhoffer et al. \(1999b\)](#); [Levy et al. \(2005\)](#); [de Vries et al. \(2006\)](#); [Högberg et al. \(2006\)](#); [Hyvönen et al. \(2008\)](#); [Pregitzer et al. \(2008\)](#); [Sutton et al. \(2008\)](#); [Laubhann et al. \(2009\)](#); [Liu and Greaver \(2009\)](#); [Solberg et al. \(2009\)](#); [Wamelink et al. \(2009a\)](#); [Wamelink et al. \(2009b\)](#); [Thomas et al. \(2010\)](#); [Butterbach-Bahl et al. \(2011\)](#); [Eastaugh et al. \(2011\)](#); [Eliasson and Ågren \(2011\)](#); [Fleischer et al. \(2013\)](#); [Lovett et al. \(2013\)](#); [de Vries et al. \(2014a\)](#); [Gundale et al. \(2014\)](#); [Frey et al. \(2014\)](#); [Fowler et al. \(2015\)](#).

## 6.2.4 Arctic and Alpine Tundra and Grasslands

Tundra areas in the U.S. are concentrated in high-elevation alpine areas in the western U.S. and high-latitude areas in Alaska. Although alpine ecosystems are limited in their spatial extent, these ecosystems are important components of many national parks (e.g., Rocky Mountain, Yosemite, Sequoia-Kings Canyon, Mount Rainier) and other Class I areas within these regions. Nitrogen deposition rates in Arctic tundra areas are generally low, but there is a distinct impact of anthropogenic pollution on N cycling that could increase with further industrial development at high latitudes ([Holtgrieve et al., 2011](#)). In addition, although baseline rates of N deposition in Arctic deposition tend to be low, isolated precipitation events carrying air masses from industrialized or agricultural regions can result in high rates of deposition ([Kuhnel et al., 2011](#)). In Svalbard (north of Norway), 10% of precipitation events were responsible for 93% of all N deposited in snow or rain ([Kuhnel et al., 2011](#)).

For Arctic tundra ecosystems, the 2008 ISA identified a single N addition experiment and cited two studies from the 1980s on the effects of decreased N availability. The two studies on plants grown under conditions of low N availability found that tundra plants responded by increasing root growth ([Bloom et al., 1985](#)) or increasing N use efficiency ([Chapin, 1980](#)). The N addition (50 or 100 kg N/ha/yr) experiment began in 1981 and caused changes in plant community composition ([Shaver et al., 2001](#)) and increases in aboveground plant growth, but losses in soil C pools that resulted in decreased ecosystem C content ([Mack et al., 2004](#)).

The 2008 ISA reported that alpine plant species are often sensitive to N enrichment because many are adapted to low nutrient availability ([Bowman et al., 2006](#)) and that N deposition may increase alpine plant productivity and alter plant community composition ([Neff et al., 2002](#); [Seastedt and Vaccaro, 2001](#); [Bowman et al., 1995](#)). Some alpine plants in the southern Rocky Mountains exhibit greater growth in response to increased N, but this species-specific growth response to N deposition is one of the mechanisms that can change community composition ([Bowman et al., 1993](#)). Many of the dominant plant species do not respond to additional N supply with increased production. Rather, many subdominant species increase in abundance when the N supply is increased ([Fenn et al., 2003a](#)). The 2008 ISA also noted that the effects of N deposition can be spatially heterogeneous in alpine tundra ecosystems, with areas that accumulate wind-blown snow receiving higher rates of winter N deposition ([Bowman and Steltzer, 1998](#)). Further, the 2008 ISA also cited evidence that chronic N additions to alpine ecosystems can accelerate the decomposition of some soil C fractions, while preserving other C fractions ([Neff et al., 2002](#)).

Research since 2008 on the effects of added N on alpine and Arctic ecosystems has included broad syntheses, a number of experiments in both Europe and Asia, and additional research in North America. [Bouskill et al. \(2014\)](#) conducted a meta-analysis of high-latitude N addition experiments and compared these results with model simulations from the Community Land Model (CLM), the land component of the Community ESM (CESM). [Bouskill et al. \(2014\)](#) identified 37 N addition field experiments from 14 sites in North America and Europe. In this synthesis, N additions significantly stimulated gross primary production (GPP;  $+44 \pm 7\%$ , mean  $\pm$  standard error), while soil respiration declined by  $12 \pm 7\%$ . Total aboveground plant biomass was not significantly affected by N additions (increase of  $15 \pm 22\%$ ), but vascular plant biomass increased by  $33 \pm 8\%$ . Notably, the modeled responses produced from CLM matched observations only for two parameters: soil organic matter and GPP. These matches occurred only under the lowest rates of N addition ( $<1$  kg N/ha/yr), suggesting that N cycling processes or parameters are not well characterized in tundra ecosystems.

Three multiyear experiments span the period before and after the 2008 ISA was published ([Table 6-6](#)). In a subalpine shrub heathland in Scotland, [Britton and Fisher \(2007\)](#) examined the effects on plant communities of burning, clipping, and N additions of 0, 10, 20, or 50 kg N/ha/yr as  $\text{NH}_4\text{NO}_3$  for 5 years. Since the 2008 ISA was published, [Britton et al. \(2008\)](#) observed that N additions increased shoot N concentration in the dominant shrub *Calluna vulgaris*, with significant increases only at the two highest levels of N addition. In assessing plant growth, [Britton and Fisher \(2008\)](#) found increased growth of the dominant alpine shrub *Calluna vulgaris* and of *Vaccinium vitis-idaea* with N additions of 20 and 50 kg N/ha/yr, but no effect with 10 kg N/ha/yr or with N at any level on three other shrub species. Notably, in a greenhouse study with *Calluna vulgaris* plants from four different geographic populations, [Meyer-Gruenefeldt et al. \(2016\)](#) observed that N additions (35 kg N/ha/yr for 2 years) increased aboveground biomass in all populations, but that responses varied by factor of two between populations. Belowground biomass was unresponsive to N addition in the greenhouse study, resulting in decreased root:shoot ratios and potentially making the plants more susceptible to drought. In a second study within Scotland, [Britton and Fisher \(2010\)](#) found that N additions of 7.5, 12.5, and 22.5 kg N/ha/yr increased thallus N concentration in three of four alpine lichen species, but decreased growth of two species and did not significantly affect growth in three other species.

ha = hectare; kg = kilogram; N = nitrogen; n/a = not applicable; NEE = net ecosystem exchange; yr = year.

Notes: single studies are reported more than once if multiple endpoints or ecosystems were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

In subalpine tundra in Sweden, a long-term experiment was started in 1989 to understand how alleviating nutrient limitations altered ecological processes, including productivity, decomposition, and the development of plant communities ([Wardle et al., 2013](#); [Nilsson et al., 2002](#)). The experimental design included six treatments, including additions of  $\text{NO}_3^-$  and  $\text{NH}_4\text{NO}_3$  at rates of 50 kg N/ha/yr. After the first 9 years, there were negative effects of both  $\text{NO}_3^-$  and  $\text{NH}_4\text{NO}_3$  on the percentage cover of the dominant ericaceous shrub *Empetrum hermaphroditum*, but increased cover of two ericaceous *Vaccinium* shrub species ([Nilsson et al., 2002](#)). An even stronger positive response was exhibited by the bunchgrass *Deschampsia flexuosa*, which became the dominant plant in plots receiving N additions. The N additions also had varying effects on the cover of the dominant bryophyte species. *Dicranum* spp. decreased in cover in response to added N and *Pleurozium schreberi* disappeared entirely from some N addition plots, while *Polia* spp., *Bryum* spp., and *Barbilophozia lycopodioides* were not significantly affected by N additions. The dominant lichen, *Cladina* spp., decreased in response to added N ([Nilsson et al., 2002](#)). The N addition treatments did not impact vascular plant diversity, but moss species richness was decreased by  $\text{NH}_4\text{NO}_3$  and lichen species richness was decreased by  $\text{NO}_3^-$ . Decomposition of pine needles in litterbags was followed for 4 years, but no significant effects of the N addition treatments were observed ([Nilsson et al., 2002](#)). In 2010, [Wardle et al. \(2013\)](#) reassessed the changes in plant cover caused by the N addition treatments. The N addition treatments increased cover of vascular plants, but decreased bryophyte cover and lichen cover. Specifically, N additions repeatedly increased cover of *Deschampsia* and decreased cover of *Empetrum*, although these changes were not always significant. Within the soil microbial community,  $\text{NH}_4\text{NO}_3$  additions decreased the abundance of fungal phospholipid fatty acids (PLFAs; a marker of microbial abundance), while bacterial PLFAs were increased by  $\text{NO}_3^-$  additions. However,  $\text{NO}_3^-$  and  $\text{NH}_4\text{NO}_3$  each decreased the fungal-to-bacterial PLFA ratio in the soil. Humus mass and C content were increased by  $\text{NH}_4\text{NO}_3$  additions, but not significantly affected by  $\text{NO}_3^-$ .

Also spanning the period before and after the 2008 ISA was a 7-year N deposition study in a subalpine grassland in the Swiss Alps, with rates of N addition of 0, 5, 10, 25, or 50 kg N/ha/yr (as  $\text{NH}_4\text{NO}_3$ ). The initial analysis of the first 3 years of data found that N additions increased aboveground plant productivity ([Bassin et al., 2007](#)). Among functional groups, sedge growth was consistently stimulated, forb growth increased strongly in the first year of the experiment, and grasses and legumes were unresponsive to N. Species richness was not influenced by the N additions, but N did alter the relative abundance of the 11 most frequently occurring species. A subsequent analysis of this experiment ([Bassin et al., 2009](#)) focused on the physiological responses of these 11 species to the 50 kg N/ha/yr treatment. The N addition treatment increased leaf concentrations of N and chlorophyll in 9 of the 11 species. Notably, the species exhibiting the largest growth response (*Carex sempervirens*) also showed the largest

increase in foliar concentrations of N and chlorophyll. Four years into the experiment, [Volk et al. \(2011\)](#) measured changes in ecosystem C fluxes in response to the 10 and 50 kg N/ha/yr treatments. Although aboveground plant growth increased, there were no significant changes in gross primary productivity or ecosystem respiration. Net ecosystem production was unaffected by the lower rate of N addition but declined with the 50 kg N/ha/yr treatment, which suggests decreases in belowground C pools.

[Bassin et al. \(2013\)](#) and [Volk et al. \(2014\)](#) reassessed this Swiss Alps grassland N addition experiment after 7 years when the experiment concluded. [Volk et al. \(2014\)](#) observed that N additions had a strong positive effect on aboveground productivity, ranging from a 31% stimulation caused by 5 kg N/ha/yr to a 60% increase caused by 50 kg N/ha/yr. Effects on belowground biomass were smaller, ranging from a 19% increase for the 5 kg N treatment to a 24% increase for the 50 kg N treatment. Thus, N additions increased the ratio of shoot-to-root biomass ([Volk et al., 2014](#)). This is consistent with a <sup>15</sup>N tracer study at the site, in which the N addition treatment increased the proportion of the <sup>15</sup>N tracer found in aboveground biomass ([Bassin et al., 2015](#)). However, the stimulation of plant N pools was relatively similar among aboveground biomass (+31%), roots (+31%), necromass (+41%), and litter [+30%; [Bassin et al. \(2015\)](#)]. Among functional groups, the longer term results were both similar and different from the results observed after the initial 3 years ([Bassin et al., 2013](#)). The effects of N addition on sedge biomass increased through time, with the highest rate of N addition (50 kg N/ha/yr) increasing sedge biomass by 360%. In this same treatment, grass biomass increased by 14%, forb biomass was unchanged, and legume biomass decreased by 43%. Unsurprisingly, these changes resulted in more sedge-dominated plant communities. Two aspects of this community change are notable: (1) changes were largely complete after 4–5 years, and (2) the lowest rate of N addition (5 kg N/ha/yr) was sufficient to cause significant changes ([Bassin et al., 2013](#)). This experiment also included an ozone fumigation treatment, but there were no interactions between ozone and added N for productivity or community composition ([Volk et al., 2014](#); [Bassin et al., 2013](#); [Bassin et al., 2007](#)) and few N × ozone interactions for leaf physiological traits ([Bassin et al., 2009](#)). Two related studies on alpine grasslands have also been conducted in the Swiss Alps by members of the same research group. At 10 sites, [Bassin et al. \(2012\)](#) found that grassland aboveground productivity increased 30% with 2 years of NH<sub>4</sub>NO<sub>3</sub> additions of 50 kg N/ha/yr. [Blanke et al. \(2012\)](#) planted seedlings of four local plant species into intact grass/soil monoliths excavated from the same Swiss alpine grassland site as [Bassin et al. \(2013\)](#), [Bassin et al. \(2009\)](#), and [Bassin et al. \(2007\)](#). Nitrogen addition (50 kg N/ha/yr) treatments increased overall biomass of the unplanted vegetation in the monoliths. Among the planted species, N additions increased biomass of the grass and decreased biomass of the forb but had no effect on the sedge or legume. Roots of the

grass, forb, and legume were colonized by arbuscular mycorrhizal fungi; N addition increased mycorrhizal root colonization in the grass ([Blanke et al., 2012](#)).

As in other environments, the plant growth response to N additions in alpine and Arctic ecosystems varies among taxonomic groups. For example, in the Swiss subalpine grassland experiment, [Bassin et al. \(2013\)](#) noted that within plant communities, sedge (Cyperaceae) species tended to show especially strong positive responses to N additions. As discussed in [Appendix 5](#), [Bowman et al. \(2012\)](#) found N additions of 5, 10, and 30 kg N/ha/yr increased cover of the sedge *Carex rupestris* from 34 to 125% within a dry meadow in Rocky Mountain National Park in Colorado. In the northern Caucasus Mountains of Russia, [Onipchenko et al. \(2012\)](#) examined the response of four different alpine plant communities to 90 kg N/ha/yr for 5 years. The N additions increased vascular plant biomass in a lichen heath community, but not in grassland, meadow, or snowbed communities. Within these communities, the response of individual plant functional groups to N varied. The N additions increased sedge biomass in the lichen heath, increased forbs and sedges in the meadow, increased grasses in the grassland, and decreased legumes in the lichen heath and meadow. Shrubs were not significantly affected by N additions.

This variation among plant species was also observed in long-term N addition experiments in moist alpine meadows at the Niwot Ridge Long-Term Ecological Research site in Colorado. In two long-term experiments lasting for 7 and 11 years, average N additions of 229 and 288 kg N/ha/yr (far exceeding background deposition of 4–6 kg N/ha/yr) increased growth of the grass *Deschampsia cespitosa*, but decreased growth of the perennial forb *Geum rossii* ([Farrer et al., 2015](#); [Farrer et al., 2013](#)). The decrease in *Geum* abundance was not necessarily due to competitive exclusion: *Geum* decreased even in study plots where *Deschampsia* had been removed ([Farrer et al., 2013](#)). Instead, *Geum* showed effects of physiological stress with N additions, with less C allocation to storage organs and lower concentrations of nonstructural carbohydrates ([Farrer et al., 2013](#)). In wet, moist, and dry alpine meadows at Niwot Ridge, two decades of N additions (averaging ~85 kg N/ha/yr) did not alter total aboveground biomass, but significantly increased graminoid abundance in the moist and wet meadows ([Yuan et al., 2016](#)).

In addition to the research on alpine tundra in Colorado, there have been several other recent publications on the effect of N additions on plant productivity in tundra ecosystems in North America. Additions of 70 kg N/ha/yr for 3 years to plots in a central Utah alpine meadow increased aboveground plant production by 10–20%, but did not significantly impact soil respiration or soil C content ([Gill, 2014](#)). Given the large contribution of root and mycorrhizal respiration to soil respiration, these results suggest a

change in C allocation toward aboveground growth. In shrub tundra in the Northwest Territories of Canada, 8 years of N additions of 10 kg N/ha/yr had no effect on overall aboveground plant biomass or the biomass of the dominant plant (*Betula*), but each of these metrics was increased by N additions at a rate of 100 kg N/ha/yr ([Zamin et al., 2014](#); [Zamin and Grogan, 2012](#)). Inflorescence production in *Betula* was unaffected at both N addition rates. Elsewhere in the Northwest Territories, [Churchland et al. \(2010\)](#) observed that a single year of N additions (100 kg N/ha/yr) increased foliar N concentrations in shrub tundra plants. In an Alaskan tundra meadow, [Kelley and Epstein \(2009\)](#) found that N additions (100 kg N/ha/yr for 3 years) increased foliar N concentrations but had no effect on aboveground plant growth. Together, the results of these studies in North America are consistent with the overall body N addition research in tundra ecosystems ([Table 6-6](#)).

The influence of N additions on tundra plant biomass and productivity has also been assessed in other areas of the world since 2008. In particular, numerous N addition experiments have been conducted in alpine grasslands within the Tibetan Plateau region of China ([Fu and Shen, 2016](#)). Although the effects of added N on plant growth clearly vary by functional type ([Fu and Shen, 2016](#)), differences between functional groups are not necessarily consistent between ecosystems. For instance, while ([Fu and Shen, 2016](#)) found that added N increased sedge biomass and decreased forb biomass in their meta-analysis of 51 Tibetan plateau studies, 4 years of  $\text{NH}_4\text{NO}_3$  additions at rates of 10, 20, 40, and 80 kg N/ha/yr caused significant increases in aboveground plant biomass and cover of grasses and forbs and either decreases or no change in sedges ([Zong et al., 2016](#)). Species-specific changes in cover and foliar N concentration on the Tibetan Plateau were observed even in studies using very high N addition rates [50, 150, or 300 kg N/ha/yr for 3 years; [Xiong et al. \(2016\)](#)]. Also on the Tibetan Plateau, 100 kg N/ha/yr over 2 years increased leaf litter N concentrations in three herbaceous species, but also changed the biochemical composition of leaf litter by increasing the concentration of cellulose and decreasing the concentration of lignin in a forb (*Gentiana straminea*) and decreasing the concentration of hemicellulose in a sedge [*Kobresia humilis*; [Zhu et al. \(2016b\)](#)]. While higher leaf litter concentrations of these structural biochemicals were linked to slower decomposition overall within this experiment, N additions did not significantly alter decomposition. As in other terrestrial ecosystems, increases in plant biomass on the Tibetan Plateau appear to be more dependent on the amount of N added (3.75 or 15 vs. 75 kg N/ha/yr) than the form of N added [ $\text{NaNO}_3$ ,  $(\text{NH}_4)_2\text{SO}_4$ ,  $\text{NH}_4\text{NO}_3$ ; [Song and Yu \(2015\)](#)].

In an Arctic shrub ecosystem in Greenland, [Arens et al. \(2008\)](#) studied the effects of N additions at 5, 10, and 50 kg N/ha/yr over 3 years on ecosystem C fluxes and community composition. Net ecosystem productivity (NPP), gross primary production (GPP), and

ecosystem respiration (ER) all increased in response to N additions, but these responses were saturated beyond 10 kg N/ha/yr. The smallest rate of N addition caused both GPP and ER to nearly double. However, soil respiration was not significantly affected by the N addition treatments. Dominant vascular plant cover was highest in the 10 kg N/ha/yr treatment. Nitrogen additions increased the cover of subdominant vascular plants from 3% in control plots to 8% in the highest N treatment. There were also other changes in the cover of plant functional groups, including a 41% increase in deciduous shrubs in the lowest N addition plots, a doubling of graminoid biomass in the moderate N treatment relative to control, and large increases in forb biomass in the moderate and high N addition treatment.

As in forests, lichens are an important component of plant communities and a significant contributor to ecosystem function in Arctic and alpine tundra ecosystems. Since 2008, there have been numerous observations of how lichens respond to added N in these systems ([Table 6-7](#)), and these responses are broadly similar to those observed in forests. [Britton and Fisher \(2010\)](#) observed increased tissue N concentrations in three of four lichen species from Scottish heathlands over the course of a growing season with N additions of 2.5 to 22.5 kg N/ha/yr. [Hogan et al. \(2010b\)](#) collected lichens from 27 heathland sites in the U.K. along a wet N deposition gradient (2–33 kg N/ha/yr) and observed increased thalli N concentrations, decreased thalli P concentrations, and increased phosphomonoesterase activity, an enzyme important for P acquisition. [Hogan et al. \(2010a\)](#) found similar results in an N addition study. [Armitage et al. \(2014\)](#) observed a decline in lichen cover in alpine heathland sites across an N deposition gradient of 0.6 to 39.6 kg N/ha/yr in the North Atlantic region of Europe. Similarly, there were decreases in lichen biomass or lichen cover with additional N in studies in Scotland ([Britton and Fisher, 2010](#)), Sweden ([Wardle et al., 2013](#)), Alaska ([Kelley and Epstein, 2009](#)), and Canada ([Zamin et al., 2014](#)).

Notes: single studies are reported more than once if multiple endpoints or ecosystems were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

Because of the often sparse cover of vascular plants in tundra ecosystems, bryophytes are often relatively larger components of plant communities than in other terrestrial systems. As with lichens, bryophyte physiology and growth in tundra ecosystems can be impacted by added N. [Armitage et al. \(2012\)](#) conducted an analysis of the tissue chemistry, growth, and cover of the bryophyte *Racomitrium lanuginosum* in alpine heathlands at 36 sites in Great Britain, Iceland, the Faroe Islands, and Norway. Estimated N deposition at these sites ranged from ~1 kg N/ha/yr to nearly 40 kg N/ha/yr. Among environmental variables that included temperature, precipitation, and grazing, N deposition was the largest influence on tissue N and P concentrations. Notably, tissue N concentration increased rapidly with N deposition rates up to 5 kg N/ha/yr, then increased at a slower rate with higher levels of N deposition. Tissue N concentration was positively related to moss shoot growth, but also positively related to shoot turnover and negatively related to moss mat depth. These effects were nonlinear and especially pronounced at high tissue N concentrations. Among other plant functional types at these sites, shrub growth decreased with greater N deposition, graminoid growth increased, and forbs were not significantly affected ([Armitage et al., 2014](#)). In related work using a subset of these sites, [Armitage et al. \(2011\)](#) conducted a 2-year transplant experiment that moved *Racomitrium* between 10 sites receiving higher N deposition (8.2–32.9 kg N/ha/yr) and a lower N site (7.2 kg N/ha/yr). When the authors transplanted *Racomitrium* from elevated N deposition sites to low N deposition sites and vice versa, tissue N concentration remained higher in the plants from higher N sites, whereas moss moved from lower N to higher N sites increased tissue N to nearly match levels in the moss natural to the site. [Armitage et al. \(2011\)](#) also observed that moss at high N sites had higher shoot growth, whereas moss transplanted to lower N sites increased in biomass due to decreasing tissue C:N and slowing decomposition ([Armitage et al., 2011](#)).

In high-latitude and high-elevation ecosystems, such as tundra, heathlands, and boreal forests, plants in the Ericaceae family are often abundant. Notable members of the Ericaceae family include blueberries and cranberries (both *Vaccinium*). Ericaceous plants uniquely host ericoid mycorrhizae, which are distinct from ectomycorrhizae and arbuscular mycorrhizae. Ericoid fungi are recognized for their ability to decompose large organic molecules and absorb organic forms of soil N ([Read et al., 2004](#)). This specialization in organic N uptake could make these mycorrhizae more sensitive to increased inorganic N availability. However, only a relatively small number of N addition studies have quantified changes in mycorrhizal growth or physiology in ecosystems supporting plants that host ericoid mycorrhizae ([Table 6-8](#)). [Ishida and Nordin \(2010\)](#) added 12.5 or 50 kg N/ha/yr for 4 or 12 years to boreal forests in Sweden and observed no change in the percentage of *Vaccinium myrtillus* roots colonized by ericoid mycorrhizae, the number of ericoid fungal species per root tip, or ericoid community composition, and observed mixed effects on ericoid species richness. [Dean et al. \(2014\)](#)

studied the response of root-associated fungi in alpine tundra in Colorado to 8 years of N additions (29 kg N/ha/yr). Ericoid fungi abundance decreased and the overall community composition of root-associated fungi changed, including a reduction in diversity and richness. Further research is needed to understand the response of ericoid mycorrhizae to added N.

Although [Bouskill et al. \(2014\)](#) observed that N additions increased fungal biomass in a meta-analysis of high-latitude N addition experiments, other studies of fungal biomass in tundra ecosystems have found negative ([Xiong et al., 2016](#); [Farrer et al., 2013](#); [Wardle et al., 2013](#)) or neutral responses ([Sundqvist et al., 2014](#)). [Bouskill et al. \(2014\)](#) did not find a significant effect of added N on total microbial biomass in their meta-analysis, with individual studies reporting a negative effect ([Farrer et al., 2015](#)), positive effect ([Xiong et al., 2016](#); [Zong et al., 2016](#)), or no effect ([Zong et al., 2016](#); [Churchland et al., 2010](#)). In a meta-analysis, [Treseder \(2008\)](#) found that N additions decreased bacterial biomass in tundra ecosystems, but this analysis included only two studies. Of the four subsequent studies of bacterial biomass, N additions had no effect in two, a positive effect in one, and a negative effect in a fourth ([Table 6-9](#)). Notably, [Bouskill et al. \(2014\)](#) observed that microbial biomass responses were positive under relatively low rates of N addition, but became negative as N addition rates exceeded ~50 kg N/ha/yr. Belowground respiration showed a similar response, but lower threshold (~25 kg N/ha/yr) at which the response switched from positive to negative.

To examine the influence of added N on organisms at higher trophic levels, [Bishop et al. \(2010\)](#) studied the effects of N additions (78 kg N/ha/yr for 5 years) on plant and arthropod communities in alpine meadows that were primary successional ecosystems on recently formed volcanic substrates on Mount St. Helens in Washington. The N additions increased foliar N concentration in the dominant graminoid but decreased foliar N concentration in the dominant legume. The N additions also increased both plant species diversity and plant cover, although in the final year of the experiment, increased browsing by small mammals negated the effect of the N additions. There was no effect on total arthropod abundance (individuals per m<sup>2</sup>), but the number of Orthoptera approximately doubled. Overall, total arthropod abundance was strongly positively related to both plant diversity and plant cover, with arthropod abundance among individual orders both positively and negatively related to plant diversity and plant cover.

## 6.2.5 Grasslands

The 2008 ISA contained limited information regarding the effects of N deposition on productivity and related aspects of eutrophication in grasslands. That assessment included the work of ([Neff et al., 2002](#)), who examined the long-term effects (+10 years) of N deposition (10 kg N/ha/yr) in an alpine meadow, where N additions stimulated aboveground NPP by 47%. Factors affecting productivity in grasslands are similar in many ways to forests, with N availability limiting primary production. Grasslands dominate largely in places where forests cannot grow because of low moisture availability, high disturbance rates (such as from fire or grazing), and/or cold temperatures and shorter growing seasons [such as at high latitudes and elevations; [Chapin et al. \(2002\)](#); [Knapp et al. \(1998\)](#)]. However, because of the commonality of N limitation to primary production ([Vitousek and Howarth, 1991](#)), many of the processes that occur when N is added to forests also occur when N is deposited onto grasslands. These include increases in primary production and foliar N, increases in allocation to aboveground biomass (increased shoot:root ratio), decreased levels of light reaching the ground surface, elevated litter inputs, and changes in the soil biota ([Aerts and Chapin, 1999](#); [Knapp et al., 1998](#)), which are described further below.

Since the 2008 ISA, further advancements in our understanding of the effects of N deposition on grasslands have occurred. A meta-analysis estimated that N additions increased grassland aboveground NPP by 53% ([LeBauer and Treseder, 2008](#)). Increased plant growth, NPP, or plant biomass in response to added N has been observed in prairies in Wyoming, Kansas, and Minnesota ([Henry et al., 2015](#); [Farrior et al., 2013](#); [Isbell et al., 2013a](#); [Hillerislambers et al., 2009](#); [Johnson et al., 2008](#)), in temperate grasslands in Ontario ([Vankoughnett and Henry, 2014](#); [Hutchison and Henry, 2010](#)) and Michigan ([Grman and Robinson, 2013](#)), in Mediterranean grasslands in California ([Tulloss and Cadenasso, 2016](#); [Borer et al., 2014](#); [Vallano et al., 2012](#)), and steppe grasslands of China ([Li et al., 2017a](#)). Although the response to N enrichment is variable among species in many terrestrial ecosystems, the comparatively rapid turnover rate of plant biomass in grasslands means that wide differences in the response of individual species to N deposition are frequently observed even in short-term studies ([Tulloss and Cadenasso, 2016](#); [Hautier et al., 2014](#); [Vankoughnett and Henry, 2014](#); [Grman and Robinson, 2013](#); [Isbell et al., 2013a](#); [Bradford et al., 2012](#); [Vallano et al., 2012](#); [Skogen et al., 2011](#)). Three new syntheses of grassland responses to N additions or N deposition have been published since the 2008 ISA. [Stevens et al. \(2015\)](#) used data from a network of 42 grassland sites on four continents and found that estimated rates of atmospheric N deposition were the strongest predictor of aboveground NPP in these ecosystems. On average, aboveground

NPP increased 3% for every 1 kg N/ha/yr increase in N deposition, and N deposition explained 16% of the variance in productivity in these systems ([Stevens et al., 2015](#)), implying that much of the variation in NPP was not understood. [Yue et al. \(2016\)](#) conducted a meta-analysis of N addition studies and found a 50.4% stimulation of grassland aboveground NPP, similar to the estimate of [LeBauer and Treseder \(2008\)](#). Aboveground plant C was stimulated by an average of 30.5% in the [Yue et al. \(2016\)](#) analysis.

The belowground productivity responses to N appear to be more mixed. [Yue et al. \(2016\)](#) found a 28% increase in belowground plant C; whereas [Li et al. \(2015\)](#) did not observe a significant change in grassland fine root biomass. Belowground net primary productivity in an experimental grassland declined with N additions when summed over a 9-year period, along with the ratio of belowground-to-aboveground net primary productivity ([Xu et al., 2017b](#)). In a controlled pot experiment, [Wang et al. \(2017b\)](#) found that both fine root production and turnover rates increased in a temperate grass species (*Bothriochloa ischaemum*) with N additions. The net result was lower standing root biomass.

The differences in how individual plant species respond to added N may in part be due to variation in functional traits, including the ability to change plant C allocation. In a common garden experiment, [Johnson et al. \(2008\)](#) grew plants that were among the most positively and negatively responsive to long-term N additions at the Cedar Creek and Konza Prairie LTER sites. The plants that were most positively affected by N additions allocated more biomass to shoots than roots and formed fewer associations with mycorrhizal fungi. Likewise, [Grman and Robinson \(2013\)](#) also found that N additions increased aboveground biomass and decreased the relative allocation of C to mycorrhizae. Of the two grass species studied, the species that more strongly decreased allocation to mycorrhizae as N availability increased also showed a greater aboveground biomass response to added N. [Bradford et al. \(2012\)](#) documented a somewhat different functional response, finding that increasing rates of N additions favored the species that showed greater leaf trait plasticity in response to the N additions. Earlier studies suggested leaf plasticity was an important determinant of plant growth responses to added N, and that the ability of a species to upregulate production if nutrients were abundant was an advantage ([Knops and Reinhart, 2000](#)). [Hillerislambers et al. \(2009\)](#) observed that N amendments (40 kg N/ha/yr) had similar effects on grasses within the same functional groups: C3 grasses tended to increase aboveground biomass and decrease seed production, while C4 grasses increased seed production and decreased aboveground biomass. In a survey of 44 species in 153 acidic grassland sites across northern and western Europe, [Pannek et al. \(2015\)](#) found that species with high relative growth rates tended to show beneficial responses to N deposition.

In multiyear studies, responses to N enrichment often varied through time. For instance, over a 7-year period of N addition, [Henry et al. \(2015\)](#) found that the stimulation of aboveground biomass ranged approximately 10 to nearly 100%. Working at a long-term biodiversity and N deposition experiment at Cedar Creek in Minnesota that used seven different N addition rates from 10 to 270 kg N/ha/yr, [Isbell et al. \(2013a\)](#) initially observed that N additions increased grassland productivity, with higher rates of N addition causing greater increases in productivity. Although N additions continued to stimulate productivity, productivity decreased in plots that lost the most species over time. In a large synthesis, [Hautier et al. \(2014\)](#) used data from studies of 41 experimental grassland communities on 5 continents and found grassland communities had greater annual variability in plant productivity (less stability) as the N input rate increased. Under ambient conditions, annual variability in plant productivity is limited by asynchronous productivity among different species, wherein slower growth by some species is balanced by more rapid growth of neighboring species. In these unmanipulated systems, the stability of plant productivity is positively associated with plant diversity ([Hautier et al., 2014](#); [Tilman et al., 2001](#); [Tilman et al., 1997](#)). With added N, the increase in annual variability in productivity could not be linked to a loss of species richness but was instead caused by a decrease in the asynchrony of productivity among individual plant species. In a more recent experiment in China, [Zhang et al. \(2016a\)](#) observed that N additions (10–500 kg N/ha/yr for 6 years) created a series of changes: decreased plant species richness, decreased asynchrony among plant species, increased aboveground productivity, and decreased stability (more annual variability) in aboveground productivity.

Nitrogen enrichment can also cause variation in plant chemistry, particularly increases in tissue N concentrations ([Lu et al., 2017](#); [Reich et al., 2003](#)). [Bradford et al. \(2012\)](#) conducted a greenhouse experiment with several grass and forb species and observed increases in shoot N concentrations, but root C:N and root mass N were not consistently affected by N additions. In a greenhouse experiment conducted by [Jamieson et al. \(2012\)](#), N addition had no effect on the concentration of a defensive compound in shoots, whereas concentrations decreased in flowers by ~35%. As in other terrestrial ecosystems, these increases in shoot N concentrations can lead to an increase in leaf-level photosynthesis if other resources are not limiting [e.g., [Lee et al. \(2001\)](#); [Reich et al. \(2003\)](#)]. However, such increases in photosynthesis vary among species and can vary temporally ([Reich et al., 2003](#); [Lee et al., 2001](#)). Within a U.K. grassland exposed to N additions of 35 or 140 kg N/ha/yr for 11 years, [Arróniz-Crespo et al. \(2008\)](#) observed decreases in cover of two bryophyte species as well as a decrease in chlorophyll fluorescence in both species (despite an increase in chlorophyll content in one species). Both bryophyte species exhibited increased activity of an enzyme involved in P acquisition (phosphomonoesterase) and decreased nitrate reductase enzyme activity, but

only one of the two bryophyte species exhibited increased tissue N concentrations and N:P ratios.

Several experiments in Ontario, Canada have examined the response of old field grasslands to the interaction between N additions and climate change in the form of altered snowpack, soil freezing, or warming. [Vankoughnett and Henry \(2014\)](#) found that N additions of 20 or 60 kg N/ha/yr increased aboveground production, but this increase varied by species. In the first year of the experiment, plant production showed a stronger response to N in plots where snow had been experimentally removed, but this interaction did not occur in subsequent years. Although the extent of the effect varied by year, [Henry et al. \(2015\)](#) found that 7 years of N additions at a rate of 60 kg N/ha/yr increased aboveground biomass and showed no interaction with experimental warming.

Effects of water availability were also observed in grassland studies by [Friedrich et al. \(2012\)](#), [Jamieson et al. \(2013\)](#), and [Farrior et al. \(2013\)](#). In a greenhouse experiment with a grass native to German grasslands, [Friedrich et al. \(2012\)](#) found that N additions of 48 kg N/ha/yr increased aboveground biomass by 500%. However, plants receiving N were more likely to suffer dieback when N additions were combined with drought. Nitrogen enrichment in a Wyoming prairie increased the production of a defensive chemical compound in an invasive plant by 37% under ambient conditions, but decreased the production of this compound by 25% when water availability was reduced ([Jamieson et al., 2013](#)). At Cedar Creek in Minnesota, [Farrior et al. \(2013\)](#) found complex responses to changes in N and water availability: N enrichment increased shoot biomass regardless of water availability, fine root biomass declined when availability of both water and N was high, and higher water availability increased fine root biomass only at low rates of N addition.

There has been less research on the effects on N enrichment on belowground C cycling in grasslands than in forests ([Yue et al., 2016](#); [Li et al., 2015](#); [Liu and Greaver, 2010](#)). In a meta-analysis, [Liu and Greaver \(2010\)](#) found that N additions to grasslands increased aboveground litter inputs, but did not significantly affect soil respiration, microbial respiration, or soil C. In part, the lack of an overall effect on these processes could be due to the combination of high variability among grasslands and the small sample sizes for the meta-analysis, as only approximately six studies were available for the [Liu and Greaver \(2010\)](#) analysis. However, a more recent meta-analysis of N addition experiments by [Yue et al. \(2016\)](#) that had larger sample sizes found somewhat similar results: belowground plant C was stimulated by 24.2%, but there were no significant effects on soil respiration, microbial respiration, litter decomposition rates, or soil organic C. Meta-analyses of changes in microbial biomass have produced inconsistent results: [Yue et al. \(2016\)](#) did not find a significant effect of added N, [Liu and Greaver \(2010\)](#)

found a negative effect, and [Geisseler et al. \(2016\)](#) observed a negative effect only with at least 5 years of N additions.

The conflicting meta-analytic results for changes in grassland soil microbial biomass could be caused by differences in analyses or data sets, or could reflect ecological complexities that require more nuanced understanding, such as the influence of P availability, varying responses among microbial taxa, or measurement techniques ([Johnson et al., 2008](#)). For instance, at Jasper Ridge in the San Francisco Bay area, [Liang et al. \(2015\)](#) did not find any significant changes in fungal lipid biomass caused by N additions (70 kg N/ha/yr), yet did observe changes in the abundance of individual amino sugars that indicated decreases in total microbial biomass and fungal biomass, and increases in bacterial biomass. In measuring the abundance of nitrite-oxidizing bacteria at Jasper Ridge, [Le Roux et al. \(2016\)](#) observed that N additions increased the abundance of *Nitrobacter*, but did not affect *Nitrospira*. In the over 150-year Park Grass Experiment, [Zhalnina et al. \(2015\)](#) observed that NaNO<sub>3</sub> additions had no effect on bacterial and archaeal biomass as assessed by 16S ribosomal RNA abundance, but (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> additions decreased bacterial and archaeal biomass. [Li et al. \(2015\)](#) found no effect of N additions on fine root biomass or mycorrhizal colonization of root tips in a meta-analysis of grassland experiments, but sample sizes were small (four biomass studies, nine mycorrhizal studies).

A number of studies have examined the effects of N additions on mycorrhizal abundance in grasslands ([Table 6-3](#)). Grassland plants predominantly host arbuscular mycorrhizal fungal associations. Like arbuscular mycorrhizal responses observed in forests [e.g., [van Diepen et al. \(2010\)](#)], arbuscular mycorrhizal responses to added N in grasslands have been inconsistent, with a similar number of studies showing no response ([Liang et al., 2015](#); [Chen et al., 2014](#); [Mandyam and Jumpponen, 2008](#)) versus showing a negative effect on colonization or growth [e.g., [Van der Heijden et al. \(2008\)](#); [Johnson et al. \(2008\)](#); [Chen et al. \(2014\)](#)].

Most studies of grassland soil microbial responses to N deposition ([Table 6-10](#)) have focused on free-living soil heterotrophs or mycorrhizal fungi, but [Weese et al. \(2015\)](#) examined the response of N fixing rhizobial bacteria in clover (*Trifolium*) as part of a 22-year chronic N addition (123 kg N/ha/yr as NH<sub>4</sub>NO<sub>3</sub>) experiment in a Michigan grassland. Clover inoculated with rhizobial bacteria from soil or bacterial strains that were collected from the long-term N addition experiment exhibited lower chlorophyll content and decreased plant biomass, including fewer leaves and stolons. These patterns were consistent across all three clover species used in the experiment. Notably, these changes did not result from a shift in the community composition of the rhizobial bacteria, but instead resulted from the evolution of new strains of the bacteria *Rhizobium*

*leguminosarum* that were less symbiotic and less cooperative in the exchange of C for N. A similar change toward less mutualistic interactions in response to N additions have been observed for mycorrhizae in grasslands ([Johnson, 1993](#)). It is unclear whether these evolutionary changes are reversible, and if so, how long this reversion would take ([Weese et al., 2015](#)).

[Zehnder and Hunter \(2008\)](#) performed a plant density manipulation experiment to examine the effect of N deposition on the interaction between a host plant from the southeastern U.S., *Asclepias tuberosa*, and its herbivore, *Aphis nerii*. Added N increased aphid population growth, plant foliar N concentrations, and plant biomass. In southern California coastal grasslands, [Borer et al. \(2014\)](#) observed that N additions (40 or 100 kg N/ha/yr as Ca[NO<sub>3</sub>]<sub>2</sub>) increased plant biomass, but only in the absence of herbivores (pocket gophers, *Thomomys bottae*).

## 6.2.6 Arid and Semiarid Ecosystems

Large portions of the western U.S. are covered by arid and semiarid ecosystems. While many of these ecosystems receive little anthropogenic N deposition compared to the eastern U.S., some areas downwind of agricultural and metropolitan centers receive high levels of atmospheric N deposition ([Fenn et al., 2003b](#)). In addition, the unique nutrient cycling processes in these systems can intensify the influence of N deposition on ecosystem processes ([Homyak et al. \(2014\)](#); see [Appendix 4](#)).

The lack of moisture in arid and semiarid climates changes the nature of how N deposition impacts biological communities in these ecosystems compared to more mesic ecosystems such as tallgrass prairies and forests. First, the strong moisture constraint on productivity limits the influence of increased N availability on plant communities [e.g., [Rao and Allen \(2010\)](#)], with shifts in community composition less likely to occur without sufficient moisture [e.g., [Concilio and Loik \(2013\)](#)]. Second, the lack of strong biological demand for N during periods of moisture limitation, combined with infrequent soil leaching and runoff events, leads to the accumulation of inorganic N in surface soils, intensifying the effects of N deposition on soil N concentrations when moisture is available [e.g., [Homyak et al. \(2014\)](#)]. Broadly, soil base saturation and pH increase as the climate becomes more arid ([Schlesinger, 2005](#)), buffering dryland ecosystems from the acidification-driven losses in biodiversity that are observed along N deposition gradients [e.g., [Simkin et al. \(2016\)](#)]. Finally, the patchy vegetation that often develops in deserts tends to create isolated islands of fertility, wherein nutrients (including N) are concentrated beneath shrub canopies ([Titus et al., 2002](#); [Schlesinger and Pilmanis, 1998](#)). Under these circumstances, anthropogenic N deposition can increase N availability in the interspaces between shrubs, allowing the growth of annual grasses and forbs, which can grow and reproduce during the brief seasonal periods with adequate moisture availability ([Brooks, 2003](#)). In particular, there have been numerous observations from semiarid and arid ecosystems that N deposition can increase the productivity and dominance of invasive grasses [e.g., [Padgett and Allen \(1999\)](#); [Brooks \(2003\)](#); [Fenn et al. \(2003a\)](#)]. This phenomenon provides a more continuous fuel bed for wildfires, increasing the potential for fire ([Rao et al., 2010](#)) and shifting plant community composition away from species that are not fire adapted ([Padgett and Allen, 1999](#); [Allen et al., 1998](#)).

There was already a large amount of information available on how N deposition impacted arid and semiarid ecosystems at the time of the 2008 ISA, especially in areas around southern California downwind of Los Angeles, where dry N deposition can be >30 kg N/ha/yr ([Bytnerowicz and Fenn, 1996](#)). In particular, the 2008 ISA described results from several N deposition studies in this region that showed increased biomass of

invasive species, high mortality of native shrubs in heavily polluted areas, and increased fire risk ([Padgett and Allen, 1999](#); [Allen et al., 1998](#)). These experiments were primarily conducted in coastal sage scrub (CSS) ecosystems or in the Mojave Desert.

The amount of land area covered by CSS in southern California has greatly declined in the past 60 years due to changes in land use, grazing, and increased wildfire frequency ([Allen et al., 1998](#)). In addition, native CSS vegetation has been replaced in many areas by annual grasses from the Mediterranean region ([Padgett et al., 1999](#); [Padgett and Allen, 1999](#); [Allen et al., 1998](#)). In the mid-1990s, N deposition had been implicated as a contributor to this ecosystem alteration because it decreased the growth of native shrubs and increased the growth of invasive grasses, with the secondary effect of increasing fire frequency ([Padgett et al., 1999](#); [Padgett and Allen, 1999](#); [Allen et al., 1998](#)). There was also evidence that the N assisted conversion from CSS to invasive annual grasses had altered the hydrology of these ecosystems ([Wood et al., 2006](#)). The loss of native vegetation in the CSS and chaparral ecosystems in southern California is particularly notable because these ecosystems are unique within the U.S., are limited in their spatial extent, and are important global and national hotspots for biodiversity.

At the time of the 2008 ISA, similar effects of N deposition on plant communities had also been observed farther east in the Mojave Desert. [Brooks \(2003\)](#) documented that  $\text{NH}_4\text{NO}_3$  additions (32 kg N/ha/yr) increased the biomass of invasive annual grasses and forbs by more than 50%. The increased growth of the invasive plants suppressed the growth of native annual plants. In particular, N additions stimulated the growth of *Bromus madritensis* beneath the dominant native shrub *Larrea tridentata*, while the invasive grasses in the genus *Schismus* and the invasive forb *Erodium cicutarium* had enhanced growth in the interspaces between shrubs. This spatial nature of these effects is important because as in the CSS, the spatially continuous fuel beds created by high grass biomass have been associated with increased fire frequency in the Mojave Desert ([Brooks et al., 2004](#); [Brooks and Esque, 2002](#); [Brooks, 1999](#)). This effect is stronger at higher elevation, likely because the higher precipitation stimulates grass productivity. Fire was relatively rare in the Mojave Desert until the 1980s ([Syphard et al., 2017](#)), but now fire occurs frequently in areas that have experienced invasion of exotic grasses ([Brooks, 1999](#)). The comparatively unresponsive nature of native Mojave vegetation to N deposition was also observed elsewhere. For instance, 3 years of N additions [40 kg N/ha/yr as  $\text{Ca}(\text{NO}_3)_2$ ] had almost no impact on leaf-level photosynthetic or hydraulic performance in *Larrea tridentata* growing north of Las Vegas, NV ([Barker et al., 2006](#)).

At the time of the 2008 ISA, N deposition effects on belowground processes in arid and semiarid lands were not well understood. In a Chihuahuan Desert grassland in New

Mexico, 10 years of N additions (10 kg N/ha/yr) increased the activity of extracellular glucosidase enzymes important in the breakdown of carbohydrates, but decreased the activity of extracellular aminopeptidase enzymes important in the decomposition of proteins and peptides ([Stursova et al., 2006](#)). In contrast, there were no differences in C mineralization (decomposition) in soils collected at a similar southern California gradient of CSS sites [4 to 23 kg N/ha/yr; [Vourlitis and Zorba \(2007\)](#)]. Along a CSS N deposition gradient in the Los Angeles area, arbuscular mycorrhizal fungi associated with the dominant sagebrush shrub declined with increasing N pollution and also in response to N additions (60 kg N/ha/yr; 4–5 years) at a relatively unpolluted site ([Sigüenza et al., 2006](#)). Evidence is conflicting about whether these changes in mycorrhizal colonization influenced the plant growth response to N deposition. An earlier study suggested that differences in mycorrhizal colonization were not responsible for the effects of N deposition on CSS plant growth in this region ([Yoshida and Allen, 2001](#)). [Sigüenza et al. \(2006\)](#) found that sagebrush inoculated with arbuscular mycorrhizae from a high N deposition site grew more slowly than those with inoculum from a low N deposition site. Grasses in semiarid ecosystems in New Mexico and Colorado grew slower when inoculated with mycorrhizae from sites that had received N additions than from sites without N additions ([Corkidi et al., 2002](#)).

Research published since 2008 has continued to concentrate on CSS and Mojave Desert ecosystems in the southern California, but new studies in southern California chaparral ecosystems, the Sonoran Desert of Arizona, and elsewhere have also been published. Most studies investigating the effects of N deposition in arid and semiarid environments published since the 2008 ISA have further emphasized that the impacts of increased N are heavily dependent on water availability ([Valliere and Allen, 2016a](#); [Rao et al., 2015](#); [Homyak et al., 2014](#); [Newingham et al., 2012](#); [Ochoa-Hueso and Manrique, 2010](#); [Rao and Allen, 2010](#)). The high dependence on precipitation is consistent with ecosystem models for C cycling in desert systems ([Shen et al., 2008](#)).

For instance, [Rao and Allen \(2010\)](#) investigated how productivity in Joshua Tree National Park annuals is altered by increasing N supply under a range of water availabilities ([Table 6-11](#)). Using a 5-year field N addition experiment and N additions of up to 30 kg N/ha/yr, the authors observed the greatest production of invasive grasses and native forbs under the highest soil N and highest watering regime. Similarly, [Newingham et al. \(2012\)](#) found that N additions of 10 or 40 kg N/ha/yr as  $\text{Ca}(\text{NO}_3)_2$  in the Mojave Desert increased branch production in creosote (*Larrea tridentata*) only during a wet year, whereas the addition of water and N significantly increased the amount of rodent herbivory.

ha = hectare; kg = kilogram; N = nitrogen; n/a = not applicable; NP = national park; P = phosphorus; yr = year.

Notes: single studies are reported more than once if multiple endpoints or ecosystems were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

A similar interaction between N and water was found in the Sonoran Desert. Herbaceous annual biomass increased with added N (60 kg N/ha/yr) during above-normal rainfall seasons, but not in low precipitation years ([Hall et al., 2011](#)). In contrast, no increases in productivity were observed in the dominant shrub *Larrea tridentata*, even during above-normal rainfall ([Hall et al., 2011](#)). Ecosystem modeling for this same study system, however, conducted by [Shen et al. \(2008\)](#) suggested observed rates of N deposition in the Phoenix region would increase *Larrea* productivity by more than an order of magnitude in wet years. Mosses in this region also appear to be influenced by N deposition, with lower moss abundance and higher tissue N concentrations at urban study sites that receive higher N deposition ([Ball and Guevara, 2015](#)).

As in other terrestrial ecosystems (see [Appendix 6.2.2](#), [Appendix 6.2.3.1](#)), increases in foliar N concentrations in ecosystems receiving chronic N additions are not necessarily associated with changes in leaf physiological function in semiarid plants. With the exception of the N fixing *Ceanothus*, shrubs in a chaparral ecosystem and a CSS ecosystem in southern California increased foliar N concentrations in response to long-term N additions (50 kg N/ha/yr for 10 years), but none of the four shrub species (*Artemisia californica*, *Salvia mellifera*, *Adenostoma fasciculatum*, *Ceanothus greggii*) increased leaf-level photosynthesis ([Pivovarov et al., 2016](#)). Several species in this study had higher dry season predawn water potential, indicating relative improvements in water availability. However, wet season water potential (predawn and midday) were unresponsive to N additions and only *Artemisia* exhibited changes in plant hydraulic function (increased stomatal conductance and sapwood conductivity and decreased wood density) that would indicate the shrubs were benefitting from greater water availability. In contrast, *Adenostoma* wood xylem became more prone to cavitation ([Pivovarov et al., 2016](#)). The limited aboveground physiological responses of the dominant shrubs in these ecosystems is consistent with the idea that other resources (e.g., water) are often more limiting to plant productivity than N in arid and semiarid ecosystems.

Other studies document the overall effect of N deposition on vegetation communities, including the occurrence of fire. At Joshua Tree National Park in the Mojave desert of California, non-native grass biomass increased significantly at three of the four study sites receiving 30 kg N/ha/yr for 2 years, but saw no change with 5 kg N/ha/yr of added N ([Allen et al., 2009](#)). Native species showed no clear response to N addition, but these plants made up a small fraction of community biomass. [Rao et al. \(2015\)](#) tried to model the effects of N deposition on the biomass of invasive annual grasses and the occurrence of wildfire in the Mojave Desert of California but were unable to effectively disentangle the effects of N deposition on fire from factors such as precipitation, distance from roads, and firefighting resources. However, in an earlier modeling study of Mojave Desert vegetation, [Rao et al. \(2010\)](#) did conclude that increases in precipitation and N deposition

raise fire risks by stimulating greater vegetation biomass, and thus fuel loads. In a study covering California deserts stretching from the Mexican border into the Great Basin, the stimulatory effect of N deposition on the growth of annual grasses was one of the largest contributors to the occurrence of large fires (>20 ha) across four semiarid ecoregions, including the Mojave Desert ([Syphard et al., 2017](#)). Additionally, [Wissinger et al. \(2014\)](#) observed higher seed production in areas of the Mojave with higher atmospheric N deposition (up to 16 kg N/ha/yr).

In arid ecosystems with low vascular plant cover, soil crusts with photoautotrophs such as cyanobacteria, green algae, bryophytes, and lichens can be important ecosystem components and large contributors to biogeochemical cycles. In the Mojave Desert, [Stark et al. \(2011\)](#) investigated the effects of 10 or 40 kg N/ha/yr N addition on the dominant biological soil-crust moss (*Syntrichia caninervis*) for a period of 5 years. Interestingly, the lower rate of N application had negative effects on the amount dead chlorotic tissue in shoots and crust regeneration, while higher rates of N addition only negatively impacted apical meristem growth. In Spain, the abundance of most pigments associated with cyanobacteria and green algae in soil crusts within Mediterranean ecosystems did not significantly vary with N deposition along a gradient, but the cyanobacterial pigment echinenone was negatively correlated with N deposition [4.3–7.3 kg N/ha/yr; [Ochoa-Hueso et al. \(2016\)](#)]. In China, [Zhou et al. \(2016\)](#) observed that high N addition rates (50 kg N/ha/yr for 4 years) decreased total chlorophyll and chlorophyll *b* content in soil crusts dominated by cyanobacteria. Lower N addition rates (3–15 kg N/ha/yr), however, did not affect cyanobacteria chlorophyll, and lichen chlorophyll was unaffected by the N addition treatments. Cyanobacteria soluble sugar concentrations, an osmolyte produced as a response to stress, increased at the second highest N dose, but other osmolytes (proline, soluble protein) and lichens were unaffected ([Zhou et al., 2016](#)).

There are very few field studies of how N enrichment impacts belowground C cycling in arid systems ([Liu and Greaver, 2010](#)). In a meta-analysis of these studies, [Liu and Greaver \(2010\)](#) found no consistent effect of N enrichment on soil respiration. [Verburg et al. \(2013\)](#) quantified the effects of increased summer precipitation and N deposition on fine root dynamics in a Mojave Desert ecosystem during a 2-year field experiment. Increased summer precipitation and 40 kg N/ha/yr N additions did not have an overall significant effect on any of the measured root parameters. Within the Sonoran Desert near Phoenix, [Marusenko et al. \(2015\)](#) observed that N additions (60 kg N/ha/yr for 8 years) increased the abundance of the *amoA* gene, which is needed for ammonia oxidation, in both archaea and bacteria. There was no increase in ammonia-oxidizing bacteria or archaea along a narrow N deposition gradient (4.3–7.3 kg N/ha/yr) in Mediterranean shrublands and grasslands in Spain, and overall bacterial abundance was negatively related to N deposition ([Ochoa-Hueso et al., 2016](#)). [Sinsabaugh et al. \(2015\)](#) conducted a

meta-analysis of soil microbial responses to N additions (5 to 560 kg N/ha/yr; 0.3 to 10 years) in arid ecosystems and identified only 8 studies of various microbial biomass responses and 10 studies of various microbial metabolic responses. Broadly, both metrics increased with the addition of low amounts of N, but responses became negative once threshold N addition rates (kg N/ha/yr: 88 for biomass, 70 for metabolism) or cumulative loads (kg N/ha: 159 for biomass, 114 for metabolism) had been reached.

In a greenhouse study with California sagebrush (*Artemisia californica*) seedlings, [Valliere and Allen \(2016a\)](#) observed that the effects of added N on root colonization by arbuscular mycorrhizal fungi depended both on whether the soil inoculum came from a high or low N deposition site and whether the seedlings were stressed by drought; root colonization was generally lower with soil inoculum from the high N deposition site, except when N was added under well-watered conditions. Notably, the same was also true for root colonization by nonmycorrhizal fungi ([Valliere and Allen, 2016a](#)). A related greenhouse study grew a non-native grass and two non-native forbs from CSS ecosystems in two trials using either sterile soils or soil inoculated from plots receiving N additions or control plots ([Valliere and Allen, 2016b](#)). This study found that N additions (57 kg N/ha/yr) had no effect on arbuscular mycorrhizal root colonization in one forb (*Hirschfeldia incana*), increased arbuscular mycorrhizal colonization in only the second trial for the other forb (*Centaurea melitensis*), and increased arbuscular mycorrhizal colonization in the second trial for the grass (*Bromus diandrus*) when it was inoculated with soil from N addition plots ([Valliere and Allen, 2016b](#)). Although there were differences in mycorrhizal colonization between the species and soil types, no direct link was observed between colonization and the plant growth response to added N; while not always significant, added N increased aboveground biomass in all plants and in all soil types. The effect of added N was larger in the second trial and in inoculated soils, but there was little difference in aboveground growth of the non-native plants between the N addition inoculum and the control soil inoculum ([Valliere and Allen, 2016b](#)). However, [Valliere and Allen \(2016a\)](#) only observed positive sagebrush seedling growth responses to added N in soils with high N deposition site inoculum, whereas sterile and low N deposition inoculum were unresponsive to added N. Thus, evidence is still mixed that soil microbial communities at sites that have experienced N additions can themselves change the growth response of plants to added N in arid and semiarid ecosystems.

[Vourlitis \(2012\)](#) measured the aboveground biomass and litter production of a post-fire chaparral and a mature CSS stand in southern California over an 8-year period. Nitrogen additions decreased NPP in the chaparral during the first 3 years of the study, but these additions increased NPP during the last 3 years of the experiment. In the CSS, the effect of added N positively correlated with precipitation and was only significant in the high rainfall years. The authors suggested N enrichment (50 kg N/ha/yr) may increase the

productivity, but temporal patterns may take years to emerge and be dependent on water availability. In contrast, shorter experiments conducted by [Vourlitis and Fernandez \(2012\)](#) and [Vourlitis et al. \(2009\)](#) in chaparral and CSS ecosystems in southern California found 4 years of dry season N addition at 50 kg N/ha/yr increased litter N and plant tissue, but had no effect on ecosystem productivity or ecosystem N storage. Another study using the same N deposition gradient in the CSS as [Padgett and Allen \(1999\)](#) found lower soil C content at high deposition sites ([Liu and Crowley, 2009](#)). Further, experimental N additions [50 kg N/ha/yr as Ca(NO<sub>3</sub>)<sub>2</sub>] decreased soil C content at the low deposition site. However, there were no clear changes in microbial community composition along the deposition gradient or as a result of the N additions.

A study by [Vourlitis and Pasquini \(2008\)](#) analyzed pre- and post-fire nutrient and soil dynamics of three southern California chaparral stands exposed to varying levels of N deposition and determined that periodic fire may not reduce N enrichment from decades of N deposition. In a subsequent study, ([Pasquini and Vourlitis, 2010](#)) exposed chaparral stands to different levels of N deposition over the first 3 years of post-fire succession. High N deposition was associated with a lower relative abundance of *A. fasciculatum* and a higher relative abundance of other shrub and herbaceous species. However, overall aboveground net productivity was not related to N deposition.

Numerous studies were also conducted on dryland ecosystems outside of the U.S., including in China. Many of these Chinese N addition experiments have been conducted in semiarid steppe ecosystems, particularly within the Inner Mongolia region. In these experiments, N additions increased plant productivity ([Zeng et al., 2016](#); [Zhang et al., 2015d](#); [Li et al., 2014](#); [Sun et al., 2014](#)), with a larger stimulation of aboveground growth than belowground growth ([Wang et al., 2015a](#); [Zhang et al., 2015d](#); [Li et al., 2014](#)). In one of these experiments, 4 years of N additions (50 kg N/ha/yr as urea) increased NEE (+53.8%), ER (+47.6%), and GEP (+47.9%) in the last 3 years of the experiment ([Wang et al., 2015a](#)). The N additions increased foliar N concentrations ([Zeng et al., 2016](#); [Zhang et al., 2015a](#)), but [Zhang et al. \(2015a\)](#) also observed that the N additions decreased the amount of N resorbed during leaf senescence in seven perennial grass, sedge, and shrub species. Effects on microbial biomass in these Chinese N addition experiments have been both positive ([Shi et al., 2016b](#); [Sun et al., 2014](#)) and negative ([Li et al., 2016a](#)).

[Huang et al. \(2015\)](#) conducted a 3-year N × water experiment focused on soil microbial community composition and function in a desert steppe ecosystem in northwestern China that receives 25 kg N/ha/yr of ambient deposition. The N addition treatment (50 kg N/ha/yr as NH<sub>4</sub>NO<sub>3</sub>) did not have consistent effects, increasing microbial respiration in the spaces between shrubs in the first year, while decreasing microbial

respiration and microbial biomass C beneath the shrubs in the abnormally dry second year. The N addition effects differed between inter-plant spaces and beneath shrub sites. In the inter-plant spaces, N additions tended to increase overall microbial abundance, with significant increases in bacteria and total microbial PLFA biomass in all 3 years and an increase in actinobacteria in the last 2 years of the experiment. Beneath the shrubs, N additions decreased bacterial biomass, fungal biomass, and total PLFA in 2 years and decreased actinobacterial biomass in all 3 years ([Table 6-12](#)).

[Zhang et al. \(2015e\)](#) studied how N added (eight levels from 10 to 500 kg N/ha/yr as  $\text{NH}_4\text{NO}_3$ ) frequently (12 doses/yr) or infrequently (2 doses/yr) over 5 years influenced plant productivity in a steppe grassland in the Inner Mongolia region of China. The higher doses of N increased aboveground NPP regardless of how frequently the N was added. However, the authors pointed to a group of similar studies that had shown small frequent N doses caused more, less, or similar growth responses relative to large infrequent N doses. As in other semiarid systems, the authors noted greater productivity responses to N in years with higher precipitation. Although the N additions increased ecosystem aboveground NPP, some individual species were less productive with added N ([Zhang et al., 2015e](#)).

In a greenhouse study of plants collected from a semiarid ecosystem in Spain, [Ochoa-Hueso and Manrique \(2010\)](#) found that grass biomass was relatively unresponsive to N enrichment of up to 50 kg N/ha, even when provided with increased water. However, forb biomass and community biomass approximately tripled when both water and N were enriched. In a related field experiment in central Spain, [Ochoa-Hueso and Stevens \(2015\)](#) added N (10, 20, or 50 kg N/ha/yr as  $\text{NH}_4\text{NO}_3$ ) to a semiarid shrubland ecosystem for 6 years. The effects on plant productivity varied by time. After 2.5 years, N additions decreased the biomass of the dominant forb species. After 5.5 years, N additions increased the biomass of plants in the Cruciferae family, but only in areas where sufficient soil P was available. The authors noted that each of the biomass assessments occurred in years with above-average precipitation. In year 4 of the experiment, [Ochoa-Hueso et al. \(2014\)](#) surveyed soil fauna (largely arthropods) and observed that the moderate dose (20 kg N/ha/yr) significantly increased the total abundance of soil fauna (organisms/g of soil), principally by increasing Collembola populations. This increase was not significant at other doses and was attributed to soil acidification. At the highest dose, soil Pauropoda increased ([Ochoa-Hueso et al., 2014](#)).

Elsewhere in Spain, [Taboada et al. \(2016\)](#) conducted a series of experiments to understand how N deposition influenced herbivorous heather beetles (*Lochmaea suturalis*) and their predators (beetles and Arachnids) in a semiarid *Calluna vulgaris* heathland. In food-choice lab experiments, beetle larvae caused significantly greater shoot weight loss in plants that had experienced high N addition rates (20, 50, or 56 kg N/ha/yr) than the low N addition rate (10 kg N/ha/yr) or control, but N addition had no influence on shoot consumption by adult beetles. [Taboada et al. \(2016\)](#) suggested that this was evidence that the larvae could detect differences in tissue N and preferred to feed on high-N shoots. The number of herbaceous heather beetle larvae was greater in plots that had received long-term N additions (56 kg N/ha/yr for 10 years) than in the control or short-term (2 year) N addition plots. In contrast, the number of predaceous Arachnids was unaffected by N additions and the number of predatory beetles was greater in the control plots, particularly in recently burned plots ([Taboada et al., 2016](#)).

---

## 6.3 Relationships between Nitrogen Deposition and Terrestrial Species Composition, Species Richness, and Biodiversity

---

### 6.3.1 Introduction

Given the role of N in biogeochemical cycling ([Appendix 4](#)), soil acidification ([Appendix 5](#)), and the growth and physiology of terrestrial organisms ([Appendix 6.2](#)), it is unsurprising that N availability can influence community composition and biodiversity. In the 2008 ISA, the evidence was sufficient to infer a causal relationship between N deposition on the alteration of terrestrial species composition, richness, and biodiversity. In the 2008 ISA, the most sensitive terrestrial taxa were lichens. Empirical evidence indicated that lichen composition and richness in the U.S. are adversely affected by deposition levels as low as 3 kg N/ha/yr. Alpine ecosystems were also found to be sensitive to N deposition. Changes in individual species were estimated to occur at deposition levels near 4 kg N/ha/yr, and modeling indicated that deposition levels near 10 kg N/ha/yr alter plant community assemblages.

Since 2008, many studies have examined the relationship between N and terrestrial community composition and species richness. The effects of N deposition on diversity have been observed in all major biomes ([Bobbink et al., 2010](#)), and these effects have been particularly well studied in the temperate ecosystems prevalent across much of the U.S. ([Murphy and Romanuk, 2016](#)). Changes in biological communities have been found across a wide range of taxonomic and functional classifications, including trees, shrubs, grasses, forbs, bryophytes, fungi (including mycorrhizae), bacteria, and arthropods. Among these effects, N deposition has been identified as a threat to 12 terrestrial plant or animal species that are listed or candidates for protection under the federal Endangered Species Act ([Hernández et al., 2016](#)).

A number of global, continental, and regional syntheses have compiled information about changes in biodiversity as a result of N deposition. Some of these studies predate the 2008 ISA and served as part of the basis for the conclusions in that assessment [e.g., [Vitousek et al. \(1997\)](#); [Wallenda and Kottke \(1998\)](#); [Gough et al. \(2000\)](#); [Bobbink et al. \(2003\)](#); [Matson et al. \(2002\)](#); [Pennings et al. \(2005\)](#); [Stevens et al. \(2004\)](#); [Suding et al. \(2005\)](#); [Phoenix et al. \(2006\)](#)]. More recent assessments have reinforced the conclusion that N deposition is a major cause of species loss in ecosystems around the world [e.g., [Bobbink et al. \(2010\)](#); [De Schrijver et al. \(2011\)](#); [Pardo et al. \(2011a\)](#); [Phoenix et al. \(2012\)](#); [van Den Berg et al. \(2016\)](#)]. Further, these new assessments have provided a more detailed understanding of both sensitive and heavily impacted species,

ecosystems, and biomes and have created a more precise understanding of the mechanisms linking species loss to N deposition. This new research, combined with information from the 2008 ISA, creates a body of evidence sufficient to infer a causal relationship between N deposition and the alteration of species richness, community composition, and biodiversity in terrestrial ecosystems.

---

### 6.3.2 Mechanisms Operating across Terrestrial Ecosystems

Given the complexities of N effects, it is difficult to develop mechanistic models that can accurately predict shifts in the composition of ecological communities as a result of N deposition. Consequently, assessments of how N deposition alters species diversity, species richness, and changes in community composition predominately rely on experimental manipulations and empirical relationships developed across large spatial and temporal scales [e.g., [Suding et al. \(2005\)](#); [Clark et al. \(2007\)](#); [Verheyen et al. \(2012\)](#); [Simkin et al. \(2016\)](#)].

Much of the ecological theory regarding the loss of species richness with N enrichment has been developed from observations of changes in plant species abundance in grasslands and other nonforest ecosystems [e.g., [Gough et al. \(2000\)](#); [Suding et al. \(2005\)](#); [Pennings et al. \(2005\)](#); [Farrer and Suding \(2016\)](#)]. Many investigators have found a unimodal relationship between plant species richness and aboveground primary productivity, such that there is a negative relationship between productivity and local-scale plant species richness in terrestrial ecosystems that takes effect once an initial threshold for minimum productivity has been reached ([Suding et al., 2005](#); [Gough et al., 2000](#); [Gross et al., 2000](#); [Grime, 1973](#)). In a synthesis of long-term (>4 years) N addition experiments (90–130 kg N/ha/yr) in open-canopy ecosystems (grasslands, tundra, etc.), [Gough et al. \(2000\)](#) found that as the relative stimulation of aboveground primary productivity by N additions increased, there was a greater relative loss of species richness. Thus, there was a direct linkage between the stimulation of productivity by added N and the loss of plant species richness.

Variation among plants in the magnitude of growth responses to added N can have critical and asymmetric effects on community composition because small differences in plant height can cause substantial differences in the amount of light absorbed by plant foliage ([Farrer and Suding, 2016](#)). There are a number of potential causes for the variation in plant response to added N within communities. Two meta-analyses published in 2005 synthesized data from nonforested N addition experiments across North America to understand the role of plant functional traits versus random effects in determining changes in community diversity ([Pennings et al., 2005](#); [Suding et al., 2005](#)). The

random-loss hypothesis of biodiversity decline suggests that rare species are most likely to disappear as increased competition for resources such as light eliminates less successful individuals, whereas the functional trait hypothesis predicts that organisms will become more or less successful when N is added depending upon particular traits. These mechanisms could operate simultaneously ([Suding et al., 2005](#)). In this synthesis, N additions increased primary production and decreased species richness in all terrestrial ecosystems ([Suding et al., 2005](#)). There was also support for random loss of species: the rarest species had a >60% chance of disappearance, while the chance of disappearance for the most abundant species was 10%. This suggests ecosystems with many rare species that experience increases in competition after N additions are especially sensitive to species loss.

There was also support for the functional trait hypothesis: N fixing forbs, species shorter in stature, and perennial plants were more likely to be lost, although there was variation among the sites in which traits made species the most sensitive to N additions. [Pennings et al. \(2005\)](#) took a somewhat different approach by following the fate of 20 individual species across experiments. They noted consistent responses in 10 of the 20 species, but for all but two species, these responses were dependent on the combination of site productivity, species richness, functional traits, and initial abundance ([Pennings et al., 2005](#)). In a related synthesis of these data to understand the environmental and experimental factors associated with the loss of species richness, [Clark et al. \(2007\)](#) observed that several individual factors were almost equally correlated to the loss of species richness, including aboveground plant production ( $r = -0.50$ ), lower soil cation exchange capacity ( $r = 0.48$ ), and length of the experiment ( $r = -0.57$ ). Overall, a full multifactor structural equation model indicated that increased risk of species loss among the study sites was tied to lower average annual minimum temperature, low soil cation exchange capacity, and larger productivity responses to N additions ([Clark et al., 2007](#)). This suggests that high latitude or high elevation ecosystems, those with low cation exchange capacity (often associated with traits such as sandy soils, low pH, low organic matter content, and highly weathered soils), and productivity that is strongly limited to N, would be the most sensitive to plant species loss—traits common in alpine and Arctic tundra, among other ecosystems.

More recently, [De Schrijver et al. \(2011\)](#) conducted a meta-analysis of plant species richness responses in N addition experiments conducted in forests (understory plants only), heathlands, grasslands, tundra, and wetlands. Additions of N increased graminoid biomass, decreased bryophyte biomass, and decreased the biomass of understory plants in forests. The addition of N decreased species richness when analyzed across experiments; within individual ecosystems the effect was only significant in grasslands and heathlands,

while other ecosystems had negative effects but small sample sizes. The loss of species richness increased with higher cumulative N loads.

The alteration of species interaction by added N occurs via several mechanisms. In addition to altered interactions between species within the same trophic level (e.g., competition between plant species), an increased supply of N can change interactions across trophic levels. These trophic shifts can include changes in the plant-fungal symbioses that occur in mycorrhizae ([Appendix 6.2.3.2](#) and [Appendix 6.3.3.3](#)), the photobiont-mycobiont relationships in lichens ([Appendix 6.2.3.3](#) and [Appendix 6.3.7](#)), and more complex changes in food webs that can occur as a consequence of decreases in plant C allocation to belowground processes ([Appendix 6.2.3.2](#)) and chemical changes in the plant tissues and litter that are consumed by herbivores and detritivores ([Appendix 6.2.3.1](#), [Appendix 6.3.3.4](#)). Changes at higher trophic levels can feed back to affect the productivity and diversity of primary producers. For instance, in a greenhouse experiment conducted by [Farrer and Suding \(2016\)](#) using plants and soils from three long-term N addition experiments (prairie, alpine tundra, arid grassland), mesocosms inoculated with microorganisms collected from soils that had received the long-term N additions were significantly more productive and less diverse than mesocosms inoculated by microorganisms from soils that had not received added N; these effects occurred regardless of whether the mesocosms received N additions. [Valliere and Allen \(2016a\)](#) conducted a similar experiment with California sagebrush (*Artemisia californica*) and observed that plant productivity was greater under low N deposition conditions when plants were grown with inoculum from low deposition sites and greater under high N deposition conditions with inoculum from high deposition sites. These types of interactions complicate predictions of species loss from N deposition.

A new analysis by [Simkin et al. \(2016\)](#) has dramatically increased our understanding of how N deposition is altering plant biodiversity in the continental U.S. They gathered data on herbaceous species richness from more than 15,000 study plots in a variety of habitats. N deposition had a strong effect on species richness, but this effect differed between closed canopy and open ecosystems (i.e., forests and nonforest). In nonforested ecosystems (grasslands, deserts, shrublands, subalpine ecosystems), there was a positive relationship between N deposition and herbaceous species richness at low rates of N deposition, then a decrease in species richness with higher rates of N deposition over a threshold of 8.7 kg N/ha/yr. The effect was notably stronger at low pH (i.e., more acidic). In forests, the relationship between N deposition and herbaceous species richness was similar, but more complex. In acidic soils, the relationship was similar to open canopy systems. In neutral or basic soils, the relationship between N deposition and species richness was consistently positive. Overall, these national-scale results are consistent with the relationship between productivity and species richness suggested by ecological theory

[e.g., [Suding et al. \(2005\)](#); [Clark et al. \(2007\)](#)] and provide evidence that vegetation on acidic soils is more susceptible to species loss under elevated N.

There are few direct analyses comparing the impacts of oxidized and reduced forms of N deposition on biodiversity. Because  $\text{NO}_3^-$  tends to be more readily lost to both leaching and denitrification than  $\text{NH}_4^+$  ([Brady and Weil, 1999](#)), it is possible that this form of N is less likely to accumulate in the soil and cause fewer changes in plant and microbial communities. The meta-analyses literature referenced previously ([Table 6-1](#)) tended to find no difference in the effects of individual forms of N on ecological and biogeochemical endpoints, such as plant productivity or microbial biomass. This is suggestive that plant diversity is also not affected, yet a number of individual studies have observed differential effects on diversity of  $\text{NH}_4^+$  versus  $\text{NO}_3^-$  additions [e.g., [Kleijn et al. \(2008\)](#); [Dias et al. \(2014\)](#)]. For example, in a nutrient-poor, Mediterranean site, an  $\text{NH}_4^+$  addition (40 kg N/ha/yr) increased plant richness, while the addition of a half  $\text{NH}_4^+$  and half  $\text{NO}_3^-$  mixture (for a total of 40 kg N/ha/yr also) did not. In the U.K., [van Den Berg et al. \(2016\)](#) observed that once an overall negative effect of N deposition on plant species richness had been accounted for, the  $\text{NH}_x:\text{NO}_y$  ratio decreased species richness in grasslands, but increased species richness in woodlands. By contrast, [Jovan et al. \(2012\)](#) observed that lichen communities in the Los Angeles basin were best predicted by total N deposition (as throughfall) than the deposition or gaseous concentrations of any particular form of N. The national-scale analysis of herbaceous species richness completed by [Simkin et al. \(2016\)](#) only evaluated total N deposition, not individual forms of deposition.

Future effects of N deposition on biodiversity will depend in part on not only N emissions, but also on the rate at which populations and communities respond to increases or decreases in emission rates and the pace at which total cumulative N deposition increases. Compared to the number of N addition studies, there have been relatively few studies of recovery following the cessation of N additions or decreases in N deposition, and nearly all of these have been in Europe ([Stevens, 2016](#)). In a review of these recovery studies, [Stevens \(2016\)](#) found that soil nitrate and ammonium concentrations recovered to levels observed in untreated controls within 1 to 3 years, but that soil processes such as N mineralization and litter decomposition were slower to recover. For instance, differences in decomposition and soil  $\text{N}_2\text{O}$  emissions persisted 4 and 7 years, respectively, after installation of a roof system to decrease atmospheric deposition to European forests ([Borken and Beese, 2002](#); [Boxman et al., 1998b](#)). Although there were observations that plant physiological processes recovered in less than 2 years, grassland plant communities were slower to recover and still differed from controls 11 to 20 years after the cessation of N additions ([Isbell et al., 2013b](#); [Stevens et al., 2012](#)). [Stevens \(2016\)](#) observed a wide range of recovery times for mycorrhizal community composition and abundance, with some recovery observed in as few as

4 years ([Emmett et al., 1998](#)) and differences persisting for as long as 28 or 48 years ([Strengbom et al., 2001](#)). Based on the slow pace at which plant community composition recovered following observed or experimental decreases in deposition elsewhere in Europe, [Stevens et al. \(2016\)](#) predicted that despite future decreases in reactive N emissions, habitat suitability would decline in 2020 and 2030 for a majority of plant species within grasslands, heathlands and bogs, and deciduous forests in Great Britain due to the cumulative effects of N deposition. Plant communities in these ecosystems were predicted to become more eutrophic: favoring grasses, decreasing the abundance of forbs and lichens, and having mixed species-specific effects on bryophytes and other plant groups ([Stevens et al., 2016](#)).

---

### 6.3.3 Forests

---

#### 6.3.3.1 Overstory Trees

The 2008 ISA reported that there was very little information on the effect of N deposition on the biodiversity of overstory trees in the U.S. However, the altered growth rates caused by N enrichment have the potential to affect forest structure and biodiversity. The life span of many trees is 100 years or more; therefore, it is difficult to observe how changes in growth or mortality affect biodiversity within established forests. The 2008 ISA cited evidence for boreal forest encroachment into grasslands under increased N deposition ([Köchy and Wilson, 2001](#)). Since the 2008 ISA, little new direct information is available on the effect of N deposition on the biodiversity of overstory trees in the U.S. or Europe. In subtropical forests in China along a rural to urban N deposition gradient of 30 to 43 kg N/ha/yr across four sites, [Huang et al. \(2012\)](#) found a decrease in tree diversity with increasing N deposition, but there were also differences in management regimes, elevation, and dominant vegetation among the study sites. There is widespread evidence of species-specific effects of N deposition on tree growth and mortality in the U.S. [e.g., [Thomas et al. \(2010\)](#); [Dietze and Moorcroft \(2011\)](#); [Horn et al. \(2018\)](#)]. Further, [Horn et al. \(2018\)](#) concluded that species with positive versus negative responses in growth or survival co-occurred in places in the U.S. This implies overstory tree community composition does shift with N deposition, but this information has not yet been transformed into a quantitative assessment of changes in tree community composition. A broad-scale analysis of changes in overstory community composition as a result of N deposition remains a research need.

---

### 6.3.3.2 Understory Plants

Compared to overstory trees, there was more information available in the 2008 ISA regarding the effects of N deposition on understory plants. A major influence on the 2008 ISA was a review by [Gilliam \(2006\)](#), who identified nine studies on N deposition effects on forest understory plant communities, all within the U.S. and Europe. All of the North American studies cited by [Gilliam \(2006\)](#) were N addition experiments within temperate forests in the northeastern U.S.; two of these studies found no significant changes in community composition ([Gilliam et al., 2006](#); [Gilliam et al., 1994](#)). Notably, research by [Gilliam et al. \(2016b\)](#) has subsequently reported decreases in understory species richness, community evenness, and diversity, and changes in community composition at one of the northeastern temperate forest sites where understory community composition had earlier been unaffected by chronic N additions ([Gilliam et al., 2006](#); [Gilliam et al., 1994](#)). In particular, the change in understory community composition caused by N additions included a large increase in the cover of blackberry (*Rubus* spp.) shrubs ([Gilliam et al., 2016b](#); [Walter et al., 2016](#)), but more broadly included an increase in nitrophilous species and a loss of more N efficient (oligotrophic) species ([Gilliam et al., 2016b](#)). In Sweden, shifts in understory plant community composition were documented along two forest N deposition gradients that ranged from 6 to 20 kg N/ha/yr ([Brunet et al., 1998](#)) and from 3 to 12 kg N/ha/yr ([Strengbom et al., 2001](#)).

Many of the mechanisms through which N additions alter plant community composition and species richness in other terrestrial ecosystems also function in forest understory environments, including shifts in mycorrhizal communities, competitive exclusion, increases in herbivory, and species-specific growth responses to increased N availability ([Gilliam, 2006](#)). However, resource heterogeneity in forests can be especially high, and limited light availability can constrain the effects of competitive exclusion ([Simkin et al., 2016](#)). Since the 2008 ISA, a number of new studies of N addition and ambient deposition effects on understory plant diversity have been conducted in temperate and boreal forests in the U.S. and Europe, as well as in subtropical forests in China ([Table 6-13](#)). In a national-scale analysis of herbaceous species richness, [Simkin et al. \(2016\)](#) found that the effect of N deposition on forest understory species richness was highly dependent on soil pH. At all soil pH values, low rates of N deposition (~5 kg N/ha/yr) had neutral or positive effects on species richness. At a low pH (4.5), species richness declined at N deposition rates >11.6 kg N/ha/yr, but among neutral and basic soils there was no point in the data set at which N deposition had a negative effect on species richness (the analysis included deposition values up to ~20 kg N/ha/yr). In a study that synthesized data from >1,200 forest understory vegetation plots in northern and central Europe, [Verheyen et al. \(2012\)](#) did not find a significant effect of increasing N deposition (8.3 to 35.7 kg N/ha/yr) on species richness. Although understory plant

species richness did not change, community composition shifted significantly away from light-demanding species and toward nutrient-demanding species. [van Dobben and de Vries \(2010\)](#) found a similar result in 366 plots in managed forests throughout western and northern Europe and in a smaller network of 197 plots within the Netherlands: N deposition was not a significant influence on plant species richness or diversity and only a minor influence on community composition via a shift toward more nitrophilic species. Soil, elevation, climate, and overstory tree composition were much more important determinants of community composition at this scale ([van Dobben and de Vries, 2010](#)). In a study of forest understory vegetation plots at 28 sites across Europe, [Dirnböck et al. \(2014\)](#) also found that although understory plant species richness was not affected by N deposition, plant communities became more strongly dominated by both more nutrient-demanding species and more shade-tolerant species as N deposition rates increased beyond identified critical loads.

There is also evidence for shifts in plant communities across local and regional N deposition gradients. In a survey of 260 sessile oak (*Quercus petraea*) forests in Ireland, [Wilkins and Aherne \(2016\)](#) observed that N deposition was negatively correlated with plant species richness and had a significant influence on community composition. Community composition and species richness were also significantly influenced by soil pH (positive effect on species richness) and atmospheric NH<sub>3</sub> concentrations (negative effect). Ten species were positively associated with total N deposition and atmospheric NH<sub>3</sub>, while 10 other species had negative associations with these N variables; each group included shrubs, trees, ferns, and bryophytes ([Wilkins and Aherne, 2016](#)). The authors suggested that focusing on a single forest type allowed them to better isolate the effect of N deposition relative to studies of broader forest communities in Europe ([Wilkins and Aherne, 2016](#)). In a survey of woodlands across the U.K., [van Den Berg et al. \(2016\)](#) observed a negative effect of N deposition on plant species richness. [Huang et al. \(2012\)](#) observed that understory plant species richness was negatively correlated with N deposition along a rural to urban gradient (30 to 40 kg N/ha/yr) of four subtropical forests in China. At a network of 40 sugar maple forest monitoring sites in Ontario, [McDonough and Watmough \(2015\)](#) observed that most of the variability in understory plant community composition could be explained by climate and soil factors, but that N deposition (8 to 12.9 kg N/ha/yr) explained a statistically significant portion of the variability. However, there was no effect on understory species richness over this relatively narrow range of N deposition.

**Table 6-13 Forest plant diversity responses to nitrogen added via atmospheric deposition or experimental treatments.**

ha = hectare; kg = kilogram; N = nitrogen; n/a = not applicable; yr = year.

Notes: Single studies are reported more than once if multiple endpoints were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

Understory plant species richness was also not affected in several N addition studies in temperate forests in the U.S. ([Chapman et al., 2016](#); [Talhelm et al., 2013](#); [Jones and Chapman, 2011](#)). In an oak forest in the Philadelphia, PA area, [Jones and Chapman \(2011\)](#) found that native understory plant diversity and richness were negatively correlated with soil inorganic N, but not significantly impacted by N additions (13 kg N/ha/yr). In a follow up at the same site, [Chapman et al. \(2016\)](#) used higher rates of N additions (100 or 200 kg N/ha/yr as NH<sub>4</sub>NO<sub>3</sub> for 4 years). Changes in total, native, or invasive species cover were not detected, but N additions increased invasive species richness in some years. In Michigan, [Talhelm et al. \(2013\)](#) found that although N additions did not alter understory plant species richness, community composition was altered. Tree sapling communities were apparently more resistant, as neither species richness nor community composition changed in response to N additions ([Talhelm et al., 2013](#)).

The effects of N additions on forest understory plant communities can be long lasting. [Strengbom and Nordin \(2008\)](#) found significant differences in understory plant communities in recently harvested regenerating Swedish forests as a result of two single additions of 150 kg N/ha 22 and 30 years earlier. The forests that received N decades earlier had denser understory vegetation, much less shrub cover, and much more herb and graminoid cover. The abundance of individual species, including ground-dwelling bryophytes and lichens, differed by as much as 20 times due to the N additions ([Strengbom and Nordin, 2008](#)). In a related study, [Hedwall et al. \(2013\)](#) found that the amount of change in understory plant community composition in regenerating forests caused by N additions was negatively correlated with the rate of N deposition along a Swedish deposition gradient of 4.4 to 16.1 kg N/ha/yr. [Wardle et al. \(2016\)](#) observed that 6 years of N additions (100 kg N/ha/yr) decreased species richness and altered community composition in boreal forest understory communities dominated by Ericaceous shrubs and bryophytes.

---

### 6.3.3.3 Microbial Diversity

There is an ongoing debate about how to define a microbial species, so taxonomists often use measures of similarity in genetic material to classify microbial diversity ([Fraser et al., 2009](#)). This can lead to discussion of biodiversity changes in terms of taxonomic community shifts or taxonomic richness. For instance, [Turlapati et al. \(2013\)](#) measured microbial diversity in surface soils at Harvard Forest by clustering operational taxonomic units (OTUs) based on 97% sequence similarity from 16S rRNA pyrosequencing.

Soils contain a high amount of microbial diversity ([Lynch et al., 2012](#)), but this diversity is not evenly distributed among phylogenetic groups. In the Harvard Forest study, [Turlapati et al. \(2013\)](#) observed that 2% of the OTUs contained >50% of the total sequences, while 80% of the OTUs were infrequently observed and contained only about 10% of total sequences. This suggests that many individual soil microbes are either from the same or closely related taxonomic groups, while concomitantly there are a large number of relatively rare taxonomic groups. Reanalyzing these data with a more detailed oligotype sequence clustering approach, [Turlapati et al. \(2015\)](#) found a more even distribution of taxonomic groups, but 2% of oligotypes still represented ~38% of the total number of sequences. In an oligotype analysis of soil fungal communities at the same site, [Morrison et al. \(2016\)](#) observed a similar distribution of fungal populations: the Basidiomycota phylum comprised 63–71% of all sequences, while the Ascomycota phylum averaged 26%, and the ectomycorrhizal genus *Russula* made up 40–50% of all sequences across plots. A shotgun metagenomics assessment of microbial communities in four northern hardwood forests in Michigan documented that taxonomic classification of the metagenomics hits via the RDP databased within MG-RAST were heavily dominated by bacteria (98% of reads), with much smaller contributions of fungi (1%) and archaea [0.03%; [Freedman et al. \(2016\)](#)]. However, annotation databases are biased toward culturable bacteria and there is transcriptomic evidence that metagenomic approaches greatly underrepresent the fungal contribution to soil metabolic function ([Freedman et al., 2016](#)).

Much of the available information about changes in microbial community composition published since 2008 has been about changes in fungal communities, including mycorrhizal species. Of the studies identified for this assessment that quantified the compositional response of forest fungal communities to N additions, one study had site-specific results, but N additions changed community composition in five of the remaining seven studies ([Table 6-14](#)). Among studies of ectomycorrhizal fungi community composition, N caused changes in six out of seven studies, including in four studies along ambient N deposition gradients ([Table 6-15](#)). As with lichens and plants, the sensitivity of ectomycorrhizal fungi appears to vary taxonomically, with these taxonomic differences apparently related to differences in functional traits such as organic N acquisition ([Lilleskov et al., 2011](#)). At Harvard Forest, [Morrison et al. \(2016\)](#) observed that N additions (50 or 150 kg N/ha/yr) decreased the relative abundance of the ectomycorrhizal genus *Cenococcum* and increased the ectomycorrhizal genera *Scleroderma* and *Rhizoscyphus*. *Scleroderma* is thought to be important in organic P acquisition, and *Rhizoscyphus* has proteolytic, cellulolytic, and partial lignin degradation capabilities, but less is known about *Cenococcum*. The overall abundance of the genus *Russula* did not change as a result of N additions, but the *Russula* species (*R. vinacea*)

that was the single most abundant OTU in the data set increased from 10% relative abundance to 28–37% in the N addition plots, while the other *Russula* decreased.

Shifts in ectomycorrhizal composition have also been observed along N depositional gradients. [Kjøller et al. \(2012\)](#) observed changes in the ectomycorrhizal community composition and a loss of ectomycorrhizal species richness across an N deposition gradient in Denmark from 27 to 43 kg N/ha/yr at the edge of a spruce forest. In Scotland, [Jarvis et al. \(2013\)](#) analyzed ectomycorrhizal fungal communities from 15 seminatural Scots pine forests and found changes in abundance of *Cortinarius* spp. at higher N deposition (9.8 kg N/ha/yr). In red spruce-dominated forests in the northeastern U.S., [Lilleskov et al. \(2008\)](#) observed changes in ectomycorrhizal communities over a much lower N deposition gradient, ranging from 2.8 to 7.9 kg N/ha/yr of wet deposition. Nitrogen deposition was positively related to fine root N concentrations, and those root N concentrations had positive relationships with the abundance of three of the ectomycorrhizal fungal morphotypes, negative relationships with three morphotypes, and ambiguous relationships with three other morphotypes. In Scots pine (*Pinus sylvestris*) forests in Germany and the U.K. arrayed along an N deposition gradient ranging from 4.6 to 28.6 kg N/ha/yr, [Cox et al. \(2010\)](#) used DNA extracted from fine roots and group sequences at 97% similarity to assess changes in ectomycorrhizal community composition. Similar to the results in the [Lilleskov et al. \(2008\)](#) study, N deposition was positively correlated to foliar N concentrations and foliar N was linked to shifts in mycorrhizal community structure. In particular, foliar N concentrations were significantly negatively correlated with ectomycorrhizal richness. Of the 35 taxa that occurred widely across the gradient, 11 showed significant responses to increased N availability: 6 taxa increased and 5 taxa decreased with greater N availability ([Cox et al., 2010](#)). Thus, the effects of N deposition on ectomycorrhizal community composition observed by [Lilleskov et al. \(2008\)](#) and [Cox et al. \(2010\)](#) were indirect.

Although shifts in fungal community composition are widely reported, these shifts are not necessarily consistent, even in similar ecosystems. [Allison et al. \(2010\)](#) conducted an N addition experiment in a recently burned boreal forest in Alaska. In that site, the forest microbial community was dominated by fungi in the Ascomycota, and N additions increased their abundance. In contrast, [Allison et al. \(2008\)](#) conducted a similar experiment in a mature boreal forest in Alaska and observed that the microbial community was dominated by Basidiomycota, and N additions did not change the overall abundance of fungi in this phylum. However, in both ecosystems, N additions greatly changed the relative abundance of individual taxa (orders and families) within these phyla ([Allison et al., 2010](#); [Allison et al., 2008](#)). Individual components of microbial communities also appear to react to N additions at different speeds. In a long-term forest N addition in Switzerland, [Gillet et al. \(2010\)](#) observed that both ectomycorrhizal and saprotrophic fungal communities responded to an increase in soil N input, but the ectomycorrhizal community rapidly decreased in species richness, whereas the saprotrophic community was less affected. The response was highly species specific, especially for the saprotrophic community. At Harvard Forest, [Frey et al. \(2004\)](#) found fungal biomass was reduced in fertilized versus control plots, and this was accompanied by a decrease in phenol oxidase activity, an enzyme produced by saprophytic, white-rot fungi to decompose lignin. Among fungal saprotrophs at Harvard Forest, [Morrison et al. \(2016\)](#) found that high rates of N addition (150 kg N/ha/yr for 25 years) decreased the abundance of the saprotrophic basidiomycete genus *Agaricus*, which has lignolytic abilities, and increased the abundance of two saprophytic ascomycete genera (*Hypocrea*, *Phialophora*) that are cellulolytic. These changes in the fungal community at Harvard Forest are consistent with observations elsewhere ([Freedman et al., 2016](#); [Edwards et al., 2011](#)) that N additions can stimulate cellulose decomposition and inhibit fungal decomposition of lignin (see [Appendix 4](#)).

Decreases in taxonomic richness among fungi appear to be less common than changes in community composition. Taxonomic richness is often used as a measure of biodiversity for microbial communities since it can be difficult to define species as noted previously. Only three studies of taxonomic richness in overall fungal communities were identified for this assessment ([Table 6-14](#)). One study saw changes at two of four study sites ([Eisenlord et al., 2013](#)); there was no effect in another study ([Krumins et al., 2009](#)); and [Morrison et al. \(2016\)](#) observed a shift in composition under a very high dose (150 kg N/ha/yr), but not a more moderate dose (50 kg N/ha/yr). Of the 11 identified ectomycorrhizal richness studies, decreases were observed in 6 studies ([Table 6-15](#)).

Compared to ectomycorrhizal fungi, there is also less information about how N additions alter arbuscular mycorrhizal and bacterial community composition ([Table 6-14](#), [Table 6-16](#)). Two studies on arbuscular mycorrhizae were identified, one in Ecuador

([Camenzind et al., 2014](#)) that observed no effect of added N (50 kg N/ha/yr for 3 years) on community composition and another in northern hardwood forests in Michigan where the effect of added N (30 kg N/ha/yr for +12 years) on community composition was dependent on the measurement technique ([van Diepen et al., 2013](#); [van Diepen et al., 2011](#)). At the Harvard Forest long-term N addition study in Massachusetts (50 and 150 kg N/ha/yr), [Turlapati et al. \(2013\)](#) and [Turlapati et al. \(2015\)](#) used molecular techniques to assess changes in bacterial community composition. Using a 97% sequence identity approach to clustering OTUs, [Turlapati et al. \(2013\)](#) found the chronic N additions caused major changes in the bacterial phyla of Acidobacteria, Proteobacteria, and Verrucomicrobia. Using the more detailed oligotype sequence clustering approach, [Turlapati et al. \(2015\)](#) observed five genera that exclusively appeared in N treated soils (*Aquabacterium*, *Nitrosospira*, *Yersinia*, *Legionella*, and *Niabella*) and eight genera that were present only in the control plots (*Comamonas*, *Microbacterium*, *Mycetocola*, *Brochothrix*, *Flavobacterium*, *Pedobacter*, *Sphingobacterium*, and *Terrimonas*). However, the N addition treatments also caused shifts in community structure within most genera. As with [Fierer et al. \(2012\)](#), microbial communities in the mineral soil were less affected by the N additions than communities in the organic soil.

Shifts in microbial community composition can alter ecosystem processes and plant community diversity, in addition to affecting plant productivity as noted previously ([Appendix 6.2.3](#)). Lower microbial diversity has been linked to slower decomposition of plant litter and can affect, for example, ecosystem C and nutrient cycling ([Bardgett and van der Putten, 2014](#); [Handa et al., 2014](#)). In a global scale study, [Delgado-Baquerizo et al. \(2016\)](#) found a positive correlation between microbial diversity and a broad suite of ecosystem services and functions. Mycorrhizal diversity has been shown experimentally to affect plant diversity. For instance, [Van der Heijden et al. \(1998\)](#) concluded that plant species composition fluctuated greatly under low arbuscular mycorrhizal diversity, whereas it increased and exhibited greater stability alongside higher mycorrhizal diversity. Specifically on N effects, [Van der Heijden et al. \(2008\)](#) observed smaller impacts on plant community composition from N additions (100 kg N/ha/yr) when plant mesocosms were inoculated with arbuscular mycorrhizal fungi than in those without fungal inoculum. Plant communities in the inoculated mesocosms had greater evenness among functional groups. Altogether, these studies suggest microbial, including mycorrhizal, diversity have a positive effect on ecosystem processes and plant community diversity. This implies that N induced decreases in microbial diversity may in turn negatively affect these endpoints.

### 6.3.3.4 Arthropod and Other Invertebrate Diversity

Arthropods can be key components of forest productivity and nutrient cycling because they can feed on living plant tissues, plant litter, or on litter-degrading fungi, and arthropod communities can be directly or indirectly altered by changes in plant productivity and chemistry ([Gan et al., 2014](#); [Throop and Lerdau, 2004](#)). Consequently, recent research has quantified the response of arthropods to added N ([Table 6-17](#)). Both before and after the 2008 ISA, Jones and colleagues published a series of studies on how N air pollution altered plant-associated insect communities in mixed conifer forests outside Los Angeles, CA ([Jones et al., 2011](#); [Jones et al., 2008](#); [Jones and Paine, 2006](#); [Jones et al., 2004](#)). [Jones et al. \(2004\)](#) observed significantly higher tree mortality and bark beetle activity at a high versus a low N pollution site. Moreover, experimental N additions at the low pollution site increased mortality and bark beetle activity relative to unfertilized control plots. In contrast, the opposite occurred at the high pollution site, with the control plots exhibiting higher tree mortality and beetle activity. The authors suggested this could be because N deposition already exceeded biological demand at the high pollution site, with additional N no longer increasing tree mortality. [Jones et al. \(2008\)](#) found that insect herbivore communities on California black oak (*Quercus kelloggii*) trees did not change in response to several years of N additions (150 kg N/ha/yr) at a relatively unpolluted and dry site, but were altered by N additions at a wetter site that received more ambient N deposition. [Jones et al. \(2011\)](#) found a similar response for insect herbivore communities associated with bracken fern plants at these sites, with no change in insect taxonomic richness at the dry and low-deposition site and increased richness at the wetter, higher deposition site. Notably, as with plant productivity responses in grassland and arid environments, the effects of added N on insect abundance and diversity appeared to be strongly dependent on climate ([Jones et al., 2011](#)).

[Gan et al. \(2013\)](#) and [Gan et al. \(2014\)](#) quantified changes in the abundance and community composition of soil microarthropods and trophic position of soil-dwelling oribatid mites at the same four northern hardwoods forests in which [Talhelm et al. \(2013\)](#) quantified changes in understory plant composition. The overall abundance of microarthropods declined by approximately 45% in response to N additions, a change that was attributed to changes in soil food webs as a consequence of previously documented decreases in litter decomposition ([Zak et al., 2008](#)), decreases in mycorrhizal productivity ([van Diepen et al., 2010](#)), and shifts in the microbial community composition ([van Diepen et al., 2013](#); [Edwards et al., 2011](#); [van Diepen et al., 2011](#)). More specifically, [Gan et al. \(2013\)](#) observed decreases in two orders of detritivores

(Oribatida, Collembola) and one order of predaceous mites (Mesostigmata), with the largest decline in the oribatid mites. The decrease in oribatid mites did not affect species richness or their trophic position, but did cause a shift in the community composition ([Gan et al., 2014, 2013](#)).

Lastly, in addition to arthropods, other soil invertebrates, such as earthworms or nematodes, can be affected by N additions ([Table 6-17](#)). [Romanowicz and Zak \(2017\)](#), for example, observed that the abundance of middens created by the non-native earthworm species *Lumbricus terrestris* was 363% higher in plots receiving N additions at one of the four sites in the study. Many northern temperate forests in the U.S. have no native earthworms and the spread of these non-native worms can cause decreases in soil C storage, a redistribution of soil C and N as earthworms consume the soil organic horizon, shifts in soil food webs, and changes in understory plant communities ([Bohlen et al., 2004](#)).

### 6.3.4 Alpine and Arctic Tundra

There was consistent and coherent evidence in the 2008 ISA indicating that alpine plant communities are among the terrestrial communities most sensitive to atmospheric N deposition. The previous assessment identified a number of factors that made these ecosystems sensitive to N deposition, including low rates of primary production, short growing seasons, low temperature, and low rates of N mineralization ([Bowman and Fisk, 2001](#); [Bowman and Steltzer, 1998](#); [Fisk et al., 1998](#); [Bowman, 1994](#); [Bowman et al., 1993](#)). Alpine plants are broadly N limited, and increased N inputs have been observed to cause changes in alpine growth and species composition ([Bowman et al., 2006](#); [Bowman and Steltzer, 1998](#); [Vitousek et al., 1997](#)). Alpine plant communities have also developed under conditions of low nutrient supply, in part because soil-forming processes are poorly developed, and this was also thought to contribute to their N sensitivity.

Many of the alpine tundra ecosystems in the U.S. are found in the western U.S., particularly in the Rocky Mountains, Cascade Mountains, and the Sierra Nevada. Atmospheric deposition tends to be low in the western U.S., but alpine sites can be affected by relatively low or moderate levels of N deposition because of their high sensitivity. In several studies, the capacity of Colorado Rocky Mountain alpine catchments to sequester N was exceeded at input levels of 10 kg N/ha/yr or less [e.g., [Baron et al. \(1994\)](#)]. Similarly, relatively low N addition rates can cause shifts in alpine plant communities. [Bowman et al. \(2006\)](#) estimated that changes in the abundance of *Carex rupestris* occurred at deposition rates of 4 kg N/ha/yr and changes in alpine tundra community composition occurred at deposition rates of approximately 10 kg N/ha/yr. In Europe, critical loads for alpine plant communities were estimated to be between 5 and 15 kg N/ha/yr ([Bobbink et al., 2003](#)).

Since 2008, there was further research in the U.S. on the effects of added N on plant communities in Colorado at the Niwot Ridge Long-Term Ecological Research Site and in Rocky Mountain National Park (RMNP), as well as on Mount St. Helens in Washington ([Table 6-18](#)). In RMNP, [Bowman et al. \(2012\)](#) conducted a 4-year study in a dry alpine meadow ecosystem where N was added at rates of 5, 10, and 30 kg N/ha/yr, while ambient N deposition was 4 kg N/ha/yr. No shifts in species richness or diversity were observed in response to the N additions; however, *Carex rupestris* increased in cover from 34 to 125% in response to the treatments ([Bowman et al., 2014](#)). More broadly, as noted in [Appendix 5](#), [McDonnell et al. \(2014a\)](#) used the ForSAFE-VEG model to assess changes in vegetation cover in subalpine ecosystems in RMNP since 1900 and forecast the changes through the end of the 21st century as a result of N deposition and climate change scenarios. Based on the model output, plant community composition changed by

10% over the past 100 years as a result of increases in N deposition, with increases in graminoid species and decreases in forb species. Over the next 100 years, forecasted changes in N deposition and climate factors are predicted to increase tree cover. At Niwot Ridge, two decades of N additions (averaging ~75 kg N/ha/yr) generally decreased plant species richness across a wet-to-dry gradient of alpine meadows, with a significant decrease in the moist meadow type ([Yuan et al., 2016](#)). Plant diversity increased with N additions (78 kg N/ha/yr for 5 years) on Mount St. Helens, but this plant community was growing on very N poor soils formed following the volcanic eruption there in 1980 ([Bishop et al., 2010](#)).

Internationally, plant diversity research has been conducted in Arctic ecosystems in Scandinavia and North Atlantic Europe (Greenland, Iceland, northern Great Britain, etc.) and in alpine ecosystems in Switzerland and China. In a subalpine grassland in the Swiss Alps, [Bassin et al. \(2013\)](#) observed that 7 years of N additions of 5 to 50 kg N/ha/yr decreased plant diversity and changed plant community composition. [Arens et al. \(2008\)](#) found no effects of N additions (5, 10, or 50 kg N/ha/yr) on plant community composition over 3 years in dwarf shrub/herb tundra ecosystems in Greenland. In Sweden, [Sundqvist et al. \(2014\)](#) did not observe any change in plant species diversity or plant species richness as a result of 3 years of N additions (100 kg N/ha/yr) to a tundra heath and a tundra meadow. Elsewhere in Sweden, [Wardle et al. \(2013\)](#) found that two decades of N additions (50 kg N/ha/yr) to a tundra meadow decreased both plant species richness and plant community diversity.

ha = hectare; kg = kilogram; N = nitrogen; n/a = not applicable; yr = year.

Notes: Single studies are reported more than once if multiple endpoints were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

Because of the similarities in soil and plant community properties, heathlands are discussed in this alpine and arctic tundra section. [Southon et al. \(2013\)](#) quantified plant species richness at heathland sites in the U.K. along an N deposition gradient (5.9–32.4 kg N/ha/yr) and observed declines in both vascular plant species richness and bryophyte species richness. Similarly, [Armitage et al. \(2014\)](#) observed changes in plant community composition and decreases in plant species richness in alpine heathlands along an N deposition gradient of 0.6 to 39.6 kg N/ha/yr across the northern U.K., Iceland, Norway, and the Faroe Islands. Three studies quantified changes in lichen species richness in alpine tundra ecosystems along atmospheric N deposition gradients in northern Europe; two observed significant declines with increases in N deposition. At 15 of the U.K. alpine tundra sites surveyed by [Armitage et al. \(2014\)](#), [Mitchell et al. \(2016\)](#) sampled soil microarthropods (oribatid, prostigmatid, and mesostigmatid mites, and Collembola). Across the gradient of sites, there was no direct influence of N deposition on microarthropod community structure or the species richness, community composition, or density for Collembola or any of the three groups of mites. However, N deposition indirectly affected microarthropod communities by altering variables such as graminoid cover, moss depth, moss cover, and plant biomass C:N ratio, all of which significantly influenced microarthropod communities ([Mitchell et al., 2016](#)).

There has been a considerable amount of new research on the effects on added N plant diversity in alpine meadows within the Tibetan Plateau region of China. In a meta-analysis of N addition studies in this region, [Fu and Shen \(2016\)](#) found that N additions decreased both plant species richness and plant diversity. [Song and Yu \(2015\)](#) examined how different rates (3.75, 15, or 75 kg N/ha/yr) and chemical forms of N ( $[\text{NH}_4]_2\text{SO}_4$ ,  $\text{NaNO}_3$ , or  $\text{NH}_4\text{NO}_3$ ) additions over 8 years influenced plant diversity and the stability of plant communities in alpine plant communities on the Tibetan Plateau in China. Throughout the experiment, there were no effects of N form. The highest rate of N addition decreased community stability (mean biomass/mean temporal standard deviation), species richness, and the dominance of community composition by individual species; other rates of N did not affect these metrics. Broadly, added N also increased the temporal synchrony of species cover, meaning that there were stronger correlations among species and functional groups in year-to-year variation in cover. This suggests that N additions can decrease compensatory effects within plant communities, wherein one species or functional group increases in cover during periods when others are exhibiting decreased growth. Instead, the high N treatment increased the abundance of both of the two dominant grass species. [Song and Yu \(2015\)](#) suggested that the reduction in compensatory growth could result from decreased competition for N. As expected, there was a strong correlation between log-transformed species variance in abundance and log-transformed mean abundance, meaning that more abundant species were also more variable in their abundance; this relationship was not affected by N additions. Notably,

there was no relationship between community stability and species richness. Although this is unusual among studies of community stability and richness [e.g., [Tilman \(1996\)](#); [Steiner et al. \(2005\)](#); [Tilman et al. \(2006\)](#); [Loreau and de Mazancourt \(2013\)](#)], the high rate of N addition caused the loss of only 2 of 20 species within these communities; neither was a dominant species in the community. In comparison, 4 years of N additions (100 kg N/ha/yr as  $\text{NH}_4\text{NO}_3$ ) had no effect on plant species richness or diversity in a less diverse (10–14 species) alpine meadow community on the Tibetan Plateau ([Zong et al., 2016](#)).

Among studies of microbial diversity ([Table 6-19](#)), three studies ([Yuan et al., 2016](#); [Farrer et al., 2013](#); [Nemergut et al., 2008](#)) investigated the effect of N additions in the Rocky Mountains. [Farrer et al. \(2013\)](#) asked whether soil microbial changes were related to the demonstrated decline in the abundance of the plant *Geum rossii* under increased N deposition. Microbial community composition changed, but the influence of this change on *G. rossii* was unclear. However, there was evidence that N additions imposed a stronger physiological C limitation on *G. rossii*. [Nemergut et al. \(2008\)](#) also found shifts in fungal and bacterial soil communities with chronic N additions (10 to 25 kg N/ha/yr for >10 years). The fungal community shifted in response to N amendments, with a decrease in the relative abundance of basidiomycetes. Bacterial community composition also shifted in the N amended soil, with increases in the relative abundance of sequences related to the Bacteroidetes and Gemmatimonadetes, and decreases in the relative abundance of the Verrucomicrobia. [Yuan et al. \(2016\)](#) observed changes in bacterial community composition after 20 years of N additions, with N additions increasing the abundance of the phyla Chloroflexi and Bacteroidetes and N additions decreasing Acidobacteria and Verrucomicrobia. Notably, forb biomass (but not grass biomass) was positively correlated with bacterial diversity and bacterial richness covaried with plant richness. Structural equation modeling revealed that the effects of N additions on bacterial community composition were primarily indirect effects occurring via changes in soil pH and forb biomass rather than direct effects of N availability ([Yuan et al., 2016](#)).

### 6.3.5 Grasslands

In the 2008 ISA, there was consistent and coherent evidence suggesting that N additions reduced plant biodiversity in grasslands in the U.S. and Europe. In the U.S., [Clark and Tilman \(2008\)](#) evaluated the effects of chronic N addition over 23 years in Minnesota prairie grasslands and found species numbers declined at the lowest addition level (10 kg N/ha/yr added to 6 kg N/ha/yr of ambient deposition). In the San Francisco Bay area of California, exotic nitrophilous grasses displaced native grass species, likely due to greater N availability from deposition—at the time approximately 10 to 15 kg N/ha/yr—and from the cessation of grazing, which previously exported N out of the ecosystem ([Fenn et al., 2003b](#); [Weiss, 1999](#)).

In Europe, there were observations of N deposition-related declines in grassland plant diversity in a variety of environments, including calcareous, neutral, and acidic soils, species-rich heaths, and montane-subalpine grasslands ([Stevens et al., 2004](#); [Bobbink et al., 1998](#); [Bobbink et al., 1992](#)). In a transect of 68 acidic grasslands across Great Britain that covered a broad range of ambient N deposition (5 to 35 kg N/ha/yr), chronic N deposition significantly decreased plant species richness ([Stevens et al., 2004](#)). Species richness declined as a linear function of the rate of inorganic N deposition, with a reduction of one species per 4-m<sup>2</sup> quadrant for every 2.5 kg N/ha/yr of chronic N deposition ([Stevens et al., 2004](#)).

Although only a few studies had examined low levels of N inputs to grasslands in the U.S. as of 2008, there were many that added higher levels of N ([Clark et al., 2007](#); [Bradley et al., 2006](#); [Suding et al., 2005](#); [Gough et al., 2000](#)) and examined how N enrichment interacted with other factors such as fire, elevated atmospheric CO<sub>2</sub>, species diversity, and climate change ([Zavaleta et al., 2003](#); [Reich et al., 2001](#); [Collins et al., 1998](#)). These studies were not necessarily designed to simulate N deposition, rather their focus was on nutrient limitation and what happened following the alleviation of this limitation. Recent gradient studies and studies using low level N addition rates verify that the direction of effect between low and high N input rates are similar. This suggests that although the magnitude of effect depends on the level of input, the direction of effect does not, and that nutrient enrichment in grasslands follows a general response. This response includes increases in aboveground production, decreases in light availability at the soil surface, changes in soil fauna, and increases in litter buildup, all of which can lead to competitive displacement of slower growing and shorter plant species from either shading and/or reduced recruitment and regrowth ([Hautier et al., 2009](#); [Bobbink et al., 1998](#); [Tilman, 1993, 1987](#)).

In total, before 2008, large-scale biodiversity assessments across gradients of atmospheric N deposition were restricted to Europe ([Stevens et al., 2004](#)). Although there was wide evidence in the U.S. linking the composition of plant and microbial communities to N availability, most of these experiments had been conducted using N addition rates considerably exceeding observed atmospheric N deposition rates in the U.S. [e.g., [Suding et al. \(2005\)](#); [Bradley et al. \(2006\)](#)]. Experiments demonstrating the sensitivity of grassland community composition to lower rates of N deposition were more limited, with evidence for Mediterranean grasslands ([Weiss, 1999](#)) and a northern prairie ecosystem ([Clark and Tilman, 2008](#)).

Since the 2008 ISA, research on the effects of anthropogenic N on biodiversity in grassland ecosystems has expanded to include a wider range of organisms and ecosystems and a further understanding of how added N (particularly at more realistic N input rates) alters biodiversity, including the species and functional groups most susceptible to increased N availability. Much of this new research has been conducted in the U.S. (particularly at Cedar Creek in Minnesota) and in western Europe, but China has also emerged as a center for research on the effects of excess N on grasslands.

As noted earlier, [Simkin et al. \(2016\)](#) quantified the effect of N deposition on species richness in the continental U.S. using data from over 15,000 plots, including grassland ecosystems. While Europe has several large-scale continental studies on the effects from N deposition ([Stevens et al., 2010a](#); [Stevens et al., 2004](#)), this is the first study of its size in the U.S. and provides a unique insight on the impacts from N deposition on U.S. grassland ecosystems. In their analysis, [Simkin et al. \(2016\)](#) observed that at very low rates of N deposition, increases in N deposition were associated with higher plant species richness in open canopy ecosystems (e.g., grasslands, shrublands, and woodlands), but species richness declined at N deposition rates above 8.7 kg N/ha/yr (5th–95th percentile: 6.4–11.3 kg N/ha/yr). Levels causing a decline in species richness are common across much of the eastern and central U.S. and also occur near urban and intensive agricultural areas in the West. Evidence of increases at low N input rates had not been observed across N deposition gradients in Europe, likely due to higher historical deposition rates. [Simkin et al. \(2016\)](#) also reported that the loss of species was strongly contingent on soil pH, with more losses occurring in more acidic soils. Notably, the authors reported that approximately 40% of grassland plots used for the study received N deposition at rates above the threshold for declines in species richness.

A number of studies in Europe have built upon the work of [Stevens et al. \(2004\)](#) in documenting N deposition impacts on grassland plant communities over long time periods and/or large geographic areas, with these studies consistently indicating changes in plant community composition and decreases in diversity as a result of N deposition

(see also [Appendix 5](#) for discussion). Changes in grassland plant diversity in the U.K. from N deposition have been particularly well documented. [Stevens et al. \(2010b\)](#) and [Maskell et al. \(2010\)](#) built on the work of [Stevens et al. \(2004\)](#) in the U.K., trying to identify whether changes in plant community composition caused by N deposition were the result of acidification or eutrophication. [Stevens et al. \(2010b\)](#) worked from the same 68 acidic grasslands in Great Britain as [Stevens et al. \(2004\)](#), but included more detailed information about soil pH and the sensitivity of individual plant species to pH and N availability. Based on these data, [Stevens et al. \(2010b\)](#) observed that N deposition mostly caused a shift toward more acid-tolerant species rather than nitrophilic species, suggesting that acidification is the primary impact of N deposition on acidic grassland plant communities. A broader analysis by [Maskell et al. \(2010\)](#), which expanded the work of [Stevens et al. \(2004\)](#) and [Stevens et al. \(2010b\)](#) beyond acidic grasslands to also include calcareous grasslands, heathlands, and mesotrophic grasslands—and also included direct soil measurements at a subset of these sites—also found that the primary link between N deposition and species loss was acidification in acidic grasslands and heathlands. However, eutrophication was the primary link between species loss and N deposition in calcareous grasslands ([Maskell et al., 2010](#)). Notably, species losses along the deposition gradient were smaller in calcareous ecosystems than in acidic ecosystems. In a similar assessment, [van Den Berg et al. \(2016\)](#) observed negative effects of N deposition on plant species richness in ecosystems across the U.K. (woodlands, heaths, bogs, and grasslands), with the exception of a positive effect of deposition on species richness in calcareous grasslands. [Henrys et al. \(2011\)](#) used data from two national observation networks over Great Britain and found clear negative trends in plant species prevalence to increasing N in all acidic grassland habitats. [Field et al. \(2014\)](#) also expanded on the work of [Stevens et al. \(2004\)](#) by surveying a broader range of ecosystem types across the U.K.: acidic grasslands, bogs, upland and lowland heaths, and sand dunes. Higher N deposition was associated with decreases in species richness and changes in community composition across all ecosystem types. Among functional groups, N deposition decreased the diversity of mosses, lichens, forbs, and graminoids, but generally increased the cover of graminoids ([Field et al., 2014](#)). [van Den Berg et al. \(2016\)](#) found that N deposition increased the ratio of grass-to-forb species in some U.K. ecosystems (heathlands, bogs, acidic grasslands), but had the opposite effect in calcareous grasslands.

Similar results were observed at broader scales in Europe. Several studies surveyed 153 acidic grassland sites across northern and western Europe ([Pannek et al., 2015](#); [Stevens et al., 2011a](#); [Stevens et al., 2011b, 2010a](#)). These sites spanned a deposition gradient of 2 to 44 kg N/ha/yr, but the decreases in plant species richness were not linear and the highest rate of species loss occurred at deposition rates <20 kg N/ha/yr ([Stevens et al., 2010a](#)). Across the gradient, most of the decline in species richness was caused by

a loss of forb species, but grass and bryophyte species also declined ([Stevens et al., 2010a](#)). As a fraction of total species richness, grass species richness increased and forb species richness declined with increasing N deposition ([Stevens et al., 2011b](#)). Notably, these changes occurred without consistent effects of N deposition on soil  $\text{NO}_3^-$ , soil  $\text{NH}_4^+$ , or tissue N concentrations in broadly sampled forb (*Galium saxatile*) and grass (*Agrostis capillaris*) species, but both soil C:N and the foliar N concentration of a bryophyte (*Rhytidiadelphus squarrosus*) were positively correlated with N deposition ([Stevens et al., 2011b](#)). [Stevens et al. \(2011b\)](#) were able to explain 24% of the total variation in plant species composition using climate, soil, and atmospheric deposition metrics. Among this 24% of the total variation, soil variables (pH, aluminum concentrations, C and N content) explained 38% of the variation and deposition represented about 10% of this variation ([Stevens et al., 2011a](#)). This influence of deposition on community composition was notably weaker than the relationship to changes in species richness. A survey of 44 species in these grasslands found that the presence of 16 species responded to N deposition, with 12 of these 16 species responding negatively ([Pannek et al., 2015](#)). In the Atlantic region of France, [Gaudnik et al. \(2011\)](#) observed that N deposition was one of the primary determinants of community composition in acidic grasslands, even though the observed range of N deposition was much smaller than in [Stevens et al. \(2004\)](#). [Dupre et al. \(2010\)](#) examined plant community composition change in acidic grasslands in north-central Europe and the U.K. over 70 years, dating back to 1939. Vegetation communities were differentiated predominately according to soil pH, soil N availability, cumulative N deposition and S deposition, and sampling date. Plot species richness declined through time for both vascular plants and bryophytes, with cumulative N deposition identified as the primary determinant of species loss.

While these N deposition gradient studies have provided strong documentation that anthropogenic N pollution is altering biodiversity in grasslands in North America and in Europe, experimental N addition studies have provided new information about the mechanisms linking N deposition to shifts in community composition. For instance, using grassland mesocosms in Switzerland receiving 150 to 200 kg N/ha/yr, [Hautier et al. \(2009\)](#) conducted a unique experiment to understand the role of light competition in the loss of species under conditions of high N availability. The addition of N increased aboveground productivity and decreased both light availability near the ground surface and species richness. An experimental increase in light availability caused by the use of plant growth lights beneath the grassland canopy further increased productivity, but also prevented the loss of plant species richness. Similarly, light competition was a mechanism behind the negative effects of N deposition on species richness in grassland sites in Israel ([Demalach et al., 2017](#)).

At Cedar Creek in Minnesota, [Reich \(2009\)](#) conducted a 10-year experiment where grassland assemblages of 16 perennial species were grown under factorial combinations of ambient and elevated CO<sub>2</sub> and ambient and elevated N. Increased N (40 kg N/ha/yr) reduced species at both ambient and elevated CO<sub>2</sub>, by 16 and 8%, respectively. The reduced losses of biodiversity at higher CO<sub>2</sub> levels remains an active area of research but is thought to be caused by greater soil water availability at higher CO<sub>2</sub> levels (from reduced stomatal conductance) that reduced the competitive displacement with N addition. An even longer experiment, 25 years, conducted at Cedar Creek and analyzed by [Isbell et al. \(2013a\)](#) also demonstrated that N enrichment decreased the number of plant species, and that over time, this effect became increasingly negative at all rates of N addition. Moreover, species losses were nonrandom, with initially dominant native perennial grasses becoming less dominant and then lost, and non-native perennial C3 grasses becoming increasingly dominant. Plot composition changed from a high-diversity, native-dominated state (C4 grasses) to a low-diversity, non-native dominated state (C3 grasses). Several earlier studies at this site also reported this general effect ([Clark and Tilman, 2008](#); [Tilman, 1987](#)). Nine native species were particularly susceptible to becoming locally extinct under chronic nutrient enrichment, including initially dominant and initially rare species. All of the findings from this seminal experiment in Cedar Creek, MN, are representative of terrestrial eutrophication, as opposed to acidification, because these soils were limed to maintain a constant pH ([Tilman, 1987](#)). However, there were no lime additions in the experiment conducted at this site by [Reich \(2009\)](#), indicating that both terrestrial eutrophication and acidification could be occurring in that experiment.

[Lan et al. \(2015\)](#) examined how N deposition altered spatial patterns in biodiversity and species-area relationships by measuring plant species loss and species richness in a grassland in Inner Mongolia in 14 different plot sizes ranging from 1 to 25 m<sup>2</sup>. The experiment included five levels of N addition between 17.5 and 280 kg N/ha/yr (NH<sub>4</sub>NO<sub>3</sub>) for 10 years. Except for the 17.5 kg N/ha/yr treatment, N additions decreased species richness. The absolute number of species lost versus the control group increased rapidly as plot size increased from 1 to 8 m<sup>2</sup>, but then stayed the same (high N doses) or decreased (low N doses). However, the proportional loss of species decreased as plot size increased, which allowed for predictions of critical loads for species loss at different plots sizes: 11.4 kg N/ha/yr at 5 m<sup>2</sup> and 17.4 kg N/ha/yr at 25 m<sup>2</sup>. A previous study at these sites using 0.5-m<sup>2</sup> plots found a critical load of 8.5 kg N/ha/yr, indicating that species loss as a consequence of N additions is sensitive to survey design.

Ecological theory suggests that plant diversity can be maintained by several factors, including disturbance [e.g., [Hobbs and Huenneke \(1996\)](#); [Mack et al. \(2000\)](#); [Davis et al. \(2000\)](#)]. Among grasslands, the managed reintroduction of some disturbances has been

proposed as a way of maintaining plant diversity in eutrophic ecosystems. In a California serpentine grassland, [Pasari et al. \(2014\)](#) examined the interactive effects of grazing and simulated N deposition (80 kg N/ha total over 4 years) on native and exotic species dynamics. With N additions, grazing helped maintain native species richness. High grazing intensity decreased exotic plant cover, but only under ambient conditions ([Pasari et al., 2014](#)). In a southern California coastal grassland, [Borer et al. \(2014\)](#) conducted several nutrient enrichment experiments, two of which involved the addition of N (40 and 100 kg N/ha/yr). At the higher N level, species richness (forbs primarily) was reduced by one species per 0.5 m<sup>2</sup> after 2 years. However, unlike in the work of [Pasari et al. \(2014\)](#), this change in diversity was not affected by the presence of pocket gophers (*Thomomys bottae*), a keystone herbivore that eliminated the effect of N on plant productivity. In an annually burned Kansas tallgrass prairie, [McLaughlan et al. \(2014\)](#) analyzed a 27-year record of plant community composition and N cycling. Despite rates of N deposition (average 7 kg N/ha/yr) persistently within the range of critical loads for temperate grasslands in the region, there was no evidence for increases in plant N concentrations, decreases in forb diversity, or shifts in the relative abundance of dominant grass species. The authors suggested that losses of N through frequent burning or grazing are sufficient to prevent grassland eutrophication at low rates of N deposition.

There is also new evidence that N additions can alter flowering, seed production, and seed abundance in grasslands. In Minnesota, [Hillerislambers et al. \(2009\)](#) developed a statistical model to determine the effects of multiple global change factors, including N deposition, on inflorescence mass. The effects of N deposition on seed production were similar within functional groups and negatively correlated with aboveground productivity: C3 grasses increased aboveground biomass and decreased seed production, while C4 grasses decreased aboveground biomass and increased seed production. In a greenhouse study of California oak savannah annual grasses, N additions (28 kg N/ha/yr for 1 year) increased seed production (g/plant) by an invasive grass ([Tulloss and Cadenasso, 2016](#)). In addition to seed production, the abundance of seed in soil seed banks is important because seed banks help in revegetation following disturbances and help maintain plant diversity, especially in small and isolated ecosystems ([Piessens et al., 2004](#)). However, N impacts on grassland seed banks are not necessarily directly related to changes in plant cover or flowering. [Basto et al. \(2015a\)](#) found that 13 years of simulated N deposition at rates of 35 or 140 kg N/ha/yr decreased cover and flowering in only one species (*Potentilla erecta*) in an acidic grassland in England, but total seed bank abundance declined by 34 and 61% in the low and high N treatments, respectively. Further, seed bank species richness declined by 29 and 41% in these treatments. Among taxa, there were decreases of >50% in the seed bank abundance of forbs, sedges, and grasses with the high N dose, but only a significant decrease (34%) in grass seed bank abundance at the lower N dose. Seed banks were quantified again 4 years after the

cessation of N additions but did not significantly recover in any metric of abundance, richness, or composition.

The Park Grass Experiment in England is the longest ecological experiment in the world and has examined the effect of various soil amendments, including N (96 kg N/ha/yr) as  $(\text{NH}_4)_2\text{SO}_4$  or  $\text{NaNO}_3$ , on grassland productivity and composition since 1856. [Zhalnina et al. \(2015\)](#) conducted 16S ribosomal RNA sequencing of soil samples from this experiment to assess bacterial and archaeal community composition ([Table 6-20](#)). Soil nitrate concentrations were positively correlated with the abundance of Thaumarchaeota and Nitrospirae DNA, whereas total soil N was negatively correlated with Firmicutes, Verrucomicrobia, and Chloroflexi. Multivariate analyses of community composition found that the primary determinants of microbial community composition were soil pH and C:N. Soil C:N was negatively correlated with Thaumarchaeota, Nitrospirae, and Gemmatimonadetes, but positively correlated with Acidobacteria and Chlamydiae. Changes in soil pH were a much larger control on microbial abundance, with significant correlations with 17 of the 37 most abundant soil microbial genera. The two different forms of N had different effects on pH, and unsurprisingly, different effects on microbial community composition. Amendments of  $(\text{NH}_4)_2\text{SO}_4$  decreased the phyla Verrucomicrobia and Chloroflexi and the genera *Bradyrhizobium*, *Paenibacillus*, and *Geobacter*, while  $\text{NaNO}_3$  increased the abundance of the phyla Thaumarchaeota and Nitrospirae and the genera *Geobacter*, *Candidatus*, *Nitrososphaera*, *Nitrospira*, and *Methylibium*. In comparison, 27 years of N additions at Cedar Creek in Minnesota changed bacterial composition ([Fierer et al., 2012](#); [Ramirez et al., 2010b](#)) but had no effect on bacterial diversity [[Fierer et al. \(2012\)](#); [Table 6-20](#)].

ha = hectare; kg = kilogram; N = nitrogen; yr = year.

Notes: Single studies are reported more than once if multiple endpoints were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

Relative to forests, there is comparably little information on how N additions shift the composition of mycorrhizal communities in grasslands ([Table 6-16](#)). In a steppe grassland in China, [Chen et al. \(2014\)](#) observed that 6 years of N additions (100 kg N/ha/yr) decreased the richness of arbuscular mycorrhizal phylotypes found in the soil, but did not affect the diversity of soil phylotypes or alter the richness or diversity of phylotypes observed in plant roots.

As with that of forests, some information is also available regarding the effects of N additions on grassland soil fauna ([Table 6-17](#)). In particular, several studies have been conducted on soil fauna and their role in soil food webs at Cedar Creek in Minnesota ([Cesarz et al., 2015](#); [Eisenhauer et al., 2013](#); [Eisenhauer et al., 2012](#)). [Eisenhauer et al. \(2012\)](#) observed that the N deposition treatment at Cedar Creek (40 kg N/ha/yr) significantly altered the abundance of 5 of 14 groups of soil biota. Simulated N deposition decreased predaceous nematode abundance by 62% but increased fungal feeding nematodes by 206%. Nematode taxon richness and microarthropod taxon richness declined by 7 and 15% under added N ([Eisenhauer et al., 2012](#)). A more detailed analysis by [Cesarz et al. \(2015\)](#) found that N enrichment increased the density of the plant-feeding Longidoridae nematode family by 148% and increased the density of a rapidly growing guild of fungal-feeding nematodes, while a slower-growing guild of predaceous nematodes declined ([Cesarz et al., 2015](#)). Overall, N additions increased nematode community composition toward nematode guilds favored by decomposition pathways dominated by fungi and away from bacterial-dominated decomposition pathways ([Cesarz et al., 2015](#); [Eisenhauer et al., 2012](#)). However, while simulated N deposition had significant effects on soil food webs, these influences were weaker than the direct effects caused by differences in plant diversity ([Eisenhauer et al., 2013](#)).

---

### 6.3.6 Arid and Semiarid Ecosystems

As of the 2008 ISA, there was consistent and coherent evidence of altered plant communities in N addition experiments in arid and semiarid ecosystems, particularly within CSS and chaparral ecosystems along the southern California coast and in portions of the Mojave Desert near large population centers. There was further additional evidence about shifts in plant and microbial community composition from N addition experiments in the Mojave, Chihuahuan, Sonoran, and Great Basin Deserts. Although many of these ecosystems are relatively remote and lightly impacted by anthropogenic N deposition, the 2008 ISA noted that deposition to some arid and semiarid ecosystems can be high downwind of major urban and agricultural areas, reaching more than 30 kg N/ha/yr in areas of southern California ([Fenn et al., 2003b](#)). Like other terrestrial ecosystems, there was widespread evidence that N additions altered plant communities by causing a

differential stimulation of growth among plant species ([Báez et al., 2007](#); [Inouye, 2006](#)), such as by favoring rapidly growing nitrophilous species ([Fenn et al., 2003b](#)). In addition to these effects on plant communities, [Egerton-Warburton and Allen \(2000\)](#) found a shift in arbuscular mycorrhizal community composition with decreased species richness and diversity along an N deposition gradient among CSS ecosystems in southern California (2 to 57  $\mu\text{g N/g}$  as soil  $\text{NO}_3^-$ ). These shifts in mycorrhizal fungal communities may facilitate replacement of native plant communities by exotic annual grasslands.

There are two ecological interactions that are particularly important controlling how N deposition influences plant community composition in arid and semiarid ecosystems: (1) the strong dependence of biological responses on an adequate water supply and (2) the ability of N deposition to promote the growth of exotic plants [particularly annual grasses; [Brooks \(2003\)](#)], which can dramatically alter the fire cycle by providing a more spatially continuous fuel supply ([Brooks et al., 2004](#)). The fire cycle impacts of increased invasive grass biomass were particularly apparent in southern California in CSS ecosystems near the coast and in Mojave Desert ecosystems inland ([Brooks et al., 2004](#); [Brooks and Esque, 2002](#); [Cione et al., 2002](#); [Yoshida and Allen, 2001](#); [Brooks, 1999](#); [Eliason and Allen, 1997](#)). Fire was relatively rare in the Mojave Desert until the past two decades, but fire now occurs frequently in areas that have experienced invasion of exotic grasses ([Brooks, 1999](#)). These interactions are apparent in an  $\text{NH}_4\text{NO}_3$  addition (32 kg N/ha/yr) study in the Mojave Desert of southern California conducted by [Brooks \(2003\)](#). In the second and wetter year of the experiment, N additions decreased species richness among native annual plants ([Brooks, 2003](#)). Overall, N additions increased the growth of the invasive grass compact brome (*Bromus madritensis*) beneath the dominant native shrub creosote bush (*Larrea tridentata*) and increased the growth of invasive grasses in the genus *Schismus* and the invasive forb *Erodium cicutarium* in the interspaces between *Larrea* shrubs, creating a more continuous fuel bed.

Since the 2008 ISA, a number of new N addition experiments and ambient N deposition gradient studies on shifts in plant community composition and diversity have been conducted, primarily in California and in arid portions of China ([Table 6-21](#)). Broadly, while some of these studies found decreases in plant species richness [e.g., [Allen et al. \(2009\)](#); [Sun et al. \(2014\)](#)], there were more frequent observations of changes in plant community composition. This disparity may be a function of both the relative brevity of these experiments (mostly 2 to 4 years) and the strong moisture limitation that constrains biological responses to added N in these ecosystems.

Within southern California, there was a continued research focus on how N deposition alters the abundance of invasive annual plants (particularly grasses) in CSS, chaparral, and Mojave Desert ecosystems ([Cox et al., 2014](#); [Pasquini and Vourlitis, 2010](#); [Allen et al., 2009](#); [Rao et al., 2009](#); [Vourlitis and Pasquini, 2009](#); [Talluto and Suding, 2008](#)). Among inland ecosystems, [Allen et al. \(2009\)](#) added N (5 and 30 kg N/ha/yr for 2 years) to four sites at Joshua Tree National Park (JOTR) in California and found that the effects of added N on native plant diversity depended on the abundance of invasive grasses. At one site where invasive grass biomass (primarily *Bromus madritensis*) was high and responded positively to added N, N additions decreased native forb species richness; at a site where invasive grasses were a small component of the plant community, N additions increased native forb cover and species richness. Given that [Rao et al. \(2009\)](#) found greater invasive annual grass cover at sites with higher N deposition across a 16-site N deposition gradient in the JOTR area, the results of [Allen et al. \(2009\)](#) imply that N deposition may be decreasing native forb richness across broad areas in the JOTR area.

Near the southern California coast, [Vourlitis and Pasquini \(2009\)](#) investigated the effects of dry-season N addition in chaparral (dominated by the shrubs *Adenostoma fasciculatum* and *Ceanothus greggii*) and CSS (dominated by the shrubs *Artemisia californica* and *Salvia mellifera*) stands over a 5-year period. The additional N (50 kg N/ha/yr) significantly altered the community composition of CSS, but not chaparral. The differences in CSS community composition were due to changes in the relative abundance of dominant shrubs, not herbaceous plant species. This is not necessarily consistent with previous research, including observations that although both native shrubs and invasive annual plants can exhibit faster growth rates with added N, high N availability can cause mortality in native shrubs ([Allen et al., 1998](#)). [Talluto and Suding \(2008\)](#) revisited 232 plots in southern California that had been dominated by CSS vegetation during a 1930s vegetation survey and found that CSS cover had declined by 49%, and only 15% of the 1930s CSS plots lacked invasive annual grasses. At a landscape scale, the conversion of CSS to invasive-dominated land was positively related to N deposition rates and fire frequency, which itself has been linked to N deposition. In another landscape-level analysis of vegetation change since the 1930s, [Cox et al. \(2014\)](#) observed that CSS converted to non-native grasslands when N deposition was greater than 11 kg N/ha/yr, more consistent with the previous results. Also in southern California, [Pasquini and Vourlitis \(2010\)](#) found evidence that N deposition caused changes in chaparral plant community composition in recently burned ecosystems, but the influence of N deposition in this study was confounded by changes in other environmental factors across the three-site N deposition gradient (8.1 to 18.4 kg N/ha/yr) used for this research.

Elsewhere in California, [Concilio and Loik \(2013\)](#) studied the effects of added N (50 kg N/ha/yr for 4 years) on sagebrush steppe ecosystems in the eastern Sierra Nevada where the invasive annual grass *Bromus tectorum* was beginning to establish. Although N addition treatments increased plant available N and total N, no changes were observed in cover, community composition, or richness of native or invasive species. *Bromus tectorum* cover was inversely related to native forb species richness, but increased N deposition did not affect plant diversity. However, [Concilio and Loik \(2013\)](#) cautioned that precipitation was below average during the study and N additions may have different effects when moisture availability is greater.

Several notable N addition studies have been conducted in the arid steppe grassland and shrubland ecosystems in northern and western China. [Zhang et al. \(2014\)](#) studied whether the frequency of additions (12 doses/year vs. 2 doses/year) altered the effect of added N on plant diversity in a steppe grassland in the Inner Mongolia region of China (eight levels from 10 to 500 kg N/ha/yr as  $\text{NH}_4\text{NO}_3$  for 5 years). Species richness declined by about 50% as N addition rates increased; plant diversity also decreased more with higher N addition rates. [Zhang et al. \(2014\)](#) noted that the declines in diversity and richness were smaller with the smaller frequent N doses than with the large infrequent doses and suggested that this implied that some N addition studies may be overestimating the negative effects on plant biodiversity. However, at the lower N addition rates (10, 20, and 30 kg N/ha/yr) that are more relevant to N deposition levels in the U.S., the effects of dose frequency were not consistently observed; species richness was sometimes (nonsignificantly) higher with the large infrequent doses at these N addition rates. The frequency of N additions did not impact the rate of species loss in perennial forbs but did affect the rate of species loss in grasses and annual and biennial forbs. Notably, N additions were associated with significant decreases in soil temperature, soil moisture, and soil pH and increases in  $\text{NH}_4^+$  and  $\text{NO}_3^-$ . All of these soil changes were correlated with each other and the proportional changes in each of these variables were correlated with the proportional loss in species richness. Among these soil traits, higher N addition frequency increased  $\text{NH}_4^+$ , but had no other significant effects. In subsequent research at these sites, [Zhang et al. \(2016b\)](#) observed that the lower plant species richness in the low frequency N addition plots relative to the high frequency plots was not caused by differences in the rate of species loss, but instead resulted from slower colonization by new species in the plots that received large infrequent N additions. In another experiment in semiarid Chinese steppe grasslands, [Li et al. \(2016a\)](#) observed that N additions (50, 100, 150 kg N/ha/yr for 8 years) decreased species richness, decreased diversity, and altered community composition for both plant and bacterial communities and that changes in plant and microbial communities were significantly correlated. [Li et al. \(2016a\)](#) also observed that N additions decreased both plant and microbial species

richness and altered microbial community composition in a semiarid Chinese steppe grassland.

A recent study by [Tian et al. \(2016b\)](#) examined how N addition at several rates affected grassland structure and function in the temperate steppe of China (20, 40, 80, 160, 320 kg N/ha/yr). They found that N addition led to increases in aboveground biomass and to shifts in relative abundance from forbs to grasses even at the lowest input rate, as reported in other studies. However, they reported a novel mechanism related to manganese (Mn) toxicity to explain reductions in forb diversity that had not been demonstrated before, but had been reported in forestry literature ([St.Clair et al., 2008](#); [St.Clair and Lynch, 2005](#)). They reported that forbs were much more prone to Mn toxicity than grasses following N addition because of physiological differences in root enzymes associated with metal uptake. Manganese accumulated more in forbs than grasses, leading to decreased forb photosynthetic rates and shifts in relative abundances towards grasses. It is unknown whether this mechanism is operating in other grassland systems.

In an arid steppe grassland in northeastern China, [Sun et al. \(2014\)](#) observed that N additions of 23, 46, 69, and 92 kg N/ha/yr (3 years, as urea) caused proportional decreases in forb species richness, but found added N caused soil bacterial communities to become more diverse except at the highest N dose ([Table 6-22](#)). [Huang et al. \(2015\)](#) conducted a 3-year N × water experiment focused on soil microbial community composition in a desert steppe ecosystem in northwestern China that receives 25 kg N/ha/yr of ambient deposition. The N addition treatment (50 kg N/ha/yr as NH<sub>4</sub>NO<sub>3</sub>) effects on microbial composition differed between inter-plant and beneath shrub sites. In the interspaces, N additions increased the portion of bacteria in total microbial biomass in all 3 years and increased actinobacteria in the last 2 years of the experiment. Beneath the shrubs, N additions broadly suppressed microorganisms in all domains. In the Sonoran Desert near Phoenix, [Marusenko et al. \(2015\)](#) found that although N additions (60 kg N/ha/yr for 8 years) increased the abundance of the *amoA* gene (needed for ammonia oxidation) in both archaea and bacteria, the community composition of ammonia-oxidizing microorganisms was unaffected.

In Mediterranean shrublands in Spain, N additions (10, 20, and 50 kg N/ha/yr for 4 years) increased the abundance of Collembola, which were a dominant component (44%) of the soil fauna. The N additions did not significantly affect soil fauna richness or diversity, but there was a significant negative relationship between richness and soil C:N ratio and a positive relationship between diversity and soil pH ([Ochoa-Hueso et al., 2014](#)).

### 6.3.7 Lichens

In the 2008 ISA, there was consistent and coherent evidence indicating that lichen communities were affected by current levels of N deposition. Lichen community composition is highly sensitive to atmospheric pollution from N and S ([Jovan, 2008](#)). Based on the widely recognized sensitivity of lichen species to air pollution, [Geiser and Neitlich \(2007\)](#) developed a model to assess local air quality in Pacific Northwest forests based on lichen community composition. In addition to being good subjects for biomonitoring, lichens constitute important components of the forest ecosystem by contributing to biodiversity, regulating nutrient and hydrological cycles, and providing habitat elements for wildlife ([McCune and Geiser, 1997](#)). The composition of the lichen community is important because individual species have different physical and physiological traits, and thus make particular contributions to the provisioning of ecosystem services.

Lichens containing a cyanobacterial photobiont appear to be more sensitive to adverse effects from atmospheric N deposition than most other lichens ([Hallingbäck and Kellner, 1992](#); [Hallingbäck, 1991](#)). In central Europe, [Hauck and Wirth \(2010\)](#) analyzed 514 lichen species and found that shade-adapted lichen species are nearly universally intolerant of high rates of N deposition. Nearly all of these shade-tolerant and pollution-sensitive species are crustose lichens ([Hauck and Wirth, 2010](#)). The decline of lichens containing cyanobacteria in parts of northern Europe has been associated with N deposition in the range of 5 to 10 kg N/ha/yr ([Bobbink et al., 1998](#)). In Sweden, the probability of occurrence for three genera of hair lichens (*Alectoria*, *Bryoria*, *Usnea*) on Norway spruce (*Picea abies*) in forest inventory plots peaked at 3–6 kg N/ha/yr of deposition and then rapidly declined; N deposition was the strongest or second-strongest environmental predictor of lichen occurrence ([Esseen et al., 2016](#)). In the U.S., lichen species are negatively affected by N inputs as low as 3 to 8 kg N/ha/yr ([Fenn et al., 2003a](#)).

In the San Bernardino Mountains, CA, up to 50% of lichen species that occurred in the region in the early 1900s have disappeared ([Fenn et al., 2003a](#); [Nash and Sigal, 1999](#)). In mixed conifer forests in California, the critical load for lichen communities has been estimated at 3.1 kg N/ha/yr ([Fenn et al., 2008](#)). Compared to California, air pollution has historically been less problematic in the Pacific Northwest and this region still has large populations of pollution-sensitive lichens ([Jovan, 2008](#); [Fenn et al., 2003a](#)). [Jovan \(2008\)](#) reported that hotspots for lichen diversity in the U.S. include Klamath-Siskiyou region along the Oregon-California border, the Okanogan highlands region in northeastern Washington, and the Blue Mountains in eastern Oregon—all areas that are relatively distant from large human population centers and industrial centers. However, lichen

communities in the Pacific Northwest are beginning to show evidence of changes in response to increased N pollution, including decreased distribution of sensitive lichen taxa and their replacement with nitrophilous species ([Geiser and Neitlich, 2007](#)).

Research on lichens since 2008 continues to indicate that lichen communities change in response to increased atmospheric N, in both U.S. and Europe. Unlike most other N deposition biodiversity studies, lichen research has been dominated by studies using measurements along ambient N deposition gradients rather than using experimental N additions ([Table 6-23](#)). Within the U.S., there are numerous examples of shifts in lichen community composition along gradients of atmospheric N deposition. Lichen community composition has been quantified in many parts of the U.S. as part of the U.S. Department of Agriculture Forest Service’s Forest Inventory and Analysis (FIA) program. [Jovan \(2008\)](#) reported the results from surveys of almost 800 plots conducted from 1998 to 2003 in California, Washington, and Oregon, documenting clear shifts in lichen community composition in forests in and around areas of intensive agricultural and industrial production in the Central Valley of California, the Willamette Valley in Oregon, and the Puget Trough (Seattle/Tacoma/Olympia) in Washington. In the northeastern U.S., [Will-Wolf et al. \(2015\)](#) analyzed approximately 600 plots of survey data collected in the 1990s and 2000s as part of the FIA program and from other sources. These data showed strong relationships between total N deposition and decreased lichen abundance, reduced species richness, and altered community composition, but the high overlap between N deposition and acidifying deposition in this region made it difficult to discern the primary influence on lichen biodiversity.

ha = hectare; kg = kilogram; N = nitrogen; n/a = not applicable; NH<sub>3</sub> = ammonia; NO<sub>2</sub> = nitrogen dioxide; ppb = parts per billion; yr = year.

Notes: Single studies are reported more than once if multiple endpoints were measured. References ordered by endpoint. Only statistically significant effects are listed as increases or decreases.

Other surveys of lichen community composition in the U.S. also documented changes even at relatively low rates of N deposition. For instance, lichen community composition in southeastern Alaska shifted toward more eutrophic species along an N deposition gradient of 0.05 to 1.05 kg N/ha/yr ([Schirokauer et al., 2014b](#)). In the northern Rockies, [McMurray et al. \(2015\)](#) observed a shift in lichen community composition at deposition rates greater than 4.0 kg N/ha/yr. In montane aspen forests in the Utah-Idaho border region, [Rogers et al. \(2009\)](#) observed a shift in lichen community composition away from nitrophilous species along a NH<sub>3</sub> concentration gradient away from urban and agricultural sources. In the Los Angeles Basin area of California, [Jovan et al. \(2012\)](#) documented increases in the abundance of eutrophic lichen species along a gradient of N deposition. In coniferous forests in the Pacific Northwest, shifts in lichen community composition and declines in oligotrophic lichen species were observed as N deposition increased to levels from 3 to 9 kg N/ha/yr range ([Geiser et al., 2010](#); [Glavich and Geiser, 2008](#)).

Outside of the U.S., changes in lichen community composition have been observed in Canada and in Europe. In the U.K., [Southon et al. \(2013\)](#) and [Field et al. \(2014\)](#) observed decreased lichen species richness in over 50 heathland survey locations along an N deposition gradient of 5.4 to 32.4 kg N/ha/yr. However, [Armitage et al. \(2014\)](#) did not find a significant change in lichen species richness along an N deposition gradient of 0.6 to 39.4 kg N/ha/yr in alpine heathlands in the North Atlantic region of Europe. In Sweden, [Johansson et al. \(2012\)](#) found additions of 6 kg N/ha/yr, applied directly onto trees in a liquid spray, in old growth boreal spruce forests changed the species composition of epiphytic lichen communities and reduced species richness. [Gibson et al. \(2013\)](#) also noted that in Cape Breton Highlands National Park in Nova Scotia, the

number of pollutant-intolerant lichen species decreased from 10 to 5 when median summer and winter atmospheric NO<sub>2</sub> concentrations increased above 0.46 and 0.15 ppb, respectively. [McDonough and Watmough \(2015\)](#) were unable to detect an influence of modeled N deposition (ranging from ca. 8 to 13 kg N/ha/yr) on epiphytic foliose lichen species richness across a network of 70 sugar maple forest monitoring plots in southern Ontario, Canada. The lack of a relationship, however, may have been caused by already low lichen richness across much of the region, due to prior and current deposition from industrial and agricultural sources ([McDonough and Watmough, 2015](#)).

---

### 6.3.8 Most Sensitive Ecosystems

The 2008 ISA reported that the most responsive ecosystems to N enrichment from atmospheric N deposition were those that receive high levels of N loading, are N limited, or contain species that have evolved in nutrient-poor environments. Species adapted to low N supply are readily outcompeted by species that have higher N demand when the availability of N is increased ([Krupa, 2003](#); [Tilman and Wedin, 1991](#); [Aerts et al., 1990](#)). As a consequence, some native species can be eliminated by N deposition ([Stevens et al., 2004](#); [Falkengren-Grerup, 1989, 1986](#); [Roelofs, 1986](#); [Ellenberg, 1985](#)).

Unlike the case of acidifying deposition where ecosystem sensitivity is tied principally to underlying geology, most terrestrial ecosystems are N limited and, therefore, sensitive to perturbation caused by N additions ([LeBauer and Treseder, 2008](#)). Consequently, little was known in the 2008 ISA about the full extent and distribution of the terrestrial ecosystems in the U.S. most sensitive to adverse impacts caused by atmospheric N deposition. Effects were most likely to occur where areas of relatively high atmospheric N deposition intersect with N limited plant communities. The factors governing the sensitivity of terrestrial ecosystems to nutrient enrichment from N deposition include the rates of N deposition, degree of N limitation, ecosystem productivity, elevation, species composition, length of growing season, and soil N retention capacity. Thus, ecosystems such as alpine tundra, which are typically strongly N limited, contain vegetation adapted to low N availability, often have thin soils with limited N retention capacity, and have short growing seasons, can be particularly sensitive to N deposition. Similarly, the ability of atmospheric N deposition to override the natural spatial heterogeneity in N availability in arid ecosystems, such as the Mojave Desert and CSS ecosystems in southern California, makes these ecosystems more prone to wildfires and sensitive to N deposition.

In the 2008 ISA, effects on individual plant species had not been well studied in the U.S. More was known about the sensitivity of particular plant communities, based largely on results obtained in more extensive studies conducted in Europe, which included

hardwood forests, alpine meadows, arid and semiarid lands, and grassland ecosystems. Among communities sensitive to N deposition, lichens and ectomycorrhizal fungi have particularly low thresholds for effects (see [Appendix 6.5.1](#) and [Appendix 6.5.2](#)). Thus, the ecosystems containing a large number and/or diversity of these organisms, such as temperate and boreal forests and alpine tundras, could be considered particularly sensitive to N deposition. More broadly, there has been substantial work on critical loads for N in U.S. ecoregions since the 2008 ISA (see [Appendix 6.5](#)), creating an improved understanding of which processes, taxa, and regions are sensitive to N deposition impacts.

---

## 6.4 Climate Modification of Ecosystem Nitrogen Response

Biotic responses to N deposition can be modified by climatic shifts in temperature and precipitation. [Appendix 13](#) provides an overview of this topic, whereas this section describes in brief some of the climate modifications specific to the N response of terrestrial ecosystems, particularly plant productivity and diversity. Shifts in temperature and precipitation can alter the effects of N deposition on these two endpoints, as well as the N response of microbial communities.

Temperature and precipitation can interact with N to affect plant productivity. As noted in [Appendix 6.2](#), [Xia and Wan \(2008\)](#) identified almost 1,600 observations of plant biomass growth in response to N additions, excluding agricultural and horticultural species ([Figure 6-1A](#)). They found that biomass responses to N increased linearly with mean annual precipitation (MAP). [LeBauer and Treseder \(2008\)](#) had a considerably smaller data set ( $n = 126$ ) than [Xia and Wan \(2008\)](#) and did not find that MAP, mean annual temperature (MAT), or latitude had significant overall influences on responsiveness of NPP to added N. However, within individual biomes, forest and tundra NPP responses to N increased with MAT, and forests also became more responsive with greater MAP. In general, as precipitation increases, water limitation to plant productivity is relieved, allowing vegetation to be more responsive to changes in N.

As also described in [Appendix 6.2](#), [Tian et al. \(2016a\)](#) developed a “N response efficiency” metric ( $100 \times (\text{ANPP}_{\text{treatment}} - \text{ANPP}_{\text{control}}) / \text{ANPP}_{\text{control}} / \text{N addition rate}$ ) in order to examine how plant growth responses per unit N changed with increasing levels of N. They found N response efficiency significantly changed with environmental factors. Response efficiency decreased with soil pH and total soil N concentration and increased with soil C:N ratios and with precipitation until annual precipitation reached 800 mm/year. The N response efficiency also peaked with moderate annual temperatures ( $\sim 8^\circ\text{C}$ ) and declined under cooler or warmer conditions ([Tian et al., 2016a](#)).

Not surprisingly, climate modification of plant productivity responses can be particularly pronounced in drier ecosystems. In the Sonoran Desert near Phoenix, [Hall et al. \(2011\)](#) added 60 kg N/ha/yr and found little or no increase in production among herbaceous annuals in low precipitation years, moderate N responses with average rainfall, and strong increases in biomass with added N during above-normal rainfall seasons. [Vourlitis \(2012\)](#) measured aboveground biomass and litter production in a mature CSS stand in southern California over an 8-year period. The effect of added N positively correlated with precipitation and was only significant in the high rainfall years. Similarly, [Zhang et al. \(2015e\)](#) observed greater plant productivity responses to N in years with higher precipitation in a steppe grassland in Inner Mongolia.

In addition to shifts in plant productivity, plant diversity can also be affected by the interactions of temperature, precipitation, and N ([Porter et al., 2013](#)). In their national-scale analysis of herbaceous species richness, [Simkin et al. \(2016\)](#) found that temperature and precipitation could moderate N effects in some instances. They did not observe a significant interaction between N and temperature or precipitation on plant species richness for closed canopy systems (deciduous, evergreen, and mixed forests), but did in open canopy systems (grasslands, shrublands, and woodlands). In these open canopy ecosystems, they found that N had a more negative effect on species richness at lower temperatures. This finding is consistent with [Clark et al. \(2007\)](#) who also found a small increase in the risk of species loss with lower annual minimum temperatures, among other factors. Even though the overall effects within closed systems were not significant, [Simkin et al. \(2016\)](#) also analyzed smaller regional forest gradients dominated by maple-birch (*Acer-Betula*), white oak (*Quercus alba*), or Douglas fir (*Pseudotsuga menziesii*) trees. At this scale, the threshold for negative deposition effects tended to be lower (7.5–9.5 kg N/ha/yr), and the negative effects of N deposition on species richness were greatest when temperature and precipitation were high.

Some studies have explored these interactive effects under future climatic and N scenarios. In ForSAFE-VEG model projections of plant community composition in three French forests, two N reduction scenarios—the maximum feasible N emission reductions scenario and the current European legislation scenario for reactive N emissions rates—resulted in gradual shifts over the next 90 years back toward the plant community composition observed at the beginning of the 20th century ([Rizzetto et al., 2016](#)). Notably, the recovery of these plant communities occurred only if climatic factors were held constant at current levels. In another modeling study, [Phelan et al. \(2016\)](#) made a similar observation for understory plant community composition in northern hardwood forests at Bear Brook Watershed in Maine and Hubbard Brook in New Hampshire: the simulated plant community composition returned toward preindustrial conditions over the

next century only in a scenario in which N deposition rates returned to background and climate was kept stable.

Finally, in addition to plant responses, climatic factors also can modify the N response of microbial communities and other soil biota. For instance, N deposition has been shown to alter the soil microbial community responsible for a step in nitrification, particularly at ambient temperature and precipitation ([Horz et al., 2004](#)). The N effect was then reduced when temperature and precipitation were increased ([Horz et al., 2004](#)). Similarly, N additions and lower precipitation interacted to shift microbial community composition in forests soils in northeastern China ([Wang et al., 2014c](#)) and in grassland soils in Inner Mongolia ([Li et al., 2016a](#)). [Jarvis et al. \(2013\)](#) found that both changes in precipitation and nitrogen were associated with shifts in ectomycorrhizal species composition in European Scots pine (*Pinus sylvestris*) stands, although their observational study did not allow them to test the interactive effects. In a Minnesota grassland, [Eisenhauer et al. \(2012\)](#) observed a decline in several categories of biota within a soil food web (numbers of nematode predators, microarthropod herbivores, and taxa richness of nematodes and microarthropods) under increased N, and a decrease in ciliate protists under high N and drought. The authors suggested the impact of drought may have been limited by the soil food web's prior adaption to dry conditions because the study was conducted on a sandy outwash soil, which dries out quickly in the summer. These studies on disparate biota and ecosystems suggest climatic factors, namely temperature and precipitation, can interact with N to affect soil biotic communities. In general, the functional implications to terrestrial ecosystems of these combined climate-and-N induced shifts in soil biota remain unclear, although there are notable exceptions [e.g., nitrification; [Horz et al. \(2004\)](#)].

Overall, studies investigating the interactive effects of climatic factors and N have been limited to date ([Porter et al., 2013](#)). Despite this, evidence suggests climatic shifts in temperature and/or precipitation can alter the effects of N on plant productivity and diversity, and soil microbial communities and other soil biota.

---

## 6.5 Critical Loads

As discussed elsewhere in this ISA (e.g., [Appendix 1](#), [Appendix 4](#), [Appendix 5](#)), critical loads (CLs) are a determination of how much atmospheric deposition can be tolerated by an environmental system before a significant change occurs. Most commonly, this approach defines a level of deposition associated with an adverse geochemical or biological response within an ecoregion. As of the 2008 ISA, most of the CLs developed for North American ecosystems were for aquatic ecosystems (lakes and streams) in

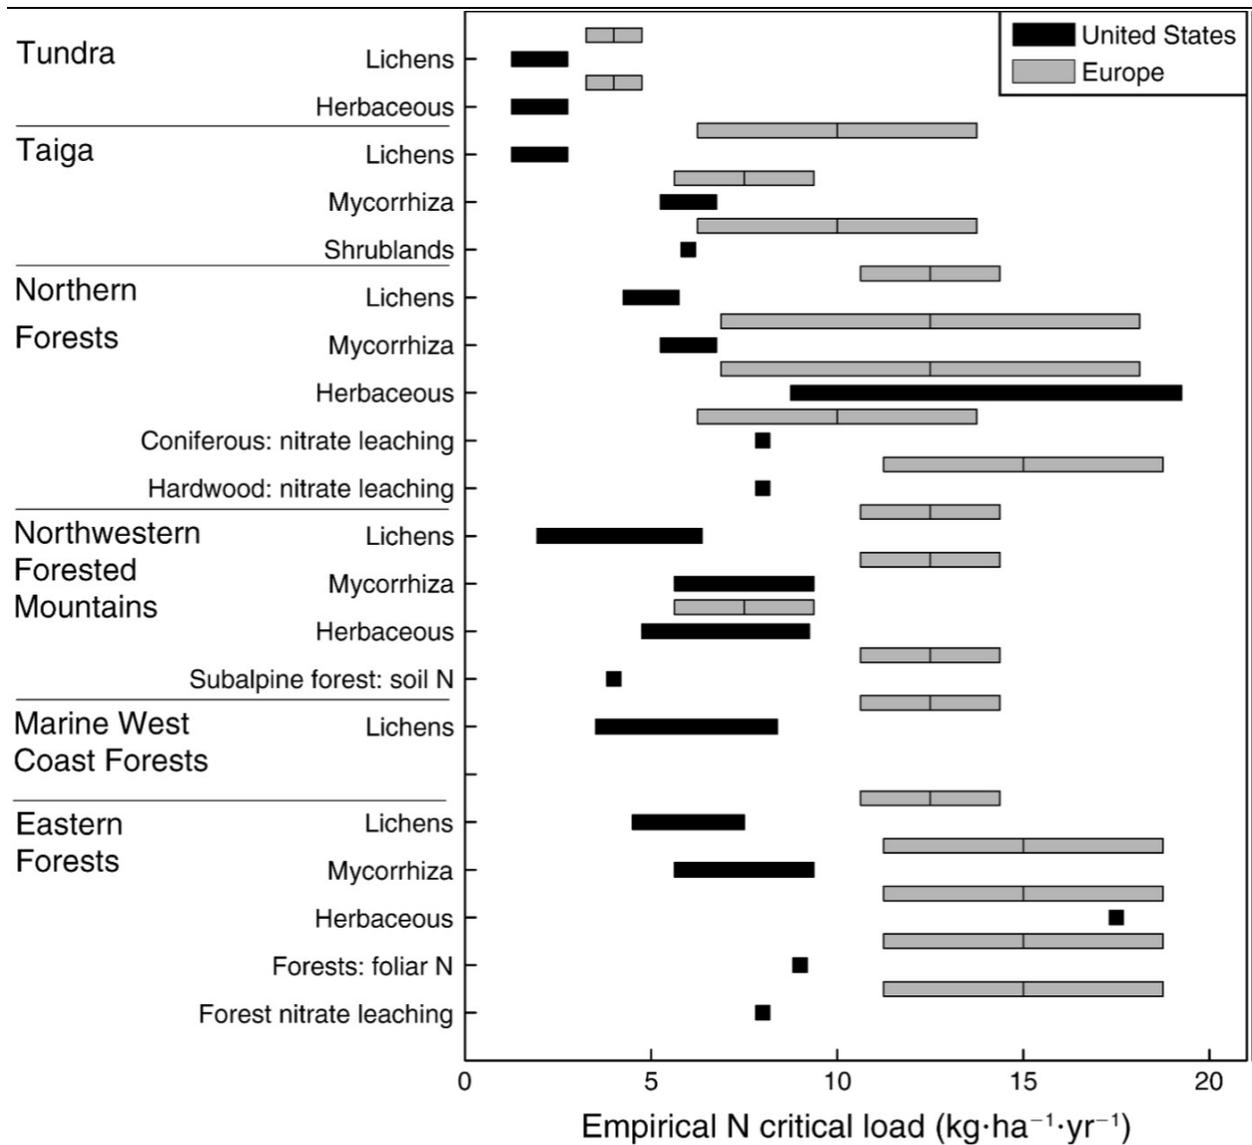

Canada and the northeastern U.S. Among terrestrial ecosystems in North America, the 2008 ISA identified efforts to develop empirical CLs for western ecosystems in the U.S., particularly alpine and arid ecosystems. The reported effect levels ranged from 4 to 5 kg N/ha/yr for changes in the abundance of individual sensitive alpine plant species, to 20 kg N/ha/yr for community level changes in alpine plant communities. [Clark and Tilman \(2008\)](#) calculated the CL for the onset of reduced relative species numbers in grasslands to be 5.3 kg N/ha/yr with a 95% inverse prediction interval of 1.3–9.8 kg N/ha/yr. A CL of 3.1 kg N/ha/yr was considered protective of lichen communities in the western U.S. ([Fenn et al., 2008](#)). However, as of 2008, there was no published CL assessment that spanned the U.S.

A large body of work has been published on CLs for N since the 2008 ISA. Most notably, the U.S. Department of Agriculture (USDA)-Forest Service (FS) created a detailed national assessment of empirically developed CLs for the U.S. ([Pardo et al., 2011c](#)), which has also been summarized into a refereed manuscript ([Pardo et al., 2011a](#)). This national CL document, *Assessment of Nitrogen Deposition Effects and Empirical Critical Loads* ([Pardo et al., 2011c](#)), reports CLs for various biological and biogeochemical endpoints in 15 terrestrial ecoregions. Additionally, in some cases, more recent CLs have been published, often falling into the range of CLs identified by the USDA-FS assessment [[Pardo et al. \(2011c\)](#); summarized in [Appendix 6.6.3](#)].

As with many published CL estimates, most of the CLs reported in the USDA-FS assessment were empirically derived, based on ecological changes observed along atmospheric N deposition gradients or in response to experimental N additions at rates near ambient deposition. Consequently, the links between N deposition and the measured response variable are direct for empirically derived CLs, and full process-level knowledge is not required. There can be a few potential sources of uncertainty with empirically derived CLs, however. The lack of a full process-based understanding can make it difficult to extrapolate observed results across space and time. Spatially, variation in biological and biogeochemical processes imposed by climate, geology, biota, and other environmental factors may alter the observed deposition-response relationship. This is particularly problematic in areas where N deposition has received sparse research attention. [Pardo et al. \(2011c\)](#) reported that for some ecoregions, a single study or very few studies were available. If the variability of ecosystem response to N deposition across an ecoregion is not available, the estimated CL for N may be relevant for only a single ecosystem type or a single subregion within the ecoregion. Whereas atmospheric deposition responds dynamically to shifts in emissions and weather patterns, ecological processes react to environmental stress at a variety of timescales. Because ecological changes can be dependent on a series of underlying processes, there can be a time lag between deposition and ecological responses. Finally, reference plots at the low end of

the deposition gradient may already have been altered from a “pristine” condition, which can bias CL estimates upwards. This shift from a background state can be particularly problematic for highly sensitive indicators, as well as in regions such as the northeastern U.S. that have long and geographically extensive histories of elevated N deposition. In the USDA-FS assessment, [Pardo et al. \(2011c\)](#) reported CLs that tended to be higher in regions experiencing greater rates of N deposition.

Because environmental factors are large influences on both biogeochemical cycling and biological processes ([Pardo et al., 2011c](#)), the discussion of terrestrial biological CLs in this ISA focuses largely on research conducted in North America. Notably, [Pardo et al. \(2011c\)](#) reported that CLs developed for Europe and China both tended to be higher than those reported in the U.S., likely because of the higher rates of N deposition in these regions ([Figure 6-4](#)). Further, because a large portion of the variation in CLs is a function of particular ecological receptors ([Pardo et al., 2011c](#)), the analysis of CL research presented here compares observations for key receptors (e.g., mycorrhizal fungi, lichens, herbaceous plants) across ecoregions, focusing on the estimates created by [Pardo et al. \(2011c\)](#) and other CL research published since 2008.

Source: [Pardo et al. \(2011a\)](#).

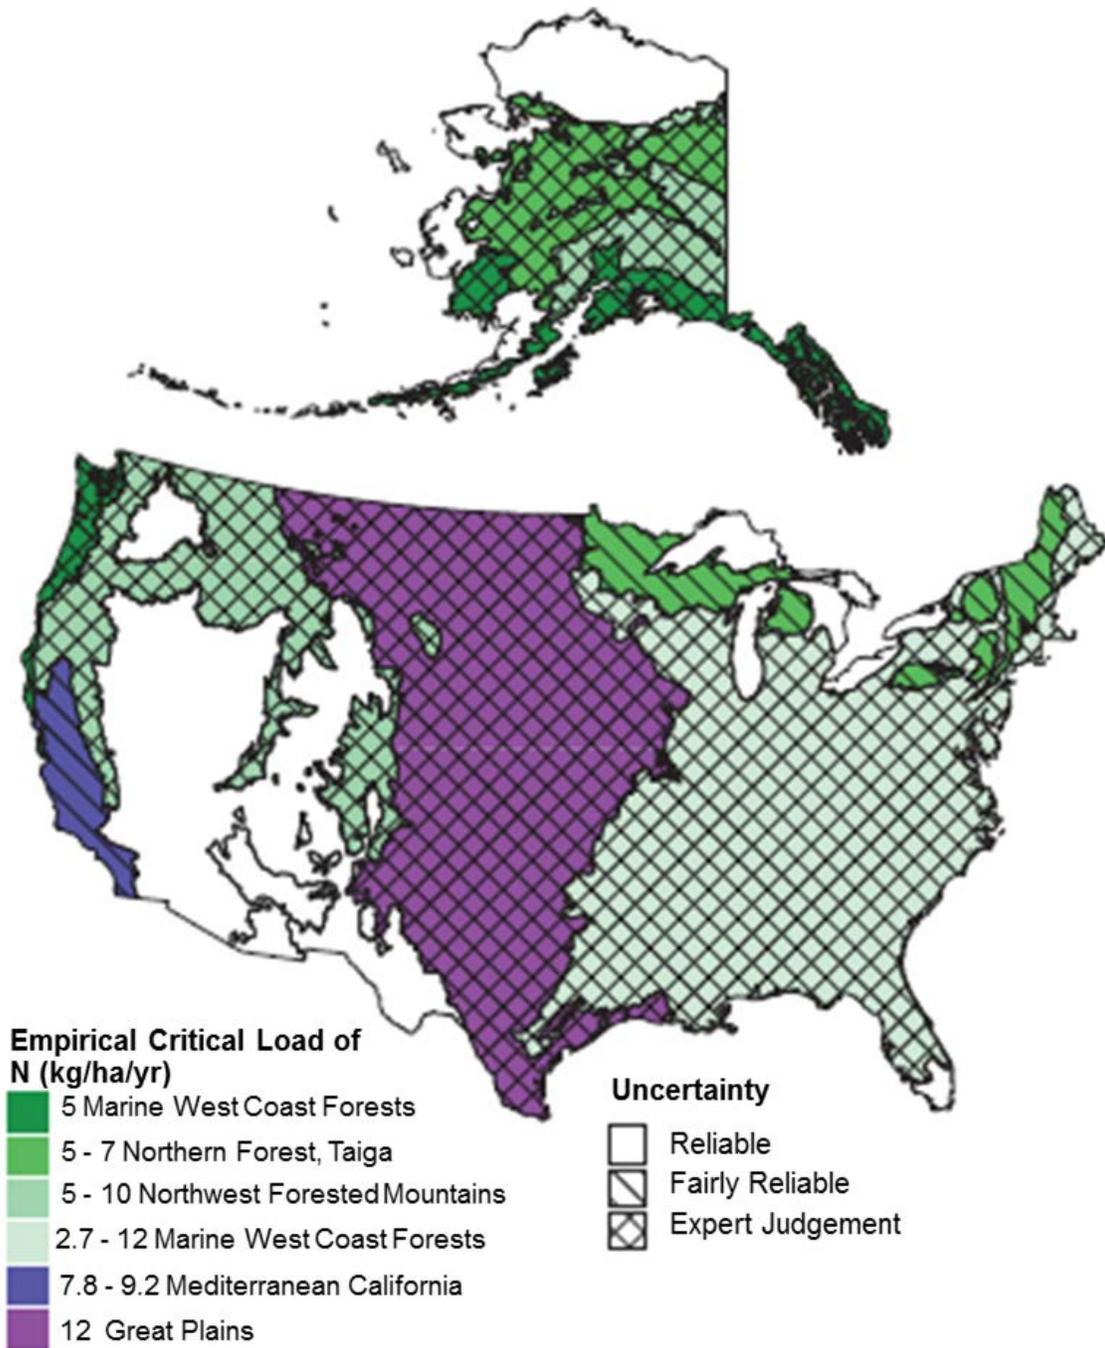

**Figure 6-4 Comparison of European and U.S. empirical critical loads for nitrogen from [Pardo et al. \(2011a\)](#).**

### 6.5.1 Mycorrhizal Fungi

Mycorrhizal fungi are symbiotic organisms hosted on the roots of many plant species, with important roles in plant nutrient acquisition, belowground C cycling, and as food sources for other organisms. As noted in [Appendix 6.2](#) and [Appendix 6.3](#), mycorrhizal fungi can be sensitive to added N, responding through changes in physiology and growth

([Table 6-2](#), [Table 6-3](#), and [Table 6-8](#)), as well as shifts in species richness and community composition ([Table 6-15](#) and [Table 6-16](#)).

Nitrogen CLs for mycorrhizal fungi range between 5 and 12 kg N/ha/yr in the U.S. ([Figure 6-5](#); [Table 6-24](#)) according to studies assessed in [Pardo et al. \(2011c\)](#) and one additional study conducted in a southern California CSS ecosystem ([Allen et al., 2016](#)). [Pardo et al. \(2011c\)](#) documented that N deposition in the range of 5 to 10 kg N/ha/yr can significantly alter ectomycorrhizal fungi community composition and decrease species richness in N limited conifer forests. Similarly, N deposition levels of 7.8 to 12 kg N/ha/yr can lead to arbuscular mycorrhizal community changes in CSS ecosystems in California and grasslands in the Midwest (see Mediterranean California and Great Plains ecoregions in [Figure 6-5](#)), due to declines in spore abundance and root colonization, and changes in community function. Based on additional analysis, [Pardo et al. \(2011c\)](#) suggested the threshold for N effects on mycorrhizae are even lower because high background deposition precludes consideration of sites receiving deposition at or near preindustrial levels. The provisional expert judgment was that CLs for mycorrhizal diversity for sensitive ecosystem types are 5 to 10 kg N/ha/yr ([Table 6-24](#)). [Pardo et al. \(2011c\)](#) indicated there is high uncertainty in this estimate because few studies had been conducted at low rates of N deposition. Since the publication of the USDA-FS assessment, there has been one additional study on CLs for mycorrhizae in the U.S. In that study, [Allen et al. \(2016\)](#) estimated an N deposition CL of 10–11 kg N/ha/yr for mycorrhizal biodiversity in southern California CSS ecosystems.

CL = critical load; ha = hectare; kg = kilogram; N = nitrogen; yr = year.

Notes: The range of CLs reported for mycorrhizal fungi is shown for each ecoregion. The hatch marks indicate increasing level of uncertainty: no hatch marks for the most certain "reliable" category, single hatching for the "fairly reliable" category, and double hatching for the "expert judgment" category. The color sequence moves from green toward blue and violet as the CL increases. As the range of the CL gets broader, the saturation of the color decreases. White areas lack data for CL determination for mycorrhizal fungi.

Source: [Pardo et al. \(2011c\)](#).

Sensitive ecosystem types in the U.S.	5–10	Diversity	Mycorrhizal	<a href="#">Pardo et al. (2011c)</a>
Scots pine forest in Scotland	5–10	Community composition	Ectomycorrhizal fungi	<a href="#">Jarvis et al. (2013)</a>

ha = hectare; kg = kilogram; N = nitrogen; yr = year.

## 6.5.2 Lichens and Bryophytes

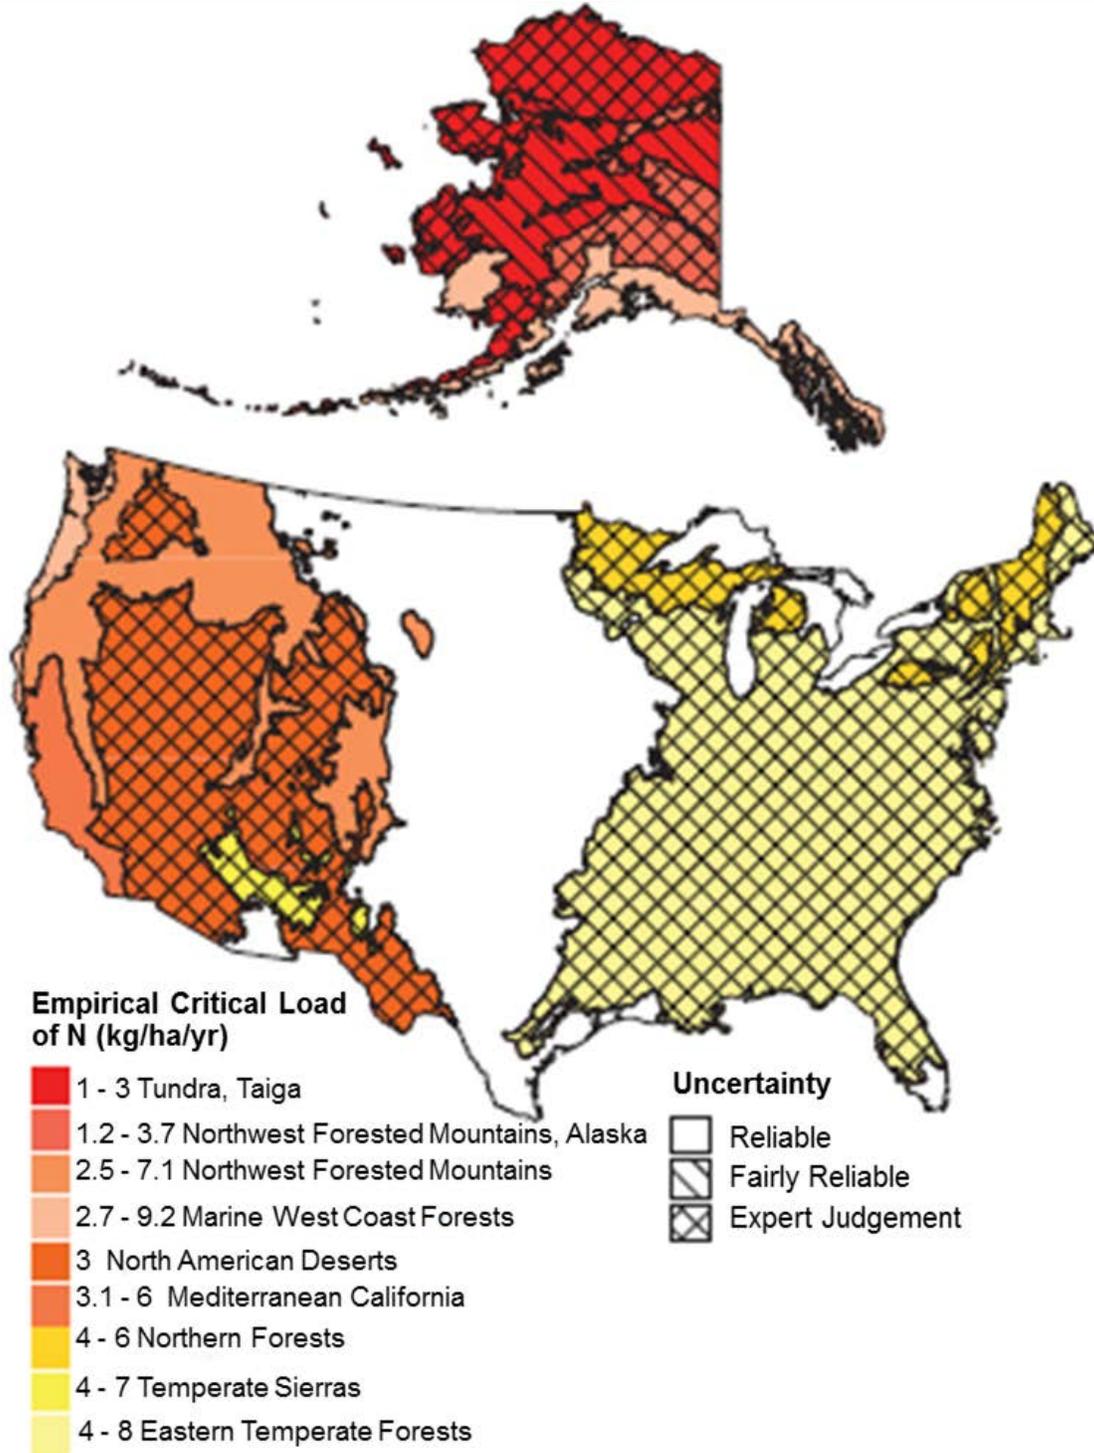

Lichens are symbioses between fungi and algae or cyanobacteria and are important components of plant communities in forests, tundra, and some arid ecosystems. Lichens contribute to ecosystem function by providing food and habitat for wildlife and affecting nutrient and hydrologic cycling. Like mycorrhizae, the growth, physiology, and community composition of lichens is sensitive to atmospheric N deposition ([Table 6-5](#), [Table 6-7](#), and [Table 6-23](#)). The 2008 ISA documented observations that N deposition altered lichen community composition at deposition rates of 3 to 8 kg N/ha/yr ([Fenn et al., 2003a](#)). In the San Bernardino Mountains in southern California, up to 50% of lichen species that occurred in the region in the early 1900s had disappeared by the 1990s ([Fenn et al., 2003a](#); [Nash and Sigal, 1999](#)). The CL has been calculated for lichen communities in mixed conifer forests in California at 3.1 kg N/ha/yr ([Fenn et al., 2008](#)). In the Pacific Northwest, lichen communities have shown evidence of changes in response to increased N pollution, including decreases in the distribution of sensitive lichen taxa and the replacement of these taxa with nitrophilous species ([Geiser and Neitlich, 2007](#)).

Since the 2008 ISA, it has become clear that although simple N deposition CL estimates for changes in lichen community composition can be constructed ([McMurray et al., 2013](#); [Fenn et al., 2008](#)), accounting for the effects of climate and other environmental factors can improve lichen CL estimates ([Blett et al., 2014](#); [Pardo et al., 2011c](#); [Geiser et al., 2010](#)), providing more refined estimates of CL variability and exceedance. As noted in [Appendix 6.2.3.3](#), changes in lichen growth are best correlated with integrated measures

of total N deposition, rather than with the deposition of a single chemical species such as  $\text{HNO}_3$  or  $\text{NH}_4^+$ . Lichen responses to N deposition such as increases in thalli N concentration and shifts in community composition have been most tightly correlated with colocated canopy throughfall measurements of  $\text{N-NO}_3^- + \text{N-NH}_4^+$  ([McMurray et al., 2013](#); [Root et al., 2013](#); [Jovan et al., 2012](#); [Fenn et al., 2007](#)) and ambient N concentrations in fine particulates of  $[\text{NH}_4]_2\text{SO}_4$  and  $\text{NH}_4\text{NO}_3$  ([Root et al., 2015](#); [Geiser et al., 2010](#)).

Lichen community composition and lichen thallus N concentrations shift continuously with all increments of N addition and the response is generally unimodal. In the latter case, the fastest rate of change occurs with the earliest increments of N addition and slows as only tolerant species are left in the community. As N deposition increases, dominance of lichen communities shifts from oligotrophic to eutrophic species (i.e., the number of oligotrophs decrease and the number of eutrophs increase). At very high deposition levels, total biodiversity decreases.

Critical loads for lichen range between 0.26 to 10.2 kg N/ha/yr based on [Pardo et al. \(2011c\)](#) and a number of studies for lichens published since 2008 ([Figure 6-6](#), [Table 6-25](#)). In the USDA-FS CL assessment, [Pardo et al. \(2011c\)](#) documented CLs for lichens of 1 to 9.2 kg N/ha/yr for Level 1 ecoregions. These CLs were predominantly based on the shift in community composition toward eutrophic lichen species and away from oligotrophs. The certainty associated with the lichen CL estimates for each ecoregion varied considerably, in part because of differences in sampling scheme and intensity. There were highly reliable CL estimates in the Pacific Northwest and California, where sampling intensity was high and the linkages between N deposition and lichen community composition have been well documented. Assessments in the eastern U.S. are more problematic due to historical and contemporary S emissions and acidifying deposition. Historical information necessary to identify a “pristine” or “clean” state has been lacking, making it difficult to determine the CL, and the resulting confidence associated with the CL was low.

CL = critical loads; ha = hectare; kg = kilogram; N = nitrogen; yr = year.

Notes: The range of critical loads reported for lichens is shown for each ecoregion. The hatch marks indicate increasing level of uncertainty: no hatch marks for the most certain "reliable" category, single hatching for the "fairly reliable" category, and double hatching for the "expert judgment" category. White areas lack data for CL determination for lichens.

Source: [Pardo et al. \(2011c\)](#).

**Table 6-25 Lichen critical loads.**

Type of Ecosystem	Critical Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Chaparral and oak woodland	5.5	Shift to nitrophyte dominance in the lichen community	California	Epiphytic lichens	<a href="#">Pardo et al. (2011c)</a> <a href="#">Fenn et al. (2010)</a>
Forest	0.26 to 0.33 kg inorganic N/ha/yr and 0.044–0.055 mg/L of ammonium wet deposition	Declines in presence and abundance of sensitive lichen communities	Western Oregon and Washington	Lichens	<a href="#">Glavich and Geiser (2008)</a>
Forest	<4.1	Poorer thallus condition	Wind River Range, WY, including the Class I Bridger Wilderness	Epiphytic lichens	<a href="#">McMurray et al. (2013)</a>
Forest	4–6 for total N deposition	Decreases in lichen species richness and N sensitive species, and poorer thallus condition	Northeastern U.S. Class I areas	Epiphytic lichens	<a href="#">Cleavitt et al. (2015)</a>
Forest	4	Degradation to lichen communities	Northern Rocky Mountains	Epiphytic lichens	<a href="#">McMurray et al. (2015)</a>
Forest	1.54 and 2.51 kg N/ha/yr of through-fall dissolved inorganic N deposition	Lichen communities and lichen N concentration	Pacific Northwest	Epiphytic lichens	<a href="#">Root et al. (2015)</a>
Mixed conifer forests	3.1	Enhanced lichen tissue N concentrations	California	Epiphytic lichens	<a href="#">Fenn et al. (2008)</a> <a href="#">Fenn et al. (2010)</a>
Mixed conifer forests	5.2	Lichen community shifted from acidophyte dominance to neutrophyte dominance	California	Epiphytic lichens	<a href="#">Fenn et al. (2008)</a> <a href="#">Fenn et al. (2010)</a>

**Table 6-25 (Continued): Lichen critical loads.**

Type of Ecosystem	Critical Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference
Mixed conifer forests	10.2	Lichen species classified as acidophytes were extirpated	California	Epiphytic lichens	<a href="#">Fenn et al. (2008)</a> <a href="#">Fenn et al. (2010)</a>
Temperate forest	3–9	Sensitive species declines of 20–40%	Western Oregon and Washington	Epiphytic lichens	<a href="#">Geiser et al. (2010)</a>
Various	1–9.2	Lichen health and community composition	U.S. (national)	Epiphytic lichens	<a href="#">Pardo et al. (2011c)</a>

CL = critical load; ha = hectare; kg = kilogram; N = nitrogen; yr = year.

In addition to the USDA-FS assessment by [Pardo et al. \(2011c\)](#), there have been a number of N deposition CL studies for lichens published since 2008, including research in the northeastern U.S. ([Cleavitt et al., 2015](#)), California ([Fenn et al., 2010](#); [Fenn et al., 2008](#)), the Pacific Northwest ([Root et al., 2015](#); [Geiser et al., 2010](#); [Glavich and Geiser, 2008](#)), and the Rocky Mountains ([McMurray et al., 2013](#)). In the northeastern U.S., [Cleavitt et al. \(2015\)](#) studied four Class I areas and found annual mean and cumulative deposition of N were strongly negatively correlated with lichen species richness, the abundance of N sensitive species, and thallus condition. The work by [Cleavitt et al. \(2015\)](#) supported the CL of 4–6 kg N/ha/yr of total N deposition for epiphytic lichens in the Northern Forests Ecoregion created by [Pardo et al. \(2011c\)](#).

Based on sampling in mixed conifer forests in the Sierra Nevada and San Bernardino Mountains in California, [Fenn et al. \(2008\)](#) developed a CL estimate of 3.1 kg N/ha/yr for throughfall N deposition based on increases in thallus N concentration for the lichen *Letharia vulpina*. Above this CL, there were shifts in lichen community composition away from acidophytic lichen species and toward lichen species considered to be neutrophytic and nitrophytic. [Fenn et al. \(2010\)](#) later applied these and other previously published CL values for lichens in California to estimate that 53 and 41% of the chaparral and oak woodland ecosystems in the state received N deposition in excess of the lichen CL of 5.5 kg N/ha/yr.

In the Wind River Range in western Wyoming, [McMurray et al. \(2013\)](#) developed a lichen CL based on study sites adjacent to the Bridger Wilderness, a Class I area downwind of an area experiencing oil and gas production. Above a threshold of 4.0 kg N/ha/yr of throughfall N deposition, [McMurray et al. \(2013\)](#) observed a degradation of lichen communities in this area that included necrotic and bleached thalli and decreased growth.

---

### 6.5.3 Herbaceous and Shrub Species

Herbaceous species and shrubs are found in grasslands, shrublands, forests, deserts, and wetlands, and comprise the majority of the roughly 26,600 vascular plant species found in North America north of Mexico ([NRCS, 2009](#)). In forests, herbaceous-layer (understory) vegetation can be important contributors to ecosystem processes such as litter production and N cycling ([Talhelm et al., 2013](#)), and can comprise up to 90% of forest plant biodiversity, including endangered or threatened species ([Gilliam, 2007](#)). As described in [Appendix 6.3.3.2](#), there is abundant evidence that forest understory vegetation composition can be sensitive to N deposition ([Table 6-13](#)).

Critical loads for herbaceous and shrub species range between 0.9 to 33 kg N/ha/yr based on studies published since 2008 ([Table 6-26](#)). In the USDA-FS assessment, [Pardo et al. \(2011c\)](#) reported N deposition CLs of 1 to 33 kg N/ha/yr for herbaceous species and shrubs across all ecoregions ([Figure 6-7](#); [Table 6-26](#)). The lowest CL was for tundra (1–3 kg N/ha/yr), while the highest was for the Mediterranean California ecoregion, specifically a mixed conifer forest ecosystem in the San Bernardino Mountains ([Pardo et al., 2011c](#)).

Among the new research published since the USDA-FS assessment was completed, [Simkin et al. \(2016\)](#) examined the influence of N deposition on species richness of grasses and forbs in over 15,000 plots located across the continental U.S. Notably, they found different relationships between N deposition and species richness in open canopy and closed canopy ecosystems, likely a function of different species loss mechanisms ([Appendix 6.3.2](#)) operating in these systems. In open canopy systems (e.g., grasslands, shrublands, and woodlands), N deposition above an average of 8.7 kg N/ha/yr led to a reduction in species richness (5th–95th percentile: 6.4–11.3 kg N/ha/yr). These rates of N deposition are common across much of the eastern and central U.S., as well as areas in the western U.S. that are downwind of major urban and agricultural areas ([Figure 6-8](#)). Average CLs for grasses and forbs did not differ widely among the grassland, shrubland, and woodland ecosystems (8.9, 8.5, and 8.5 kg N/ha/yr). The calculated CL for closed canopy systems was considerably higher: 13.4 kg N/ha/yr (5th–95th percentile: 6.8–22.2 kg N/ha/yr). At higher levels of N input, processes such as competitive exclusion and soil acidification occur, decreasing species richness. There are two important observations from this analysis. First, increases in N deposition below the CL levels could increase species richness, particularly in open canopy ecosystems. Second, the effects of N deposition on species richness were often pH dependent (see [Appendix 6.3.2](#)). [Simkin et al. \(2016\)](#) also developed more localized CL estimates. In forests, these ranged from a low of 7.9 kg N/ha/yr in open canopy eastern forests to a high of 15.3 kg N/ha/yr in northwestern forested mountains. In the Great Plains region, [Simkin et al. \(2016\)](#) estimated CLs for grasses and forbs of 8.3–9.8 kg N/ha/yr in the open canopy systems to 11.3–19.6 kg N/ha/yr in closed canopy systems. In arid ecosystems, [Simkin et al. \(2016\)](#) estimated a CL of 8.3–9.9 kg N/ha/yr for open canopy ecosystems and 13.5–17 kg N/ha/yr for closed canopy ecosystems.

**Table 6-26 Herbaceous and shrub critical loads.**

Type of Ecosystem	Critical Load (kg N/ha/yr)	Biological and Chemical Effects	Study Site	Study Species	Reference

EUNIS = European Nature Information System; ForSAFE-VEG = a dynamic forest ecosystem model; ha = hectare; kg = kilogram; N = nitrogen; SMART2 = a simple soil acidification and nutrient-cycling model; yr = year.

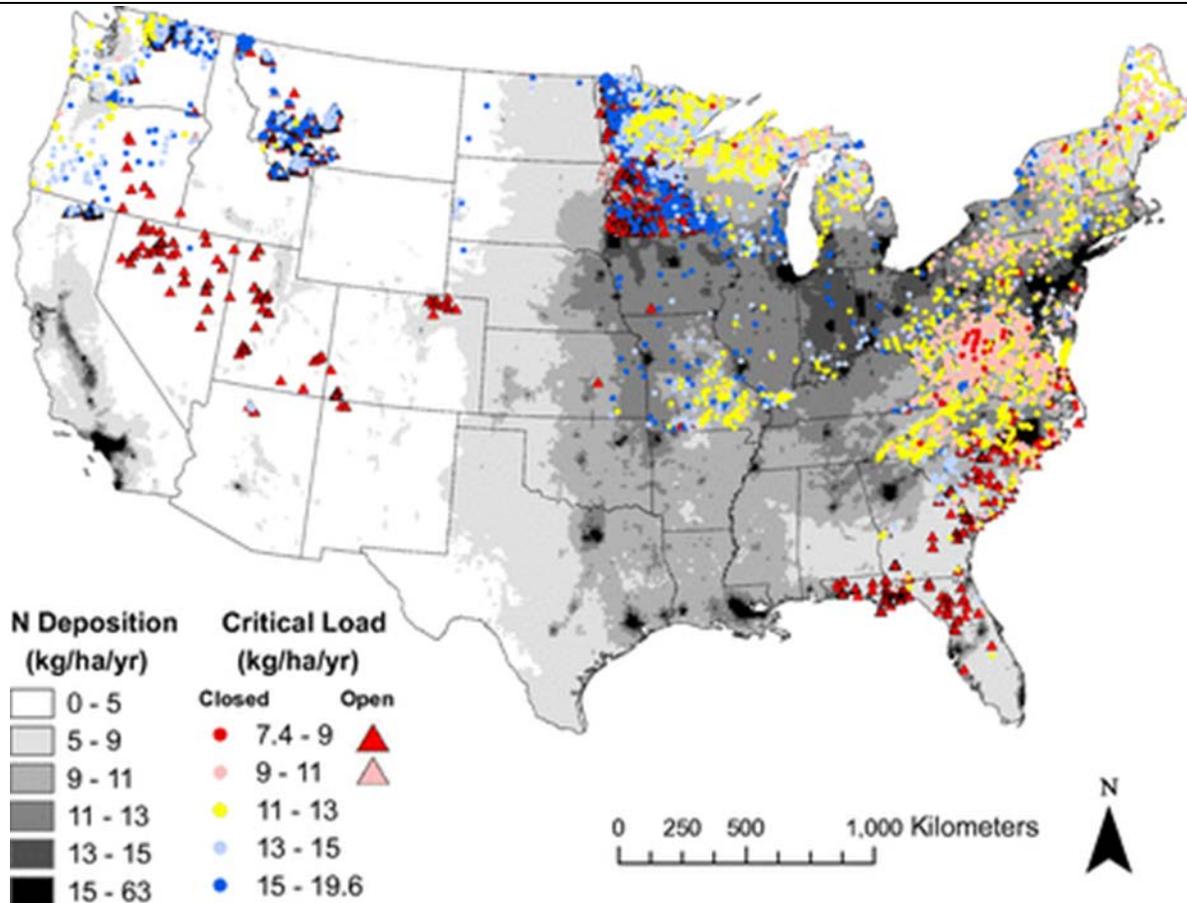

CL = critical load; ha = hectare; kg = kilogram; N = nitrogen; yr = year.

Notes: The range of CLs reported for herbaceous plants and shrubs is shown for each ecoregion. The hatch marks indicate increasing level of uncertainty: no hatch marks for the most certain "reliable" category, single hatching for the "fairly reliable" category, and double hatching for the "expert judgment" category. White areas lack data for CL determination for herbaceous species and shrubs.

Source: [Pardo et al. \(2011c\)](#).

**Figure 6-7** Map of critical loads for herbaceous plants and shrubs by ecoregion in the U.S.

ha = hectare; kg = kilogram; N = nitrogen; yr = year.

Notes: The 3,317 open sites (combined grassland, shrubland, and woodland vegetation types) are portrayed with triangles, and the 11,819 closed canopy sites (deciduous, evergreen, and mixed forests) are portrayed with circles. Background deposition values are the average of 27 years of wet deposition (NADP 1985–2011) plus the average of 10 years of dry deposition (from Community Multiscale Air Quality model, 2002–2011). Other variation in CLs is due to the other predictor variables (soil pH, temperature, and precipitation).

Source: [Simkin et al. \(2016\)](#).

**Figure 6-8 Nitrogen deposition (gray scale) and critical loads for nitrogen deposition based on total graminoid plus forb species richness (colored symbols).**

Within the Colorado Rocky Mountains, there were several efforts to develop CLs based on both empirical and modeled data. In the Rocky Mountain National Park, [Bowman et al. \(2012\)](#) calculated an empirical CL of 3 kg N/ha/yr to protect natural community cover based on large increases in the abundance of the sedge *Carex rupestris* to additional N deposition. [McDonnell et al. \(2014a\)](#) applied the ForSAFE-VEG model to develop a long-term CL estimate aimed at avoiding future (2010–2100) changes (of more than 10%) in subalpine plant biodiversity in Rocky Mountain National Park. The estimated

CL to protect future plant diversity was 1.9–3.5 kg N/ha/yr, a value already exceeded in the study area. [Sverdrup et al. \(2012\)](#) also used the ForSAFE-VEG model to understand how long-term CLs would be influenced by climate change, but worked from a synthetic alpine and subalpine vegetation data set developed from observations at national parks in the northern and central Rocky Mountains region of the U.S. They determined CL values of 1 to 2 kg N/ha/yr to protect against a future change in plant diversity of 5–20%.

Notably, CLs protecting against future biodiversity changes may not be comparable directly to other CLs protective against current changes to herbaceous and shrub biodiversity ([Table 6-26](#)). Critical loads are expressed on an annual basis, and CLs protective of future biodiversity may be lower generally than shorter-term CLs to avoid the accumulating effects of deposition over longer periods of time. Consideration of future temperature increases, among other factors, however, may complicate this relationship. In their simulations, [McDonnell et al. \(2014a\)](#) concluded that where the CL was between 1.9 and 3.5 kg N/ha/yr depended upon future temperatures. Higher simulated temperatures resulted in CL values higher in the range, closer to 3.5 kg N/ha/yr. They attributed this to the increased N uptake of the vegetation with higher temperatures, allowing an increase in deposition while protecting against shifts in plant diversity. Thus, among other factors, comparison of CLs protecting against future versus current changes likely requires a consideration of the underlying assumptions about future conditions.

In addition to the CL estimates for plant species richness ([Simkin et al., 2016](#)), two other CL estimates have been developed for arid and semiarid ecosystems. [Pardo et al. \(2011c\)](#) determined a CL of 3–8.4 kg N/ha/yr for North American deserts based on a decrease in native forbs. [Rao et al. \(2010\)](#) developed unique CL estimates for the rate of N deposition that would increase the probability of vegetation productivity in two arid ecosystems within Joshua Tree National Park in southern California exceeding a wildfire risk threshold. To do this, [Rao et al. \(2010\)](#) applied the DayCent model. The risk of exceeding the wildfire risk threshold of 1,000 kg of biomass/ha increased rapidly above CLs of 2.1 and 3.6 kg N/ha/yr for the two ecosystem types. The risk of exceeding the threshold increased until N deposition levels reached 5.5 and 8.8 kg N/ha/yr for the two ecosystem types. Notably, contemporary rates of N deposition at the study sites were 3 to 8 kg N/ha/yr, and up to 16 kg N/ha/yr has been observed in areas adjacent to these desert ecosystems and downwind from or near urban areas ([Fenn et al., 2010](#)). In southern California, [Cox et al. \(2014\)](#) modeled the influence of environmental factors such as climate, land use, and N deposition on the conversion of CSS ecosystems to exotic annual grasslands from 1930 to 2009. Here, conversion of CSS to exotic grasslands was more likely to occur if N deposition exceeded 11 kg N/ha/yr. This CL estimate was similar to a CL of 10 kg N/ha/yr for CSS developed by [Pardo et al. \(2011c\)](#).

## 6.5.4 Trees

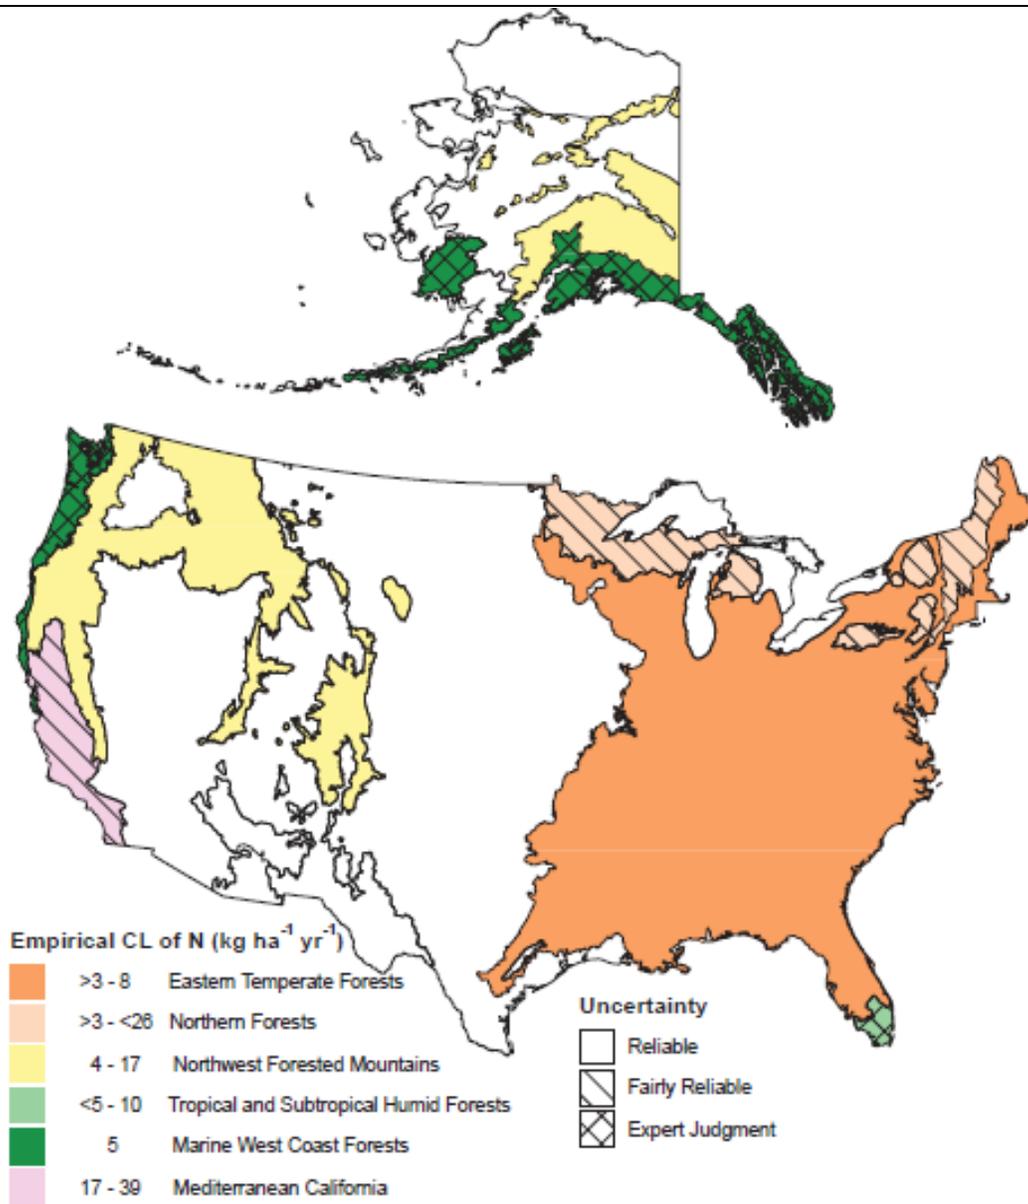

As noted in [Appendix 6.3.3.1](#), there are relatively few direct observations of overstory tree community composition change, likely because it is difficult to observe changes for long-lived organisms in slowly developing communities. However, there is more abundant evidence of changes in tree growth, mortality, and physiology ([Appendix 6.2.3.1](#)). Notably, CLs for trees due to N + S deposition are presented in [Appendix 5](#).

Nitrogen CLs for trees range between >3 to 39 kg N/ha/yr based on studies compiled in [Pardo et al. \(2011c\)](#) and one other study published since 2008 ([Table 6-27](#)). In the USDA-FS assessment, [Pardo et al. \(2011c\)](#) reported that N CLs for forest ecosystems ranged from >3 to 39 kg N/ha/yr ([Figure 6-9](#)). Estimates of 3–26 kg N/ha/yr for declining forest growth and increased mortality were based on the forest inventory data analysis conducted by [Thomas et al. \(2010\)](#) and a chronic N addition experiment conducted in red spruce forests in the northeastern U.S. ([McNulty et al., 2005](#)). In California mixed conifers, [Pardo et al. \(2011c\)](#) reported a CL of 17 kg N/ha/yr for decreased fine root biomass and 39 kg N/ha/yr for forest sustainability, both developed from observations reported by [Fenn et al. \(2008\)](#). In one additional study subsequent to the USDA-FS assessment, [Fleischer et al. \(2013\)](#) reported that greater rates of N deposition increased canopy photosynthetic capacity in evergreen needleleaf forests below a CL threshold of 8 kg N/ha/yr.

**Table 6-27 Tree critical loads.**

Type of Ecosystem	Critical Load kg N/ha/yr	Biological and Chemical Effects	Study Site	Study Species	Reference
Evergreen forest	~8	Saturation of photosynthetic capacity of the canopy	32 forest sites around the globe	Conifer	<a href="#">Fleischer et al. (2013)</a>
Various forests	>3–39	Tree growth and survival; other various effects	U.S. (national)	Various	<a href="#">Pardo et al. (2011c)</a>

ha = hectare; kg = kilogram; N = nitrogen; yr = year.

CL = critical load; ha = hectare; kg = kilogram; N = nitrogen; yr = year.

Notes: The range of CLs reported for forest ecosystems is shown for each ecoregion; this map does not include the responses of mycorrhizal fungi, lichens, or understory herbaceous plants already represented. The hatch marks indicate increasing level of uncertainty: no hatch marks for the most certain "reliable" category, single hatching for the "fairly reliable" category, and double hatching for the "expert judgment" category. White areas lack data for CL determination for forest ecosystems.

**Figure 6-9** Map of critical loads for forest ecosystems by ecoregion in the U.S.

---

## 6.5.5 Critical Loads Exceedance Studies

In the USDA-FS assessment of N deposition CLs, [Pardo et al. \(2011c\)](#) evaluated the CL exceedances for mycorrhizal fungi, lichens and bryophytes, herbaceous plants and shrubs, and forests using N deposition estimates produced by the Community Multiscale Air Quality (CMAQ) model v.4.3. This CMAQ model used data reported in 2001 for the simulations of wet plus dry N deposition. [Pardo et al. \(2011c\)](#) concluded that large parts of the eastern U.S., as well as localized areas in the West, experience rates of N deposition that exceed the CL for sensitive ecosystem components. In this assessment, [Pardo et al. \(2011c\)](#) determined that the resources most threatened by elevated N deposition included freshwater diatoms, lichens, bryophytes, and herbaceous plants.

In addition to [Pardo et al. \(2011c\)](#), several studies have quantified N deposition CL exceedance at the regional scale for herbaceous plants. In the [Simkin et al. \(2016\)](#) analysis of herbaceous species richness in over 15,000 plots over the continental U.S., approximately 41% of grassland plots were experiencing N deposition in exceedance of the CL for plant species richness. [Clark et al. \(2013\)](#) used 26 years (1985–2010) of N deposition data with ecosystem-specific functional responses from local field experiments and a national CLs database to generate estimates of herbaceous species loss. In scenarios using the low end of the CL range, N deposition exceeded CLs over 0.38, 6.5, 13.1, 88.6, and 222.1 million ha for the Mediterranean California, North American Desert, Northwestern Forested Mountains, Great Plains, and Eastern Forests ecoregions, respectively, with corresponding species losses ranging from <1 to 30%. When scenarios assumed less sensitivity (using a common CL of 10 kg N/ha/yr, and the high end of the CL range) minimal losses were estimated. The large range in projected impacts among scenarios highlights the uncertainty in current CLs estimates for plant diversity in the U.S.

[McLauchlan et al. \(2014\)](#) analyzed a 27-year record of ecophysiological, community, and ecosystem metrics for an annually burned Kansas tallgrass prairie. Despite observed rates of atmospheric N deposition (7 kg N/ha/yr from 2002 to 2009) that exceed the minimum estimated CL for herbaceous plants in tallgrass prairie of the Great Plains of North America [5–15 kg N/ha/yr; [Pardo et al. \(2011c\)](#)], there were no observations of plant community composition change or effects on plant physiology that signaled an obvious influence of N deposition: plant N concentrations and plant N availability did not increase, aboveground NPP was unchanged, forb diversity did not decline, and the relative abundance of dominant grasses did not shift toward more eutrophic species. Thus, current rates of N deposition do not appear to be altering ecosystem function in this grassland, even though these rates exceed minimum CLs. The authors offered a couple of potential explanations for this lack of response, including sequestration of the additional

N into soil organic matter pools and offsetting removal of N by biomass burning and/or grazing.

Finally, [Clark et al. \(2018\)](#) estimated CL exceedance areas for the conterminous U.S. over a more than 200 year period. In this study, they examined six CL types, with three N CLs germane to terrestrial ecosystems: (1) changes in forest tree health, (2) changes in lichen communities, and (3) changes in herbaceous and shrub plant community composition. Overall, this analysis showed terrestrial N CLs have been exceeded for many decades in areas across the U.S. Minimum values for these CLs were already exceeded by 1855 for the first two CLs, and the latter CL was exceeded between 1935 and 1955. Exceedance areas peaked in 1995 for changes in lichen communities and plant community composition at 3.47 and 2.87 million km<sup>2</sup>, respectively, before declining marginally by 2006. The minimum forest tree health CL was exceeded in 2.41 million km<sup>2</sup> by 1855 and did not change much over time, primarily because the relatively low CL compared to deposition values in the Eastern Temperate and Northern Forests ecoregions.

---

## 6.6 Summary

---

### 6.6.1 Physiology, Growth, and Productivity Summary

At the time of the 2008 ISA, there was evidence sufficient to infer a causal relationship between N deposition and the alteration of the biogeochemical cycling of C in terrestrial ecosystems. This evidence included observations that added N increased plant productivity across a broad range of terrestrial ecosystems. The 2008 ISA, however, made no explicit statement regarding the effects of N deposition on physiology, growth, and productivity.

Since the 2008 ISA, a more complete understanding of how N deposition effects terrestrial organisms and ecosystems has been developed, the effects of N deposition in terrestrial ecosystems in North America and Europe have been more widely documented, and a significant new body of research has observed N deposition impacts in Asia (particularly China). These efforts have provided further evidence that added N alters plant physiological processes, stimulates the growth of most plants, and broadly increases productivity ([Liu and Greaver, 2010](#); [LeBauer and Treseder, 2008](#); [Xia and Wan, 2008](#)). Moreover, studies have shown species-specific effects of N deposition on tree growth and mortality ([Horn et al., 2018](#); [Dietze and Moorcroft, 2011](#); [Thomas et al., 2010](#)). There is also widespread evidence that N additions affect soil microbial physiology and biomass (see [Appendix 4](#) for soil extracellular enzyme responses), particularly by decreasing the abundance of symbiotic mycorrhizal fungi ([Li et al., 2015](#); [Treseder, 2008](#)). There have also been numerous observations that additional N can alter arthropod performance and abundance among both detritivores and herbivores [[Throop and Lerdau \(2004\)](#); [Table 6-17](#)]. Thus, it is apparent that plants, microorganisms, and ecosystem-scale productivity are sensitive to N availability. **This body of evidence is sufficient to infer a causal relationship between N deposition and the alteration of the physiology and growth of terrestrial organisms and the productivity of terrestrial ecosystems.**

Although plants are broadly sensitive to added N, it is clear that the effects of N on plant growth and productivity vary considerably among plant tissues ([Li et al., 2015](#); [Xia and Wan, 2008](#)), individual species and functional types ([Xia and Wan, 2008](#)), and biomes ([LeBauer and Treseder, 2008](#)). In a meta-analysis of 1,600 observations, short-lived plant functional types tended to have stronger relative responses than long-lived plants; herbaceous plants responded more than woody plants, and annual herbs responded more than perennial herbs [[Xia and Wan \(2008\)](#); [Figure 6-1](#)]. Shrubs were notably less

responsive than trees ([Figure 6-1](#)), potentially because of the prevalence of shrubs in more arid environments; overall, biomass responses increased linearly with mean annual precipitation ([Xia and Wan, 2008](#)). There is also now more consistent and widespread evidence that N additions increase aboveground biomass more than belowground biomass, raising the shoot:root ratio among plants ([Li et al., 2015](#); [Lu et al., 2011b](#)).

The increase in aboveground growth of individual plant species is the best documented response of plants to N, with fewer studies documenting belowground growth responses and more complex physiological and ecosystem-scale responses (e.g., [Figure 6-1](#) and [Figure 6-2](#)). [LeBauer and Treseder \(2008\)](#) found that N additions stimulated aboveground productivity, but the relative stimulation was smaller than the response of individual plants identified by [Xia and Wan \(2008\)](#). Belowground net primary productivity responses to added N have not yet been synthesized because of lack of data ([LeBauer and Treseder, 2008](#)). [Liu and Greaver \(2009\)](#) did not find a significant effect on net ecosystem exchange, but forest ecosystem C content was increased by 6%.

In the 2008 ISA, the increase in plant growth and terrestrial productivity was attributed to increases in foliar N content and related increases in photosynthesis. As noted earlier, increases in plant N concentrations are widespread ([Koricheva et al., 1998](#)), particularly in the foliage. [Koricheva et al. \(1998\)](#) had previously quantified increases in foliar N concentrations among woody plants; [Xia and Wan \(2008\)](#) expanded this analysis to other plant functional groups, with an overall stimulation of +28.5%. Aside from smaller responses among legumes and broader functional groups containing legumes, there was a relatively narrow range of responses across functional groups (+24–34%). Root N concentrations show similar responses ([Li et al., 2015](#); [Xia and Wan, 2008](#)). Given the mechanistic and empirical relationships between greater foliar N concentrations, higher leaf concentrations of the C assimilating enzyme RuBisCo ([Evans, 1989](#)), and greater maximum rates of leaf-level photosynthesis in vascular plants ([Wright et al., 2004](#)), the increases in foliar N observed with greater N supply have been linked to higher rates of leaf-level photosynthesis [e.g., [Teskey et al. \(1994\)](#)]. Alternately, there was evidence in the 2008 ISA that much of the additional foliar N could be physiologically inactive ([Bauer et al., 2004](#)), consistent with the significant increase in free amino acids observed by [Koricheva et al. \(1998\)](#). Increases in photosynthesis following N additions have been observed across a variety of plant functional types, but higher rates of photosynthesis have not been universally observed in long-term experiments [e.g., [Gulmon and Chu \(1981\)](#); [Lajtha and Whitford \(1989\)](#); [Newman et al. \(2003\)](#); [Chen et al. \(2005b\)](#); [Elvir et al. \(2006\)](#); [Talhelm et al. \(2011\)](#)] and there have not been any broad syntheses or meta-analyses of either leaf-level photosynthesis or gross primary productivity. There is a similar mechanistic and empirical relationship between tissue N concentrations and respiration rates, but this relationship has shifted in long-term N addition studies,

providing further evidence that much of the additional tissue N is physiologically inactive [e.g., [Drake et al. \(2008\)](#); [Burton et al. \(2012\)](#)].

Decreases in the quantity of C allocated belowground to roots, mycorrhizae, and root exudation could provide a mechanism that increases aboveground plant growth in plants and ecosystems that do not show gains in photosynthesis [e.g., [Talhelm et al. \(2011\)](#)]. Plants provide mycorrhizal fungal symbionts with C in exchange for nutrients, and the abundance of mycorrhizal fungi and the rates at which these fungi colonize roots declines when N is added to terrestrial ecosystems ([Treseder, 2004](#)), a finding that has since been corroborated ([Li et al., 2015](#); [Treseder, 2008](#)). The decrease is particularly well documented for ectomycorrhizal fungi ([Table 6-2](#)), but can also occur with arbuscular mycorrhizal fungi [[van Diepen et al. \(2010\)](#); [Table 6-3](#)].

Nitrogen deposition can affect the physiology and abundance of soil microorganisms through decreases in soil pH, increases in inorganic N availability, changes in soil food webs, and shifts in the quantity and quality of available C ([Xia et al., 2015](#); [Manning et al., 2008](#); [Treseder, 2008](#); [Koricheva et al., 1998](#)). There were some observations in the 2008 ISA that added N decreased microbial biomass. There is now more abundant evidence that N deposition can affect microbial communities. In meta-analyses, N additions have been shown to decrease microbial biomass ([Treseder, 2008](#)), microbial biomass C ([Liu and Greaver, 2010](#)), and microbial biomass N ([Lu et al., 2011b](#)). In a meta-analysis, [Treseder \(2008\)](#) found that the negative effects of added N on microbial biomass increased in magnitude with the duration of the N additions and the cumulative amount of added N. Notably, these observations of soil microbial biomass would include the hyphal biomass of mycorrhizal fungi. There are fewer observations of N addition effects at the level of individual microbial domains (e.g., bacteria, fungi), functional groups (e.g., saprotrophic vs. mycorrhizal fungi), or other higher level taxonomic groups, and aside from the aforementioned decreases in mycorrhizal fungi, effects at these scales appear to be less consistent ([Table 6-4](#)).

---

## 6.6.2 Biodiversity Summary

The 2008 ISA found evidence sufficient to infer a causal relationship between deposition and the alteration of species richness, species composition, and biodiversity in terrestrial ecosystems. Since 2008, there is now more widespread documentation of decreases in lichen species richness as the result of N deposition in the U.S. [e.g., [Jovan \(2008\)](#); [Geiser et al. \(2010\)](#)], and there are now direct observations that: (1) N deposition in the U.S. is altering herbaceous plant species richness across a broad range of ecosystems, including forests, grasslands, arid and semiarid ecosystems, and alpine tundra

[e.g., [Simkin et al. \(2016\)](#)], and (2) N deposition in the U.S. is changing mycorrhizal community composition [e.g., [Lilleskov et al. \(2008\)](#); [Allen et al. \(2016\)](#)]. Further, based on changes in mortality and growth rates of overstory tree species, there is also now indirect evidence that N deposition is altering overstory tree community composition [e.g., [Thomas et al. \(2010\)](#); [Dietze and Moorcroft \(2011\)](#); [Horn et al. \(2018\)](#)]. **The body of evidence is sufficient to infer a causal relationship between N deposition and the alteration of species richness, community composition, and biodiversity in terrestrial ecosystems.**

In forests, research since 2008 has provided evidence of altered understory plant, soil microbial, arbuscular and ectomycorrhizal, and arthropod communities. Three new assessments using forest inventory plots from the eastern U.S. have observed effects on growth and mortality that likely impact forest overstory tree composition [e.g., [Thomas et al. \(2010\)](#); [Dietze and Moorcroft \(2011\)](#); [Horn et al. \(2018\)](#)]. However, these data sets and analyses have not directly been applied to assess changes in forest overstory composition either in North America or Europe. Evidence for altered forest understory plant communities (also known as herbaceous layer or groundcover vegetation) come from both the 2008 ISA and the literature published since 2008. [Gilliam \(2006\)](#) reviewed nine studies on the effects of N deposition on forest understory plant communities in North America and Europe, including two European studies that documented shifts in understory plant community composition along N deposition gradients ([Strengbom et al., 2001](#); [Brunet et al., 1998](#)). In a new analysis of understory plant community composition, [Simkin et al. \(2016\)](#) observed that N deposition increased herbaceous plant species richness where soil pH was neutral or basic, but that N deposition above 11.6 kg N/ha/yr decreased herbaceous species richness on acidic soils. Similar studies of plant community composition have been conducted across N deposition gradients in Europe, with both [Verheyen et al. \(2012\)](#) and [Dirnböck et al. \(2014\)](#) finding shifts in plant community composition toward more nutrient-demanding and shade-tolerant plant species, but no loss of species richness. For soil microbial communities, [Zechmeister-Boltenstern et al. \(2011\)](#) observed shifts in soil microbial community composition along an N deposition gradient in Europe and multiple N addition studies identified since 2008 have observed changes in microbial community composition [e.g., [van Diepen et al. \(2010\)](#); [Hobbie et al. \(2012\)](#); [Zhao et al. \(2014a\)](#)]. Among studies of how N affects forest ectomycorrhizal community composition, there were changes in six out of seven studies identified ([Table 6-15](#)). This included four studies where shifts in community composition could be directly or indirectly linked to N deposition gradients in the U.S. or Europe.

Since 2008, new studies have quantified the impact of N additions on species richness, species diversity, and community composition among vascular plants, bryophytes, lichens, and soil microorganisms in alpine and Arctic tundra ecosystems in North

America, Europe, and Asia. Within the U.S., several N addition studies have documented changes in plant community composition, including experiments in Colorado ([Farrer et al., 2015](#); [Bowman et al., 2012](#)) and Washington ([Bishop et al., 2010](#)). In the North Atlantic region of Europe, [Armitage et al. \(2014\)](#) observed shifts in community composition and decreases in plant species richness among alpine heathlands located along an N deposition gradient. Similarly, [Southon et al. \(2013\)](#) found decreasing vascular plant species richness with increasing N deposition in heathlands in the U.K. [Arens et al. \(2008\)](#) did not observe changes in community composition as a result of N additions in Greenland, but shifts in plant community composition were observed in longer (7 to 8 years) experiments in tundra ecosystems in China ([Song and Yu, 2015](#)), Switzerland ([Bassin et al., 2013](#)), and Sweden ([Wardle et al., 2013](#)). Shifts in microbial community composition were observed in several N addition experiments, including in the U.S. in Colorado ([Farrer et al., 2013](#); [Nemergut et al., 2008](#)).

New research on lichens has added further evidence that lichen communities in the U.S. and Europe are sensitive to current levels of atmospheric N deposition. Shifts in lichen community composition attributable to atmospheric N pollution have been observed in forests throughout the West Coast ([Jovan et al., 2012](#); [Geiser et al., 2010](#); [Jovan, 2008](#)), in the Rocky Mountains ([McMurray et al., 2015](#); [Rogers et al., 2009](#)), and in southeastern Alaska ([Schirokauer et al., 2014b](#)). Outside of the U.S., changes in lichen community composition have been observed with increased atmospheric NO<sub>2</sub> concentrations in Nova Scotia, Canada ([Gibson et al., 2013](#)) and experimental N additions in Sweden ([Johansson et al., 2012](#)).

Since 2008, there have been direct observations of reduced species richness along atmospheric N deposition gradients for grasslands in the U.S. ([Simkin et al., 2016](#)) and in Europe ([Pannek et al., 2015](#); [Field et al., 2014](#); [Gaudnik et al., 2011](#); [Stevens et al., 2011a](#); [Stevens et al., 2011b](#); [Dupre et al., 2010](#); [Stevens et al., 2010b](#); [Stevens et al., 2010a](#)). Studies in both the U.S. and in Europe have found that the effects of N deposition on grassland communities are often dependent on soil pH [e.g., [Stevens et al. \(2010b\)](#); [Stevens et al. \(2011a\)](#); [Maskell et al. \(2010\)](#); [Simkin et al. \(2016\)](#)]. Information about changes in mycorrhizal communities in grasslands was limited and provided mixed results ([Chen et al., 2014](#)); while of the five studies identified investigating compositional changes to soil microbial communities in grasslands, four observed shifts in composition ([Table 6-20](#)).

Research since 2008 from N deposition gradient studies and N addition experiments in U.S. arid and semiarid regions has been dominated by research from southern California, which has provided evidence that higher N availability alters plant community composition through an increase in invasive annual plants ([Cox et al., 2014](#); [Allen et al.,](#)

[2009](#); [Rao et al., 2009](#)). Many of these studies documented changes in plant community composition, with fewer observations of plant species loss. Evidence for shifts in plant community composition is particularly strong for CSS and chaparral ecosystems near the southern California coast and in areas of the Mojave Desert downwind of major southern California population centers. An important effect of N deposition in arid ecosystems is an increase in N availability in the interspaces between shrubs, allowing the growth of annual grasses and forbs, which can grow and reproduce during the brief seasonal periods with adequate moisture availability ([Brooks, 2003](#)). This phenomenon provides a more continuous fuel bed for wildfires, increasing fire frequency and shifting plant community composition away from species that are not fire-adapted ([Padgett and Allen, 1999](#); [Allen et al., 1998](#)). Relative to plants, there are fewer studies of N effects on microbial biodiversity in arid and semiarid ecosystems, with these studies showing mixed results ([Table 6-22](#)).

---

### 6.6.3 Critical Loads Summary

The 2008 ISA documented efforts to develop CLs in the U.S. However, the CLs for terrestrial ecosystems available in 2008 were for a subset of western ecosystems. There were no published assessments of N deposition CLs spanning ecosystems across the U.S. Since the 2008 ISA, there has been substantial work on CLs for N for U.S. ecoregions. A large body of work has been published on CLs for N since the 2008 ISA. Notably, the USDA-FS published *Assessment of Nitrogen Deposition Effects and Empirical Critical Loads* ([Pardo et al., 2011c](#)), which reports CLs for various biological and biogeochemical endpoints in terrestrial ecoregions (Omernick Level 1) in the U.S.

Most of the published CLs included in the [Pardo et al. \(2011c\)](#) assessment or published subsequently have covered lichens, mycorrhizae, and herbaceous and understory plant species. There are still relatively few observations of CLs for overstory tree species. There do not appear to have been any CLs published for birds, mammals, or arthropods in terrestrial ecosystems. In general, CLs were higher in regions that experienced greater rates of ambient N deposition. In part, these higher critical loads may represent previous ecological change caused by historical N deposition. This pattern would explain why the empirical CL is often above ambient deposition even as that deposition increases in the same ecosystem type across a region ([Pardo et al., 2011c](#)). The CLs published since the publication of the USDA-FS assessment by [Pardo et al. \(2011c\)](#) often fall into the range of CLs identified by [Pardo et al. \(2011c\)](#), particularly if these CLs assess similar ecological endpoints. The new information is presented in tandem with the CLs by [Pardo et al. \(2011c\)](#) in [Table 6-28](#). Notably, the CLs reported for [Pardo et al. \(2011c\)](#) are a

range for the entire Level 1 ecoregion, whereas the new CL estimates are either for the entire ecoregion or specific ecosystems within each respective ecoregion.

## APPENDIX 7 AQUATIC BIOGEOCHEMISTRY

This appendix summarizes recent advancements in understanding the effects of nitrogen (N) and sulfur (S) deposition on aquatic biogeochemical processes and cycles. Freshwater systems of the U.S. include lakes (lentic systems), rivers and streams (lotic systems), and wetlands. The latter, including bogs, fens, marshes, and swamps, are discussed in [Appendix 11](#) and [Appendix 12](#). The freshwater section ([Appendix 7.1](#)) is further subdivided into N and S sources ([Appendix 7.1.1](#)); ecosystem processes, effects, and indicators ([Appendix 7.1.2](#)); monitoring ([Appendix 7.1.3](#)); modeling ([Appendix 7.1.4](#)); national scale sensitivity and chemical recovery ([Appendix 7.1.5](#)); water quality criteria ([Appendix 7.1.6](#)); and a summary ([Appendix 7.1.7](#)).

[Appendix 7.2](#) is an overview of the complex biogeochemical processes affected by N loading to estuaries (where fresh water from rivers meets the salt water of oceans) and other near-coastal areas such as lagoons and open ocean areas near coastlines. Inputs of N, including atmospheric deposition ([Appendix 7.2.1](#)), to the highly variable estuarine environment ([Appendix 7.2.2](#)), and factors such as dissolved oxygen (DO; [Appendix 7.2.3](#)) and pH ([Appendix 7.2.4](#)) affect N cycling. Key processes and indicators of N cycling are discussed in [Appendix 7.2.5](#) and [Appendix 7.2.6](#) followed by monitoring ([Appendix 7.2.7](#)), modeling ([Appendix 7.2.8](#)), national scale sensitivity ([Appendix 7.2.9](#)), water quality criteria ([Appendix 7.2.10](#)), and a summary ([Appendix 7.2.11](#)).

Biological effects and indicators linked to altered aquatic biogeochemistry are discussed in [Appendix 8](#) (Biological Effects of Freshwater Acidification), [Appendix 9](#) (Biological Effects of Freshwater Nitrogen Enrichment), [Appendix 10](#) (Biological Effects of Nitrogen Enrichment in Estuaries and Near-Coastal Systems), and [Appendix 12](#) (Non-Acidifying Effects of Sulfur).

---

### 7.1 Biogeochemistry of Nitrogen and Sulfur in Freshwater Systems

As described in the *2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur—Ecological Criteria* (hereafter referred to as the 2008 ISA), the most common and well-documented aquatic effects are acidification and eutrophication, which may occur simultaneously in some water bodies. Since the 2008 ISA, there have been additional estimates of the proportion of total N loading in freshwater systems attributed to atmospheric deposition and refinements in spatial and temporal trends of N and S deposition across the U.S. Chemical indicators of N deposition identified by the 2008

ISA were nitrate ( $\text{NO}_3^-$ ) and dissolved inorganic nitrogen (DIN) concentrations in surface waters. Surface water chemistry indicative of acidic conditions and acidification effects includes concentrations of sulfate ( $\text{SO}_4^{2-}$ ),  $\text{NO}_3^-$ , inorganic aluminum (Al), calcium (Ca), sum and surplus of base cations, acid neutralizing capacity (ANC), and surface water pH. Continued monitoring of these indicators provides some evidence of chemical recovery from acidification in some U.S. surface waters. A number of studies since 2008 have focused on improving understanding of aquatic acidification and eutrophication processes mediated by N. Many of these have focused on pathways of pollutant and other constituent movement within ecosystems, including monitoring studies of various kinds. **The body of evidence is sufficient to infer a causal relationship between N and S deposition and the alteration of freshwater biogeochemistry**, which is consistent with the conclusions of the 2008 ISA.

Acidification of freshwater ecosystems occurs in response to either S or N deposition alone or in combination. This is because both N and S deposition can act as acidifying agents. Acidifying deposition effects on biogeochemical processes in soils ([Appendix 4](#)) have significant ramifications for the water chemistry and biological functioning of associated surface waters. Surface water chemistry integrates direct air-to-water deposition with deposition impacts on soil chemistry of hydrologically connected terrestrial ecosystems within the watershed. Deposited N and S interact with the soils and sediments of terrestrial and aquatic ecosystems via oxidation and reduction reactions as well as biological uptake and microbially mediated processes.

Acidification of fresh water may occur as a chronic or an episodic condition ([Appendix 8.2](#)). The 2008 ISA defined chronic acidification by reference to annual average conditions, often quantified as summer and fall chemistry for lakes and as spring baseflow chemistry for streams. Episodic acidification refers to conditions during rainstorms or snowmelt when water has a relatively short residence time in soil before entering surface water. During these stormflow events, proportionately more water drains through upper soil horizons, providing less neutralization of atmospheric acidity compared with flow through deeper soil horizons. Episodes of acidification are typified by lower pH, lower ANC, and higher inorganic Al concentration in surface water than during baseflow conditions. The short-term change in chemical conditions may be toxic or lethal to aquatic biota ([Appendix 8](#)). These conditions are caused partly by acidifying deposition ( $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ ) and partly by natural processes, including base cation dilution and flushing of organic acids into drainage water. It is known that the biota in many streams/lakes are impacted when the ANC is consistently below 50  $\mu\text{eq/L}$ . For this reason, the U.S. EPA National Lakes Assessment used an ANC threshold of  $>50 \mu\text{eq/L}$  as indicative of nonacidified water bodies ([U.S. EPA, 2009b](#)).

In aquatic systems, N is a nutrient that stimulates growth of primary producers (algae and/or aquatic plants). Even small inputs of N in low nutrient water bodies such as remote headwater and lower order streams and alpine lakes can increase nutrient availability, alter the balance of N and phosphorus (P) nutrients, affect biogeochemical processing of N and increase the productivity of photosynthesizing organisms, resulting in an increase in pool of fixed carbon (C). Nutrient enrichment leads to changes in aquatic assemblages and biodiversity in freshwater ([Appendix 9](#)) and coastal regions ([Appendix 10](#)). The freshwater ecosystems in the U.S. most likely to be sensitive to nutrient enrichment from N deposition are headwater streams, lower order streams, and alpine lakes which have very low nutrients and productivity and are far from local pollution sources [[Appendix 9.1.1.2](#); [U.S. EPA \(2008a\)](#)]. High-elevation lakes in the western U.S. are naturally oligotrophic and are considered among the aquatic ecosystems most sensitive to N deposition ([Williams et al., 2017b](#)). A portion of these lakes and streams in the western U.S. are in Class I wilderness areas ([Williams et al., 2017b](#); [Clow et al., 2015](#); [Nanus et al., 2012](#)). In higher order streams, N deposition typically mixes with N derived from other nonatmospheric sources, including urban/suburban point and nonpoint sources, industrial sources, and agricultural sources. The long-held paradigm that fresh waters are typically P limited has been replaced by an understanding that both N and P can limit primary production, and that nutrient limitation can be a dynamic and transient process ([Paerl et al., 2016b](#); [Paerl et al., 2014](#); [Conley et al., 2009](#); [Paerl, 2009](#)). Although over-enrichment with P is not specifically addressed in this assessment, recent trends in increased atmospheric deposition of P ([Appendix 9.1.1.2](#)) have ramifications for nutrient stoichiometry.

The geochemical processes and associated chemical indicators discussed in this appendix can be considered to indicate or suggest eutrophication or acidification. Some of the biogeochemical alterations associated with N and S deposition link directly to the biological effects discussed in subsequent appendices. Others do not cause direct biological effects but are precursory steps to changes in soil or water chemistry that can lead to biological effects. [Table 7-1](#) summarizes the key freshwater indicators for N driven nutrient enrichment and acidification and the section of the ISA that discusses each endpoint.

A separate appendix addresses the biogeochemistry of terrestrial responses to nutrient and acidic additions ([Appendix 4](#)). Aquatic and terrestrial systems are interconnected and many of the biogeochemical processes discussed herein bridge the transitions between these two environmental compartments.

**Table 7-1 Summary of key freshwater indicators of eutrophication and acidification.**

## 7.1.1 Nitrogen and Sulfur Sources

In fresh water, both S and N can contribute to acidification while nutrient enrichment effects are associated with N. Long-range atmospheric transport of N and S can affect remote freshwater catchments far from pollutant sources. Major sources of N and S and deposition trends are discussed in [Appendix 2](#).

### 7.1.1.1 Nitrogen Sources

Since the 2008 ISA, additional analyses have refined the understanding of N sources and deposition trends ([Appendix 2](#)) to freshwater systems. [Sobota et al. \(2013\)](#) synthesized data on N inputs to lands and waterways throughout the U.S. They found that human-caused N inputs are ubiquitous but spatially heterogeneous. The highest N loads

generally occurred in the Midwest, Mid-Atlantic region, central and southern California, and portions of the Columbia River Valley. Synthetic fertilizer was estimated to be the single largest source of human-caused N inputs to 41% of the water resource units analyzed, followed by atmospheric deposition (33%) and biological N fixation (22%). A tool for calculating net anthropogenic nitrogen inputs (NANI) was developed for watersheds across the contiguous U.S. at the county level ([Hong et al., 2013, 2011](#)). The NANI Calculator Toolbox takes into consideration fertilizer N application, agricultural N fixation, net food and feed imports, and atmospheric sources of N. Unlike S, geological sources of N are rare.

In a U.S. Geological Survey (USGS) National Water Quality Assessment (NAWQA) report on occurrence and distribution of nutrients in streams and groundwater (based on water quality assessments conducted from 1992 to 2001), atmospheric deposition was identified as the largest nonpoint source of N in the less developed watersheds (areas dominated by forest or rangeland with  $\leq 5\%$  urban and  $\leq 25\%$  agricultural land) in the eastern part of the country where deposition rates have historically been highest, in areas near the Great Lakes, and the mountainous west ([Dubrovsky et al., 2010](#)). Atmospheric sources have been shown to be quantitatively important ( $>33\%$  of total input) to Lake Tahoe, CA/NV ([Sahoo et al., 2013](#); [Dolislager et al., 2012](#)), Flathead Lake, MT ([Ellis et al., 2015](#)), and Nine Mile Run in Pittsburgh, PA ([Divers et al., 2014](#)). Even in lowland lakes, N from atmospheric sources has been shown to contribute appreciably to the total input of N. In a study of nutrient sources to Saginaw Bay, MI, N deposition was estimated to comprise 10 to 11% of the total N input from 1987 to 2002 ([He et al., 2014](#)).

Nitrogen is deposited in various reduced and oxidized forms, including organic N, and, in wet or dry forms as well ([Appendix 2](#)). Oxidized N is emitted into the atmosphere mainly from motor vehicles, electricity generating units, and industry. Reduced N is emitted mainly from agricultural sources such as livestock and fertilizer applications. Direct deposition of N to open water surfaces constitutes an appreciable source of N to relatively large freshwater lakes and rivers, estuaries, and coastal marine waters ([Appendix 7.2.1](#)). Alternatively, N can be deposited in the watershed of receiving waters and then move through soils before entering surface waters. Atmospheric deposition of reduced N has increased relative to oxidized N in parts of the U.S. including the East and Midwest in the last few decades, shifting from a  $\text{NO}_3^-$  dominated to an ammonium ( $\text{NH}_4^+$ ) dominated condition, and this trend is expected to continue under existing emissions controls ([Li et al., 2016d](#); [Pinder et al., 2008](#); [U.S. EPA, 2008a](#)). Since the 2008 ISA, there is a greater understanding of the potential ecological changes associated with the increase in deposition of reduced N relative to oxidized N in terrestrial, freshwater and coastal systems ([Section IS. 2.2.5](#)).

[Table 7-2](#) summarizes key studies that have quantified total N loading in freshwater systems from atmospheric deposition. In the 2008 ISA, the difficulty in determining the percentage of atmospheric N in lowland waters was noted because there are so many other point and nonpoint sources of N to drainage waters in these areas ([U.S. EPA, 2008a](#)). As described in the 2008 ISA, a large fraction of atmospheric N deposition is retained in most forested ecosystems with less retention in urban, suburban, and agricultural lands ([U.S. EPA, 2008a](#)). The atmospheric fraction that does leach to streams can make a substantial contribution to total N inputs to downstream waters, especially in the eastern U.S. ([Driscoll et al., 2003d](#)). Apportionment of N sources to identify the contribution of atmospherically derived N was described in a few studies in the 2008 ISA ([U.S. EPA, 2008a](#)). In Spatially Referenced Regressions on Watershed Attributes (SPARROW) modeling studies, approximately 70% of the N in headwater streams in the northeastern U.S. was judged to be from N deposition ([Alexander et al., 2007](#); [Moore et al., 2004a](#); [Alexander et al., 2002](#)).

Several new studies published since the 2008 ISA further quantified N sources, including atmospheric contribution, to lakes and streams ([Table 7-2](#)). [Sebestyen et al. \(2008\)](#) showed the dominant direct role of atmospheric  $\text{NO}_3^-$  in snowmelt runoff at Sleepers River, VT. At peak flow, 48% of  $\text{NO}_3^-$  was from atmospheric sources in this forested watershed. In the Uinta Mountains, UT, at least 70% of  $\text{NO}_3^-$  was atmospherically deposited to high alpine lakes from distant anthropogenic sources ([Hundey et al., 2016](#)). Approximately 60% of the reactive N was from agriculture, based on isotopic analysis and modeling of snow, inflow and lake  $\text{NO}_3^-$ . The authors suggested these findings are widely applicable to other western U.S. alpine sites based on comparison of isotope and precipitation data in the region.

Additional information is available since the 2008 ISA on atmospheric contributions of reduced versus oxidized N to lakes. In Lake Tahoe, where a total maximum daily load (TMDL) allocation was adopted in 2011 by California and Nevada to reduce nutrient loading, atmospheric N represented approximately 57% of the total N loading to the lake ([Sahoo et al., 2013](#)). In this large alpine lake in the Sierra Nevada mountain range, an estimated 185 metric tons of N was directly deposited from the atmosphere, with  $\text{NH}_4^+$  as the dominant component and nitric acid plus  $\text{NO}_3^-$  representing a smaller, but not insignificant, proportion of total N ([Dolislager et al., 2012](#)). In Flathead Lake, MT, atmospheric loading of  $\text{NH}_4^+$  averaged 44% of the total load between 1985 and 2004 and was the primary form of N in atmospheric deposition ([Ellis et al., 2013](#)). There was an increase in atmospheric loading of  $\text{NO}_3^-$  + nitrite ( $\text{NO}_2^-$ ; +48%) and  $\text{NH}_4^+$  (+198%) and decrease in total P loading (-135%)

**Table 7-2 Summary of recent studies quantifying nitrogen deposition contribution to total nitrogen loading in freshwater systems.**

Region	Total N Loading Due to Atmospheric Deposition	Method	Reference
Lake Tahoe, CA	Approximately 57%, NH <sub>3</sub> as the dominant component and nitric acid and NO <sub>3</sub> <sup>-</sup> representing a smaller but not insignificant proportion of total N.	Field data and Lake Tahoe watershed model	<a href="#">Sahoo et al. (2013)</a> <a href="#">Dolislager et al. (2012)</a>
Flathead Lake, MT	Atmospheric loading of NH <sub>4</sub> <sup>+</sup> averaged 44% of total load between 1985 and 2004 and was the primary form of N in deposition.	Field data and statistical analysis, linear regression	<a href="#">Ellis et al. (2013)</a>
Unita Mountains, UT	At least 70% of NO <sub>3</sub> <sup>-</sup> in the high alpine lakes is from atmospheric deposition. Most reactive N originates from agricultural activities (approximately 60%).	Isotopic analysis and bayesian-based stable isotope mixing model	<a href="#">Hundey et al. (2016)</a>
Saginaw Bay, MI	N deposition was estimated to be 10 to 11% of total N from 1987–2002.	Multiple databases of land use/cover, hydrography, animal production, fertilizers, combined wastewater overflows	<a href="#">He et al. (2014)</a>
St. Lawrence River, Quebec City	Atmospheric N contributed about 0 to 4% of total N load in the summer; in the spring, this source represented 4 to 11% of total N.	Isotopic analysis	<a href="#">Thibodeau et al. (2013)</a>
Quinnipiac River, CT	Atmospherically deposited NO <sub>3</sub> <sup>-</sup> represented <6% of N loading; however, during storm events, atmospheric deposition represented up to 50% of stream NO <sub>3</sub> <sup>-</sup> but varied widely by site.	Stable isotope ratios	<a href="#">Anisfeld et al. (2007)</a>
Baltimore Long-Term Ecological Research site	Atmospheric contributions ranged from 5 to 94% during storm flow conditions and represented approximately 50% of the highest NO <sub>3</sub> <sup>-</sup> loads during storms.	N watershed mass balances and stable isotopes	<a href="#">Kaushal et al. (2011)</a>
Tributary to Teff Run, MD	Contributions of atmospheric N to surface water in an Appalachian Mountain stream were most evident during hydrological episodes, but baseflow accounted for much of the NO <sub>3</sub> <sup>-</sup> loss in stream water.	Isotopic analysis	<a href="#">Sabo et al. (2016)</a>
Nine Mile Run in Pittsburgh, PA	34% of NO <sub>3</sub> <sup>-</sup> in stream water was atmospheric in origin during storm events while 94% of stream water NO <sub>3</sub> <sup>-</sup> was from sewage sources during baseflow conditions.	Stable isotope ratios	<a href="#">Divers et al. (2014)</a>
Suburban watershed (Lisha)	About 40% or more of NO <sub>3</sub> <sup>-</sup> in stream water in a suburban watershed during storm runoff was attributed to direct NO <sub>3</sub> <sup>-</sup> deposition.	Stable isotope ratios	<a href="#">Burns et al. (2009)</a>

**Table 7-2 (Continued): Summary of recent studies quantifying nitrogen deposition contribution to total nitrogen loading in freshwater systems.**

Kill) in eastern New York			
Sleepers River watershed, northeastern Vermont	In this forested watershed 48% of $\text{NO}_3^-$ was from atmospheric sources at peak flow. More than half of the $\text{NO}_3^-$ in soil and shallow groundwater after the start of snowmelt originated directly from atmospheric deposition.	Isotopic tracers and mixing analysis Stable isotope ratios, hydrochemistry, end-member mixing analyses	<a href="#">Sebestyen et al. (2008)</a>
<b>Key pre-2008 literature</b>			
16 northeastern watersheds	Approximately 70% of the N in headwater streams was from N deposition and the net transport of N from headwater streams was between 40 and 65% of total N.	SPARROW	<a href="#">Alexander et al. (2002)</a> ; <a href="#">Alexander et al. (2007)</a>
16 large northeastern river basins	N deposition contributes approximately 31% of the total N load to large river basins, although this fraction varies regionally. Values for watersheds in northern New England were substantially higher and atmospheric deposition dominated.		<a href="#">Boyer et al. (2002)</a>
Eight watersheds in New York and New England	Atmospheric deposition was second largest N input for the eight watersheds (11 to 36% of total) with four watersheds ranging from 34 to 36%.	PnET-BGC and WATERS N	<a href="#">Driscoll et al. (2003d)</a>

N = nitrogen;  $\text{NH}_3$  = ammonia;  $\text{NH}_4^+$  = ammonium;  $\text{NO}_3^-$  = nitrate; SPARROW = Spatially Referenced Regressions on Watershed Attributes.

In the studies reviewed in the 2008 ISA, the role of atmospheric deposition in downstream urban and residential water bodies was rarely addressed ([U.S. EPA, 2008a](#)). New studies using stable isotope ratios to quantify N loading in streams have characterized the contributions of atmospheric N in these systems. Several of these studies have shown shifts to higher atmospheric N contributions during storm events. In the Quinnipiac River in Connecticut which drains into Long Island Sound, atmospherically deposited  $\text{NO}_3^-$  averaged <6% of average N loading during baseflow conditions; however, during storm events, atmospheric deposition represented up to 50% of stream  $\text{NO}_3^-$ , although the amount varied widely by site ([Anisfeld et al., 2007](#)). In the St. Lawrence River outlet at Quebec City, Canada, isotopic analysis of N inputs indicated that atmospheric N contributed about 0 to 4% of total N load in the summer, while in the spring this source was 4 to 11% of total N ([Thibodeau et al., 2013](#)). In forested, agricultural and urban watersheds at the Baltimore Long-Term Ecological Research site,

atmospheric N contributions ranged from 5 to 94% during storm flow conditions and represented approximately 50% of peak storm  $\text{NO}_3^-$  ([Kaushal et al., 2011](#)). In Nine Mile Run in Pittsburgh, PA, 34% of  $\text{NO}_3^-$  in stream water was atmospheric in origin during storm events, whereas during baseflow conditions 94% of stream water  $\text{NO}_3^-$  was from storm drain and wastewater treatment sources ([Divers et al., 2014](#)). In another study in Pennsylvania, stream water from Spring Creek was monitored at sites from upstream to downstream during storm flow events to assess changes in N sources ([Buda and DeWalle, 2009](#)). For the forested upstream site, the atmospheric contribution varied by storm size. In the downstream urbanized watershed, atmospheric  $\text{NO}_3^-$  was an important N source at peak flow, especially during short-duration storms when overland flow was prevalent.

[Burns et al. \(2009\)](#) applied dual isotope analysis of  $\text{NO}_3^-$  to determine the dominant sources and processes that affect  $\text{NO}_3^-$  concentrations in six streams on different land uses in New York. The dual isotope data revealed varying sources and processes that affect  $\text{NO}_3^-$  concentration among the six stream watersheds. Atmospheric  $\text{NO}_3^-$  was about half of stream  $\text{NO}_3^-$  during storms because of rapid shunting of runoff through storm drains. The suburban watershed that had no septic or wastewater influence showed  $\text{NO}_3^-$  concentrations only slightly higher than those observed in two forested watersheds. Overall, these studies appear to have characterized relatively well the atmospheric contribution of N to water bodies that have multiple sources of N. Results show substantial variability, with atmospheric sources typically being most pronounced during high-flow conditions.

---

#### 7.1.1.2 Sulfur Sources

The 2008 ISA reported that there were both depositional and geological sources of  $\text{SO}_4^{2-}$  to aquatic ecosystems.  $\text{SO}_x$  deposition to ecosystems is primarily in the chemical form  $\text{SO}_4^{2-}$ , which is a moderately mobile anion in the soil solution and surface water of many glaciated acid-sensitive watersheds in the northeastern U.S. Note that  $\text{SO}_4^{2-}$  is less mobile in unglaciated watersheds of the southeastern U.S. ([Rice et al., 2014](#)). Other major sources of  $\text{SO}_4^{2-}$  in ecosystems include mineralization of S from organic matter and weathering of geologic sources of S, including pyrite minerals. Anthropogenic soil and rock disturbance in the form of road cuts or mine tailings can increase geological contributions of  $\text{SO}_4^{2-}$  to soil or surface water by exposing S bearing minerals to oxygen ( $\text{O}_2$ ), promoting mineral oxidation and the release of  $\text{SO}_4^{2-}$ . Acid mine drainage is one result of this process and is prevalent in many parts of the Appalachian Mountain region. New published evidence regarding the influence of geologic sources of S or acid mine drainage on stream chemistry has not been reviewed for this ISA.

The 2008 ISA described how SO<sub>x</sub> deposition causes the release of S from terrestrial to aquatic ecosystems via SO<sub>4</sub><sup>2-</sup> leaching, and other changes in surface water chemistry caused by increasing SO<sub>4</sub><sup>2-</sup> concentrations. At that time, acidification of surface waters at most locations in the U.S. where acidification has been documented in response to deposition was caused mainly by SO<sub>4</sub><sup>2-</sup> ([Driscoll et al., 2001b](#); [Sullivan, 2000](#)). This was partly due to the mobility of SO<sub>4</sub><sup>2-</sup> in many (especially northeastern) waters draining from terrestrial ecosystems to aquatic ecosystems. It was also known that the mobility of SO<sub>4</sub><sup>2-</sup> varies geographically, with S adsorption on soils most significant in regions that were unglaciated during the most recent glaciation. This includes many acid-sensitive watersheds in the southeastern U.S. In the most recently glaciated Northeast and upper Midwest, a substantial component of the atmospherically deposited S accumulates in organic pools in soil, although microbial mineralization can transform this organic S back into more mobile SO<sub>4</sub><sup>2-</sup>.

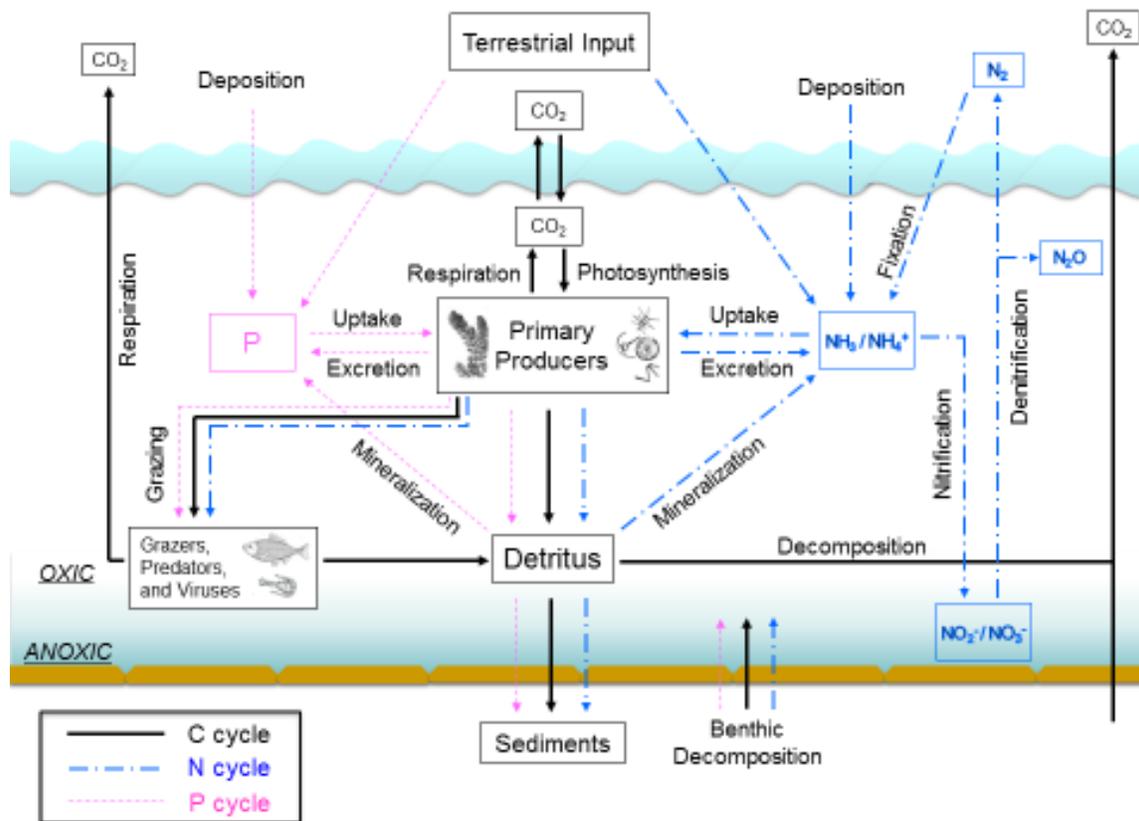

A mass balance study by [Mitchell et al. \(2011\)](#) of 15 watersheds located in the northeastern U.S. and southeastern Canada suggested substantial sources of SO<sub>4</sub><sup>2-</sup> in watershed soils. The internal S sources were attributed mainly to mineralization of S stored in soils in response to decades of atmospheric S deposition. In a study of 16 lakes from the original Adirondack Long-Term Monitoring program from 1984 to 2010 [Mitchell et al. \(2013\)](#) observed discrepancies in the calculated S mass balances that were associated with discharge. These results suggested that internal S sources have become more important to the watershed S budget as atmospheric S deposition has decreased. Declines in lake SO<sub>4</sub><sup>2-</sup> concentrations have been observed in locations where S deposition has decreased significantly, such as in the Adirondack Mountains [[Mitchell et al. \(2013\)](#); [Appendix 7.1.5.1](#)].

---

## 7.1.2 Ecosystem Processes, Effects, and Indicators

New information on biogeochemical indicators and processes of eutrophication and acidification are presented in the following sections, along with summaries of information from the 2008 ISA. These processes may occur either in sequence or simultaneously in a given geographic area. Impacts of N and S deposition on aquatic ecosystems can be described by changes in acid-base chemical indicators including SO<sub>4</sub><sup>2-</sup> concentration, NO<sub>3</sub><sup>-</sup> concentration, DIN concentration, inorganic Al concentration, base cation concentrations, base cation surplus (BCS), pH, and ANC. Surface water NO<sub>3</sub><sup>-</sup> concentration can reflect both eutrophication and acidification. Water pH and the concentrations of ANC, SO<sub>4</sub><sup>2-</sup>, and inorganic Al are commonly used indicators of the likelihood of surface water acidification ([U.S. EPA, 2008a](#)). As reported in the 2008 ISA and summarized in [Figure 7-1](#), the biogeochemical cycles of N, P, and C are linked in

freshwater ecosystems. Nitrogen deposition can alter the pools and fluxes of the C, N, and P cycles, including nitrification and denitrification. Sulfur deposition adds  $\text{SO}_4^{2-}$  directly to soil solutions and to surface waters with effects on ecosystems ([Appendix 12](#)), but many ecological effects are mediated through the indirect effects of  $\text{SO}_4^{2-}$  on the exchange of acidic and basic cations on soils. The chemical indicators of deposition discussed below also link to biological effects of acidifying deposition ([Appendix 8](#)) and freshwater N enrichment ([Appendix 9](#)).

C = carbon;  $\text{CO}_2$  = carbon dioxide; N = nitrogen; P = phosphorus.  
 Modified from [U.S. EPA \(2008a\)](#).

### 7.1.2.1 Nitrogen in Surface Waters

As reviewed in the 2008 ISA and supported by more recent studies, the fate and transport of deposited N is influenced by characteristics of the catchment and the receiving waters. Retention of N varies among watershed types such that similar amounts of deposition can result in different rates of N leaching, depending on catchment characteristics [[Appendix 9.1.1.2](#); [Bergström \(2010\)](#)]. In most surface waters of the U.S., dissolved inorganic N (DIN, the sum of the concentrations of  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ , and nitrite) is overwhelmingly dominated by  $\text{NO}_3^-$ . As summarized in the 2008 ISA, high concentrations of  $\text{NO}_3^-$  in lakes and streams, indicative of terrestrial ecosystem N saturation, have been found at a variety of locations throughout the U.S. Surface water  $\text{NO}_3^-$  is a chemical indicator for both eutrophication and acidification. Nitrate contributes to the acidity of many lakes and streams in the eastern U.S. that have been affected by acidifying deposition, especially during spring snowmelt and under high-flow conditions.

In the 2008 ISA, a study evaluating the relationship between wet deposition and DIN concentration in 4,296 lakes across Canada, Europe, and the U.S. showed a significant correlation between increases in N wet deposition and increases in lake DIN concentration ([Bergström and Jansson, 2006](#)). More recent studies from some regions of the U.S. [e.g., [Eshleman et al. \(2013\)](#); [Driscoll et al. \(2016\)](#); [Strock et al. \(2014\)](#); [Eshleman and Sabo \(2016\)](#); [Appendix 7.1.5.1](#)] showed recent declines in concentrations of  $\text{NO}_3^-$  in surface waters that are consistent with declines in N deposition. Using the Lake Multi-Scaled Geospatial and Temporal Database of the Northeast Lakes of the U.S. (LAGOS-NE) containing water quality data from 2,913 lakes, [Oliver et al. \(2017\)](#) identified atmospheric deposition as the main driver of declines in total N (TN) deposition and lake TN:total P (TP) ratios from 1990 to 2011.

Reactive N can be taken up by terrestrial and aquatic biota or stored in soils and/or sediments, be re-emitted back to the atmosphere by the microbial process of denitrification ([Appendix 7.1.2.3](#)), or carried downstream in a dissolved state, most typically as  $\text{NO}_3^-$ , because much of the deposited  $\text{NH}_4^+$  is either taken up by biota or nitrified to  $\text{NO}_3^-$ . Typically, a rather large percentage of the N deposition to a given watershed is taken up or stored and is not denitrified or made available for leaching to surface waters. On average, for a large watershed with mixed land use, it has been estimated that roughly 75% of N inputs are retained in the watershed and 25% are exported downstream regardless of the dominant N input, including deposition ([Howarth et al., 2012](#); [Howarth et al., 1996a](#)). This stored N does not contribute directly to water acidification or eutrophication and represents a significant portion of the incoming N deposition to forested ecosystems in the U.S. The portion of the N deposition that is not

retained or lost to denitrification can contribute to water acidification or eutrophication, both on a chronic and especially an episodic basis.

It was well understood at the time of the 2008 ISA that streams and their associated sediments can transform nutrients, store them for the short term, or serve as a sink for N loss from the watershed through denitrification. It is important to consider the balance between how much and how long streams retain elements versus transport them downstream. This balance is key to modeling watershed nutrient export. Headwater streams can play disproportionately large roles in N transformation and N cycling in aquatic ecosystems, and they are important to predicting effects of N loading on downstream ecosystems. Atmospheric deposition may represent a significant source of N to some headwater streams [[Lawrence et al. \(2015b\)](#); [Table 7-2](#)], which often have increased water residence time and solute retention due to increased interactions between surface and groundwater in the hyporheic zone.

The majority of atmospherically deposited N is either denitrified or accumulates in watershed soils, vegetation, or groundwater ([Galloway et al., 2008](#)). The relative partitioning of N loss via denitrification versus watershed storage is poorly known ([Galloway et al., 2004](#)). Watershed denitrification hot spots and hot-moments tend to occur in areas characterized by wet conditions, including wetlands and riparian zones. Such ecosystems can be highly efficient in removing N from surface waters via denitrification ([Galloway et al., 2003](#)). Nitrogen in fresh waters is also controlled by hydrological conditions. For example, [Lusardi et al. \(2016\)](#) showed that spring-fed rivers of northern California had higher  $\text{NO}_3^-$  and  $\text{PO}_4^{3-}$  concentrations and cooler temperatures than rivers that were fed more by runoff. Recent studies have added more quantitative context to hydrologic processes that control nutrient cycling, including hydrologic exchange between the streams and the groundwater. This hyporheic exchange can contribute to N retention in streams because it promotes denitrification associated with anoxic flow paths through organic stream bottom substrates. For example, [Hall et al. \(2009b\)](#) observed in a tracer study in the Sawtooth Mountains of Idaho that assimilation and hydrologic storage can be important for retaining N at the watershed scale. The study stream was not solely a conduit for nutrients at high flow. It had as high an uptake velocity for N during the snowmelt high flow as during summer baseflow.

Influence of beaver and human-made dams on  $\text{NO}_3^-$  uptake in a small headwater stream in the Rocky Mountains was investigated by [Hubbard et al. \(2010\)](#). Dams influenced stream water geochemistry because a portion of the stream water flow was diverted into the more reactive hyporheic zone. Highly oxic and anoxic regions of the streambed developed around the more permanent structures. This enhanced N cycling in the hyporheic zone and increased the potential for denitrification and  $\text{NO}_3^-$  uptake. In parts of

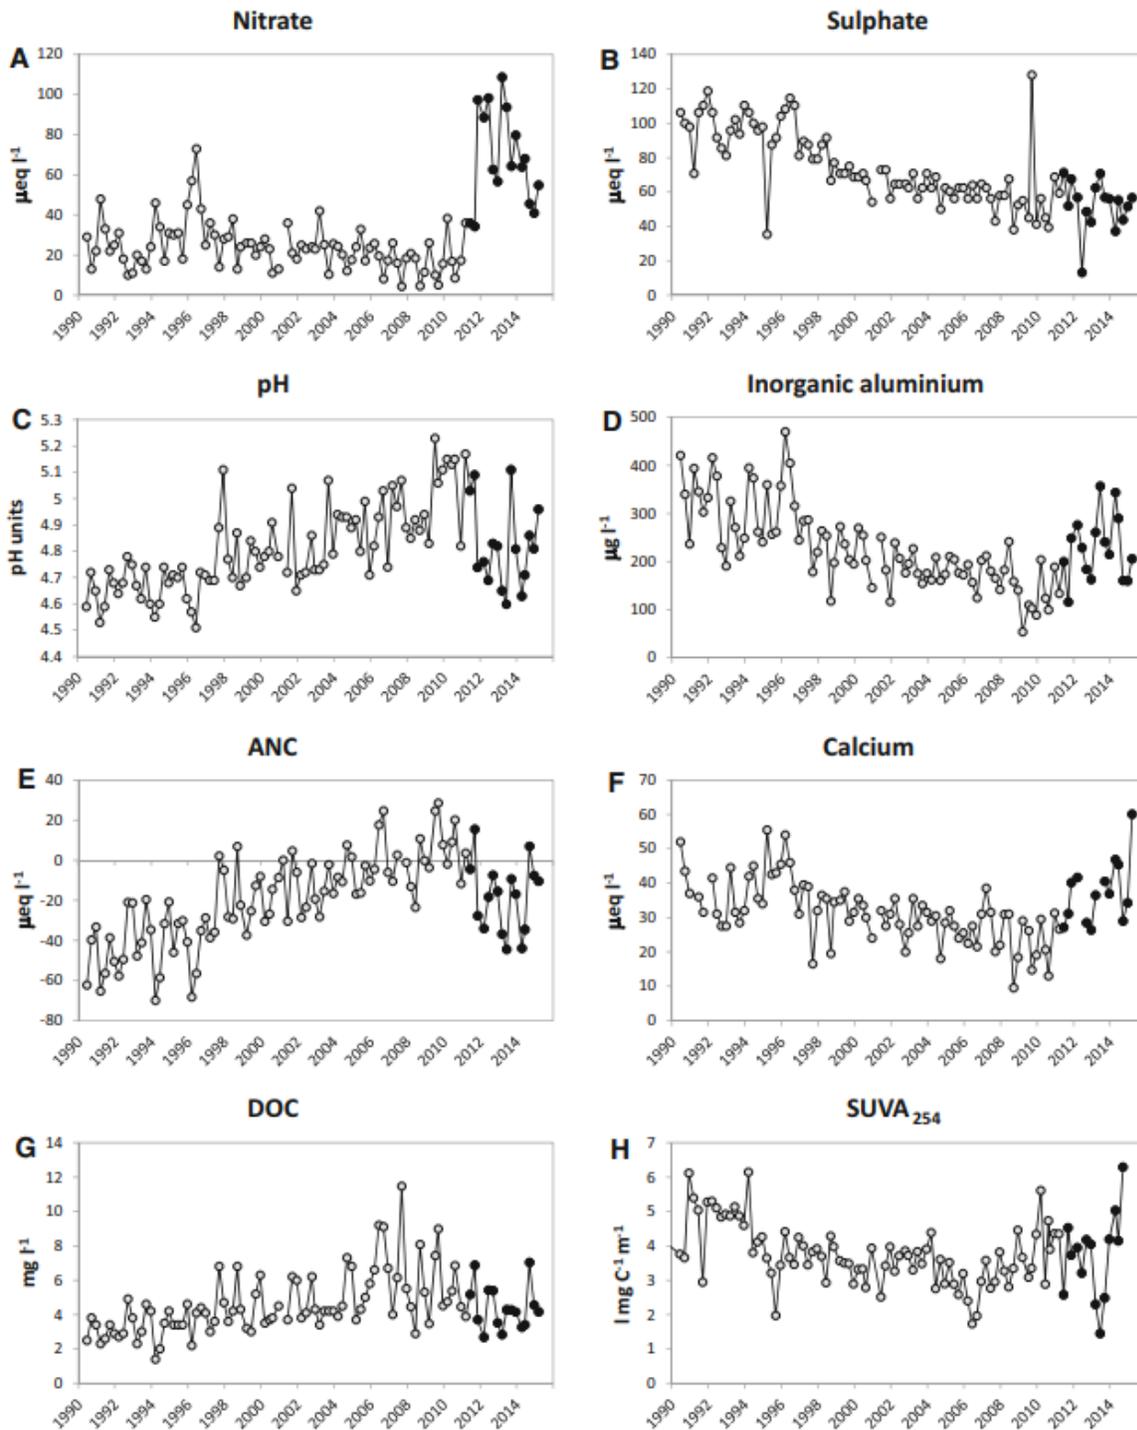

the western U.S. Rocky Mountains, there was a strong positive correlation between surface water  $\text{NO}_3^-$  concentration and atmospheric N deposition ([Elser et al., 2009b](#); [Bergström and Jansson, 2006](#)). Such a correlation does not always occur elsewhere because nonatmospheric watershed sources of N are often larger than atmospheric sources, depending mainly on land use. Analysis of increasing  $\text{NO}_3^-$  trends over three decades in streams draining into Lake Ontario, Canada, [Eimers and Watmough \(2016\)](#) suggested that tributary loading, rather than atmospheric deposition, may have played a dominant role in causing the recent observed increase in  $\text{NO}_3^-$  concentrations in the waters of Lake Ontario. The authors pointed to an observed trend in Ontario towards more annual grain crop production that required more N fertilizer addition and less reliance on perennial crops. This shift in crops could be contributing to the observed increase in  $\text{NO}_3^-$  concentration in the lake.

Studies have been conducted in recent years to elucidate processes affecting surface water  $\text{NO}_3^-$  concentrations, including experimental studies, isotopic analyses, monitoring, and observational studies. The concentration of  $\text{NO}_3^-$  may vary widely between baseflow and peak flow conditions ([Table 7-2](#)). Seasonality in surface water chemistry can be caused, in part, by differential hydrologic flows from watershed seeps and glaciers. These flows can influence  $\text{NO}_3^-$  leaching to surface waters. [O'Driscoll and DeWalle \(2010\)](#) showed that seeps are generally  $\text{NO}_3^-$  sinks with  $\text{NO}_3^-$  concentrations decreasing downslope from seep locations in Baldwin Creek in southwestern Pennsylvania. During cold and wet periods, however, the seeps frequently acted as  $\text{NO}_3^-$  sources to the stream. Locations where upwelling groundwater saturates the surface for most of the year and excess groundwater can be delivered to the stream channel via surface flow paths may provide seasonally linked water quality functions that can modify the effects of N deposition.

Changes in the amount of  $\text{NO}_3^-$  leaching and disruption of N cycling can occur with events in the watershed, including wildfire and timber extraction. Human activities have contributed to greater frequency and magnitude of wildfire in many parts of the U.S., which is well known to increase  $\text{NO}_3^-$  leaching. The area impacted by fire has increased in response to climate change, past fire suppression, and increased human presence in forested ecosystems ([Bladon et al., 2014](#)). Extreme events have the potential to delay ecosystem recovery from past water acidification. [Evans et al. \(2017\)](#) assessed the role of wildfire in regulating the chemistry of a mountain lake in a moorland catchment in the U.K. affected by a large fire. The lake had been subjected to more than two decades of ecosystem monitoring prior to the fire. The most pronounced change in lake chemistry was a substantial increase in lake  $\text{NO}_3^-$  concentration to peak values of 111  $\mu\text{eq/L}$  (1.55 mg/L) 2 years after the fire. Past N deposition may have been high enough to make the catchment more susceptible to  $\text{NO}_3^-$  leaching and accompanying reacidification in

response to the fire ([Figure 7-2](#)). The increase in the concentration of this mobile acid anion increased lake acidity and the concentration of inorganic Al. These changes represented a reversal in the ongoing documented recovery from past acidification. Forest disturbance, including clear-cut logging, also contributes to increased leaching of inorganic N, with potential impacts on downstream nutrient concentrations and acid-base chemistry. [Schelker et al. \(2016\)](#) evaluated N dynamics in Sweden over a 10-year period after tree harvesting. DIN leaching in first order streams increased substantially (~15 times) subsequent to logging. In the larger streams,  $\text{NO}_3^-$  leaching was seasonal and increased in response to logging in the mid-sized, but not the largest, streams. Thus, the increased mobilization of  $\text{NO}_3^-$  in first-order streams caused by logging can affect some downstream locations at certain times.

Nitrogen deposition to snow and glaciers is an important source of N to alpine lakes and streams which are fed by meltwaters. Since the 2008 ISA, several studies indicate that glacial meltwater has higher  $\text{NO}_3^-$  than snowmelt water in some regions of the U.S. This may influence interpretation of biological data from high elevation lakes and streams [[Baron et al. \(2009\)](#); [Saros et al. \(2010\)](#); [Slemmons et al. \(2015\)](#); [Slemmons et al. \(2013\)](#); [Appendix 9.3.2.1](#)]. In two sets of high-elevation lakes in the U.S. Rocky Mountains—those fed by snowpack melt alone and those fed by both glacial and snowpack meltwaters—the  $\text{NO}_3^-$  concentrations in the glacially influenced lakes were one to two orders of magnitude higher than in the lakes that were fed only by snowmelt ([Saros et al., 2010](#)). The higher concentration of  $\text{NO}_3^-$  in glacial meltwater relative to seasonal snowpack meltwater was attributed, at least in part, to reduced contact with watershed soils where microbial communities could rapidly assimilate the available N. This contrasts with snowmelt watersheds where the meltwater typically percolates through soils before reaching the streams ([Saros et al., 2010](#)). [Williams et al. \(2007\)](#) found that, in the Colorado Front Range, rock/glacier outflow had  $\text{NO}_3^-$  concentrations of 69  $\mu\text{eq/L}$  compared to snow with 7  $\mu\text{eq/L}$ . In two proximal lakes in the central Rocky Mountains,  $\text{NO}_3^-$  concentration from glacier-fed Jasper Lake, was 2  $\mu\text{eq/L}$  compared to the snowpack-fed Lake Albino where  $\text{NO}_3^-$  concentration was only 0.03  $\mu\text{eq/L}$  ([Slemmons et al., 2015](#)). In contrast, in the Northern Cascade Mountains, WA, differences in  $\text{NO}_3^-$  concentration between glacier-fed and snowpack-fed lakes were much smaller and not statistically significant in some years ([Williams et al., 2016b](#)).

Notes: Samples collected before the May 2011 fire are denoted by grey circles, and those from after the fire by black circles.  
 Source: [Evans et al. \(2017\)](#).

**Figure 7-2** Quarterly measured concentrations of a range of water chemistry variables at Blue Lough from 1990 to 2014.

Advances in isotopic analyses have improved techniques for investigating the role of  $\text{NO}_3^-$  in N cycling. [Curtis et al. \(2012\)](#) used the dual isotope technique at four moorland watersheds in Great Britain to investigate  $\text{NO}_3^-$  production in surface waters. An estimated 79–98% of the annual median  $\text{NO}_3^-$  had been microbially produced, indicating that both reduced and oxidized N deposition may cycle through the microbial flora and contribute similarly to  $\text{NO}_3^-$  leaching. This is important because atmospheric deposition of  $\text{NH}_4^+$  has been increasing in many areas of the eastern U.S. while deposition of oxidized N forms ( $\text{NO}_y$ ) has decreased ([Appendix 2](#)). [Goodale et al. \(2009\)](#) characterized the amount, form, isotopic composition ( $^{15}\text{N}$  and  $^{18}\text{O}$ ), and seasonality of stream N in forested subwatersheds of the Susquehanna River. Atmospheric deposition contributed substantial N to this river, which provides two-thirds of the annual N load to Chesapeake Bay. Retention of atmospherically deposited N in the watershed was estimated to be higher than 95%. Nevertheless, stream  $\text{NO}_3^-$  patterns exhibited substantial seasonality. Peak values of  $\text{NO}_3^-$  (14–96  $\mu\text{eq/L}$ ) were reached during summer. Lowest values (<1  $\mu\text{eq/L}$ ) occurred in October. The summer's increase in net soil nitrification and in-stream heterotrophic N uptake in response to litterfall during autumn were identified as likely important drivers of the observed  $\text{NO}_3^-$  seasonality. Other studies that included mixed land uses found far lower N retention at larger spatial scales, including the Susquehanna River ([Howarth et al., 2006](#); [Boyer et al., 2002](#)). Using stable isotope analysis, atmospheric deposition was identified as an important source of stream  $\text{NO}_3^-$  concentration at a low  $\text{NO}_3^-$  site at Fernow Experimental Forest, WV ([Rose et al., 2015b](#)). Based on more than 30 years of monitoring data, three hardwood watersheds appeared to be less responsive to changes in N deposition than the one study watershed that had coniferous vegetation. The percentage of stream  $\text{NO}_3^-$  concentration contributed by atmospheric deposition in the study watersheds increased during high-flow periods.

Watershed N budgets and empirical models can be useful for assessing the relative magnitude and sources of N inputs and losses to watersheds via riverine export. A variety of computational approaches can be used. [Alexander et al. \(2002\)](#) compared predictions of total N and stream N transport of six watershed models and showed that models with greater precision were those that had the most detailed descriptions of N sources, water N attenuation, and water flow paths. [Han and Allan \(2008\)](#) compared N budget estimation approaches for 18 catchments located in the vicinity of Lake Michigan. The most robust model suggested that riverine N export constituted about 21% of N inputs. Using a larger data set, [Howarth et al. \(2012\)](#) estimated that 25% of N inputs are exported from the watershed on average. The improved ability to predict N export using methods that incorporated description of agricultural N sources was particularly noticeable when applied to watersheds that had pronounced diversity of land use and geology ([Han and Allan, 2008](#)). Comparisons of watershed N budgets across the U.S. indicates that there is geographic variation in the proportion of N inputs that are exported, and the scaling of

export with runoff indicates that drier conditions may lead to lower proportions of N inputs that are exported by rivers ([Sobota et al., 2009](#)).

Overall, some studies show recent declines in concentrations of  $\text{NO}_3^-$  and TN in surface waters that are consistent with declines in N deposition. Advances in isotopic analysis have allowed for greater characterization of how  $\text{NO}_3^-$  in surface waters affects N cycling and has led to improved understanding of how factors such as seasonality and contribution of snowmelt affect  $\text{NO}_3^-$  concentrations.

---

### 7.1.2.2 Sulfate in Surface Waters

Measurements of  $\text{SO}_4^{2-}$  concentration in surface waters provide important information regarding the probable extent of cation leaching in soils and how  $\text{SO}_4^{2-}$  concentrations relate to ambient and past levels of atmospheric S deposition. The 2008 ISA documented widespread declines in surface water  $\text{SO}_4^{2-}$  concentration in response to decreasing S deposition over previous decades. Assessments of acidifying deposition effects reported in the 2008 ISA dating from the 1980s showed  $\text{SO}_4^{2-}$  to be the primary strong acid anion in most, but not all, acid-sensitive waters in the U.S. ([Webb et al., 2004](#); [Driscoll et al., 2001b](#); [Driscoll et al., 1988](#); [Driscoll and Newton, 1985](#)). At the time of the 2008 ISA, available data indicated that before the peak of S emissions in the 1970s and 1980s,  $\text{SO}_4^{2-}$  concentrations in surface waters increased in response to S deposition. After the emissions peak, there were decreasing regional trends in  $\text{SO}_4^{2-}$  surface water concentrations in the 1980s, 1990s, and thereafter, particularly in the Northeast. In some regions, especially the Blue Ridge Mountains region in Virginia, surface water  $\text{SO}_4^{2-}$  remained relatively stable even as emissions declined, due to changes in S adsorption on soils and the release of historically deposited S from soils into surface water. The rate of surface water response was variable by watershed, and some model results suggested that chemical recovery may be delayed as adsorption decreases and accumulated S leaches from watersheds, even as emissions and deposition decline. Recent studies on  $\text{SO}_4^{2-}$  concentration in surface waters continue to show evidence of chemical recovery consistent with reductions in S deposition ([Appendix 7.1.5.1](#)).

Drought has been shown in some situations, where geological S sources are prevalent, to be a partial cause of lake acidification. This was documented at lakes in the Murry-Darling Basin in Australia by [Li et al. \(2017b\)](#). Pyritic sediment rewetting after the drought (2007–2010) caused an extreme decrease in the water pH around the lake margins from above 7 to near 3.

---

### 7.1.2.3 Nitrogen Transformations

Nitrogen in surface waters can undergo various chemical transformations in the water column ([Appendix 7.1.2.3.1](#)) and sediments ([Appendix 7.1.2.3.2](#)). It was well known at the time of the 2008 ISA that nitrification and denitrification are quantitatively important portions of the N cycle and that these processes can be influenced by atmospheric inputs of oxidized and reduced N. Nitrification can be important even when N deposition is low. More recent research has further substantiated earlier findings and provided additional quantitative context. At some locations, new research suggests that denitrification may play a larger role than was previously recognized in removing oxidized N from the watershed.

#### 7.1.2.3.1 Water Column Transformations

Much of the deposited  $\text{NH}_4^+$  is either taken up by vegetation or nitrified to  $\text{NO}_3^-$ , which is more mobile in soils than  $\text{NH}_4^+$ . The  $\text{NO}_3^-$ , in turn, can be leached to drainage water or denitrified and released back to the atmosphere as gaseous  $\text{N}_2\text{O}$  or  $\text{N}_2$ . During the nitrification process,  $\text{NH}_4^+$  is oxidized to  $\text{NO}_3^-$  and the  $\text{NO}_3^-$  that is produced can contribute to acidification of soil and drainage waters. The 2008 ISA concluded that nitrification in soil solution is stimulated at soil C:N ratios less than about 20 to 25 ([U.S. EPA, 2008a](#); [Aber et al., 2003](#)). Since the 2008 ISA, additional isotope, modeling, observational, and experiment studies have further characterized denitrification processes.

Only a small portion of the N added to the land surface by human activities is carried by stream flow to estuaries and the ocean ([Boyer et al., 2002](#); [Howarth et al., 1996a](#)). Streams have been shown to provide an important ecosystem service by acting as N sinks ([Mulholland et al., 2008](#)). Denitrification is a critical process that removes N from stream water. Changes in  $\text{N}_2$  concentration over space or time have been used to estimate the denitrification rate at the scale of stream reaches ([McCutchan et al., 2003](#); [Laursen and Seitzinger, 2002](#)) to large river basins ([Mulholland et al., 2008](#); [Alexander et al., 2000](#)).

Nitrous oxide ( $\text{N}_2\text{O}$ ), which is emitted to the atmosphere during the process of denitrification, is a potent greenhouse gas. [Beaulieu et al. \(2011\)](#) presented results of  $^{15}\text{N}$  tracer addition to 72 headwater streams draining multiple land uses across the U.S. Denitrification in the streams produced  $\text{N}_2\text{O}$  at rates that increased with stream  $\text{NO}_3^-$  concentration. The study streams were mostly sources of  $\text{N}_2\text{O}$  to the atmosphere. Results of this study reiterated previous findings that suggested that the process of denitrification may be quantitatively important. In another isotopic study, [Mulholland et al. \(2009\)](#) measured denitrification rates using  $^{15}\text{N}$  tracer addition to 49 streams, including

reference, agricultural-impacted, and suburban/urban streams. The fraction of total  $\text{NO}_3^-$  removed from stream water by denitrification ranged from 0.5 to 100%, with a median of 16%. Removal was related to  $\text{NH}_4^+$  concentration and the ecosystem respiration rate. Although the areal denitrification rate increased with increasing  $\text{NO}_3^-$  concentration, the efficiency of  $\text{NO}_3^-$  removal from water via denitrification declined. This resulted in a smaller proportion of stream water  $\text{NO}_3^-$  load removed over a given length of stream at higher N loading.

Freshwater nutrient cycling studies have also focused some attention on N fixation. In Waco Reservoir, TX, [Scott et al. \(2008\)](#) measured N fixation over a 19-month period and linked those data with nutrient-loading estimates derived from a physically based watershed model. Readily available topographic, soil, land cover, effluent discharge, and climate data were used in the Soil and Water Assessment Tool (SWAT) model in order to derive estimates of nutrient loading from the watershed to the reservoir. Results suggested that human activities in the watershed can exert significant control over planktonic N fixation.

#### **7.1.2.3.2 Sediment Nitrogen Transformations**

The deposition and transport of N derived from human sources is partially ameliorated by bacterially mediated denitrification in sediments. The conversion of  $\text{NO}_3^-$  to  $\text{N}_2$  gas permanently removes N from the watershed ([Seitzinger et al., 2006](#); [Galloway et al., 2003](#)). It has been estimated that denitrification in lakes may remove up to about 30% of the inputs to surface waters ([McCrackin and Elser, 2012](#); [Harrison et al., 2009](#); [Wollheim et al., 2008](#)).

Residence time of water in the sediments and hydraulics can be important controls on nutrient uptake in headwater streams. [Drummond et al. \(2016\)](#) characterized water transient storage zones and their effects on nutrient uptake in the sediments of two headwater streams in Spain. These zones represented regions of slow-moving water and temporary water retention in stream sediments. Modeled exchange between the water column and retention zones explained more than 40% of the variation in  $\text{NH}_4^+$  uptake.

A study by [Bellinger et al. \(2014\)](#) provided additional evidence that bacterially mediated denitrification in lake sediments can partly ameliorate the effects of N loading from the atmosphere by permanently removing some of the N inputs. [McCrackin and Elser \(2012\)](#) also measured denitrification in sediments, in this case from lakes in the Colorado Rocky Mountains. The study lakes received either elevated (357–571 eq N/ha/yr) or low (<142 eq N/ha/yr) inputs of atmospheric N deposition. The  $\text{NO}_3^-$ -N concentration was significantly higher in high-deposition lakes (0.1582 mg/L) compared to low deposition

lakes (0.0462 mg/L). The researchers concluded that the sampled lakes were capable of removing a significant portion of N inputs via denitrification in the lake sediment. They found no difference between high- and low-deposition lakes in the extent to which chronic N loading has altered sediment denitrification capacity. The abundance of denitrifying bacteria in this study was largely related to light availability. An earlier study by [McCrackin and Elser \(2010\)](#) measured rates of denitrification and N<sub>2</sub>O production during denitrification in the sediments of 32 Norwegian lakes at the high and the low ends of a gradient of atmospheric N deposition. They also found that denitrification varied with N loading. The findings also suggested that lake sediments may be an important source of N<sub>2</sub>O emissions, which play a role in climate warming, particularly in areas that are subject to elevated N deposition levels. Results of new research by [McCrackin and Elser \(2012\)](#) support growing evidence that lake sediments can play important roles in N removal, although it appears that recent levels of N deposition have not altered the abundance of denitrifying bacteria or saturated the capacity for sediment denitrification in Rocky Mountain lakes.

Organic matter can also influence the rate of denitrification in sediments. [Fork and Heffernan \(2014\)](#) investigated how DOC derived from terrestrial ecosystems affects the rate of denitrification in river sediments. They examined the extent to which higher concentrations of DOC in black water rivers stimulate or inhibit denitrification. Results supported the hypothesis that terrestrially derived DOC might indirectly inhibit denitrification via a decrease in autochthonous production. Therefore, changes in DOC concentration might change the ability of inland waterways to remove reactive N from the aquatic ecosystem.

---

#### **7.1.2.4 Sulfur Transformations**

Studies of S cycling reported in the 2008 ISA emphasized the importance of S adsorption and desorption and their interactions with soil pH ([Appendix 4](#)). The importance of S adsorption on soils in the southern Appalachian Mountains was further confirmed by S budget studies reported by [Rice et al. \(2014\)](#). In addition, internal watershed sources of SO<sub>4</sub><sup>2-</sup> (e.g., S mineralized from soil organic matter), which were previously relatively minor sources to surface water in the northeastern U.S., have become proportionately more important as S deposition has declined ([Appendix 4](#)).

Both chronic and episodic leaching of SO<sub>4</sub><sup>2-</sup> from terrestrial ecosystems influence surface water acidification. The literature reviewed in the 2008 ISA did not fully address how terrestrial S cycling affects water sulfate concentrations. More recently, [Rice et al. \(2014\)](#) calculated SO<sub>4</sub><sup>2-</sup> mass balances for 27 watersheds in the Appalachian Mountain region.

Results suggested that many watersheds where  $\text{SO}_4^{2-}$  inputs are currently retained will begin releasing more  $\text{SO}_4^{2-}$  to drainage water in the near future. [Dewalle et al. \(2016\)](#) evaluated Appalachian forested watersheds and estimated the lag times between changes in S deposition and consequent watershed responses. Lag times were generally consistent and significant for S in the forest basins that demonstrated relatively high soil S retention and high N retention. [Strock et al. \(2016\)](#) investigated the effects of extreme (wet or dry) weather on the chemistry of 84 lakes across the northeastern U.S. The average differences in lake water  $\text{SO}_4^{2-}$  concentrations were about 2–3  $\mu\text{eq/L}$  higher in 2001 (dry year) as compared with the average observed during the entire study period 1990–2010. This has implications for S cycling as the climate changes.

Some of the  $\text{SO}_4^{2-}$  leached from soil, as well as the  $\text{SO}_x$  deposited directly into surface water, is reduced and retained in aquatic sediments as hydrogen sulfide, especially in wetlands. However, S stored in reduced form in sediments can be subsequently reoxidized and become available for down-gradient transport as  $\text{SO}_4^{2-}$  during periods of high discharge, particularly during hydrologic events that follow periods of drought. The leaching of  $\text{SO}_4^{2-}$  then can contribute to a variety of ecological effects ([Appendix 8](#) and [Appendix 12](#)). When  $\text{SO}_4^{2-}$  is released from catchment soils to drainage water, it is accompanied by an equivalent amount of cationic counter-charge in the form of acidic ( $\text{H}^+$ ,  $\text{Al}^{3+}$ ) or basic ( $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{K}^+$ , and  $\text{Na}^+$ ) cations ([U.S. EPA, 2008a](#)), affecting the concentrations of parameters addressed in the following sections of this report.

---

### 7.1.2.5 Surface Water pH

Surface water pH is commonly used as an indicator of acidification. This was the case in the 2008 ISA, and nothing has changed in that regard in more recent years. It correlates with other biologically important components of surface water acid-base chemistry, including estimates of organic acidity and concentrations of inorganic Al and  $\text{Ca}^{2+}$ . Low pH can have direct toxic effects on aquatic species [[Driscoll et al. \(2001b\)](#); [U.S. EPA \(2008a\)](#); [Appendix 8.3](#)] and this was widely understood at the time of the 2008 ISA. Low pH can disturb normal ion osmoregulation in aquatic biota. Threshold pH levels for adverse biological effects are described in [Appendix 8](#) and [Table 8-2](#). A pH value of 6.0 is often considered the level below which biota are at increased risk from acidification, but some waters can have pH below this threshold in the absence of acidic deposition. This is most commonly caused by relatively high levels of natural organic acidity. Below pH 5.5, inorganic Al often becomes the greatest threat to aquatic biota, especially in low-DOC waters. In the 2008 ISA, increasing trends in pH in surface waters in the northeastern U.S. were common through the 1990s up to 2004 and have continued in

more recent times at many locations ([Appendix 7.1.5.1](#)). Rates of change have generally been relatively small.

Surface water pH (as well as other parameters) is sensitive to hydrological conditions at the time of sampling. [Burns et al. \(2008b\)](#) sampled 12 Catskill mountain streams within the Neversink River watershed in New York for stream chemistry. The measured pH values in 2003 were generally lower than those in 1987 and this was attributed to higher stream flow during the summer of 2003, rather than to chronic acidification during the intervening period. There were no significant differences in biota observed between 1987 and 2003. Although surface water pH is a common alternative to ANC as an indicator of acidification, at pH values above about 6.0, pH is of less value as an indicator of either sensitivity to acidification or level of effect. In addition, pH measurements (especially at these higher values) are sensitive to levels of dissolved CO<sub>2</sub> in the water, which is influenced by plant root respiration.

---

#### **7.1.2.6 Surface Water Acid Neutralizing Capacity**

The most widely used measure of surface water acidification, and subsequent recovery under reduced acid deposition, is ANC. Most aquatic critical load (CL) studies conducted in the U.S. have used surface water ANC as the principal metric of water quality change in response to changes in acidic deposition ([Appendix 7.1.5.2](#)). It is typically either determined by Gran titration in a laboratory (titrated ANC) or calculated from the charge balance (calculated ANC or CALK). Titrated ANC is useful because it reflects the ANC of the complete chemical system, which is typically decreased by acidic deposition in acid-sensitive landscapes. The ANC is associated with the surface water constituents that directly cause or reduce acidity-related stress, in particular pH, Ca<sup>2+</sup>, and inorganic Al concentrations. The ANC is generally a more stable measurement than pH because ANC is insensitive to changes in CO<sub>2</sub> and it reflects sensitivity and effects of acidification in a linear fashion across the full range of ANC values. Therefore, ANC is usually the preferred indicator for assessment of surface water acidification and recovery. Both titrated and calculated ANC values are commonly determined in studies aimed at resource characterization or long-term monitoring. Models simulate calculated ANC. The two measures can differ greatly, depending mainly on the amount of organic acidity and dissolved Al in the water. The BCS ([Lawrence et al., 2007](#)) is an alternate index to ANC that integrates acid-base status and accounts for the influence of natural organic acidity.

As described in the 2008 ISA, ANC is typically used as the primary chemical indicator for assessing past effects of acidifying deposition on aquatic biota and the recovery expected from decreasing acidic atmospheric deposition ([Sullivan et al., 2006a](#); [Aber et](#)

[al., 2003](#); [Bulger et al., 2000](#)). Notably, the ANC level that reflects recovery of pH or inorganic Al may differ between the acidification and recovery phases [[Hesthagen et al. \(2008\)](#); [Appendix 7.1.5.1](#)]. In general, ANC measures over the past two to three decades in the northeastern U.S. suggest rather modest increases in ANC in many surface waters in response to large decreases in acidic deposition and surface water  $\text{SO}_4^{2-}$  concentration ([Appendix 7.1.5.1](#)).

Information on biological indicators of acidification such as fish species richness that are associated with changes in ANC are presented in [Appendix 8](#). There is often a positive relationship between ANC and number of fish species, at least for ANC values between about 0 and 50 to 100  $\mu\text{eq/L}$  ([Cosby et al., 2006](#); [Sullivan et al., 2006a](#); [Bulger et al., 1999](#)). Lakes and streams having ANC  $<0$   $\mu\text{eq/L}$  generally do not support fish. Loss of fish species seems to occur with decreases in ANC below a threshold of approximately 50 to 100  $\mu\text{eq/L}$  ([Sullivan et al., 2006a](#)).

Sensitive water bodies can be defined as those that have ANC of 100  $\mu\text{eq/L}$  or less. Sensitivity increases with further decreases in ANC. Al mobilization is largely confined, however, to waters that have pH less than about 5.5, which corresponds with ANC in the range of about 10 to 30  $\mu\text{eq/L}$  in low-DOC to moderate-DOC (less than about 400  $\mu\text{M}$ ) waters in the Northeast. Therefore, inorganic Al is not a useful indicator of acidification or chemical recovery in waters that have ANC higher than about 10–30  $\mu\text{eq/L}$ . Thus, evaluation of improvement in biologically relevant water chemistry in response to decreases in acidic deposition should perhaps include assessment of response using both the ANC and inorganic Al metrics.

[Povak et al. \(2013\)](#) reported the ANC of over 900 streams in the southern Appalachian Mountains, and estimated ANC at other stream segments throughout the region using observed relationships between ANC and watershed characteristics. Low stream ANC was commonly found at locations that exhibited siliciclastic geology; cool, short, and moist growing seasons; high clay soil content; low soil pH; and small forested watersheds.

[Sullivan \(2017\)](#) constructed a map of surface water ANC across the U.S. that included nearly 20,000 unique locations sampled between 1980 and 2011 ([Figure 8-11](#)). Samples expected to be strongly influenced by acid mine drainage, sea salt spray, or road salt application were excluded. He found 6,065 sites that had ANC  $<100$   $\mu\text{eq/L}$ . Waters having ANC  $\leq 0$   $\mu\text{eq/L}$  were mostly restricted to northern New York, New England, the Appalachian Mountain chain, upper Midwest, and Florida. In addition, low, but positive, ANC values were found in high-elevation portions of the West and parts of Arkansas and the Gulf states. These spatial patterns in surface water ANC are thought to mainly reflect the influence of soil base cation supply on ANC.

---

### 7.1.2.7 Base Cation Concentrations

Quantitatively, the most important component of the overall surface water acidification and chemical recovery response to atmospherically deposited S and N (and associated  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  concentrations) has been a change in base cation supply ([Charles and Christie, 1991](#)). As stated in the 2008 ISA, decreases in base cation concentrations in surface waters in the eastern U.S. over the past two to three decades have been ubiquitous and closely tied to trends in  $\text{SO}_4^{2-}$  concentrations in surface waters. In most regions, rates of decrease for base cations have been like those for  $\text{SO}_4^{2-}$  plus  $\text{NO}_3^-$ , with the exception of streams in western Virginia and in Shenandoah National Park, which are strongly affected by  $\text{SO}_4^{2-}$  adsorption on soils. The 2008 ISA concluded that acidifying deposition has been an important cause of decreasing amounts of exchangeable base cations on soils. This influences base cation leaching to surface waters and soil buffering of deposition acidity. Surface water base cation concentrations increase with acidification and generally decrease under reduced levels of acidic deposition. However, in some watersheds that have acidified, concentrations of  $\text{Ca}^{2+}$  and other base cations have become substantially reduced from likely preindustrial levels, in response to depletion by many years of acidic deposition. This base cation depletion constrains surface water ANC and pH recovery, as described in the 2008 ISA. Recent results have further corroborated these earlier findings. More recent studies have included experiments (liming), modeling, and gradient studies with geographical focus on the Adirondack Mountains, southern Appalachian Mountains, Rocky Mountains, and the Hubbard Brook Experimental Forest (HBEF) in New Hampshire.

Base cations are contributed to soils and surface waters through weathering and atmospheric base cation deposition ([Appendix 4](#)). Estimates of base cation weathering ( $\text{BC}_w$ ) largely control simulated base cation concentrations in drainage water and are needed for evaluating CLs of surface water acidity using steady-state models ([Appendix 8](#)). [McDonnell et al. \(2012\)](#) developed an approach for regionalizing  $\text{BC}_w$  using regionally specific empirical relationships. The dynamic model MAGIC was used to calibrate  $\text{BC}_w$  in 92 watersheds distributed across the southern Appalachian Mountains. About one-third of the study region had  $\text{BC}_w$  estimates that were less than 1,000 eq/ha/year, with lowest values for watersheds located in national parks and wilderness areas.

Base cation surplus is defined as the difference between the summed concentrations of base cations (Ca, Mg, Na, K) and strongly acidic inorganic anions ( $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ , chloride), minus an estimate of the strongly acidic organic anions estimated from dissolved organic C and an assumed charge density. These strongly acidic organic anions are dissociated at low pH, and function essentially as mineral acid anions in terms of their

effect on ANC. The BCS is an alternative statistic to ANC for use mainly in waters that have appreciable natural organic acidity.

In high-elevation portions of three watersheds in the southern Appalachian Mountains, [Knoepp et al. \(2016\)](#) found that stream acid-base chemistry was related to the concentrations of N and Al in the soil O-horizon and to the total amount of C and Ca in the soil. Each watershed contained four to six first-order catchments with moderate to high levels of acid sensitivity (ANC 11–50  $\mu\text{eq/L}$ ). Differences across catchments in stream ANC, pH, and the ratio of Ca:Al concentrations were also significantly correlated with watershed vegetation, as reflected in basal area, tree height, and diameter at breast height.

In the Muskoka River Watershed in Ontario, Canada, further improvement in lake ANC and pH might be limited by Ca depletion, which can be made worse by tree harvesting ([Reid and Watmough, 2016](#)). More than 60% of the tree Ca is commonly found in the bark and boles, which are largely removed from the watershed during timber extraction. The authors estimated that timber harvesting at planned levels will cause approximately a 30% increase in the number of sampled lakes that decline to Ca levels below 1 mg/L.

Changes in acidic deposition exert complex effects on the concentration of Ca in surface waters. During the early phases of soil and water acidification, acidic deposition increases the leaching of Ca from soil to drainage water. This Ca leaching causes increased concentrations of Ca in streams and lakes. In base-poor watersheds having thin soils, the rate of Ca leaching can exceed the resupply via weathering and atmospheric input. Over time, soil base saturation decreases, and the concentration of Ca in runoff decreases, perhaps to levels lower than what existed prior to the advent of acidic deposition. Decreases in acidic deposition will further accentuate this Ca depletion. Decline in lake water Ca concentration has severe consequences for some species of zooplankton, especially *Daphnia* species that have high Ca requirements. [Jeziorski et al. \(2008\)](#) documented major reductions in abundance of Ca rich *Daphnia* spp., keystone herbivores in pelagic food webs, in association with decreases in the concentration of Ca in lake water. They reported that a high proportion of Canadian Shield lakes had Ca concentration near or below the threshold level (1.5 mg/L) for decreased survival and fecundity in laboratory studies. Ecological impacts of these changes on food webs may be substantial.

Increased atmospheric transport of dust enriched with nutrients, metals, and base cations to alpine watersheds in the western U.S. has been shown to alter lake biogeochemical processes. [Ballantyne et al. \(2011\)](#) examined temporal trends in dust deposition from sediment cores collected from two lakes in Colorado with distinct physical and chemical properties. Recent increases in dust deposition and its enrichment in various elements,

including Ca, has contributed base cations to drainage water and altered the biogeochemistry of the two study lakes.

Liming studies confirm ecosystem responses when depleted base cation pools in soils are restored by addition of base cations experimentally or for management purposes. In a base cation addition study (45,000 kg of calcium silicate [wollastonite,  $\text{CaSiO}_3$ ]) in HBEF, increases in the concentrations of Ca and decreases in the concentrations of  $\text{H}^+$  and inorganic Al in stream water were observed and stream ANC increased ([Cho et al., 2012](#)). By the end of 2010, an estimated 3 to 5% of added Ca was exported in stream water and the Ca retained in the watershed was detected in lower soil horizons or taken up by vegetation ([Shao et al., 2016](#); [Johnson et al., 2014](#)). Exchangeable Ca increased significantly and exchangeable Al decreased significantly in the organic and upper mineral soils over the years following wollastonite addition ([Johnson et al., 2014](#)).

---

#### **7.1.2.8 Surface Water Aluminum**

As stated in the 2008 ISA, the concentration of dissolved inorganic monomeric Al in surface waters is an especially useful indicator of acidifying deposition effects because (1) it is toxic to many species of aquatic biota ([Appendix 8](#)) and (2) it generally does not leach from soils to surface waters in the absence of input of strong acids [e.g., sulfuric acid, nitric acid, strong organic acid anions; [Driscoll et al. \(1988\)](#); [Lawrence et al. \(2007\)](#)]. It has well-documented effects on aquatic biota at specific thresholds ([Appendix 8](#)). In the 2008 ISA, limited data suggested that some acid-sensitive surface waters in regions of the northeastern U.S. have elevated inorganic Al concentrations, which have been induced by years of acidifying deposition and pose threats to aquatic life. Since the 2008 ISA, several monitoring studies have reported decreases in inorganic Al suggestive of chemical recovery of surface waters [[Warby et al. \(2008\)](#); [Strock et al. \(2014\)](#); [Driscoll et al. \(2016\)](#); [Baldigo et al. \(2016\)](#); [Appendix 7.1.5.1](#)].

---

#### **7.1.2.9 Surface Water Dissolved Organic Carbon Concentration**

An especially important, and relatively new, area of research focus in the context of recovery from surface water acidification has been the observed increase in DOC or total organic carbon (TOC) concentration in many surface waters recovering from acidification. This has implications with respect to water toxicity and cycling of C, Al, and N. Changes in lake DOC are important because DOC helps to regulate biological, chemical, and physical lake characteristics by adding C, changing pH, affecting nutrient cycling, and changing the availability of toxic metals, including Al. Lake DOC regulates

UV light penetration into the water column and the amount and depth of photosynthetically active radiation (PAR), which affects the lake mixing depth, especially in small lakes. Increased DOC contributes to shallower mixing depth and greater fluctuation in diel temperature and may affect lake nutrient status ([Gerson et al., 2016](#)). Increases over the past two to three decades in lake DOC in the northeastern U.S. have likely been part of the chemical recovery from previous lake acidification ([SanClements et al., 2012](#); [Monteith et al., 2007](#)) and/or caused or exacerbated by changes in climate, including precipitation patterns ([Couture et al., 2012](#); [Weyhenmeyer and Karlsson, 2009](#)).

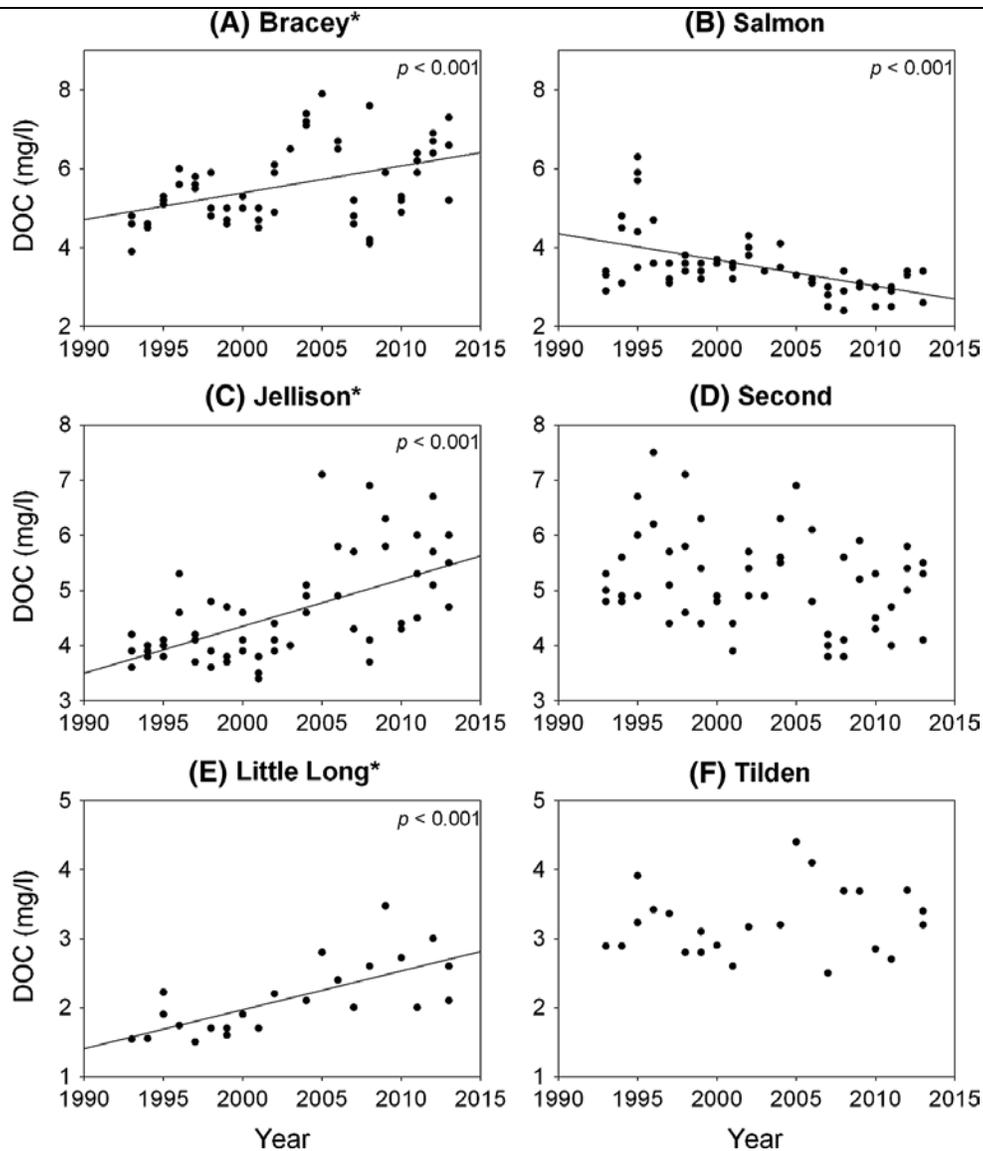

The 2008 ISA reported widely observed increased concentrations of DOC or TOC in surface waters across North America and Europe and that these increases were at least partly related to changes in atmospheric deposition of S and N. Thus, it has been recognized for well over a decade that surface water organic carbon concentrations have decreased to some extent in many water bodies that previously experienced water acidification. Therefore, DOC concentration would likely increase with recovery. More recent research on this topic has been diverse and has included experiments, observation, isotope studies, and synthesis and integration work. Overall, they illustrate relatively large increases in DOC with acidification recovery in some aquatic systems. This response constrains the level of ANC, and especially pH, recovery, but decreases the toxicity of dissolved Al by converting some of it from inorganic to organic forms ([Lawrence et al., 2013](#)). As a result of this widely observed pattern, surface water DOC concentration has become an important focus of water acidification and recovery research ([Appendix 7.1.5.1](#)).

DOC is comprised of a diverse mix of organic matter and functional groups. [Wood et al. \(2011\)](#) noted that dark, aromatic-rich organic matter with relatively high humic content and of allochthonous origin may be more effective in ameliorating metal bioavailability and toxicity than other organic materials. In addition, part of the protection provided by DOC may involve physiological mechanisms other than metal complexation ([Wood et al., 2011](#)). Soil mechanisms that contribute to higher DOC in surface waters are discussed in [Appendix 4](#). At the Niwot Ridge Long-Term Ecological Research site in Colorado, [Miller and Mcknight \(2015\)](#) reported downstream transport of dissolved organic matter (DOM) that had been produced in alpine lakes during low-flow periods.

Recent research suggested that increases in lake DOC may have changed key functions of affected lakes, causing decreased vertical distribution of phytoplankton and changes in phytoplankton species composition. This was investigated by [Brown et al. \(2017\)](#), who demonstrated that increases in lake DOC can potentially change the thermal structure of lakes, but that effects are variable. They analyzed fossil diatom remains in sediment cores collected from three pairs of small remote Maine lakes. Each pair consisted of one lake

that showed recent increases in DOC since the early 1990s and a similar lake that did not show increasing DOC. The focus was on changes in the relative abundances of diatom taxa that were known to reflect effects on thermal stratification, specifically *Discostella stelligera* and *Aulacoseira* spp. [Saros et al. \(2012\)](#) had constructed a diatom inference model for reconstructing past lake mixing depth based on the relative abundance of *D. stelligera*, which prefers shallower mixing depth. [Stone et al. \(2016\)](#) expanded this model and included species of *Aulacoseira*. [Brown et al. \(2017\)](#) hypothesized that those lakes that had experienced recent DOC increases (shown in [Figure 7-3](#)) would show increased diatom turnover and increases in the relative abundance of *D. stelligera* and *Aulacoseira* spp. since the 1990s. The three study lakes that had no increase in DOC also showed minimal change in the identified sensitive taxa. The three lakes that experienced recent increases in DOC showed variable diatom responses. Results were interpreted as being indicative of the potential of DOC to change the physical and biological structure of lakes that have experienced past or ongoing chemical recovery from prior lake acidification. The largest changes in diatom taxa occurred in two of the lakes that had experienced recent increases in DOC.

DOC effects on N cycling have been further elucidated since the 2008 ISA. [Rodriguez-Cardona et al. \(2016\)](#) and [Wymore et al. \(2016\)](#) suggested greater  $\text{NO}_3^-$  removal from drainage water under conditions of relatively high DOC and high ratio of  $\text{DOC}:\text{NO}_3^-$  concentration. Results of the study of [Fork and Heffernan \(2014\)](#) further suggested that the indirect effects of DOC on light will be important in determining how N cycling responds to increasing concentrations of DOC in surface waters. Under conditions of increased DOC, the quality of DOM may change, as may its binding with dissolved Al ([Fakhraei and Driscoll, 2015](#)). Dynamics of DOC may also have consequences for eutrophication of downstream ecosystems, but interactions appear to be complex.

Notes: Linear regression lines are shown for significant trends ( $p < 0.05$ ). Asterisk indicates lakes with a significant DOC increase. Source: [Brown et al. \(2017\)](#).

**Figure 7-3 Dissolved organic carbon (DOC) concentrations from 1993 to 2013 for Bracey Pond (a), Salmon Pond (b), Jellison Pond (c), Second Pond (d), Little Long Pond (e), and Tilden Pond (f) in Maine.**

Short-term studies to characterize acid-base chemistry have provided information on surface water quality and biogeochemistry of organic materials. [Kang and Mitchell \(2013\)](#) studied spatial and temporal variation in the quantity and quality of DOC, N, and S in Adirondack Mountain surface waters over a 14-month period. This investigation

included the sampling of two upland streams, two wetland-influenced streams, and one lake outlet (Arbutus Lake). The DOC and dissolved organic N (DON) concentrations increased as water was transported through wetland areas. Results highlighted the value of applying multiple approaches for understanding the biogeochemistry of DOM. The acid-base chemistry of DOC has been further investigated in several other studies. [Porcal et al. \(2009\)](#) confirmed that DOC concentrations in lakes and streams throughout much of Europe and North America have increased over the last three decades. Possible reasons for this change proposed by [Porcal et al. \(2009\)](#) included increased atmospheric CO<sub>2</sub> concentration, climate warming, decreased S deposition (and associated changes in water pH and ionic strength), and hydrologic changes caused by drought and precipitation. Any changes in DOC concentration or properties will impact the acid-base chemistry of surface waters and perhaps the composition of aquatic biota. In a laboratory study, [Al-Reasi et al. \(2013\)](#) performed titrations for a range of freshwater DOM isolates. In general, the proton site density ( $L_T$ ) exhibited maxima near proton binding constants ( $pK_a$ ) values of 3.5 and 10, reflecting the presence of both strong and weak organic acids. The Proton Binding Index parameter was described to summarize the chemical reactivity of DOM based on the  $pK_a$  values and the  $L_T$ . Results of this study provided a rationale for describing the protection provided by DOM against metal, including inorganic Al, toxicity. Recent additional research has also focused on improving scientific understanding of variation in the importance of organic versus mineral acids in controlling the acidity of soil water and surface water. [Chapman et al. \(2008\)](#) analyzed seasonality in soil water and surface water chemistry in two U.K. headwater watersheds. Strong seasonal patterns were observed for both ANC and DOC. Acidic deposition-controlled acidity during winter, whereas organic acids were more important during summer. The observed increase in DOC concentration in drainage water over the previous two decades was attributed mainly to climate warming, increased CO<sub>2</sub>, and/or decreased acidic deposition.

[SanClements et al. \(2012\)](#) used a chemical signature of terrestrial DOM to investigate the extent to which increased DOC concentrations in surface water since about 1993 in the northeastern U.S. have been driven by decreasing acidic deposition and increasing solubility of soil organic matter. They used fluorescence spectroscopy to characterize the quality of DOM in stored samples that had been collected from nine acid-sensitive lakes in Maine. Decreases in lake water SO<sub>4</sub><sup>2-</sup> concentration were associated with increases in DOC concentration and a shift during ecosystem recovery from microbial to terrestrially derived DOM. Changes in the quality or quantity of DOM can affect aquatic ecosystem functions. Dissolved organic matter is important for providing food for microbes, attenuating light, buffering pH, binding Al, and controlling the cycling of nutrients ([SanClements et al., 2012](#)).

The amount and composition of DOC mobilized from upland soils to surface waters is an important link in the global C cycle. The relationship between ultraviolet (UV) absorbance and DOC concentration has been shown to reflect the aromaticity of the DOC. [Dawson et al. \(2009\)](#) reported a change in correspondence between UV absorbance and DOC concentration over a period of 22 years at two moorland watersheds in Scotland. The DOC concentration has increased over time, while the proportion of hydrophobic DOC has decreased. A model analysis by [Dawson et al. \(2009\)](#) suggested that S deposition was the only factor that could reasonably explain the observed long-term DOC trend at both sites.

[Valinia et al. \(2015\)](#) used visible near-infrared spectroscopy of lake sediments to reconstruct the reference condition TOC in Swedish lakes. Long-term monitoring data were used to simulate recent changes in TOC and then analyzed using two empirical models. The first predicted historical TOC trends between reference conditions in the year 1860 and peak acidification in approximately the year 1980. The second model predicted TOC between 1988 and 2012 in conjunction with partial chemical recovery from acidification. The models were driven by lake and watershed area, the number of wetlands, historical S deposition, and current water chemistry. The researchers estimated that the present-day TOC concentrations are similar to reconstructed reference conditions in Swedish lakes. Thus, it was deemed unlikely that the TOC concentrations in Swedish lakes will continue to increase with continued controls on acidic deposition.

In a monitoring study from the Czech Republic, [Hruška et al. \(2009\)](#) reported high DOC in two watersheds: 18.8 mg/L and 20.2 mg/L at the acidic and base-rich watersheds, respectively. Between 1993 and 2007, the concentrations of DOC in stream water increased by about 65% at both streams. Increases in stream water DOC were associated with small increases in stream pH, but large decreases in ionic strength due to declining acidic deposition. Although neither of the catchments showed changes in soil water pH, DOC concentrations in soil water tripled. [Hruška et al. \(2009\)](#) concluded that the change in ionic strength of soil water and stream water, rather than acidity, was the major cause of increased stream water DOC. Changes in temperature, precipitation, and discharge during the study suggested that climate change may be an additional important control of DOC dynamics. The role of ionic strength in modifying temporal patterns of surface water DOC in the U.S. has not been studied at the time of this writing. [Evans et al. \(2017\)](#) also documented decreased lake DOC in response to reacidification of a moorland lake catchment in the U.K. In addition, the quality of the DOC changed towards higher levels of aromatic organic compounds and an increase in particulate organic C.

---

### 7.1.2.10 Climate Modification of Ecosystem Response to Nitrogen and Sulfur

Surface water chemistry and chemical recovery ([Appendix 7.1.5.1](#)) of fresh waters are occurring within the context of projected changes in annual mean temperature and magnitude of precipitation associated with climate change ([Greaver et al., 2016](#)). In acid sensitive regions, altered hydrologic regimes are likely to affect weathering rate of base cations, lake water levels, and organic matter inputs to catchments ([Adrian et al., 2009](#); [Porcal et al., 2009](#)). Projected shifts in runoff, timing, and quantity of flushing will alter the frequency and duration of episodic events and the concentrations of nutrients and chemical indicators in surface waters ([Adrian et al., 2009](#); [Whitehead et al., 2009](#)). Extreme weather years (wet or dry) can shift water chemistry responses such as DOC and  $\text{SO}_4^{2-}$  concentrations ([Strock et al., 2016](#)). Increased loading of DOC to surface waters, attributed in part to increasing temperatures and changes in precipitation, may affect biogeochemical processes and nutrient availability ([Daggett et al., 2015](#); [Zhang et al., 2010](#); [Weyhenmeyer and Karlsson, 2009](#)). [Appendix 13](#) includes a more detailed discussion of how climate (e.g., temperature and precipitation) modifies ecosystem response to acidification.

---

### 7.1.3 Freshwater Monitoring and Databases

Long-term monitoring of surface water chemistry over time has enabled a greater understanding of ecosystem response to deposition of N and S, including chemical and biological responses. Monitoring data inform determination and quantification of temporal trends and many monitoring studies for acidification have been ongoing for one or two decades, in some cases longer. Such data were available and incorporated into the 2008 ISA. Since that time, nearly a decade's worth of additional data have been added to some of these databases. This is noteworthy because short-term temporal variability can mask small changes that are part of a long-term trend. The availability of these additional data facilitates trend detection now, compared with 2008. A number of monitoring studies have been conducted or continued in recent years that document nutrient dynamics in water bodies in response to N inputs. Recent evidence that P deposition is increasing ([Appendix 9.1.1.4](#)) may contribute to total nutrient loading and affect shifts in lake nutrient status.

---

### 7.1.3.1 Acidification

A number of freshwater monitoring studies have been conducted using data collected over the previous one to three decades that have documented ecosystem chemical damage and recovery ([Appendix 7.1.5.1](#)) caused by acidifying deposition of S and/or N. Many of these studies have been conducted in the U.S., especially in the Northeast and the southern Appalachian Mountains ([Table 7-3](#)), including a number of studies since 2008. Two surface water chemistry monitoring programs that have been especially useful to inform the assessment of aquatic ecosystem responses to changes in acidic atmospheric deposition have been Temporally Integrated Monitoring of Ecosystems [TIME; [Stoddard et al. \(1996\)](#)] which is no longer operating, and the U.S. EPA Long-Term Monitoring (LTM) project ([Stoddard et al., 1998](#); [Ford et al., 1993](#)). These U.S. EPA monitoring efforts focus on portions of the U.S. most affected by the acidifying influence of S and N deposition, including lakes in the Adirondack Mountains of New York and in New England, and streams in the Northern Appalachian Plateau and the Blue Ridge physiographic provinces in Virginia and West Virginia. Both projects are operated cooperatively with numerous collaborators in state agencies, academic institutions, and various federal agencies.

The Adirondack Lakes Survey Corporation (ALSC) has been monitoring Adirondack lakes for about 30 years. This work has mainly focused on acid-base chemistry but has also involved some fish monitoring and measurement of parameters relevant to nutrient enrichment. Monitoring data have shown some chemical recovery from lake acidification, reflected in increased pH and ANC and decreased inorganic Al concentrations ([Appendix 7.1.5.1](#)). HBEF in NH also has several decades of monitoring data. The central and southern Appalachian Mountains region is important because (1) it contains an abundance of low-ANC streams situated on base-poor geology, (2) atmospheric S and N deposition have been high, (3) S adsorption on soils complicates acidification/recovery responses, and (4) much of the acid-sensitive landscape is managed as national park and wilderness area. New studies have been conducted of stream acid-base chemistry throughout this region in West Virginia, Maryland, Virginia, and Tennessee. More recent monitoring studies are highlighted below and in [Table 7-3](#).

Since the early 2000s, U.S. EPA, together with states, tribes, other entities, and individuals, have collaborated on a series of statistically representative surveys (National Aquatic Resource Surveys [NARS]) of the nation's waters, including surveys of lakes ([U.S. EPA, 2016h](#), [2009b](#)), streams ([U.S. EPA, 2016i](#)), wetlands ([U.S. EPA, 2016j](#)), and coastal waters ([U.S. EPA, 2016g](#)). Based on standard sampling and analysis protocols and consistent quality assurance, these surveys periodically assess the magnitude and spatial extent of water quality issues and concerns across the U.S.

**Table 7-3 Monitoring and resurvey results of aquatic acidification and/or chemical recovery since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur—Ecological Criteria.**

Process	Acidification Indicator	Nutrient Enrichment Indicator	Type of Ecosystem	Region	Time Period	Ambient N/S Deposition kg/ha/yr	Effect of Deposition	Publication
Chemical recovery	pH, ANC, SO <sub>4</sub> <sup>2-</sup> , DOC	N/Ap	12 streams	Adirondack Mts.	1980s–2008	Variable	On average, pH increased by 0.28; ANC increased 13 µeq/L; rate of decrease in stream SO <sub>4</sub> <sup>2-</sup> concentration was 2 µmol/L/yr between 1999 and 2008 at a high-DOC stream and 0.73 µmol/L/yr at a low-DOC stream.	<a href="#">Lawrence et al. (2011)</a>
Chemical recovery	pH, ANC, SO <sub>4</sub> <sup>2-</sup> , DOC, NO <sub>3</sub> <sup>-</sup> , Al <sub>i</sub>	NO <sub>3</sub> <sup>-</sup>	48 lakes (16 lakes that were part of the original ALTM monitoring project and addition of new lakes in 1992)	Adirondack Mts.	1982–2015		All study lakes showed significant decreases in the concentration of SO <sub>4</sub> <sup>2-</sup> in lake water consistent with reductions in S deposition. Concentration of NO <sub>3</sub> <sup>-</sup> declined at variable rates in 33 of the 48 study lakes. Widespread increases in ANC in 42 of the 48 study lakes and in lab pH in 33 of the 48 study lakes. Al <sub>i</sub> decreased in 45 of the 48 lakes. Dissolved organic C increased in 29 of the 48 lakes. Most of the 48 ALTM lakes showed significant decreases in the concentrations of base cations. Eleven of the 16 original ALTM lakes showed increases in lake ANC between 1982 and 2013.	<a href="#">Driscoll et al. (2016)</a>

**Table 7-3 (Continued): Monitoring and resurvey results of aquatic acidification and/or chemical recovery since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur-Ecological Criteria.**

Process	Acidification Indicator	Nutrient Enrichment Indicator	Type of Ecosystem	Region	Time Period	Ambient N/S Deposition kg/ha/yr	Effect of Deposition	Publication
Chemical recovery	ANC, DOC	NO <sub>3</sub> <sup>-</sup>	TIME lakes	Adirondack Mts.	1991–2007	Variable	Percentage acidic lakes decreased from 15.5 to 8.3%; calculated ANC increased at more than twice the rate as Gran ANC, which was attributed to increase in DOC.	<a href="#">Waller et al. (2012)</a>
Chemical recovery	SO <sub>4</sub> <sup>2-</sup> , DOC	N/Ap	Nine lakes	Maine	1993–2009	Wet S = 6.2 (1980) to 1.5 (2010) N = 3	Decreases in lake SO <sub>4</sub> <sup>2-</sup> correlated with increases in DOC and a shift from microbial to terrestrially derived organic matter.	<a href="#">SanClements et al. (2012)</a>
Chemical recovery	NO <sub>3</sub> <sup>-</sup>	NO <sub>3</sub> <sup>-</sup>	Lakes	Adirondack Mts. and New England	2000–2010	N/Av	Lake NO <sub>3</sub> <sup>-</sup> concentrations declined at rate of -0.05 µeq/L/yr and there was a shift to nontoxic (organic) Al.	<a href="#">Strock et al. (2014)</a>
Chemical recovery	Al <sub>i</sub>	N/Ap	Resurvey of 113 lakes	Northeastern U.S.	1986–2001	N/Av	In 2001, only 7 lakes, representing 130 lakes in population, had Al <sub>i</sub> >2 µmol/L (toxic threshold to brook trout), compared with 20 sampled lakes (representing 449 lakes in population) in 1986.	<a href="#">Warby et al. (2008)</a>

**Table 7-3 (Continued): Monitoring and resurvey results of aquatic acidification and/or chemical recovery since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur-Ecological Criteria.**

Process	Acidification Indicator	Nutrient Enrichment Indicator	Type of Ecosystem	Region	Time Period	Ambient N/S Deposition kg/ha/yr	Effect of Deposition	Publication
Chemical recovery	SO <sub>4</sub> <sup>2-</sup> , NO <sub>3</sub> <sup>-</sup> , ANC	NO <sub>3</sub> <sup>-</sup>	Two streams	Western MD	1990–2005	N/Av	Concentrations of SO <sub>4</sub> <sup>2-</sup> in stream water decreased at a rate of about 3 µeq/L/yr in response to 34% reduction in wet S deposition. Trends in stream NO <sub>3</sub> <sup>-</sup> appeared to be related to watershed factors, especially forest disturbance. Rate of ANC increase during the period 1996–2005 was about half the rate of the entire study period, suggesting that chemical recovery may be slowing or coming to an end.	<a href="#">Eshleman et al. (2008)</a>
Chemical recovery	Ca <sup>2+</sup> , Mg <sup>2+</sup> , SO <sub>4</sub> <sup>2-</sup>	NO <sub>3</sub> <sup>-</sup>	Two streams (manipulated and control)	Bear Brook, ME	1988–2006	Wet S = 6 (1987) to 2.3 (2006)	Concentrations of Ca and Mg in stream water decreased more than SO <sub>4</sub> <sup>2-</sup> concentration, causing stream acidification in control stream.	<a href="#">Navrátil et al. (2010)</a>
Chemical recovery	ANC	N/Av	64 streams	Western Virginia	1987–2011	Wet S = 9 (1980) to 3.7 (2010) Wet N = 4.7 (1980) to 3.0 (2010)	At most sites underlain by base-poor bedrock, ANC decreased despite reductions in S deposition. This response was related to depletion of base cations.	<a href="#">Robison et al. (2013)</a>
S adsorption	SO <sub>4</sub> <sup>2-</sup>	NO <sub>3</sub> <sup>-</sup>	Stream watershed	Noland Divide, GSMNP, TN	1991–2006	S = 28	Sulfur adsorption on soil is important on average. During large precipitation events, SO <sub>4</sub> <sup>2-</sup> was more mobile and caused stream acidification.	<a href="#">Cai et al. (2010)</a>

**Table 7-3 (Continued): Monitoring and resurvey results of aquatic acidification and/or chemical recovery since the 2008 Integrated Science Assessment for Oxides of Nitrogen and Sulfur-Ecological Criteria.**

Process	Acidification Indicator	Nutrient Enrichment Indicator	Type of Ecosystem	Region	Time Period	Ambient N/S Deposition kg/ha/yr	Effect of Deposition	Publication
Pyrite weathering	SO <sub>4</sub> <sup>2-</sup>	N/Ap	High elevation lakes	Colorado	1985–2008	N/Av	Lake SO <sub>4</sub> <sup>2-</sup> concentration decreased at a rate of –0.12 to –0.27 µeq/L/yr. Climate warming appears to have affected pyrite weathering and lake SO <sub>4</sub> <sup>2-</sup> concentration.	<a href="#">Mast et al. (2011)</a>
ANC production	Alkalinity, Ca <sup>2+</sup>	N/Ap	Streams and rivers	Eastern U.S.	Varies, at least 25 yr of monitoring data per site	Varies	Acidifying deposition is one contributor along with carbonate lithology and watershed topography to significantly increasing alkalinity trends (in 64% of 97 river and stream sites). Most rapid rates of alkalization occurred at sites with the highest elevation and greatest inputs of acidifying deposition.	<a href="#">Kaushal et al. (2013)</a>
ANC production	Alkalinity, SO <sub>4</sub> <sup>2-</sup> , NO <sub>3</sub> <sup>-</sup> , Ca <sup>2+</sup> , Mg <sup>2+</sup>	N/Ap	Rivers	U.S.	Varies, average monitoring data spanned 50 yrs (range 27 to 65 yr)	Varies	Increasing alkalinity observed in 14 of 23 rivers attributed to recovery from acidification, agricultural processes and changing land uses.	<a href="#">Stets et al. (2014)</a>

In the most recent U.S. EPA National Lakes Assessment, based on lake surveys conducted in 2012, more than 1,000 lakes, ponds, and reservoirs (representing approximately 100,000 water bodies) were sampled for their water quality and biological and habitat conditions using generally comparable field and laboratory protocols ([U.S. EPA, 2016h](#)). Inclusion criteria were water bodies >1 hectare, at least 1 m deep, a minimum of 0.1-hectare open water and minimum water residence time of 1 week. Chemical indicators in the lake surveys included acidification. This survey updated the previous National Lakes Assessment ([U.S. EPA, 2009b](#)). In the earlier National Lakes Assessment that was conducted in 2007 ([U.S. EPA, 2009b](#)), ANC and pH were among the chosen chemical indicators used to assess biological integrity. However, due to logistical considerations, included sites were restricted to lakes larger than 10 acres (4 ha). This constraint eliminated from consideration many of the most acid-sensitive and acid-impacted lakes. In the more recent 2012 lakes survey, the size criterion for inclusion was decreased to lakes >1 hectare ([U.S. EPA, 2016h](#)).

The U.S. EPA also conducted a National Rivers and Streams Assessment (NRSA) during the period 2008–2009 ([U.S. EPA, 2016i](#)). Nearly 2,000 perennial river and stream sites were sampled, representing nearly 1.2 million miles of stream reach. Stream size ranged from very small headwaters to very large rivers. The NRSA reported four chemical stressors: total N, total P, salinity, and acidification along with biological indicators including benthic macroinvertebrates and fish. In the 2012 survey, 97% of lakes were classified in the least disturbed condition for acidification. During the period 2008–2009 ([U.S. EPA, 2016i](#)) acidification was found to be a problem in less than 1% of the stream and river length in the U.S. ([U.S. EPA, 2016i](#)). These results emphasize the finding that acidification impacts are largely confined to relatively small areas of high sensitivity and/or to relatively small lakes and tributary streams.

The U.S. Geological Survey (USGS) has operated several long-term monitoring efforts, including the National Ambient Water Quality Assessment (NAWQA) program that was created in 1991 to assess the nation's water quality in 51 study units defined primarily by major drainage divides. These units comprise approximately 50% of the conterminous U.S. Major objectives of the NAWQA program have been to determine the condition of the nation's streams, rivers, and groundwater; whether these conditions are changing over time; and how these conditions are affected by natural features and human activities. The major priority of the NAWQA program since its inception has been the study of watersheds that have experienced impacts from agriculture and various forms of development. The location of sites, sampling frequency, and types of measurements all reflect this priority. The NAWQA data set has also been used to develop predictive models for occurrence of macroinvertebrates and fish in U.S. streams and identify the relative importance of factors, including nutrients, in species distributions ([Carlisle and](#)

[Meador, 2007](#); [Carlisle et al., 2007](#); [Meador and Carlisle, 2007](#)). Additional USGS monitoring programs have included the Hydrologic Benchmark Network (discontinued in 1997), the New York District of the USGS for the water supply watershed for New York City (in the Catskill Mountain region), and a monitoring project conducted by USGS in the Adirondack Mountains at Buck Creek, NY.

Studies by [Kaushal et al. \(2013\)](#) and [Stets et al. \(2014\)](#) assessed changes in, and controls on, carbonate alkalinity of rivers in the U.S. Alkalinity was defined (in equivalent concentrations, expressed as  $\mu\text{eq/L}$ ) as:

$$[\text{ALK}] = [\text{HCO}_3^-] + [\text{CO}_3^{2-}] + [\text{OH}^-] - [\text{H}^+]$$

Equation 7-1

which is mathematically equivalent to ANC defined as the difference between the equivalent sum of the base cations and the mineral acid anions ([Charles and Christie, 1991](#)). [Kaushal et al. \(2013\)](#) reported trends in alkalinity in 97 rivers and streams in the eastern U.S. They found significant increases in alkalinity, a product of chemical weathering, at 62 (64%) of the study sites, with no sites showing significant decreases. Trends of increasing alkalinity were weakly related to the presence of carbonate lithology in the watershed, acidic deposition, and topography. The authors interpreted the generally increasing alkalinity as reflective of human impacts on weathering rates. The role of temperature in modifying weathering rates was not assessed.

---

### 7.1.3.2 Eutrophication

A number of monitoring studies have been conducted or continued in recent years that have documented the effects of N input on the  $\text{NO}_3^-$  flux and/or trophic state of fresh waters. Monitoring studies linked to eutrophication response and published since the 2008 ISA are highlighted in this section. In the most recent National Lakes Assessment, about one-third of the lakes in the continental U.S. were judged to have excess N, suggesting that N nutrient pollution is a widespread concern across the country ([U.S. EPA, 2016h](#)). Chemical indicators in the lake surveys included DO, N, and P. Benthic macroinvertebrates, chlorophyll *a*, and zooplankton were the biological indicators assessed by the sampling protocols. Algal toxin (microcystin) and cyanobacteria were also evaluated in the water bodies. Lakes that had high levels of N were 1.6 times as likely to have a degraded benthic macroinvertebrate community. Increases in both cyanobacteria (8.3% increase) and microcystin toxin (9.5% increase) were reported in the most recent lake sampling compared to the previous National Lakes Survey conducted in 2007 ([U.S. EPA, 2016h, 2009b](#)). In the NRSA, 41% of the nation's river and stream miles were rated poor for N compared to least-disturbed reference conditions ([U.S. EPA,](#)

[2016i](#)). Streams in the Plains and Lowlands were most impacted by N, followed by the mountainous areas east of the Mississippi River (Eastern Highlands).

Since the 2008 ISA, surface water chemistry data from long-term monitoring by federal, state, and local agencies as well as university research groups and nonprofits has been combined into publicly available metadatabases. The Lake Multi-Scaled Geospatial and Temporal Database of the Northeast Lakes of the U.S. (LAGOS-NE) is an integrated database that includes lake surface water chemistry data from a 17-state region ([Soranno et al., 2015](#)). A Georeferenced Lake Nutrient Chemistry (GLNC) database containing N and P water chemistry from 1964–2015 from 3,602 western U.S. mountain lakes has combined data from the National Park Service (NPS), U.S. Fish and Wildlife Service (USFS), the U.S. EPA National Lakes Assessments, and academic researchers for assessing nutrient deposition effects in the region ([Williams et al., 2017b](#)). These databases have been used to assess temporal and spatial trends of lake nutrient chemistry in response to environmental stressors including atmospheric deposition.

Research published since the 2008 ISA and described in detail in [Appendix 9.1.1.4](#) provided evidence suggesting that predominantly dry deposition of fine (<10 µm) and coarse (<100 µm) particulates containing P “dust” plays a role in the enrichment effects of N deposition to fresh waters and their catchments. Among the large natural P emission sources are soils, vegetation, and biomass combustion ash. Other notable sources include industry, agriculture, and mining. Although P is not a criteria pollutant, inputs of P may contribute to eutrophication and affect shifts in lake trophic status from P to N limitation or to colimitation. Data from the U.S. EPA National Lakes surveys and National Rivers and Streams surveys were analyzed by [Stoddard et al. \(2016\)](#) to determine whether total P (TP) concentrations changed between 2000 and 2014. They found increases in TP continentally and especially at sites that exhibited low disturbance ([Appendix 9.1.1.2](#)). In addition, they observed that TN was strongly correlated with TP in lakes and streams on a national scale. Although the authors determined that TP was increasing at “minimally disturbed sites,” they observed that TN was not increasing at those sites. A 5-year, Community Atmospheric Model (CAM<sub>4</sub>) simulation by [Brahney et al. \(2015\)](#) suggested that P deposition may play a large role in alpine lake trophic status and that TP deposition may have increased globally by 1.4 times the preindustrial deposition rate. A global-scale analysis by [Tipping et al. \(2014\)](#) suggested that oligotrophic lakes are most likely to experience effects of atmospheric P deposition, with implications for changes in productivity in response to anthropogenically emitted N.

Regional monitoring data have been used to infer the N saturation status of watersheds in forested ecosystems based on NO<sub>3</sub><sup>-</sup> leaching to surface waters. [Yanai et al. \(2013\)](#) conducted a detailed time-series analysis of precipitation and stream chemistry data

(1965–2007) to examine the N budget of a forested reference watershed at HBEF in New Hampshire. They found that decreases in stream  $\text{NO}_3^-$  preceded decreases in atmospheric N deposition. [Eshleman et al. \(2013\)](#) evaluated changes in the concentrations of  $\text{NO}_3^-$  in streams impacted by atmospheric N deposition in the Appalachian Mountains during the period 1986–2009. Long-term monitoring of nutrient dynamics has also been conducted in the western U.S. [Mast et al. \(2014\)](#) measured long-term changes in stream  $\text{NO}_3^-$  concentration over three decades at the Loch Vale watershed in Rocky Mountain National Park. During the last 15 years, surface waters in the Green Lakes Valley at the Niwot Ridge Long-Term Ecological Research site in Colorado have been subjects of a wide variety of monitoring and process studies that focused on surface waters as integrators of changes in environmental conditions and the response to external stressors, including atmospheric deposition and climate change ([Miller and Mcknight, 2015](#); [Elser et al., 2009b](#); [Elser et al., 2009a](#); [Gardner et al., 2008](#)).

---

#### 7.1.4 Models

Models used to assess the effects of N and S deposition on U.S. ecosystems were described in the 2008 ISA (Annex A) and [Appendix 4](#) of this ISA. The most frequently used ecosystem models for aquatic systems situated in small watersheds have included the Model of Acidification of Groundwater in Catchments (MAGIC) and the Photosynthesis and Evapotranspiration-Biogeochemical (PnET/BGC) model [[U.S. EPA \(2008a\)](#); [Appendix 4.5](#)]. The ForSAFE model [Wallman et al. \(2005\)](#) has also been applied widely, especially in Europe, and has been linked with a terrestrial plant biodiversity model, VEG, and recently applied at several locations in the U.S. [[McDonnell et al. \(2014a\)](#); [Phelan et al. \(2016\)](#); [Appendix 4.5.1.4](#)]. The Very Simple Dynamic (VSD) soil acidification model is used in Europe to simulate acidification effects in soils when observed data are sparse ([Appendix 4.5.1.3](#)). It has not been used widely in the U.S. Three other models, SPARROW, Watershed Assessment Tool for Evaluating Reduction Scenarios for Nitrogen (WATERS-N), and the Surface Water Assessment Tool (SWAT) have been used to evaluate N loading to large river systems. Another model that has been applied to analysis of nutrient enrichment in aquatic systems is AQUATOX ([Carleton et al., 2009](#)), which simulates nutrient dynamics and effects on aquatic biota. Such models were earlier summarized in Table A-8 in the 2008 ISA ([U.S. EPA, 2008a](#)).

In the 2008 secondary NAAQS review for oxides of N and S, an aquatic acidification index (AAI) was developed to relate (1) atmospheric concentrations of  $\text{SO}_x$  and  $\text{NO}_y + \text{NH}_y$  to N and S deposition levels using transference ratios ([Appendix 2](#)) and (2) to relate deposition to ANC values, using a modified Steady-State Water Chemistry

(SSWC) model ([Appendix 4](#)) and water chemistry data for over 6,000 sites in the U.S. The ANC values were grouped by site into ecoregions and evaluated by considering the distribution of predicted ANC values ([Scheffe et al., 2014](#)).

---

#### **7.1.4.1 Updates to Key Previously Identified Models**

[Zanchi et al. \(2016\)](#) developed an approach to include lateral flow in ForSAFE. Results were assessed by comparison with research values at the Vindela Research forest in northern Sweden. Simulation of both saturated and unsaturated soil zones improved agreement between measured and modeled water flows. This model improvement will likely enhance the ability to simulate the export of elements from soil to drainage water using ForSAFE. In 2011, The SPARROW modeling group published a new set of regional models as a special issue ([Preston et al., 2011](#)). Other models have been used for assessing nutrient loading to freshwater systems. SWAT has been adopted as part of U.S. EPA's Better Assessment Science Integrating Point and Nonpoint Sources (BASINS) platform in support of TMDL model development ([Gassman et al., 2007](#)).

---

#### **7.1.4.2 New Models (Published since 2008)**

Several new freshwater acidification or eutrophication models have been developed and published since 2008. The Watershed Analysis Risk Management Framework (WARMF) is a model for evaluating point and nonpoint pollution, including N fate and transport ([Dayyani et al., 2013](#); [Herr and Chen, 2012](#)). A new national water quality modeling system (Hydrologic and Water Quality System [HAWQS]) is under development by Texas A&M University and U.S. Department of Agriculture (USDA) for U.S. EPA's Office of Water (<https://epahawqs.tamu.edu/>). The model is intended to assist resource managers and policy makers in evaluating the effectiveness of water pollution control efforts. HAWQS will support application of SWAT and SPARROW and will include simulations of nutrients and other pollutants. [Table 7-4](#) summarizes recent process-based model estimates of surface water acidification and chemical recovery in the U.S.

**Table 7-4 Recent process-based model estimates of surface water acidification and chemical recovery in the U.S.**

Model	Nutrient Enrichment	Acidification	Type of Ecosystem	Region	Model Application and Findings	Publication
PnET-BGC		X	30 watersheds in Great Smoky Mts. NP	Southern Appalachian Mtns.	Stream recovery has been limited.	<a href="#">Fakhraei et al. (2016)</a>
PnET-BGC		X	44 representative watersheds	Adirondack Mtns.	Larger historical lake acidification in lakes having lower ambient ANC.	<a href="#">Zhai et al. (2008)</a>
MAGIC		X	66 stream watersheds	Southern Blue Ridge Mtns.	All modeled streams had preindustrial ANC >30 µeq/L. Median stream lost about 25 µeq/L of ANC between 1860 and 2005.	<a href="#">Sullivan et al. (2011b)</a>
PnET-BGC		X	128 acid-impaired lakes	Adirondack Mtns.	Of 128 acid-impaired lakes that were modeled, 97 had ambient ANC below target of 20 µeq/L and 83 were below target of 11 µeq/L. TMDL corresponding to a moderate emissions control scenario (60% decrease in S deposition) was 7.9 meq/m <sup>2</sup> /yr.	<a href="#">Fakhraei et al. (2014)</a>
PnET-BGC		X	Streams, watershed	HBEF, NH	Simulations under changing climate reflected later snowpack development, earlier spring snowmelt, greater ET, and slight increase in water yield. Net soil mineralization and nitrification caused simulated soil and water acidification.	<a href="#">Pourmokhtarian et al. (2012)</a>
PnET-BGC, SAFE, VSD, MAGIC			Inter-model comparison	HBEF, NH	Hindcast and forecast projections were qualitatively similar, but temporal patterns of simulated change in chemistry differed substantially among models.	<a href="#">Tominaga et al. (2010)</a>

**Table 7-4 (Continued): Recent process-based model estimates of surface water acidification and chemical recovery in the U.S.**

Model	Nutrient Enrichment	Acidification	Type of Ecosystem	Region	Model Application and Findings	Publication
PnET-BGC		X	Three multipollutant scenarios	Adirondack Mtns.	Predicted ANC recovery closely related to percentage of watershed in conifers, elevation, and lake area.	<a href="#">Wu and Driscoll (2009)</a>

ANC = acid neutralizing capacity; ET = evapotranspiration; HBEF = Hubbard Brook Experimental Forest; L = liter; m = meter;  $\mu\text{eq}$  = microequivalent; meq = milliequivalent; MAGIC = Model of Acidification of Groundwater in Catchments; PnET-BGC = Photosynthesis and Evapo Transpiration-Biogeochemical; S = sulfur; SAFE = Soil Acidification in Forest Ecosystems; TMDL = total maximum daily load; VSD = Very Simple Dynamic; yr = year.

### 7.1.5 National-Scale Sensitivity and Response

The 2008 ISA documented that by the end of the 1980s, the regions of the U.S. with many acid-sensitive waters and ecosystems were well recognized. These acid-sensitive ecosystems are mostly located in upland mountainous terrain in the eastern and western U.S. and are underlain by bedrock that is resistant to weathering, such as granite or quartzite sandstone. However, a similar map for areas sensitive to the eutrophication effects of N were not available. There is strong evidence demonstrating that biogeochemical sensitivity to deposition-driven eutrophication and acidification is the result of historical loading, geologic/soil conditions (e.g., mineral weathering and S adsorption), and nonanthropogenic sources of N and S loading to the system. There is no single deposition level applicable to all ecosystems in the U.S. that can describe the onset of eutrophication or acidification. There are new publications that address recovery of freshwater ecosystems at either the national scale or in specific regions. National scale sensitivity of freshwater systems to N-nutrient effects is discussed in [Appendix 9.1.1.2](#).

#### 7.1.5.1 Chemical Recovery

Chemical recovery of previously acidified surface water is required to support biological recovery. An aquatic ecosystem in chemical recovery will have trends in water quality indicators ( $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ , pH, ANC, inorganic monomeric Al) towards inferred preindustrial values (see [Integrated Synthesis](#)). Preindustrial water quality indicator values are inferred from models, paleolimnology samples, or historical samples of biological communities. Preindustrial water quality varied across the conterminous U.S. in response to variation in climate, geology, and biological communities. In general,

biological recovery has lagged chemical recovery in previously acid-impacted and more recently recovering surface waters ([Appendix 8](#)).

Surface water  $\text{NO}_3^-$  is a chemical indicator for both eutrophication and acidification. Several studies since the 2008 ISA have documented decreased surface water  $\text{NO}_3^-$  concentration attributed to decreases in atmospheric deposition. [Eshleman et al. \(2013\)](#) evaluated changes in the long-term concentration of  $\text{NO}_3^-$  in surface waters impacted by atmospheric N deposition in the Appalachian Mountains during the period 1986–2009. Regional  $\text{NO}_x$  emissions progressively decreased during the study period. Decreases in the annual surface water  $\text{NO}_3^-$  concentration and the  $\text{NO}_3^-$  yield were observed over the study period, which corresponded to generally comparable declines in annual wet N deposition. [Eshleman and Sabo \(2016\)](#) evaluated changes in  $\text{NO}_3^-$  concentration over time in tributary streams of the upper Potomac River. The basin-wide decrease, based on results at the Washington, D.C. station was  $-0.023$  mg N/L/year over 26 years (total change of  $-0.59$  mg N/L). They attributed observed decreases in discharge-weighted annual mean  $\text{NO}_3^-$  concentrations across the basin (mean decrease was 37%) largely to decreases in atmospheric N deposition. [Mast et al. \(2014\)](#) measured long-term changes in stream  $\text{NO}_3^-$  concentration over three decades at the Loch Vale watershed in Rocky Mountain National Park. The concentrations of  $\text{NO}_3^-$  in stream water increased during the early 1990s, peaked in the mid-2000s, and then declined by more than 40%. The recent decreases in stream  $\text{NO}_3^-$  corresponded with decreases in  $\text{NO}_x$  emissions and N deposition. As was found by [Eshleman et al. \(2013\)](#) in Maryland, similarities in the timing and magnitude of  $\text{NO}_3^-$  concentrations in stream water and N deposition suggested that stream chemistry is responding to changes in atmospheric deposition of N. However, the response was complicated in this case by a drought in the early 2000s that enhanced N export for several years. In the Adirondack region concentration of  $\text{NO}_3^-$  declined at variable rates in 33 of the 48 study lakes since 1992 ([Driscoll et al., 2016](#)). [Strock et al. \(2014\)](#) analyzed recent trends in lake chemistry using long-term data from lakes in the Adirondack Mountains and New England. Lake  $\text{NO}_3^-$  concentration showed no trend prior to 2000. During the 2000s, the wet deposition of  $\text{NO}_3^-$  declined more than 50%, and lake  $\text{NO}_3^-$  concentration declined subsequent to 2000 at a rate of  $-0.05$   $\mu\text{eq/L/yr}$ . TN declined in surface waters at a rate of 1.1% per year from 1990 to 2011 in an analysis of lake data from 17 states in the Midwest and northeastern U.S. ([Oliver et al., 2017](#)). Random forest analysis of the data showed atmospheric deposition was the top driver of observed declines in TN.

Evidence of chemical recovery from acidification has been provided by monitoring efforts spanning several decades ([Appendix 7.1.3](#)) and the use of models to hindcast and forecast the acid-base chemistry and N response in soils and surface waters ([Appendix 7.1.4](#)). Model projections of past and future changes in surface water

chemistry in response to changes in acidic deposition using the MAGIC and PnET-BGC models are summarized in [Table 7-5](#).

**Table 7-5 Model projections of surface water sulfate and associated acid neutralizing capacity, shown as changes between dates, for Adirondack and Shenandoah streams.**

Source: [U.S. EPA \(2008a\)](#).

As reported in the 2008 ISA, lake and stream ANC values decreased throughout much of the 20th century in a large number of acid-sensitive lakes and streams throughout the eastern U.S. This effect has been well documented in monitoring programs, paleolimnological studies, and model simulations. Since about 1990, the ANC values of many previously acidified lakes and streams have shown some increases, but such increases have been relatively modest in most cases. [Kahl et al. \(2004\)](#) summarized 20 years of chemical monitoring data from regional U.S. EPA programs in the northern and eastern U.S. Surface water chemistry improved over the 20-year period in many lakes and streams; moderate, but significant increases in ANC and pH were observed. [Stets et al. \(2014\)](#) found widespread increasing alkalinity concentrations at 14 of 23 sites across the conterminous U.S. over the last half of the 20th century and the early 21st century. Results showing decreases in NO<sub>3</sub><sup>-</sup> and SO<sub>4</sub><sup>2-</sup> concentrations and cation:alkalinity ratios at many sites were consistent with recovery from water acidification. Agricultural lime contributed alkalinity at some locations. These findings are important because large rivers constitute important pathways for transport of nutrients and other constituents to coastal waters and may influence coastal acidification and Ca supply.

Trends in surface water chemistry, including evidence for chemical recovery, are reported in several acid-sensitive regions of the U.S. where long-term monitoring programs have been in place several decades. These include the Adirondacks and the northeastern U.S. (see [Appendix 16](#)). In some portions of the Appalachian Mountains, chemical recovery of

surface waters has not always followed decreases in deposition due to high S absorption in watershed soils ([Appendix 16 Smoky Mountains Case Study](#)).

A long-term delay in surface water recovery from past acidification has been noted by [Likens et al. \(1996\)](#) at HBEF. This delay was attributed mainly to changes in base cation concentration. Similarly, based on an analysis of Adirondack lakes, [Lawrence et al. \(2013\)](#) concluded that chemical recovery processes in response to decreases in acidic deposition are complex and require evaluation of multiple chemical metrics in addition to ANC, including DOC, inorganic Al, and BCS. As an example of the complexity, the lower threshold of ANC required to protect brown trout in Norway against acidification damage was earlier estimated to be 20 µeq/L ([Lien et al., 1996](#)). This critical ANC limit may be lower in humic lakes (~8 µeq/L) because about one-third of the organic acid anions may act essentially as strong acid anions ([Lydersen et al., 2004](#); [Driscoll et al., 1994](#)). Inclusion of strong organic acids in the ANC calculation can be useful because the relationships between pH, inorganic Al, and ANC may have changed in response to increased concentrations of DOC and TOC. This is particularly true in lakes having higher DOC and TOC compared with clear water lakes. [Hesthagen et al. \(2008\)](#) estimated that threshold ANC values to prevent damage to brown trout had increased by 1995 to 48 µeq/L. The authors suggested that the higher ANC threshold for 1995 was attributable to lower pH and higher inorganic Al at a given ANC level.

#### 7.1.5.1.1 Adirondacks

At the time of the 2008 ISA, several studies reported chemical recovery from acidification in Adirondacks lakes ([Driscoll et al., 2007a](#); [Momen et al., 2006](#); [Driscoll et al., 2003c](#)) based on long-term monitoring efforts in the region ([Appendix 7.1.3.1](#)). [Driscoll et al. \(2003c\)](#) evaluated changes from 1982 to 2000 in the original 16 Adirondack LTM lakes and from 1992 to 2000 in the complete set of 48 Adirondack LTM lakes. They found that nearly all study lakes showed marked decreases in  $\text{SO}_4^{2-}$  concentration and several lakes showed declines in  $\text{NO}_3^-$  concentration. They found that 7 of the 16 original monitoring lakes showed statistically significant increases in ANC, with a mean rate of increase of 0.78 µeq/L/year. In a study of 30 of the 48 lakes studied by [Driscoll et al. \(2003c\)](#), pH increased in 25 lakes and ANC increased in 12 of the 30 lakes ([Momen et al., 2006](#)). Concentrations of dissolved  $\text{NO}_3^-$  were inversely correlated with concentrations of chlorophyll *a* in 11 lakes. Chlorophyll *a* increased in concentration in 9 lakes. The increase in pH observed in most of these lakes may have stimulated productivity so that N assimilation by plankton increased, indicating recovery from acidification to eutrophication, rather than to preindustrial conditions.

Monitoring data since the 2008 ISA continues to show chemical recovery in the Adirondack region. As described in the Adirondacks case study ([Appendix 16](#)), significant decreases in lake  $\text{SO}_4^{2-}$  concentrations ( $-2.14 \mu\text{mol/L/year}$ ) corresponding to significant declines in total S deposition were observed in monitoring data from 1984 to 2010 ([Mitchell et al., 2013](#)). Surface water ANC and pH recovery has been documented by [Lawrence et al. \(2013\)](#) and [Lawrence et al. \(2011\)](#) in studies of Adirondack streams and lakes. On average, the pH increased by only 0.28 pH units and ANC by  $13 \mu\text{eq/L}$  in 12 streams that were monitored over a period of 23 years. During that period, there was an approximate 50% reduction in atmospheric deposition of S in the Adirondack region. The percentage of Adirondack lakes that were acidic decreased from an estimated 15.5 to 8.3% using data from the TIME monitoring program ([Waller et al., 2012](#)). Decreases in lake water  $\text{SO}_4^{2-}$ , and to a lesser extent  $\text{NO}_3^-$ , concentrations generally were accompanied by increases in lake ANC. [Driscoll et al. \(2016\)](#) observed increases in ANC and pH and marked decreases in dissolved inorganic Al in 45 of 48 study lakes in the Adirondack region from 1982 to 2015, corresponding to decreases in acidifying deposition. Changes were most pronounced in the acid-sensitive thin-till drainage lakes. In another Adirondack long-term study that focused on 43 lakes sampled by the Adirondack Lakes Survey Corporation during three time periods (1984–1987, 1994–2005, and 2008–2012), the average concentration of inorganic Al decreased from  $2.2 \mu\text{M}$  (a level above that generally considered toxic to brook trout,  $2 \mu\text{M}$ ) to  $0.66 \mu\text{M}$  ([Baldigo et al., 2016](#)).

Interpretation of long-term trends in Adirondack surface water chemistry, as summarized above, has also been augmented by results of repeated surveys of the chemistry of lakes initially surveyed several decades previously. [Warby et al. \(2008\)](#) resurveyed 113 lakes throughout the Northeast in 2001 that had previously been sampled by the U.S. EPA in 1986 to assess chemical recovery from lake acidification. Decreases in total Al and inorganic Al concentrations were widespread and were largest in the Adirondack Mountains ( $-2.59$  to  $-4.60 \mu\text{mol/L}$ ). In 2001, only 7 study lakes (representing 130 lakes in the population) had inorganic Al concentrations above a toxic limit of  $2 \mu\text{mol/L}$ , compared with 20 sampled lakes (representing 449 lakes in the population) in 1986. Thus, it was estimated that in 2001 more than 300 northeastern lakes no longer had summer inorganic Al concentrations at levels considered harmful to aquatic biota. [Michelena et al. \(2016\)](#) reported changes in the water chemistry of 30 Adirondack lakes in response to reductions in acidic deposition from 1994 to 2012. The water quality of the study lakes generally improved during the study period, but the responses were sporadic and complex. Lake pH values increased until about 2002 and then fluctuated. Inorganic Al concentrations generally decreased throughout the period of record. During the early years of monitoring, the average pH increased dramatically from about 5.5 to 6.0. This increase was followed by a period of reacidification for about 5 years, followed by another period of increased pH.

This 5-year cycle was then repeated to a muted extent, even though acidic deposition continued to decline.

Chemical recovery from surface water acidification in the Adirondack Mountains has been accompanied by increasing concentrations of DOC, including organic acids, which have complicated and restricted recovery from acidification (Section DOC). Long-term monitoring of 48 Adirondack lakes by [Driscoll et al. \(2016\)](#) showed patterns of increasing DOC in 29 study lakes concurrent with decreases in acidic deposition. [Lawrence et al. \(2013\)](#) evaluated long-term changes in DOC and BCS (which reflects the calculated ANC and includes an adjustment for strong organic acid anions). Increases in DOC concentration from 1994 to 2011 contributed to organic complexation of Al. This reduced the fraction of monomeric Al that was in the inorganic (and potentially toxic) form from 57% in 1994 to 23% in 2011. Thus, the higher DOC found during latter sampling increased the organic acidity of the lake water and limited ANC recovery, but at the same time it decreased the toxicity of dissolved Al to aquatic biota. Similarly, [Strock et al. \(2014\)](#) reported trends in recovery from toxic Al levels caused by acidification of surface waters. They analyzed recent trends in lake chemistry using long-term data from lakes in the Adirondack Mountains and New England. During the 2000s, the wet deposition of  $\text{NO}_3^-$  declined more than 50%. The lake  $\text{NO}_3^-$  concentration, which showed no trend prior to 2000, declined subsequent to 2000 at a rate of  $-0.05 \mu\text{eq/L/year}$ . There was a shift to nontoxic (organic) forms of Al. Despite the Al recovery, both the ANC and pH in the study lakes failed to show evidence of appreciable chemical recovery; rather, the lakes continued to exhibit variable trends in ANC and pH.

The PnET-BGC model has been applied in the Adirondack region to assess chemical recovery. Model results from [Fakhraei et al. \(2014\)](#) suggested that ambient ANC values were below the target value of  $20 \mu\text{eq/L}$  in 97 of the 128 lakes that were judged to be acid impaired under Section 303(d) of the Clean Water Act (CWA); 83 lakes had ANC below the target value of  $11 \mu\text{eq/L}$ . A moderate emissions control scenario (60% decrease from the ambient atmospheric S deposition) was projected to recover the ANC of lakes by  $0.18$  and  $0.05 \mu\text{eq/L/year}$  on average during the periods 2022 to 2050 and 2050 to 2200, respectively. Model results suggested that controlling S deposition to Adirondack lake watersheds was more effective as a means to recover acidic lakes than was controlling N deposition in this region. [Wu and Driscoll \(2009\)](#) applied the PnET-BGC model to predict the responses of lake ANC during the period 2001 to 2050. Based on three multipollutant scenarios, predicted ANC recovery was associated with higher elevation, smaller lake area, and higher percentage of watershed area in coniferous vegetation. The variables lake depth and the square of the lake elevation explained 40% of the variation in predicted lake water ANC.

### 7.1.5.1.2

#### Northeast

The Northeast U.S. also has several decades of monitoring data, especially for HBEF ([Appendix 7.1.3.1](#)). [Strock et al. \(2016\)](#) documented decreases in water transparency and increases in DOC in lakes in Acadia National Park in Maine over a period of 14 years (1995–2008). Larger transparency decreases were noted in clear water lakes (–0.3 m/year) compared with the brown water lakes (–0.1 m/year). In the Catskill Mountains, NY, 23 years of stream water chemistry data showed significant decreasing  $\text{SO}_4^{2-}$  (mean trend of –2.5  $\mu\text{eq/L/year}$ ), while no significant trends were observed for  $\text{NO}_3^-$  ([Mchale et al., 2017](#)). A decreasing trend in inorganic Al and increasing trends in pH and ANC were evident under both low- and high-flow conditions. [Fuss et al. \(2015\)](#) examined long-term trends in soil solutions and surface waters from the early 1980s to 2011 at the HBEF in New Hampshire. They found that rates of annual average ANC increase during the period 1982–2011 were similar to what was observed during snowmelt, although the ANC during snowmelt was 10  $\mu\text{eq/L}$  lower than annual averages. In a summary of 20 years of data at Bear Brook, [Norton et al. \(2010\)](#) observed decreases in pH, base cation concentrations, and ANC, and increases in inorganic Al concentration in the East Bear reference watershed. These observations indicate that under ambient deposition conditions acidification continues even though S deposition and stream  $\text{SO}_4^{2-}$  concentrations have declined. [Laudon and Norton \(2010\)](#) analyzed 212 hydrological episodes in Bear Brook using the ANC Dilution Model (ADM) of [Laudon and Bishop \(1999\)](#). The results showed that 18 years of experimental addition of N and S to the West Bear Brook watershed had not altered the most important natural causes of episodic stream acidification: base cation dilution, processes associated with deposition of marine sea salts, and contributions of organic acidity during rain and snowmelt events. The results further indicated that the contributions of  $\text{SO}_4^{2-}$  to the observed ANC decreases in West Bear Brook during episodes increased steadily since the beginning of experimental watershed treatment. In contrast, the role of  $\text{NO}_3^-$  in episodic acidification events remained relatively constant after an early increase. Model stimulations at HBEF using the PnET-BGC model showed later development of snowpack, earlier snowmelt, higher evapotranspiration, and increased water yield expected with current and projected trends of increasing temperature will increase net soil N mineralization and nitrification ([Pourmokhtarian et al., 2012](#)). This could contribute to acidification of soil and stream water. In a model study comparison, [Tominaga et al. \(2010\)](#) noted that hindcast (1850–1992) and forecast (2005–2100) projections were qualitatively similar across MAGIC, PnET-BGC, SAFE, and VSD watershed acidification models at HBEF, although projected stream ANC and soil base saturation differed substantially through time.

#### 7.1.5.1.3 West

Surface water acidification, and presumably also chemical recovery, have been limited in the western U.S. Although acidification sensitivity has been shown to be high at many locations, acidic deposition levels have also mostly been lower. [Mast et al. \(2011\)](#) examined trends in precipitation chemistry and other factors that influence long-term changes in chemistry of high-elevation lakes in three Colorado wilderness areas during the years 1985 through 2008. Sulfate concentrations in precipitation decreased at rates of  $-0.15$  to  $-0.55$   $\mu\text{eq/L/year}$  at 10 monitoring stations in Colorado. In lakes where  $\text{SO}_4^{2-}$  was primarily derived from atmospheric sources, the lake  $\text{SO}_4^{2-}$  concentrations decreased by  $-0.12$  to  $-0.27$   $\mu\text{eq/L/year}$ . In lakes where  $\text{SO}_4^{2-}$  likely originated primarily from watershed weathering, the  $\text{SO}_4^{2-}$  concentrations in lake water increased, rather than decreased, from 1985 to 2008.

#### 7.1.5.1.4 Appalachians

Not all acid-sensitive regions of the U.S. have shown improvements in surface water quality with decreasing deposition trends. Monitoring data from the Great Smoky Mountains NP ([Appendix 16](#)) indicate that the high S absorption in watershed soils in this region delay recovery from previous stream acidification ([Cai et al., 2010](#)). The majority (about 61%) of the net  $\text{SO}_4^{2-}$  entering the study watershed was retained. However, during large precipitation events,  $\text{SO}_4^{2-}$  in wet deposition moved more directly and rapidly to streams, contributing to episodic stream acidification. [Cai et al. \(2010\)](#) concluded that base cation depletion from soils could limit chemical recovery from acidification of streams in the study watershed. Stream chemistry from 1993–2014 at 42 monitoring sites in the park did not show substantial changes over the recent period of long-term monitoring ([Fakhraei et al., 2016](#)). An empirical modeling study by [Robinson et al. \(2008\)](#) of baseflow water chemistry at 90 streams in Great Smoky Mountains National Park during the years 1993–2002 indicated significant decreasing trends in stream pH and  $\text{SO}_4^{2-}$  at lower elevation sites over time, but no long-term trends in stream  $\text{NO}_3^-$  or ANC. An estimated 30% of the sample sites were simulated to decrease pH to less than 6 within 10 years. The models explained 71% of the variability in pH and 86% of the variability in ANC. Soil retention of  $\text{SO}_4^{2-}$  and assimilation of  $\text{NO}_3^-$  into plants were important biogeochemical processes regulating stream chemistry. The stream pH at base flow has not yet shown signs of recovery in response to recent decreases in acidic deposition. The model developed for elevations between 305 and 1,070 m predicted that median pH values will decrease below 6 within 34 years if the observed statistical trends continue. The state of Tennessee currently lists streams within the park with mean pH below 6 as impaired under the Clean Water Act

Section 303d ([Appendix 16](#), Southeast case study), so the model by [Robinson et al. \(2008\)](#) indicated biologically significant ongoing acidification.

[Singh et al. \(2016\)](#) assessed DOC trends in a forested stream at the Coweeta Hydrologic Laboratory in the southeastern U.S. over a period of 25 years. Concentrations and fluxes of DOC decreased by 34 and 56%, respectively, between 1988 and 2001, corresponding with the stream acidification phase. During the period 1997 to 2012, DOC concentration increased in association with increases in precipitation and the number and intensity of short-duration storms during the early part of the growing season.

Several model applications have been conducted in the southern Appalachian Mountains to simulate stream chemistry and critical or target loads. These studies have employed the MAGIC, PnET-BGC, and SSWC models. Results of these studies have reinforced the widespread acid sensitivity of this region and the importance of S adsorption and base cation depletion to stream responses to changes in levels of acidic deposition. Critical and target loads ([Section IS.2.2.3](#)) for resource recovery/protection were quantified [[McDonnell et al. \(2012\)](#); [McDonnell et al. \(2010\)](#); [McDonnell et al. \(2013\)](#); [McDonnell et al. \(2014b\)](#); [Sullivan et al. \(2011c\)](#); [Fakhraei et al. \(2016\)](#); [Appendix 8.5.4](#)]. An important outcome of critical load modeling studies in the Appalachian Mountains is the suggestion that complete stream acid base chemistry recovery may not be possible ([Appendix 8.5.4](#)). [Sullivan et al. \(2011b\)](#) applied the MAGIC model to estimate the S target load for protecting aquatic resources in 66 stream watersheds in the Southern Blue Ridge province of the Appalachian Mountains at different points in the future. For some of the modeled sites, if S deposition was decreased to zero and maintained at that level throughout the simulation, one or more of the selected critical ANC levels (0, 20, 50, 100  $\mu\text{eq/L}$ ) could not be achieved by 2100. This was likely largely due to the simulation result suggesting that many of the streams did not exhibit such a high ANC during preindustrial times, in the absence of acidic deposition. For other sites with large watershed acid buffering capacity, even very high-sustained S deposition would not reduce stream ANC below thresholds associated with biological harm.

Monitoring studies suggested that the rate of stream ANC recovery in this region may be slow in the Southeast and that base cation depletion in soils contributed in the last two decades to further aquatic acidification despite reductions in S deposition ([Robison et al., 2013](#); [Cai et al., 2010](#)). [Rice et al. \(2014\)](#) examined the source-sink behavior of  $\text{SO}_4^{2-}$  in 27 unglaciated forested watersheds across a latitudinal gradient from Pennsylvania to Georgia and found that many of the watersheds still retain  $\text{SO}_4^{2-}$  under conditions of decreased S deposition. The specific years when the watersheds will likely cross over from retaining to releasing  $\text{SO}_4^{2-}$  varied from north to south, with the south generally showing later cross-over dates. [Eshleman et al. \(2008\)](#) used data from two long-term monitoring

stations in western Maryland to assess the recovery of stream water ANC due to declines in acidic deposition. Stream water  $\text{SO}_4^{2-}$  concentration declined at the two study sites between 1990 and 2005 by about  $3 \mu\text{eq/L/year}$  in response to a 34% reduction in wet atmospheric S deposition. However, trends in  $\text{NO}_3^-$  concentration were more strongly related to watershed factors, especially forest disturbance. Although ANC increased throughout the study, the rate of increase in later years (1996–2005) was only about half as large as the rate of increase in ANC over the entire study period. This result might suggest a slowing of chemical recovery from previous acidification ([Eshleman et al., 2008](#)). This supposition was further substantiated by [Robison et al. \(2013\)](#), who analyzed the chemistry of stream samples collected quarterly from 1987 to 2011 at 64 sites in the southern Appalachian Mountains of western Virginia. At most of the study streams, the pH increased over time. However, at most sites underlain by base-poor bedrock, ANC decreased even though S deposition decreased. These decreases in stream ANC were associated with depletion of base cations in watershed soils.

Stream acid-base chemistry from 1999 to 2014 in a group of 40 stream reaches in the Upper Savage River watershed in western Maryland showed statistically significant decreases in stream concentrations of  $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$  that were qualitatively and quantitatively consistent with decreases in wet S and N deposition ([Kline et al., 2016](#)). Stream ANC increased by significant amounts in 10–20% of the monitored streams, but the magnitude of recovery was too small compared with natural variability to detect a regional ANC recovery. The percentage of streams having  $\text{ANC} \leq 0 \mu\text{eq/L}$  decreased from about 7% in 1999 to 0 in 2014. The percentages of streams having ANC values less than  $50 \mu\text{eq/L}$  and less than  $100 \mu\text{eq/L}$  also decreased markedly between 1999 and 2014. Concentrations of base cations (Ca, Mg, K) decreased, moderating regional ANC recovery.

---

### 7.1.5.2 Critical Loads

A critical load (CL) is a quantitative estimate of exposure to one or more pollutants below which significant harmful effects on specified sensitive elements of the environment do not occur according to present knowledge [[Nilsson and Grennfelt \(1988\)](#); [Spranger et al. \(2004\)](#); [Section IS. 2.2.3](#)]. These CLs can be used as early warning signals to indicate likely ecosystem sensitivity to change in N or S. Empirical CLs are developed from observational data while steady-state and dynamic models develop relationships between deposition, water quality measurements and biogeochemistry for watersheds.

For acidification, CLs from empirical data as well as modeling approaches are available for acid-sensitive regions of the U.S. ([Appendix 8.5.3](#)). Generalized empirical estimates are based on acidification or increased surface water  $\text{NO}_3^-$  leaching. Empirical CLs to protect

against aquatic acidification in U.S. ecosystems are summarized in [Table 8-7](#). Both steady-state ([Appendix 8.5.4.1.2.1](#)) and dynamic models ([Appendix 8.5.4.1.2.2](#)) have been used to quantify relationships between deposition and biogeochemistry for watersheds in order to develop CL estimates to protect against acidification or promote recovery of acid-base chemistry. Recent CL modeling studies in the U.S. to protect against aquatic acidification are summarized in [Table 8-8](#). Most aquatic CL studies conducted in the U.S. have used surface water ANC as the principal metric of water quality change in response to changes in acidic deposition, although ANC should not necessarily be used as the only environmental predictor of biological harm on which to base CLs. Other potentially useful variables include water pH, inorganic Al, and BCS. Since the 2008 ISA, dynamic modeling of CLs in the U.S. to achieve various ANC targets has been focused mostly on the Adirondack and Appalachian Mountains. The CL can be calculated to represent the individual or combined deposition load of S and/or N to which a stream and its watershed could be subjected and still have a surface water ANC within a targeted range.

For nutrient enrichment, diatoms are among the most sensitive aquatic organisms, thereby providing a basis for assessing aquatic ecosystem protection against nutrient enrichment across ecosystems. The lake water  $\text{NO}_3^-$  concentration has been identified as a useful chemical criterion indicative of biological change in the diatom community. Recently, [Williams et al. \(2017b\)](#) used phytoplankton biomass N to P limitation shifts as the basis for CL calculations. Critical loads ([Section IS.2.2.3](#)) for nutrient enrichment are described in [Appendix 9.5](#) and summarized in [Table 9-4](#).

---

## 7.1.6 Water Quality Criteria

The term “water quality criteria” is used in two sections of the Clean Water Act: Section 304(a)(1) and Section 303(c)(2). The term has a different impact in each section. In Section 304, the term refers to a scientific assessment of ecological and human health effects that U.S. EPA recommends to states and authorized tribes for establishing water quality standards that ultimately provide a basis for controlling discharges or releases of pollutants or related parameters. Ambient water quality criteria associated with specific water body uses, when adopted as state or tribal water quality standards under Section 303 of the CWA, define the level of a pollutant (or, in the case of nutrients, a condition) necessary to protect designated uses in specific water bodies.

U.S. EPA develops Water Quality Criteria (WQC) using existing scientific knowledge to determine when water is unsafe for people and wildlife. These criteria are developed as recommendations. State and tribal governments may adopt these criteria or use them as guidance in developing their own. U.S. EPA bases aquatic life criteria on how much of a

chemical can be present in surface water before it is likely to harm plant and animal life. WQC are determined to protect aquatic life, biology, human health, microbial/recreational, and sediment condition. For aquatic life, the criteria are designed to protect both freshwater and marine organisms from short-term and long-term exposure to pollutants. Biological criteria indicate the health of water bodies based on how many and what kinds of organisms are present. More details about the scientific basis for these criteria may be found at <https://www.epa.gov/wqc/basic-information-water-quality-criteria>.

The U.S. EPA is working with the states to develop numeric nutrient criteria to better define levels of N and P that affect U.S. waters. The numeric values include both causative (N and P) and response (chlorophyll *a*, turbidity) variables. The U.S. EPA's National Nutrient Program recommended nutrient criteria for rivers and streams in 14 ecoregions of the U.S. (based on Omernik Level III ecoregions) to use as starting points for states to develop their own criteria ([U.S. EPA, 1998b](#)).

WQC indicators related to N are available for 10 states to date ([Table 7-6](#)) including Oregon, California, Arizona, Colorado, Montana, Utah, and Mississippi which have numeric nutrient criteria. These criteria may include a variety of N species and chlorophyll *a* ([Table 7-6](#)). For Washington and Louisiana, which lack explicit numeric nutrient criteria, U.S. EPA aggregate Level III ecoregion nutrient criteria for rivers and streams were used ([Table 7-6](#); <http://www2.epa.gov/nutrient-policy-data/ecoregional-criteria-documents>). Florida has numeric nutrient criteria for TN for most of the state. The compiled state WQC vary greatly in spatial resolution and N forms addressed. Mississippi applies only one criterion for the entire state. By contrast, California has a patchwork of criteria designated by regional water boards.

U.S. EPA Aggregate Level III Omernik Ecoregion Nutrient Criteria for Rivers and Streams (from U.S. EPA Ecoregional Nutrient Criteria Documents for Rivers and Streams; available at <http://www2.epa.gov/nutrient-policy-data/ecoregional-nutrient-criteria-documents-rivers-and-streams>) were developed for states to provide a more spatially even set of standards for TN and chlorophyll *a* ([Table 7-7](#)). The regionally based criteria are designed to reflect characteristics such as soils, vegetation, climate, geology, and land cover, which are relatively similar within each ecoregion. Pristine or minimally impacted waters from each region are used as a basis for developing ecoregion-specific nutrient criteria. The aggregate ecoregion criteria are mapped in [Figure 7-4](#) and [Figure 7-5](#).

The ambient water quality criteria for NH<sub>3</sub> was recently updated to reflect the sensitivity of freshwater unionoid (order Unionoida) mussels to this nutrient ([U.S. EPA, 2013a](#)). The acute criterion is 17 mg total NH<sub>3</sub><sup>-</sup>-N (TAN)/L, and the chronic criterion is 1.9 TAN/L at pH 7 and temperature 20°C.

### 7.1.7 Freshwater Biogeochemistry Summary

In the 2008 ISA, the body of evidence was sufficient to infer a causal relationship between N and S deposition and the alteration of biogeochemical cycling of N and C in freshwater ecosystems, and between acidifying deposition and changes in biogeochemistry of fresh waters. The strongest evidence for a causal relationship between acidifying deposition and aquatic biogeochemistry comes from studies of changes in surface water chemistry, including concentrations of  $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ , inorganic Al, Ca, sum and surplus of base cations, ANC, and surface water pH. Data from long-term monitoring, experimental manipulations, and modeling studies provide consistent and coherent evidence for biogeochemical changes associated with acidifying N and S deposition. As reviewed in the 2008 ISA and newer studies, biogeochemical processes and surface water chemistry are influenced by characteristics of the catchment and the receiving waters. Atmospheric deposition affects the chemistry, and often also the biology, of each type of freshwater environment. These waters may be chronically acidified or subject to occasional episodes of decreased pH, decreased ANC, and increased inorganic Al concentration. Increased N deposition to freshwater systems via runoff or direct atmospheric deposition, especially to N limited and N and phosphorus (P) colimited systems, can stimulate primary production. New information on biogeochemical cycling of N and S, acidifying deposition effects on biogeochemical processes and changes to chemical indicators of surface water chemistry associated with acidification and N nutrient enrichment is consistent with the conclusions of the 2008 ISA, and **the body of evidence is sufficient to infer a causal relationship between N and S deposition and the alteration of freshwater biogeochemistry.**

Indicators of altered N cycling include changes in the concentrations of  $\text{NO}_3^-$  in surface waters. It was well known at the time of the 2008 ISA that key processes such as nitrification and denitrification are quantitatively important portions of the N cycle and that they can be influenced by atmospheric inputs of oxidized and reduced N. More recent research has further substantiated these earlier findings and provided additional quantitative context. Some new research suggests that denitrification may, in some situations, produce more  $\text{N}_2\text{O}$  in relationship to surface water  $\text{NO}_3^-$  concentration than was previously widely recognized. The quantity and timing of  $\text{NO}_3^-$  leaching into surface waters is an indicator of terrestrial N cycling in the associated watershed. The concentration of  $\text{NO}_3^-$  in drainage water provides an index of the balance between removal and addition of N to terrestrial ecosystems. Studies of several types have been conducted in recent years to elucidate these processes, including experimental studies, isotopic analyses, monitoring, and observational studies.

As stated in the 2008 ISA, decreases in base cation concentrations in surface waters in the eastern U.S. over the past two to three decades have been ubiquitous and closely tied to trends in  $\text{SO}_4^{2-}$  concentrations in surface waters. As reported in the 2008 ISA, lake and stream ANC values decreased throughout much of the 20th century in a large number of acid-sensitive lakes and streams throughout the eastern U.S. This effect has been well documented in monitoring programs, paleolimnological studies, and model simulations. As stated in the 2008 ISA, the concentration of dissolved inorganic monomeric Al in surface waters is an especially useful indicator of the adverse impacts of acidifying deposition. Since the 2008 ISA, several monitoring studies have reported decreases in inorganic Al suggestive of chemical recovery of surface waters [[Warby et al. \(2008\)](#); [Strock et al. \(2014\)](#); [Driscoll et al. \(2016\)](#); [Baldigo et al. \(2016\)](#); [Appendix 7.1.5.1](#)].

Monitoring data have proven to constitute a reliable means with which to confirm environmental models and evaluate damage/recovery of ecosystems in response to changes in acidic atmospheric deposition. A number of freshwater monitoring studies have documented ecosystem damage and recovery caused by acidifying deposition of S and/or N. Many of these studies have been conducted in the U.S., especially in the northeast and the Appalachian Mountains. Since 2008, TIME, LTM, and other long-term studies have documented and quantified the responses of surface waters to changes in acidic deposition and other ecosystem drivers. Although many of these monitoring programs were in existence at the time of the 2008 ISA and were considered in that analysis, more recent publications reflect the longer period of monitoring record and strengthen previous conclusions.

With long-term decreases in atmospheric S deposition, the effects of future increases in precipitation that may occur in some areas in response to climate change will likely become increasingly important in regulating the amount of  $\text{SO}_4^{2-}$  mobilized from internal watershed sources. A number of S cycling studies ([Rice et al., 2014](#); [Mitchell et al., 2013](#)) have emphasized the importance of S adsorption and desorption and their interactions with soil pH. In addition, internal watershed sources of S, which were earlier believed to be relatively minor in the northeastern U.S., have and will likely continue to become proportionately more important as S deposition continues to decline.

Reductions in  $\text{SO}_x$  deposition have not consistently resulted in increases of ANC in surface water. The quantitatively most important component of the overall surface water acidification and chemical recovery responses has been change in base cation supply. This was highlighted in the assessment of [Charles and Christie \(1991\)](#) and in the 2008 ISA. Base cations are added to watershed soils by weathering of minerals and atmospheric deposition, and are removed by uptake into growing vegetation or by leaching. Acidic deposition increased leaching of base cations, as  $\text{SO}_4^{2-}$  anions in soil

solution carried along base cations to maintain the charge balance. In watersheds that have received high levels of historical acidic deposition, current exchangeable concentrations of  $\text{Ca}^{2+}$  and other base cations are substantially reduced from likely preindustrial levels, having been depleted by many years of acidic deposition. This base cation depletion constrains ANC and pH recovery of surface waters, as described in the 2008 ISA. Recent results have further corroborated earlier findings and have included experiments, modeling, and gradient studies.

Recent research has described an ecosystem recovery response to decreasing  $\text{SO}_4^{2-}$  deposition that was not a major focus of the 2008 ISA: DOC increases in surface water. Such changes have been attributed to increased atmospheric  $\text{CO}_2$  concentration, climate warming, decreased S deposition with associated changes in water pH and ionic strength, and hydrologic changes associated with drought and precipitation. Although not all increases in DOC are directly caused by decreases in acidifying deposition, any changes in DOC concentration or properties can impact the acid-base chemistry of surface waters and perhaps the composition of aquatic biota. It has been recognized that surface water DOC concentrations had decreased to some extent as a result of acidification, and that DOC would likely increase with recovery. However, the strength of this response and the magnitude of DOC changes have exceeded scientific predictions. Recent research on this topic has been diverse and has included experiments, observation, isotope studies, and synthesis and integration work. Overall, these studies illustrate large increases in DOC with acidification recovery in some aquatic systems. Increases in DOC constrain the extent of ANC and pH recovery, but decrease the toxicity of dissolved Al by converting some of it from inorganic to organic forms ([Lawrence et al., 2013](#)). However, DOC is not an indicator of recovery everywhere; some recovering sites have not shown increasing trends in DOC.

Taken together, results of recent acid-base chemistry studies in the northeastern U.S. confirmed the previously observed pattern of gradual surface water ANC and pH recovery, in some cases more marked decrease in inorganic Al concentrations, and important interactions with DOC. It is important to recognize that recent changes in atmospheric S and N deposition, although substantial in many areas of the U.S., have not occurred in a vacuum. Other important ecosystem drivers have also changed, including various kinds of disturbance, and these changes have varied by region. The potential importance of such factors was known at the time of preparation of the 2008 ISA. More recent work has further confirmed the importance of these linkages, especially those related to climate ([Appendix 13](#)).

---

## 7.2 Biogeochemistry of Nitrogen in Estuarine and Near-Coastal Systems

In the 2008 ISA, the evidence was sufficient to infer a causal relationship between N deposition and alterations in the biogeochemical cycling of N and carbon (C) in estuarine and near-coastal marine systems. Since the 2008 ISA, additional studies have quantified atmospheric N deposition to estuaries, especially along the Atlantic coast. New evidence supports that total N loading to watersheds includes atmospherically deposited N with other nonatmospheric sources of N and that total N loading, from dominantly oxidized N inputs to dominantly reduced forms of N, have ramifications for N cycling and biological response in some estuaries. There is additional evidence that N alters biogeochemistry of coastal ecosystems, especially regarding microbial-mediated N transformations, which play large roles in N cycling within estuaries. Research and modeling since the 2008 ISA have shown that many of these N processes such as dissimilatory  $\text{NO}_3^-$  reduction to  $\text{NH}_4^+$  (DNRA) are more important in the estuarine environment than previously thought, and that rates of N cycling can be highly variable. Key processes affected by N loading include nitrification and denitrification. Eutrophication from N loading may also affect carbonate chemistry in coastal areas, along with atmospheric  $\text{CO}_2$  inputs and other factors, contributing to acidifying conditions in some circumstances such as where there is spatial or temporal decoupling of production and respiration processes. Monitoring of coastal areas shows that excess nutrient inputs continues to be a widespread problem in many parts of the U.S. **The body of evidence is sufficient to infer a causal relationship between N deposition and the alteration of biogeochemistry in estuarine and near-coastal marine systems**, which is consistent with the findings of the 2008 ISA.

Atmospherically deposited N to watersheds, along with other nonatmospheric sources of N, influence processes that operate along the headwater to ocean continuum. Total N loading to estuaries includes riverine transport of N and direct deposition of N to the estuary itself. This influx of N alters N and C cycling and leads to estuary eutrophication, the process of nutrient over-enrichment. Eutrophic systems are characterized by an increase in the rate of supply of organic matter (primary production and organic C accumulation) in excess of what an ecosystem is normally adapted to processing ([Diaz et al., 2013](#); [Nixon, 1995](#)). Estuary eutrophication is indicated by water quality deterioration, including development of hypoxic zones, species mortality, and formation of harmful algal blooms (HABs). Biological indicators of estuarine condition (e.g., chlorophyll *a*, HABs, macroalgae, submerged aquatic vegetation [SAV]) are described in [Appendix 10](#). [Andersen et al. \(2006\)](#) suggested eutrophication be defined as “the enrichment of water by nutrients, especially N and P and organic matter, causing increased growth of algae and higher forms of plant life to produce an unacceptable deviation in structure function and stability of organisms present in the water and to the

quality of water concerned, compared to reference conditions.” This appendix considers biogeochemical processes affected by N loading, which is a topic not covered in detail in the 2008 ISA. Although this ISA includes both N and S deposition, seawater contains high concentrations of  $\text{SO}_4^{2-}$  so atmospheric inputs of S are unlikely to contribute substantially to biogeochemistry in coastal areas and will not be discussed further in the following sections.

Estuarine biogeochemistry is complicated because it directly controls more than just the N cycle; the response to N loading resulting in eutrophication impacts the chemical cycling of metals and DO ([Appendix 7.2.3](#)), redox conditions, pH ([Appendix 7.2.4](#)), and ultimately energy transfer (e.g., food webs from microbes to humans). The response to N loading is also tightly controlled by water residence time, the availability of organic matter (C) and its lability and reactivity. Excess nutrient inputs are occurring within the context of other stressors such as climate change ([Appendix 7.2.6.12](#)) and rising atmospheric  $\text{CO}_2$ , which further modify coastal biogeochemistry ([Doney, 2010](#)). In the complex environment of the freshwater-to-ocean continuum, there are many chemical and biological indicators of eutrophic condition. One approach is to measure total nutrient loading and concentrations; however, these data need to be interpreted in the context of the physical and hydrological characteristics that determine ecosystem response. Water quality measures such as pH and DO, along with key biological indicators, such as chlorophyll *a*, phytoplankton abundance, harmful algal blooms (HABs), macroalgal abundance, and SAV, can all be used to assess responses to nutrient loading ([Table 7-8](#)). The following sections highlight post-2007 research focusing on N biogeochemistry in estuaries and near-coastal areas.

**Table 7-8 Summary of key indicators of nitrogen enrichment in estuaries.**

Endpoint	Section of ISA That Discusses Endpoint

Harmful algal blooms	<a href="#">10.2.2</a>
Macroalgal abundance	<a href="#">10.2.3</a>
Submerged aquatic vegetation	<a href="#">10.2.5</a>

### 7.2.1 Nitrogen Sources

In the 2008 ISA, it was well understood that the importance of atmospheric deposition as a cause of estuarine eutrophication is determined by the relative contribution of the atmospheric versus nonatmospheric sources of N input ([U.S. EPA, 2008a](#)).

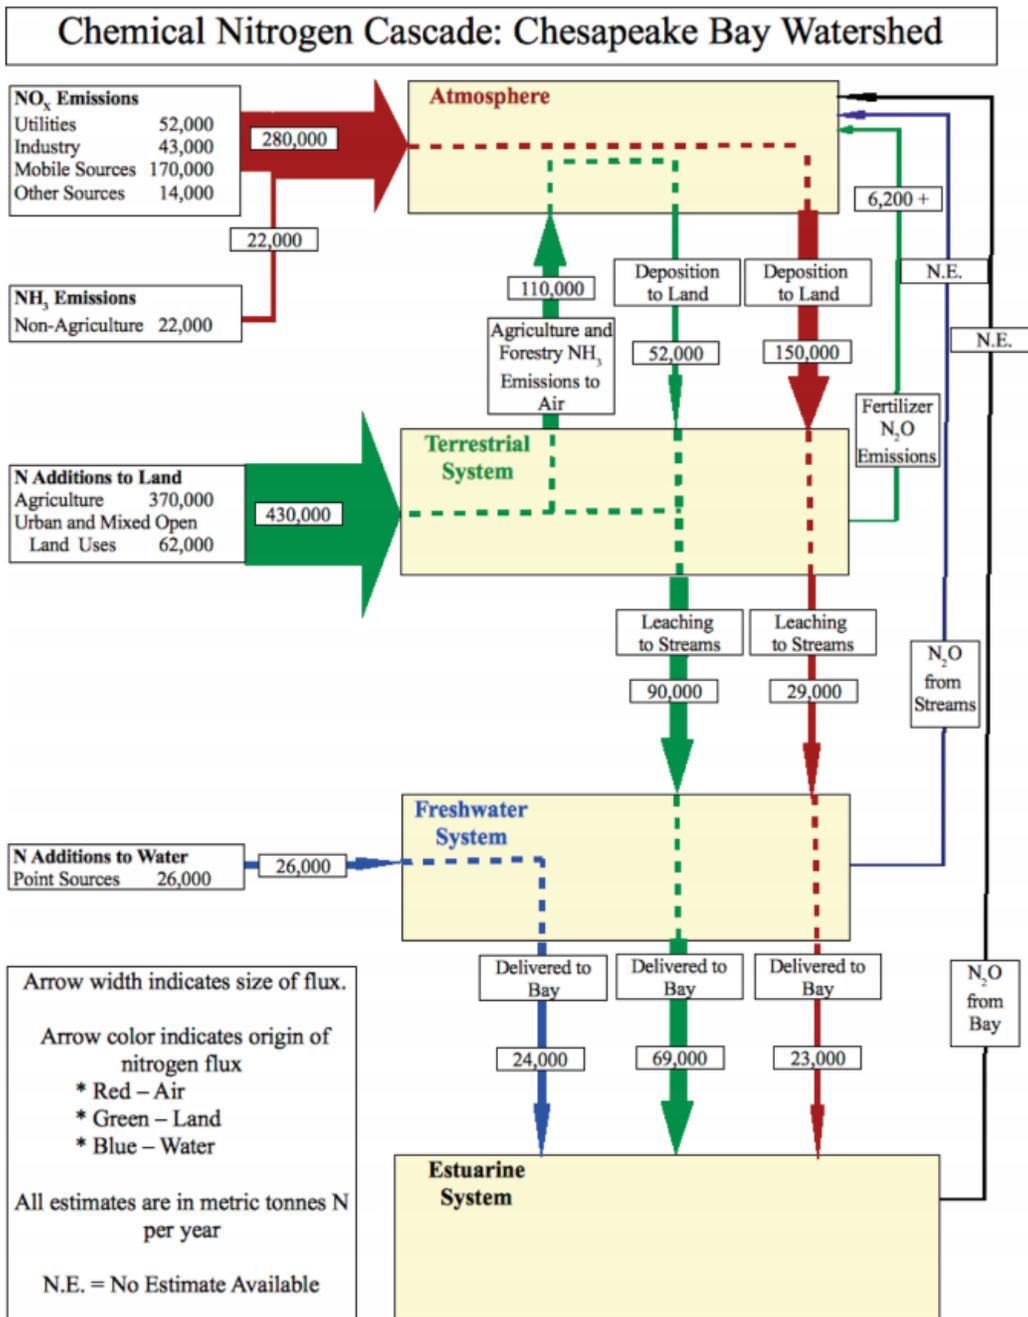

Atmospherically deposited N from combustion of fossil fuels (NO<sub>x</sub>), agricultural sources (NH<sub>3</sub>, NH<sub>4</sub><sup>+</sup>) and organic N combine with N from other anthropogenic and natural sources to contribute varying total N inputs in coastal regions. It is the cumulative effects from multiple sources that contributes to ecosystem enrichment ([Paerl et al., 2002](#)).

Atmospheric deposition of reduced N has increased relative to oxidized N in parts of the U.S. including the East and Midwest in the last few decades ([Appendix 2](#)), and this trend is expected to continue in the future under existing emissions controls ([Pinder et al., 2008](#); [U.S. EPA, 2008a](#)). Thus, the form of inorganic N input to coastal areas is changing over time. This has ramifications for N cycling. The increase in highly bioreactive reduced N from deposition and other sources is often a preferred form of N for phytoplankton including unwanted or harmful species ([Appendix 10.3.3](#)). Deposition of oxidized and reduced forms of N are detailed in [Appendix 2](#).

In many places throughout the U.S., nonpoint sources are now the dominant sources of N to water bodies ([Howarth, 2008a, b](#); [Howarth et al., 2002](#)). Releases of N from agricultural, urban, and mixed land uses comprise a significant portion of the nonpoint

sources in many watersheds ([Birch et al., 2011](#); [Alexander et al., 2008](#)). The Chesapeake Bay is an example of a well-studied coastal system where N fluxes have been relatively well characterized (atmospheric inputs represent approximately 25% of total N budget; [Figure 7-6](#)). In management of coastal eutrophication, both point and nonpoint sources have been identified as targets for control of N inputs ([Stephenson et al., 2010](#); [Paerl et al., 2002](#)). Nonpoint sources include diffuse agricultural runoff and wet and dry deposition from the atmosphere. Nitrogen sources also cause production of excess organic matter that feed respiration by microbial decomposers. In estuaries adjacent to areas of coastal upwelling, such as some locations along the Pacific coast of the U.S., oceanic inputs of nutrients can also represent an important source of N to estuarine waters ([Brown and Ozretich, 2009](#)).

Estimates of the contribution of atmospheric deposition to the overall estuary N load exhibit wide variability due in part to the difficulty associated with quantifying multiple agricultural and mobile and stationary fuel combustion emissions sources and N transformations and losses as the N moves from the terrestrial watershed to and within the estuary ([U.S. EPA, 2008a](#); [NRC, 2000](#)). Despite high variability, it appears that atmospheric sources of N loading to estuaries can be quantitatively important, based on studies reviewed in the 2008 ISA and newer studies ([Table 7-9](#)). For example, atmospheric N loads to estuaries in the U.S. were estimated to be as high as 72% for St. Catherine's/Sapelo estuary in Georgia ([Castro et al., 2003](#)). In another study considering atmospheric deposition of N to the East Coast and Gulf of Mexico, direct deposition of N was estimated to contribute from 10 to over 40% of N loading to estuarine, coastal, and open marine waters ([Paerl et al., 2002](#)). In Chesapeake Bay, studies reviewed in the 2008 ISA indicated that atmospheric deposition makes a substantial contribution (up to 50%) to the overall N budget ([Howarth, 2008b](#); [Boyer et al., 2002](#)).

**Figure 7-6** Chemical nitrogen cascade in the Chesapeake Bay watershed (metric tons/year).

**Table 7-9 Summary of studies quantifying atmospheric nitrogen contribution to total nitrogen in coastal areas via watersheds and/or direct deposition to estuary surface waters.**

Region	Total N Loading Due to Atmospheric Deposition	Model	Reference
U.S. coastal areas	N deposition to land surfaces that is subsequently exported from watersheds to the coastal zone is responsible for 17 to 21% of the total N input.	NEWS SPARROW	<a href="#">McCrackin et al. (2013)</a>
Gulf of Mexico in the Mississippi/Atchafalaya River basin	Atmospheric deposition contribution, which may include volatilized losses from natural, urban, and agricultural sources, was estimated to be 26% of total N transported to the Gulf of Mexico.	SPARROW using CMAQ total deposition	<a href="#">Robertson and Saad (2013)</a>
Northeast and mid-Atlantic coastal region	Identified wet deposition to the watershed as the dominant source of N to the estuaries of the Connecticut, Kennebec, and Penobscot rivers, but the third largest source (20%) for the region as a whole, after agriculture (37%) and sewage and population-related sources (28%).	SPARROW	<a href="#">Moore et al. (2011)</a>
Narragansett Bay	Combined direct atmospheric deposition to the estuary and atmospheric deposition to the watershed were responsible for 20% of N loading to the bay.		<a href="#">Vadeboncoeur et al. (2010)</a>
Waquoit Bay Estuaries in Cape Cod	Since 1990 wastewater N loads have increased about 80% while loads from atmospheric deposition have decreased by about 41% with no change in total loading on a decadal scale.	NLM	<a href="#">Valiela et al. (2016)</a>
Small-to-medium sized estuaries of southern New England	Direct atmospheric deposition to estuary surface averaged 37%, and indirect atmospheric deposition via the watershed averaged 16% of total N loading, although the percentage varied widely for each individual estuary.	NLM	<a href="#">Latimer and Charpentier (2010)</a>
Tampa Bay	Direct and indirect atmospheric loading were estimated to be 30 and 41%, respectively, of total N loading to the bay.	WDT	<a href="#">Poor et al. (2013b)</a>
	Direct and indirect atmospheric loading were estimated to be 17 and 40%, respectively, of total N loading to the bay.	CMAQ modified with University of California Davis aerosol module	<a href="#">Poor et al. (2013a)</a>
Chesapeake Bay	Atmospheric loading is 24% of total N loading.		<a href="#">Birch et al. (2011)</a>
	Half of the atmospheric source of N to the watershed originates outside of the watershed; indirect loading of atmospheric N via watershed inputs are larger than direct loading to tidal waters.	Chesapeake Airshed Model, combining CMAQ and regression model for wet deposition	<a href="#">Linker et al. (2013)</a>

**Table 7-9 (Continued): Summary of studies quantifying atmospheric nitrogen contribution to total nitrogen in coastal areas via watersheds and/or direct deposition to estuary surface waters.**

Region	Total N Loading Due to Atmospheric Deposition	Model	Reference
Gulf of Mexico in the Mississippi/Atchafalaya River basin	Atmospheric deposition to watersheds in the basin contributed about 16% of the total N load, second to N from corn and soybean production (52%).	SPARROW	<a href="#">Alexander et al. (2008)</a>
Pacific Northwest, Yaquina Bay	Direct deposition represented only 0.03% of N inputs and watershed inputs of N fixing red alder ( <i>Alnus rubra</i> ) was a greater source of N to the watershed than atmospheric deposition (8%).		<a href="#">Brown and Ozretich (2009)</a>
<b>Key pre-2008 literature</b>			
34 Atlantic and Gulf coast estuaries	The contribution of atmospheric deposition (including directly onto the water surface and onto the watershed) was 7–72% of the total N.	WATERS-N	<a href="#">Castro et al. (2001); Castro et al. (2003)</a>
10 estuaries along the U.S. east coast	Total atmospheric inputs (watershed runoff plus direct deposition to the surface of the estuary) accounted for 15 to 42% of total N inputs. In four of the estuaries direct deposition was 35 to 50% of the total atmospheric N inputs.		<a href="#">Castro and Driscoll (2002)</a>
Chesapeake Bay	Atmospheric deposition makes a substantial contribution (about 25%) to the overall N budget.		<a href="#">Howarth (2007)</a>
16 northeastern river basins	Atmospheric deposition averaged 31% of total N inputs; values for watersheds in northern New England were substantially higher and atmospheric deposition dominated. Estimated riverine export of N amounted to 25% of total N inputs.		<a href="#">Boyer et al. (2002)</a>
Based on 34 Atlantic and Gulf coast estuaries	In systems with watershed area to estuarine surface area ratios greater than 15, N deposition is not as important (comprising less than 25% total N input) as in estuaries that are large relative to their watershed.		<a href="#">Castro et al. (2001)</a>

CMAQ = Community Multiscale Air Quality; N = nitrogen; NEWS = Nutrient Export from Watersheds; NLM = Nitrogen Loading model; SPARROW = Spatially Referenced Regressions on Watershed Attributes; WATERS-N = Watershed Assessment Tool for Evaluating Reduction Scenarios for Nitrogen; WDT = Water Deposition Tool.

In a series of studies reviewed in the 2008 ISA, the model Watershed Assessment Tool for Evaluating Reduction Scenarios for Nitrogen (WATERS-N) estimated that the contribution of atmospheric deposition (including directly onto the water surface and indirectly onto the watershed) was 7–60% of the total N input to 34 Atlantic and Gulf coast estuaries ([Castro et al., 2003](#); [Castro et al., 2001](#)). Nitrogen deposition contributed 20–86% (average = 48%) of the total N input to 22 watersheds having watershed area to estuarine surface area ratio less than 15. In systems with a ratio greater than 15, N deposition is not as important, comprising less than 25% of total N input across 12 systems ([Castro et al., 2001](#)).

Since the 2008 ISA, additional modeling studies have estimated the amount and proportion of current and future N loading expected to result from atmospheric deposition ([Table 7-1](#)). The Nutrient Export from Watersheds (NEWS) and SPARROW models agreed that 62–81% of N delivered to the coastal zone in the continental U.S. is anthropogenic in source ([McCrackin et al., 2013](#)). Model results showed that atmospheric N deposition that is subsequently transported to estuaries represents 17–21% of the total N exported to the coastal zone ([McCrackin et al., 2013](#); [Moore et al., 2011](#)). Using SPARROW atmospheric N deposition was identified as the dominant source of delivered N to estuaries along the Atlantic Coast and the Gulf of Mexico ([McCrackin et al., 2013](#)). Using SPARROW, the atmospheric deposition contribution (which may include volatilized losses from natural, urban, and agricultural sources) was estimated to be 26% of total N transported to the Gulf of Mexico in the Mississippi/Atchafalaya River basin ([Robertson and Saad, 2013](#)). [Moore et al. \(2011\)](#) found that SPARROW identified atmospheric deposition to watersheds as the dominant source of N to the estuaries of the Connecticut, Kennebec, and Penobscot rivers, but the third largest source (20%) for the Northeast and mid-Atlantic coastal region as a whole, after agriculture (37%) and sewage and population-related sources (28%). In contrast, atmospheric deposition is a less substantial source of N to some estuaries, especially in the Pacific Northwest. In Yaquina Bay estuary, OR, direct deposition represented only 0.03% of N inputs and watershed inputs of N fixing red alder (*Alnus rubra*) trees was a larger (8%) source of N to the watershed than atmospheric deposition ([Brown and Ozretich, 2009](#)). In Yaquina Bay estuary, the ocean is the primary source of N during the dry season and the river is the primary source during the wet season.

A modeling study conducted by [Vadeboncoeur et al. \(2010\)](#) estimated that the third largest source of N loading (via the watershed and directly to the water body) to Narragansett Bay in the year 2000 was atmospheric deposition (20%). Future scenarios suggested that very aggressive reductions in both fertilizer use and atmospheric deposition would be needed for Narragansett Bay to return to early 20th century levels of N loading ([Vadeboncoeur et al., 2010](#)). [Latimer and Charpentier \(2010\)](#) applied the

Watershed N Loading Model (NLM) to small- to medium-sized estuaries of southern New England. Direct atmospheric deposition to the water surface made up an average of 37% of the N input, although the percentage varied widely for individual estuaries ([Latimer and Charpentier, 2010](#)). In the same study, wastewater represented 36% of the total N inputs. Indirect atmospheric deposition within the watershed was estimated to be 16% and the fertilizer component was 12%. The relative magnitudes of these source types varied across estuaries. In another modeling study with NLM using data going back to 1990, atmospheric deposition decreased by about 41% while wastewater inputs have increased 80% with a net result that total loads have not changed on a decadal scale in the Waquoit Bay estuaries in Cape Cod, MA ([Valiela et al., 2016](#)). Using the Watershed Deposition Tool (WDT), [Poor et al. \(2013b\)](#) estimated direct atmospheric loading of 1,080 metric tons of N and 1,490 metric tons of N from indirect atmospheric loading (assuming a watershed-to-bay transfer rate of 18%) for Tampa Bay using data from 2002. Thus, atmospheric sources were an estimated 71% of the total N loading. Key studies from the 2008 ISA on atmospheric N loading to estuaries are summarized in [Table 7-9](#), along with newer estimates.

Near NH<sub>3</sub> emission sources, such as large mammal and poultry livestock operations, N deposition is expected to increase 10–40% by 2020 according to different regulation and reduction scenarios ([Pinder et al., 2008](#)). Many of the agricultural emission sources are located in sensitive watersheds such as the Chesapeake Bay and Pamlico Sound, NC ([Pinder et al., 2008](#)). [Birch et al. \(2011\)](#) estimated that 24% of the reactive N that reached Chesapeake Bay originated as emissions to the atmosphere that were then deposited in the watershed to land and water, 57% came from terrestrial N additions from nonpoint source runoff, and the remaining 19% was estimated to come from direct discharges of N to freshwater ecosystems. The results of a modeling study that integrated the airshed, watershed, and estuary indicated that atmospheric deposition represented one of the largest inputs of N to the Chesapeake Bay watershed, and about half of it originated outside the watershed ([Linker et al., 2013](#)). Atmospheric N loading to tidal waters was included in the Chesapeake Bay 2010 TMDL, the first time that atmospheric deposition has been included in a plan for nutrient load reduction ([U.S. EPA, 2010](#)). The explicit TMDL N allocation was determined to be 7.1 million kg per year of total N atmospheric deposition loads directly to Chesapeake Bay and tidal tributary surface waters. It was based on the 2020 CMAQ N deposition scenario described by [Linker et al. \(2013\)](#). [Appendix 2](#) provides more detailed discussion of N source apportionment.

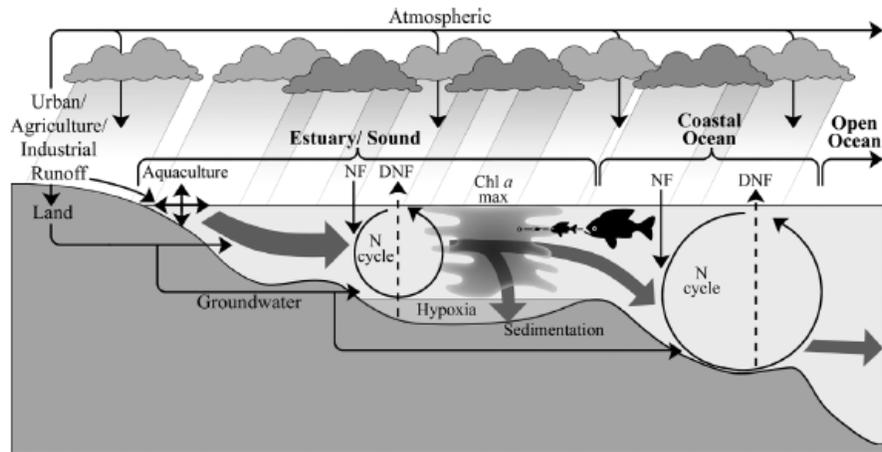

Although the geographic scope of this ISA is limited to estuaries and near-coastal areas of the U.S., some evidence indicates that the open ocean may be affected by atmospheric deposition of N ([Ren et al., 2017](#); [Kim et al., 2011](#)). [Ren et al. \(2017\)](#) provided <sup>15</sup>N stable isotope evidence that N emissions have changed the biogeochemical cycling of N in the

open ocean in nutrient-limited low-latitude regions such as the northwestern Pacific Ocean. Changes in  $\delta^{15}\text{N}$  over time were documented in coral skeletons over a period of 45 years at Dongsha Atoll in the northern South China Sea. The proximity of this water body to anthropogenic N emissions sources in Asia and its depth (1,300 m) both contribute to its sensitivity to N deposition and changes in nutrient cycling.

---

## 7.2.2 The Estuary Environment

Atmospherically deposited N, along with other sources of N to coastal systems, influences uptake and conversion processes that operate along the freshwater-to-ocean continuum [[Seitzinger et al. \(2006\)](#); [Paerl and Piehler \(2008\)](#); [Figure 7-7](#)]. Conditions in upstream terrestrial systems, such as nutrient loading or land use, can exert strong influences on coastal habitats and processes [[Ruttenberg and Granek \(2011\)](#); [Appendix 4](#)]. In addition to inputs of N from outside sources, the varying rates of different N cycling processes, as well as C availability and reactivity within estuaries themselves, can also affect the magnitude of eutrophication experienced as a result of external N enrichment ([Newell et al., 2016](#); [Anderson et al., 2014b](#); [Smyth et al., 2013](#); [Crowe et al., 2012](#)). Estuaries are heterogeneous environments characterized by physicochemical gradients of salinity and both naturally and anthropogenically derived nutrients. Water quality in estuaries is highly variable due to physical and chemical aspects of each estuary ([Appendix 10.1.4](#)) and factors such as temperature and precipitation ([Rheuban et al., 2016](#)). At the upstream end of an estuary, the water is primarily fresh much of the time. Nonpoint source runoff of N from the land surface, only a part of which is of atmospheric origin (mainly deposition to land and subsequently leached to the river water), dominates new N inputs. Downstream, freshwater inflows gradually mix with salt water to form mesohaline segments of the estuary. These changes in salinity impact the ionic strength of the water. Further along the salinity gradient, a significant fraction of the terrestrial biologically available N load is assimilated by phytoplankton and benthic flora, removed by microbes in the process of denitrification or advected to the ocean ([Paerl et al., 2002](#)). Direct atmospheric N inputs also impact the lower estuary, although the relative importance of N deposition in this zone is uncertain and variable ([Paerl et al., 2002](#)). In many estuary and sound ecosystems, primary production and phytoplankton biomass are highest at mid-estuary locations, where N loads and decreasing rates of flushing (increasing residence times) overlap.

Chl a = chlorophyll a; DNF = denitrified; N = nitrogen; N<sub>2</sub> = nitrogen; NF = nitrogen (N<sub>2</sub>) fixation.  
 Source: From [Paerl and Piehler \(2008\)](#).

**Figure 7-7** Schematic diagram illustrating sources, transformations, and fate of nitrogen along the estuary-to-ocean continuum. Surface, subsurface, and atmospheric pathways of externally supplied or new nitrogen inputs attributable to anthropogenic activities are shown as internal nitrogen cycling. The combined anthropogenic nitrogen inputs are shown as a thick arrow (upstream), which decreases in thickness downstream as a portion of the nitrogen inputs settles to the bottom sediments and is buried and/or denitrified. Nitrogen (N<sub>2</sub>) fixation is a biologically mediated new nitrogen input. The linkage of anthropogenically enhanced nitrogen inputs to accelerated primary production or eutrophication and its trophic and biogeochemical fate are also shown.

### 7.2.3 Dissolved Oxygen and Hypoxia

Low oxygen (hypoxia) or the absence of oxygen (anoxia) in coastal waters have implications for N cycling. Oxygen depletion mainly occurs in bottom waters under stratified conditions. The extent of hypoxia in U.S. waters and effects of low DO on biota are discussed in [Appendix 10.2.4](#). Biogeochemical processes that occur in the sediment of estuarine and near-coastal ecosystems are important to the cycling of N that is deposited or transported to estuarine ecosystems. Inputs of C and a stratified water column that separates well-oxygenated surface water from bottom water and sediments is generally required for formation of hypoxic zones ([Jewett et al., 2010](#)). Eutrophication-induced hypoxia, which has been documented globally, can be

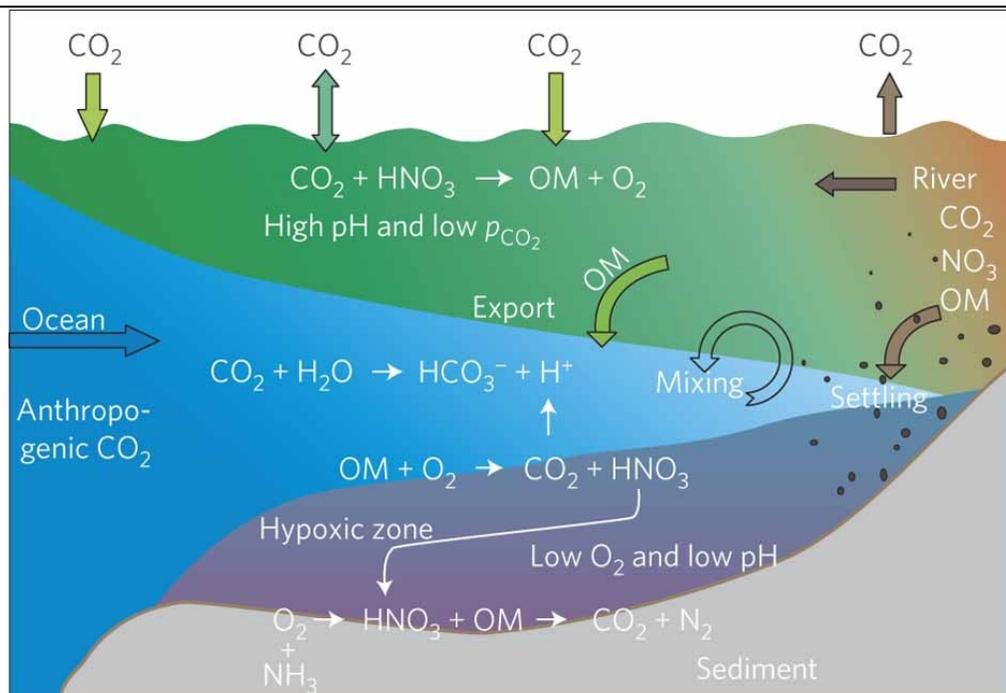

characterized by both the duration of the hypoxic event and the ecosystem response ([Diaz et al., 2013](#); [Diaz and Rosenberg, 2008](#)). Summer hypoxia is most common, followed by systems that experience periodic O<sub>2</sub> depletion that may occur more often than seasonally. Development of seasonal hypoxia is common in shallow coastal regions that receive high inputs of nutrients, including N, from coastal rivers. Development of hypoxia is increasingly becoming a concern throughout the U.S. and internationally ([Jewett et al., 2010](#); [Diaz and Rosenberg, 2008](#)). [Middelburg and Levin \(2009\)](#) provided a review of coastal hypoxia and linkages with biogeochemistry. Changes in bottom water O<sub>2</sub> concentrations influence chemical exchange between sediment and bottom water. [Rabalais et al. \(2010\)](#) provided a synthesis of knowledge regarding hypoxia in coastal waters. Hypoxic water masses (less than approximately 30% saturation) are more likely to occur in marine waters where and when water residence time is long, water exchange is limited, the water column stratifies, and the production and movement of C to bottom waters are relatively high. [Howarth et al. \(2011\)](#) reviewed the complex interactions between biogeochemical cycling, eutrophication, and hypoxia in coastal marine systems. Biochemical feedbacks under eutrophic conditions accelerate further eutrophication and hypoxia. In locations where coastal upwelling can be a large source of nutrient loads such as the Pacific Northwest, advection of upwelled water can introduce hypoxic water into estuaries that is not or poorly related to anthropogenic eutrophication ([Brown and Power, 2011](#); [Brown and Ozretich, 2009](#)).

---

#### 7.2.4 Estuarine and Near-Coastal pH

Estuarine carbonate chemistry is complex, responding to a wide variety of natural, anthropogenic, physical (mixing), chemical, and biological drivers ([Cai et al., 2011c](#)). Measured pH is often used as a proxy for the carbonate chemistry system. The pH of estuarine waters can affect N cycling processes and reflect coastal acidification. Since the 2008 ISA, a number of papers have identified links between nutrient enrichment and coastal acidification, and several mechanisms have been identified ([Baumann and Smith, 2018](#); [Cai et al., 2017b](#); [Hu et al., 2015a](#)). One of the initial studies found that CO<sub>2</sub> production during decomposition of organic matter delivered to coastal zones from rivers experiencing eutrophication has enhanced the acidification of coastal subsurface waters ([Figure 7-8](#)) in the Gulf of Mexico and the East China Sea ([Cai et al., 2011c](#)). A key condition for development of hypoxia/anoxia eutrophication responses and acidification responses is the spatial or temporal decoupling of production and respiration. In many systems, the decoupling comes in the form of thermal or salinity driven stratification which limits mixing of surface and bottom water masses. Dissolution of atmospheric anthropogenic CO<sub>2</sub> into the ocean which has led to long-term decreases in pH injects

atmospheric anthropogenic CO<sub>2</sub> into the bottom waters of the system via mixing. Primary production in the surface waters result in localized basification of surface waters and produces particulate organic matter which falls through the pycnocline. In addition, terrestrially derived organic matter is also delivered by rivers and can contribute to respiration further increasing the dissolved inorganic C pool. CO<sub>2</sub> produced from decomposition of this labile and reactive organic matter associated with eutrophication combines with atmospheric anthropogenic CO<sub>2</sub> and reduced buffering capacity to lower pH in a synergistic manner (Cai et al., 2011c). There is also the possibility of increased pH due to N-enhanced rates of photosynthesis. As described in Figure 7-8 vertical decoupling of primary production and respiration can lead to acidification in subsurface waters.

OM = organic matter.  
Source: Cai et al. (2011c).

**Figure 7-8 A conceptual model for a large river plume eutrophication and subsurface water hypoxia and acidification.**

Acidification processes have also been shown to be seasonally variable. Wallace et al. (2014) found that Long Island Sound and Narragansett Bay had partial pressure of CO<sub>2</sub> >1,000 μatm measured in the water during summer months while exposed to extreme eutrophication; temperature changes accounted for <5% of the partial pressure of CO<sub>2</sub>

increase. Consequently, they conclude that the links between eutrophication, hypoxia, and acidification can be a function of nutrient loading rates. This acidification response is driven not only by the remineralization of autochthonous carbon but also inputs of anthropogenic allochthonous carbon as well as the acidic contribution from the discharged sewage itself ([Wallace et al., 2014](#)). In contrast, [Baumann and Smith \(2018\)](#) suggested that the thermal pathway of metabolic coastal acidification driven by increased respiration can be a direct response to warming. Other works also evaluate how reduced buffering capacity caused by changes in riverine delivery of alkalinity in response to climate change also contribute to the development of acidic conditions ([Cai et al., 2017b](#); [Hu et al., 2015a](#)).

Production of CO<sub>2</sub> by living algae and seagrasses during the night can also drive acidification. In a eutrophic seagrass ecosystem in Cape Cod, MA, there was a very pronounced diel pattern of pH, with moderate pH during the day, but by dawn very acidic waters resulted from overnight community respiration ([Howarth et al., 2014](#)). During the daytime, CO<sub>2</sub> was drawn down through primary production, and as a consequence the pH steadily climbed (e.g., basification). In this system, CO<sub>2</sub> remained supersaturated (low pH) and the net effect was to increase acidification, due to slow exchange of CO<sub>2</sub> with the atmosphere. This additional CO<sub>2</sub> further acidifies marine waters as it dissociates into carbonate ions and hydrogen ions ([Sunda and Cai, 2012](#); [Cai et al., 2011c](#); [Howarth et al., 2011](#)). An important additional source of organic matter leading to overall declines in pH is potentially allochthonous organic matter inputs that have been increasing in many coastal watersheds from changing land use ([Wilson et al., 2016](#); [Wetz and Yoskowitz, 2013](#)). Nitrogen-driven eutrophication and anthropogenically enhanced allochthonous organic matter loading operate simultaneously.

Biogeochemical modeling of eutrophically driven ocean acidification coupled to data collected from the Gulf of Mexico, the Baltic Sea, and the East China Sea predicted that eutrophication would cause a 0.24 to 1.1 unit decrease in pH of bottom waters, and also that increasing atmospheric CO<sub>2</sub> will synergistically amplify eutrophically driven acidification ([Sunda and Cai, 2012](#); [Cai et al., 2011c](#)). The increase in atmospheric CO<sub>2</sub> dissolution is also expected to alter the N cycle in the ocean, with implications for the entire ecosystem. Acidification will result in decreased rates of nitrification, which, combined with expected increasing N deposition, will likely cause the NH<sub>4</sub><sup>+</sup> concentration of the water to rise ([Lefebvre et al., 2012](#)). Models show that while the impact of each acidification pathway (N enrichment and atmospheric CO<sub>2</sub> dissolution) may be moderate, the combined effect of the two may be much larger than would be expected by just adding the effects of each pathway together ([Sunda and Cai, 2012](#); [Cai et al., 2011c](#)).

More recent work has identified some similar dynamics in Chesapeake Bay, where anoxia related to eutrophication is driving acidification and carbonate mineral dissolution (Cai et al., 2017b). Ocean acidification has detrimental effects on marine calcifiers and is projected to alter marine habitat and food webs affecting a wide range of marine ecosystem processes (Marshall et al., 2017; Mostofa et al., 2016; Andersson et al., 2015; Sunda and Cai, 2012; Doney et al., 2009). Decreased concentration of carbonate ions (which organisms such as calcareous plankton, oysters, clams, sea urchins, and coral take up to build shells) are observed in acidic conditions [Hettinger et al. (2012); Kroeker et al. (2013); Barton et al. (2015); Chan et al. (2016); Appendix 10.5].

---

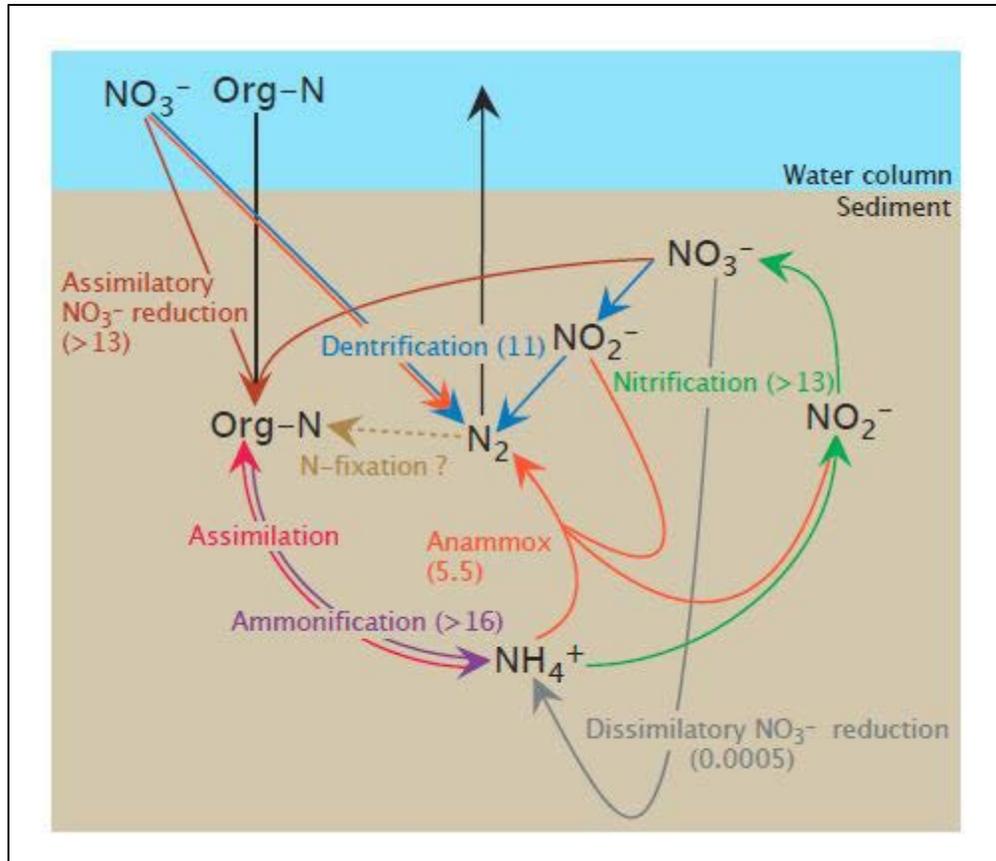

## 7.2.5 Nitrogen in Surface Waters

In most estuaries, N inputs from atmospheric deposition, wastewater and agricultural runoff control eutrophication (Valiela et al., 2016; Howarth et al., 1996a; Vitousek and Howarth, 1991) and can be linked to changes in biological indicators of nutrient enrichment known to be sensitive to shifts in N loading (Appendix 10). In many estuaries, this occurs with a simultaneous increase in P as N, and P runoff loads are often coupled, especially where agricultural or human waste sources dominate. In general, estuaries tend to be N limited (Howarth et al., 2011; Paerl and Piehler, 2008; Elser et al., 2007; Howarth and Marino, 2006; NRC, 2000; Nixon, 1995; Howarth, 1988). However, more recent studies show that some estuaries are P limited, or colimited by N and P, or switch seasonally between N and P limitation (Howarth et al., 2011; Paerl and Piehler, 2008; Howarth and Marino, 2006). To date, several states have developed site-specific or state-wide numeric nutrient criteria to address nutrient pollution problems (Appendix 7.2.9). Adopted criteria include TN,  $\text{NO}_3^-$  as N, DIN as N, or TMDLs. In some estuaries, especially in the Pacific Northwest, nutrients from upwelling and oceanic exchange caused by regional wind patterns likely control primary production rather than anthropogenic nutrient loading (Brown and Ozretich, 2009; Hickey and Banas, 2003). Quantification of N in the estuarine environment can be highly variable both spatially and temporally due to the physiochemical gradients within estuaries (Appendix 10.1.4, the influence of natural and anthropogenic stressors, and factors such as precipitation and warming (Appendix 10.1.4.1). For example, analysis of 22 years of water quality data from Buzzards Bay, MA by Rheuban et al. (2016) indicated that climate related stressors of warming and precipitation appeared to influence ecosystem response to TN over time. Since the 2008 ISA, additional thresholds of response to N have been identified for biological indicators (Appendix 10.6).

---

## 7.2.6 Nitrogen Cycling

Some of the key processes involved in N cycling in estuarine and near coastal environments include N sinks such as denitrification and N<sub>2</sub> production via anaerobic ammonium oxidation (anammox), bioavailable N sources such as N fixation and DNRA, and other N cycling processes including nitrification ([Figure 7-9](#)). A major control on these processes is C availability and reactivity ([Plummer et al., 2015](#)). Benthic DO concentrations (hypoxia) and S cycling may also affect the occurrence and rates of many of these N cycling processes. Recent research has shown that many of these N cycling processes are more important in the estuarine environment than previously thought, and that the rates of different N cycling processes can be highly variable, depending on environmental factors such as N availability, organic C source, temperature, seasonality, oxygen levels, microbial community structure, aquatic habitat type, and others ([Newell et al., 2016](#); [Plummer et al., 2015](#)). Some processes were relatively well understood at the time of the 2008 ISA while the role of others such as DNRA has been characterized only recently as an important pathway in which N is conserved in coastal ecosystems.

Notes: Numbers in parentheses are rates of the reactions in  $\mu\text{mol}/\text{m}^2/\text{h}$  as measured by [Crowe et al. \(2012\)](#).

**Figure 7-9** New complexities in nitrogen cycling have been detailed since the 2008 ISA as shown in this illustration of the sedimentary N cycle in the Lower St. Lawrence estuary.

### 7.2.6.1 Nitrogen Fixation

Nitrogen fixation is the microbially mediated conversion of atmospheric nitrogen gas ( $\text{N}_2$ ) to a bioavailable form of N (i.e., ammonia [ $\text{NH}_3$ ]). The community of N fixing microorganisms is more diverse in estuarine and coastal waters than previously thought, and N fixation occurs more widely than previously assumed. Advances in research methods for measuring heterotrophic N fixation have led to the discovery that rates of N fixation in coastal sediments can cause the sediments to be a significant source of N to the ecosystem ([Newell et al., 2016](#)). [Newell et al. \(2016\)](#) reported on several studies of N fixation rates in coastal sediments (measured as sediment  $\text{N}_2$  uptake) with rates ranging from  $-12$  to  $-250 \mu\text{mol N}/\text{m}^2/\text{h}$ . In some cases, these higher rates of N fixation can

potentially exacerbate the eutrophic conditions already experienced in an estuary, as was the case in Narragansett Bay, RI, where up to 30% of the N added to the system came from N fixation in some years ([Newell et al., 2016](#); [Fulweiler and Heiss, 2014](#)).

Research in the past decade has also sought to determine what environmental factors may cause sediments to switch from acting as a sink to acting as a net source of N due to increased N fixation. Organic matter enrichment appears to be one factor. [Fulweiler et al. \(2008\)](#) noted a “threshold” of organic enrichment at 0.3 g C/m<sup>2</sup>/day, below which N fixation took place at high rates but above which the rates of N fixation declined and the sediments became a net sink of N due to denitrification ([Fulweiler et al., 2008](#)).

In Copano Bay, a shallow bay on the Gulf of Mexico in Texas, periods of drought coincided with higher rates of N fixation ([Bruesewitz et al., 2013](#)). Thus, base flow conditions allowed primary production to continue, even when external sources of N via riverine transport and runoff were very low.

---

#### **7.2.6.2 Role of Dissolved Organic Nitrogen**

Recent research has shown the importance of measuring DON fluxes, as they can be a more significant internal source of N from the sediments than previously assumed. Terrestrial inputs of DON are poorly characterized, and these fluxes are not routinely included in estuarine nutrient budgets. [Alkhatib et al. \(2013\)](#) found that DON fluxes out of the sediments, at rates of 110 to 430 μmol/m<sup>2</sup>/day, were at times greater than NO<sub>3</sub><sup>-</sup> flux into the sediments in the St. Lawrence estuary and Gulf of St. Lawrence. Many species of algae and bacteria will take up DON; thus, this flux of DON out of the sediments leads to an important sink for N within the system ([Alkhatib et al., 2013](#)). Reactivity of organic matter is another key factor in DON availability.

---

#### **7.2.6.3 Dissolved Inorganic Nitrogen**

Dissolved inorganic nitrogen (NH<sub>4</sub><sup>+</sup> plus [NO<sub>2</sub><sup>-</sup> + NO<sub>3</sub><sup>-</sup>]) plays an important role in N cycling and primary productivity. N laden organic matter may be transported to estuaries and coastal waters from river basins. Estuarine benthic communities degrade this allochthonous organic matter, releasing NH<sub>4</sub><sup>+</sup> at the aerobic sediment-water interface, and NH<sub>4</sub><sup>+</sup> further enhances estuarine productivity via oxidation to NO<sub>3</sub><sup>-</sup>. Generally, NH<sub>4</sub><sup>+</sup> is considered the preferred form for some phytoplankton, including harmful species, due to lower energy requirements for uptake [[Glibert et al. \(2016\)](#); [Appendix 10.2.2](#) and [Figure 10-7](#)]. Remineralization of organic matter is sensitive to redox conditions ([Reddy and Patrick, 1984](#)), sediment grain size ([Nowicki and Nixon, 1985](#)), and temperature

([Kemp and Boynton, 1984](#)). If  $\text{NH}_4^+$  has to compete with saltwater cations for adsorption sites, then excess  $\text{NH}_4^+$  becomes free in these saline waters ([Gardner et al., 1991](#)).

The understanding of DIN's role in estuarine and near-coastal nutrient enrichment is an active field of research. [Cornwell et al. \(2014\)](#) measured September 2011 versus March 2012 benthic nutrient fluxes in the San Francisco Bay and delta and ascertained that sediment DIN is an important source of N to the water column and system productivity. [Paudel et al. \(2017\)](#) examined the effect of flow regimes on DIN release at the sediment-water interface. They compared two south Texas estuaries: the Nueces and the Guadalupe. The Guadalupe has eight times the inflow of the Nueces. They observed significantly different  $\text{NH}_4^+$  concentrations between the estuaries; however, the  $\text{NO}_2^- + \text{NO}_3^-$  concentration did not differ significantly. Using the coastal water phytoplankton Redfield ratio (ratio of N:P in phytoplankton) of 16:1, they found the Nueces N:P ratio below the Redfield but the Guadalupe above, suggesting that the Nueces was N limited.  $\text{NH}_4^+$  releases were greater in the Nueces estuary due to its higher organic content in sediment. In the Guadalupe estuary, finer sediment particles may retain N.

[Buzzelli et al. \(2013b\)](#) applied the Land-Ocean Interactions in the Coastal Zone (LOICA) approach to gain understanding about the seasonal budgets for DIN in two south Florida estuaries—Caloosahatchee River estuary (CRE) and the St. Lucie estuary (SLE)—during the years 2002 to 2008. The analysis included the contribution of direct wet atmospheric N deposition to estuarine loading. They compared the production of C, N, and P in the two estuaries and source attribution. These two watersheds are highly disturbed due to urban growth and agriculture and flush at substantially different rates. They sought to understand the optimum metabolism of each estuary from a C, N, and P production and consumption perspective to better inform coastal watershed management planning. Both estuaries have similar agricultural and urban land use; however, study authors observed increased DIN in the CRE during the wet season but not in the SLE. The SLE's "muck-like" sediment reduces light penetration and isolates the water column from the benthic zone ([Buzzelli et al., 2013a](#); [Sime, 2005](#)). External loading influenced the SLE's production of C, N, and P more than the CRE. Even though the CRE is 2.5 times larger (and receives double the freshwater inflow) as compared with the SLE, the CRE's DIP and DIN loadings are only 60–70% of SLE's loadings when spatially normalized.

---

#### **7.2.6.4 Nitrification**

Nitrification is the microbially mediated conversion of  $\text{NH}_4^+$  to  $\text{NO}_3^-$ ; thus, exchanging one bioavailable N form for another. The process includes  $\text{NH}_3$  oxidation to  $\text{NO}_2^-$ ,

followed by  $\text{NO}_2^-$  oxidation to  $\text{NO}_3^-$ . This importance was well known at the time of preparation of the 2008 ISA. More recent research has provided additional quantitative context, including new studies in North America and Europe. Where DIN loading is not dominated by  $\text{NO}_3^-$ , the oxidation of  $\text{NH}_4^+$  to form  $\text{NO}_3^-$  largely controls the relative abundance of oxidized and reduced DIN in estuaries. Nitrification rates are often correlated with suspended particulate matter and  $\text{NH}_4^+$  concentration in water ([Damashek et al., 2016](#)).

There have been new findings about the process of nitrification since the 2008 ISA. It has generally been assumed that the first step of nitrification ( $\text{NH}_4^+$  oxidation to  $\text{NO}_2^-$ ) is the rate-limiting step ([Damashek et al., 2015](#)). However, recent research indicates that physical factors such as salinity, temperature, pH, DO concentration, and light can affect the rates to the extent that the two steps of nitrification may not always be “coupled” as is often assumed ([Heiss and Fulweiler, 2016](#); [Bristow et al., 2015](#)). In some cases, the rate for the second step of the nitrification process may be higher than for the first step. For example, results showed that rates of  $\text{NO}_2^-$  oxidation to  $\text{NO}_3^-$  were negatively correlated with light and pH, indicating in part that  $\text{NO}_2^-$  oxidation rates are higher when the pH is lower ([Heiss and Fulweiler, 2016](#)). Decoupling of the two nitrification steps was also observed in the Gulf of Mexico hypoxic zone, where the first step occurred at rates of up to 30 times higher than the second step, a result the authors concluded was due to environmental factors such as temperature, substrate availability, and hypoxic conditions ([Bristow et al., 2015](#)). These results add complexity to the understanding of nitrification rate and the degree to which that process is affected by environmental factors and support the need to measure the two steps of nitrification separately to better predict the effects of perturbations to the N cycle in coastal waters.

Nitrification makes denitrification possible to some degree, and the reactions are often assumed to be coupled, as nitrification provides the  $\text{NO}_3^-$  starting point for the N reduction process of denitrification. Since the 2008 ISA, the degree of coupling (and “decoupling”) between nitrification and denitrification reactions has been the subject of much research (see discussion in [Appendix 7.2.6.8](#)).

---

#### **7.2.6.5 Dissimilatory Nitrate Reduction to Ammonium**

DNRA has been characterized as an important pathway in which N is conserved in coastal ecosystems ([Giblin et al., 2013](#)). Although DNRA was not discussed in the 2008 ISA, more recent research has established DNRA as a potentially important N reduction pathway, and one that varies in magnitude depending on a range of environmental factors. Ammonium produced via DNRA can enhance productivity and respiration,

which in turn may exacerbate hypoxia ([McCarthy et al., 2015](#)). Rates of DNRA usually vary seasonally and peak in the warmer summer months. [Bernard et al. \(2015\)](#) found that in Little Lagoon, AL, DNRA accounted for up to 30–40% of the annual  $\text{NH}_4^+$  flux, and up to 80% of the seasonal  $\text{NH}_4^+$  flux during summer months. Also in the summer, DNRA rates (study average:  $52.1 \mu\text{mol N/m}^2/\text{h}$ ) outpaced the removal of  $\text{NO}_3^-$  via conversion to  $\text{N}_2$  (denitrification; study average  $7.7 \mu\text{mol N/m}^2/\text{h}$ ), resulting in more bioavailable N retained in the system. This could help promote eutrophic conditions ([Bernard et al., 2015](#)).

Several reasons have been proposed for observed seasonal peaks in DNRA rates. These include warmer temperatures, higher sulfide ( $\text{HS}^-$ ) and oxygen concentrations, and more  $\text{NO}_3^-$  availability. Higher  $\text{HS}^-$  concentrations are shown to favor DNRA rather than denitrification ([Kraft et al., 2014](#); [Howarth et al., 2011](#)). In the Niantic River estuary, CT, one study area with the highest rates of DNRA was also found to have high  $\text{HS}^-$  concentrations and reaction rates of sediment denitrification, anaerobic oxidation of ammonium ([Appendix 7.2.6.7](#)), and DNRA varied considerably within the estuary. Approximately one-third of the total area of the estuary exhibited rates of DNRA that exceeded denitrification by at least 20%, although denitrification accounted for about 90% of  $\text{NO}_3^-$  reduction across the entire estuary ([Plummer et al., 2015](#)). Sulfide was found to predict 44% of the variability in a DNRA ratio metric, while organic carbon abundance and organic carbon source were less strongly correlated with DNRA ([Plummer et al., 2015](#)). [Decleyre et al. \(2015\)](#) observed wide variations in N removal pathway rates over small distances in the Paulina polder mudflat (Westerschelde estuary, Netherlands). Rates of DNRA varied significantly on a small scale of less than 2 m and were significantly related to  $\text{HS}^-$  production.

[Jäntti and Hietanen \(2012\)](#) demonstrated that DNRA controlled the overall  $\text{NO}_3^-$  reduction under conditions of low oxygen. DNRA is thought to provide energy to diatoms in dark and/or hypoxic conditions ([Glibert et al., 2016](#); [Kamp et al., 2011](#)). A study from Australia's Yarra River estuary found that DNRA rates were increased under oxygen saturation and depressed under hypoxic conditions ([Roberts et al., 2014](#)).

---

#### 7.2.6.6 Denitrification

Bioavailable N removal from estuarine and near-coastal ecosystems occurs via several different pathways in the N cycle. These pathways include sediment burial, uptake by plants, denitrification ( $\text{NO}_3^-$  reduction to  $\text{N}_2$ ) and anaerobic  $\text{NH}_4^+$  oxidation to  $\text{N}_2$  (termed anammox; [Appendix 7.2.6.7](#)). In some areas, uptake by vegetation such as SAV can represent a significant N sink ([Zarnoch et al., 2017](#); [Boynton et al., 2014](#); [Hayn et al.,](#)

[2014](#)). However, much of the N contributed to estuaries by atmospheric deposition and other nonpoint and point sources of N is removed from the aquatic ecosystem by either denitrification or anammox ([Damashek et al., 2015](#); [Ward, 2013](#); [Boynton and Kemp, 2008](#)). These processes predominate in the anoxic sediments if the water body is well mixed and occur in the water column of stratified hypoxic systems. Since the 2008 ISA, there have been additional insights into factors that affect abundance, biodiversity, and biological activity of denitrifying microbial communities ([Appendix 7.2.6.9](#)).

Denitrification can occur in both the hypoxic water column and hypoxic sediments, although in most estuaries sediment processing probably exceeds water column processing ([Seitzinger et al., 2006](#)). Denitrification is a very important sink for N in most estuaries ([Hayn et al., 2014](#); [Nixon et al., 1996](#)). Because N is such an important limiting factor for primary production in estuaries, the removal of N through denitrification is a valuable ecosystem service in terms of constraining the extent and magnitude of eutrophication ([Smyth et al., 2013](#); [Piehler and Smyth, 2011](#)). In the eutrophic Baltic Sea, denitrification in sediments is important for partially mitigating the adverse effects of eutrophication ([Jäntti and Hietanen, 2012](#)). However, denitrification rates are not always high enough to result in a net sink of N within an estuary or embayment. [Barnes and Upstill-Goddard \(2011\)](#) reported measurements of dissolved nitrous oxide (N<sub>2</sub>O), inorganic N, O<sub>2</sub>, and turbidity in six estuaries in the U.K. and results suggested that the main source of N<sub>2</sub>O was nitrification; denitrification did not appear to be a significant NO<sub>3</sub><sup>-</sup> sink in that ecosystem.

Denitrification was found to be the primary pathway for N reduction in the Niantic River estuary in Connecticut, accounting for an average of 90% of total N reduction, a result that is in line with measurements from other temperate estuaries ([Plummer et al., 2015](#)). Estuaries and coastal embayments with longer water residence times and shallower water depths have also been found to exhibit greater rates of denitrification ([Hayn et al., 2014](#)). Shallow waters enhance denitrification because they lead to a greater level of interaction between N in the water and sediments ([Hayn et al., 2014](#); [Nixon et al., 1996](#)). An analysis of estuary nutrient budgets for North Atlantic estuaries by [Nixon et al. \(1996\)](#) suggested that the fractional transport of nutrients through estuaries to the continental shelf is inversely correlated with water residence time; specifically, the fraction of the total export of N from the estuary is roughly proportional to the log mean residence time of the water in the estuary. [Hayn et al. \(2014\)](#) studied the nutrient dynamics of West Falmouth Harbor on Cape Cod, MA, a shallow estuary that experienced a large increase in N load from human activities without a substantial change in P load. Since the 1990s, this estuary received a threefold increase in N inputs caused by groundwater contamination by a municipal wastewater treatment plant. During summer, the Falmouth Harbor retained most of the N load contribution and also imported some additional N from the

adjacent Buzzards Bay; during spring and fall, N was exported from the harbor to the bay.

Inhibition of denitrification rates by  $\text{HS}^-$  has been widely observed. [Plummer et al. \(2015\)](#) found that denitrification rates were inversely related to pore water  $\text{HS}^-$  (as a measure of  $\text{SO}_4^{2-}$  reduction), consistent with previous studies. Organic carbon abundance and organic carbon source were also shown to be related to denitrification rates in that study ([Plummer et al., 2015](#)).

[Smyth et al. \(2013\)](#) measured the  $\text{N}_2$  fluxes in five major estuarine habitat types in Bogue Sound, southeastern North Carolina: salt marshes, seagrass beds, oyster reefs, and intertidal and subtidal flats. Based on the distribution of habitats across the study estuary, it was estimated that about 76% of the watershed N load was removed by denitrification in the estuary each year. Results suggested that the amount of N removed by denitrification from an estuary depends on the amount and type of habitats located in that estuary. Each habitat had a characteristic impact on N cycling in the sediment ([Smyth et al., 2013](#)). [Piehler and Smyth \(2011\)](#) and [Smyth et al. \(2013\)](#) concluded that more structured habitats such as oyster reefs and seagrass beds provided especially high N removal per unit estuary area. Calculations showed that the SAV habitat produced the highest value of N removal in terms of an ecosystem service valued at \$3,000/ac/year, compared with a \$400/ac/year value provided by a subtidal flat habitat ([Piehler and Smyth, 2011](#)).

---

#### 7.2.6.7 Anammox

Anammox removes N from estuaries by producing  $\text{N}_2$  gas. This process can in some cases be a significant pathway for N removal, depending on environmental factors, although it is typically secondary to denitrification in N removal. Anammox and denitrification are usually highly correlated ([Plummer et al., 2015](#); [Lisa et al., 2014](#)). A review of several studies revealed that anammox rates in coastal sediments can potentially range up to  $52 \mu\text{mol N/m}^2/\text{h}$  ([Plummer et al., 2015](#)). [McCarthy et al. \(2015\)](#) found that up to 29% of the N removal (mean =  $11.8 \pm 1.7\%$ ) from the Mississippi River TN load to the Louisiana-Texas continental shelf may be due to anammox under hypoxic conditions. The median denitrification rate measured in that study, which includes anammox, of  $88.1 \mu\text{mol N/m}^2/\text{h}$  was found to be comparable to other studies ([McCarthy et al., 2015](#)). In the Niantic River estuary, CT, anammox rates ranged from 0 to  $3.1 \mu\text{mol N/m}^2/\text{h}$ , accounting for 3.5% of total N reduction, while denitrification accounted for 91% of total N reduction ([Plummer et al., 2015](#)). Anammox was also found to be a significant N sink in the lower St. Lawrence estuary, where it was measured at a

rate of  $5.5 \pm 1.7 \mu\text{mol N/m}^2/\text{h}$  ([Crowe et al., 2012](#)). In the Cape Fear estuary, NC, anammox rates ranged from 0.17 to 4.77 nmol N/g wet sediment/h, with the highest rates measured during the winter ([Lisa et al., 2015](#)). Anammox rates in this study were also found to be inversely related to temperature.

Several studies have linked anammox activity to N loading. In the Chesapeake Bay, higher anammox activity was associated with higher concentrations of  $\text{NO}_3^-$  in the tidal freshwater segment and was not observed in the lower saline part of the estuary ([Rich et al., 2008](#)).

---

#### **7.2.6.8 Nitrification/Denitrification Uncoupling**

Sediment N cycling is dynamic, and rates of various processes fluctuate over time. Recent research has highlighted the importance of quantifying each process, the resulting N fluxes, and environmental controls on these reactions. Denitrification has long been assumed to be coupled with nitrification; however, the extent of that coupling is increasingly understood to be dependent on environmental factors. [Hines et al. \(2012\)](#) found that 43% of denitrification was coupled to nitrification in the upper Cape Fear River estuary, NC. [Lisa et al. \(2015\)](#) found that nitrification and denitrification rates were significantly coupled (correlated) in the Cape Fear River estuary, and that this coupling was driven by organic carbon mineralization. The study found that tidal changes and salinity fluctuations did not affect the coupling of nitrification/denitrification on the same scale ([Lisa et al., 2015](#)). Under some conditions, such as warmer summer conditions, DNRA may be the favored N reduction pathway over denitrification, which can also lead to uncoupling of nitrification/denitrification rates. In Little Lagoon, AL, DNRA rates can be much higher in the summer and are correlated with higher concentrations of  $\text{HS}^-$  ([Bernard et al., 2015](#)). Seasonality was also a factor in the San Francisco Bay, where coupling of nitrification/denitrification was more prominent in the late summer; in the spring, high  $\text{NO}_3^-$  concentrations in the water drove denitrification ([Cornwell et al., 2014](#)).

---

#### **7.2.6.9 New Insights Regarding the Abundance, Biodiversity, and Biological Activity of Estuarine Microbial Communities**

Since the 2008 ISA, there is new information on the abundance, diversity ([Appendix 10.3.4](#)) and biological activity of microbial communities and their role in N cycling. Quantification of functional genes reflect changes in microbial function and have been linked to forms of N. For example, in seasonally anoxic bottom waters in

Chesapeake Bay, [Eggleston et al. \(2015\)](#) observed that relative expression of genes involved in denitrification and DNRA were coincident with changes in concentrations of  $\text{NO}_3^-$ ,  $\text{NO}_2^-$ , and  $\text{NH}_4^+$ . In an analysis of denitrifiers in San Francisco Bay estuary, N was identified as one of the key factors (along with salinity, organic C, and several metals) affecting community structure and function and denitrification rates ([Mosier and Francis, 2010](#)). Seasonal inputs of N loading from the watershed affect microbial community structure and biodiversity, which in turn affect rates of processes involved in N cycling ([Lisa et al., 2015](#); [Lisa et al., 2014](#)).

---

### 7.2.6.10 Archaea and Nitrogen Cycling

Prior to the 2000s, it was generally believed that  $\text{NH}_3$  oxidation was accomplished only by Proteobacteria ([Damashek et al., 2015](#); [Kowalchuk and Stephen, 2001](#)). Complexity increased with the discovery that some archaea (also called Thaumarchaeota), a primitive life form separate from bacteria, can also oxidize  $\text{NH}_3$  ([Brochier-Armanet et al., 2008](#); [Könneke et al., 2005](#)). These ammonia-oxidizing archaea (AOA) are dominant in some estuaries ([Moin et al., 2009](#)). Ammonia-oxidizing bacteria (AOB) are important in others ([Abell et al., 2010](#)). These two life forms can vary spatially and seasonally in importance in still other estuaries ([Damashek et al., 2015](#); [Urakawa et al., 2014](#); [Zheng et al., 2014](#)). Benthic  $\text{NH}_3$  oxidizers may be able to oxidize a significant quantity of  $\text{NH}_4^+$  in  $\text{NH}_4^+$  rich systems, such as the Sacramento River ([Damashek et al., 2015](#)). Several studies that have examined changes in AOA and AOB relative abundance and community structure associated with N loading are reviewed in [Appendix 10.3.4](#).

---

### 7.2.6.11 Role of Benthic Macrofauna in Nitrogen Cycling

The role of benthic macrofauna (including crustaceans and molluscs) in N and C cycling and their ability to modulate water quality have significant implications for estuarine functioning ([Rose et al., 2015a](#); [Bricker et al., 2014](#); [Petersen et al., 2014](#); [Rose et al., 2014](#); [STAC, 2013](#); [Carmichael et al., 2012](#); [Volkenborn et al., 2012](#); [D'Andrea and DeWitt, 2009](#); [Cerco and Noel, 2007](#)). Activities of burrowing macrofauna can create areas of oxic-anoxic oscillations, which vary on the order of minutes to hours and affect geochemical reactions and microbial activity in sediments ([Volkenborn et al., 2012](#)). Burrowing mudshrimp (*Upogebia pugettensis*) were shown to increase the rate of N cycling processes and DIN fluxes in an intertidal mud flat in the Yaquina River estuary in Oregon ([D'Andrea and DeWitt, 2009](#)). [Stief \(2013\)](#) reviewed the contributions of benthic macrofauna to the turnover of N and to emissions of greenhouse gasses such as nitrous oxide from the estuary to the atmosphere. Sediment burrowing macrofauna stimulated

nitrification and denitrification in the sediment. Together these facilitate removal of N from the estuary system. Benthic macrofauna intensify the coupling among water, benthos, and atmosphere by enhancing turnover and transport of N.

The use of shellfish for remediation of coastal N enrichment has been explored due to the ability of these organisms to modulate nutrient dynamics and water quality ([Reitsma et al., 2017](#); [Ferreira and Bricker, 2016](#); [Petersen et al., 2016](#); [Bricker et al., 2014](#); [STAC, 2013](#); [Cercó and Noel, 2007](#); [Carmichael et al., 2004](#)). These filter feeders store nutrients in shell and tissue that are permanently removed from the estuary with shellfish harvest. Biodeposits (partially digested phytoplankton expelled from suspension feeding bivalves) may remove additional N through acceleration of denitrification processes in underlying sediments ([Pollack et al., 2013](#); [STAC, 2013](#); [Stephenson et al., 2010](#)). For example, in the Mission-Aransas estuary in Texas, oyster reefs were estimated to remove 502.5 kg N/km<sup>2</sup> through denitrification of biodeposits and 251.3 kg N/km<sup>2</sup> in burial of biodeposits to sediments ([Pollack et al., 2013](#)). Oyster harvest in the same estuary was calculated to remove approximately 21,665 kg N/year.

Additional studies have reported N removal by shellfish in U.S. waters. [Carmichael et al. \(2004\)](#) directly measured N removal in the oyster *C. virginica* in transplant studies to five Cape Cod estuaries with different N loadings. Estimated N removal of different sources was ≤15% of land-derived N loads and <1% of phytoplankton. Nitrogen removal by oysters in the Great Wicomico River, which drains into the Chesapeake Bay, was estimated to be 15.2 tons/year [total area 2.8 × 10<sup>5</sup> m<sup>2</sup>; [Cercó \(2015\)](#)]. Based on model estimates for Chesapeake Bay harvesting 7.7 × 10<sup>6</sup> harvest-sized oysters (76 mm) removes 1 ton of N from the bay ([Higgins et al., 2011](#)). In the same study, an offset of approximately 10 to 15% of total N load in some basins (cultivation of 200 × 10<sup>6</sup> oysters/year) was calculated. [Holmer et al. \(2015\)](#) recommended harvest of mussels within 1 year of the production cycle for the most efficient N removal.

Over time, shellfish excretion and subsequent sedimentation may contribute to development of hypoxic conditions. A shellfish farming operation may shift from a net sink to a net source of N. Oyster reef restoration projects in several locations throughout the U.S. have been evaluated for effects on N cycling; however, this process appears to be dependent on local habitat and growing conditions and may vary by orders of magnitude ([Cercó, 2015](#); [Smyth et al., 2015](#); [Kellogg et al., 2014](#); [Plutchak et al., 2010](#)). In Great Bay estuary, NH, eutrophication enhanced oyster feeding rates and enhanced biodeposit quality. Thus, oyster-mediated ecosystem services may be expected to vary with environmental conditions ([Hoellein et al., 2015](#)).

Recent evaluation of oysters in Chesapeake Bay for inclusion in TMDL nutrient reductions reported enhanced denitrification in association with oyster reefs; however,

the effect was highly variable and not reliable unless direct measurements were conducted on individual reefs ([STAC, 2013](#)). The potential for shellfish aquaculture to be included in proposed nutrient trading markets for achieving pollution control under the Clean Water Act is being evaluated in Chesapeake Bay ([Stephenson et al., 2010](#)). Some recent modeling studies showed that mean N removal by shellfish aquaculture compares favorably with reported N removal effectiveness of agricultural best management practices and stormwater control measures ([Rose et al., 2015a](#); [Rose et al., 2014](#)).

---

#### **7.2.6.12 Climate Modification of Ecosystem Response to Nitrogen**

Altered biogeochemical processes due to N loading are occurring within the context of climate change. Microbial diversity is affected by environmental gradients within estuaries, a condition that may be exacerbated under climate change. For example, freshwater and nutrient contributions to estuaries are expected to rise due to predicted increases in surface water flow and runoff from watersheds ([Rabalais et al., 2010](#); [Adrian et al., 2009](#); [Whitehead et al., 2009](#)). [Howarth et al. \(2012\)](#) demonstrated larger N fluxes (larger percentage delivery of human N inputs) in wetter climates with more discharge, across 154 different watersheds in the U.S. and Europe. Temperature modification leading to sea level rise and inputs of fresh water will likely influence the delivery of nutrients and organic matter, alter salinity gradients, and increase stratification within estuaries ([Statham, 2012](#)). Eutrophic conditions and the extent and duration of hypoxia are predicted to increase with anticipated changes in temperature and precipitation ([Altieri and Gedan, 2015](#); [Rabalais et al., 2009](#); [Boesch et al., 2007](#)). High organic loads and freshwater inputs associated with extreme weather events may further enhance thermal stratification and contribute to hypoxia ([Wetz and Yoskowitz, 2013](#)). Increased thermal stratification will worsen hypoxia where it already occurs and may facilitate its formation at other locations ([Rabalais et al., 2010](#)).

The “benthic filter” is a term given to the benthic microbe and algal communities that remove N via uptake and denitrification and bury N from shallow estuarine and coastal waters. Nitrogen removal via the benthic filter is an important mediator of nutrient enrichment in shallow estuaries along the Atlantic and Gulf coasts of the U.S. where this feature is common ([Anderson et al., 2014b](#)). The filtering function of this top layer of sediment is affected by nutrient delivery as well as light availability, temperature, and resuspension caused by wind and storms. Thus, the benthic filter and the N removal services it provides are expected to be highly susceptible to climate change impacts ([Anderson et al., 2014b](#)).

---

## 7.2.7 Monitoring Data

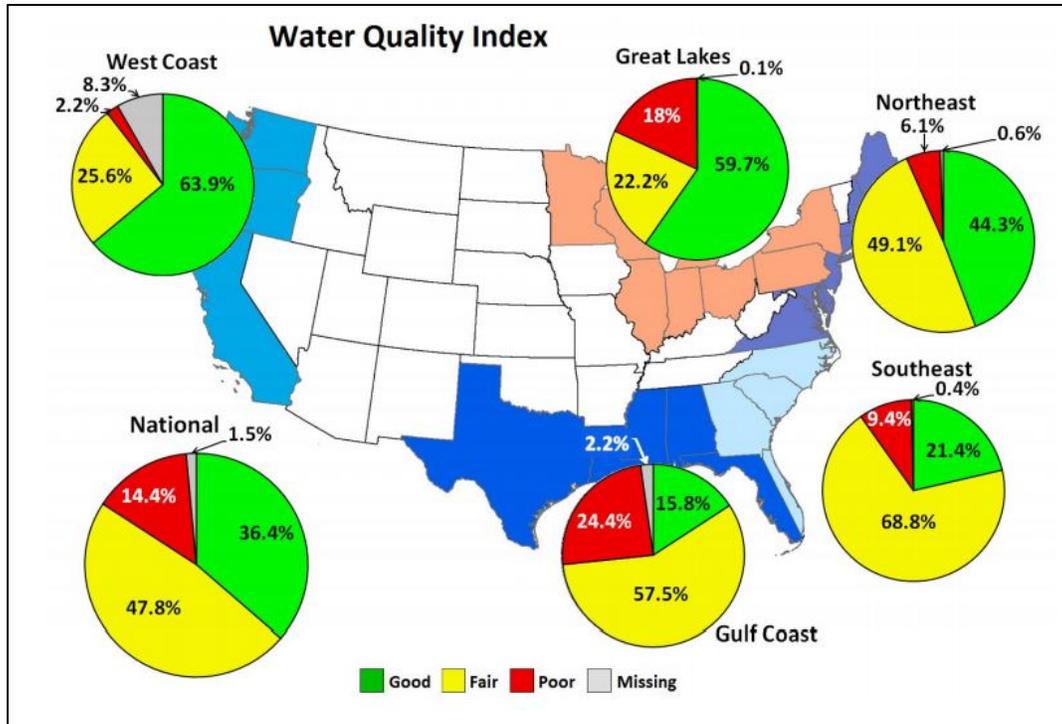

Monitoring data provide temporal trends of biogeochemical processes and indicators associated with eutrophication and coastal acidification in estuaries and coastal ecosystems. These data document and quantify changes that occur in response to environmental stressors, including N deposition. Many monitoring studies for eutrophication have been ongoing for one or two decades, in some cases longer. Monitoring for coastal acidification is more recent. Analysis of historical data suggest that some coastal areas have been experiencing long-term acidification.

---

### 7.2.7.1 Eutrophication

Since the 2008 ISA, nearly a decade's worth of additional data have been added to some of the monitoring programs described below. The availability of these additional data facilitates trend detection now, compared to 2008. The U.S. EPA Estuary Data Mapper tool accessed at <https://www.epa.gov/hesc/about-estuary-data-mapper-edm> allows users to retrieve and visualize estuary data from several federal agencies to access water and sediment quality, freshwater discharge, tides, N deposition, and other parameters.

The NARS include a survey of coastal waters called the National Coastal Condition Assessment (NCCA). U.S. EPA, together with the states, tribes, other entities, and individuals, have collaborated on these statistically representative surveys since the early 2000s. The NCCA survey uses standardized field protocols and indicators of coastal condition including N, water clarity, chlorophyll *a*, and DO concentrations. The NCCA 2010 used a consistent set of data from three periods (1999–2001, 2005–2006, and 2010) to evaluate change in coastal conditions over time (U.S. EPA, 2016g). This analysis included only the Northeast, Southeast, Gulf, and West Coast regions. (The change analysis does not include the Great Lakes because they were not part of this survey until 2010.) The change analysis showed that scores on the water quality index remained relatively similar between 2005–2006 and 2010, after a significant decrease in the percentage of area rated good from 1999–2000 to 2005–2006. The Gulf Coast had the greatest proportion of waters (24.4%) rated poor for water quality compared to the other regions surveyed for the NCCA in 2010 (Figure 7-10). The NCCA report noted that these findings support the need for continued attention to coastal stressors at national, regional, state, and watershed scales to identify and mitigate challenges where they exist and protect areas that are still in good condition (U.S. EPA, 2016g).

Source: [U.S. EPA \(2016g\)](#).

**Figure 7-10 Percentage of area in each coastal region scoring good, fair, and poor based on the Water Quality Index for the NCCA 2010.**

Additional long-term monitoring surveys conducted with help from the U.S. EPA include those undertaken by individual National Estuary Programs (NEP) around the U.S. The NEP is a nonregulatory program designed to protect and restore the water quality and ecological integrity of estuaries of national significance, of which there are currently 28. The NEPs develop and implement long-term management plans that contain actions to address water quality priorities, which are defined by local, city, state, federal, private, and nonprofit stakeholders. In many cases these priorities include reducing and mitigating the occurrence of eutrophic conditions in large estuaries, goals often accompanied by long-term monitoring of nutrients and eutrophication indicators. For instance, the Tampa Bay Estuary Program works with the Southwest Florida Water Management District's Surface Water Improvement and Management Program to collect monitoring data on trends in seagrass coverage, which is greatly affected by water clarity [often an indicator of excessive N loads to the bay; [Sherwood \(2017\)](#)]. The most recent analysis of monitoring data showed that Tampa Bay's seagrass area continues to recover, with the addition of 1,360 acres of seagrass coverage reported from 2014 to 2016. Tampa Bay's total seagrass coverage is now estimated to be 41,655 acres as of 2016, which now

exceeds the total estimated seagrass coverage in the 1950s period (40,420 acres) for the first time since monitoring began ([Sherwood, 2017](#)). See the Tampa Bay Case Study ([Appendix 16](#)) for additional information on this coastal system.

The NEP's Long Island Sound Study has conducted two decades of monitoring to identify N sources and track water quality conditions and eutrophic indicators over time. The Long Island Sound Study uses several indicators, including the NCCA's Water Quality Index, to evaluate changes from year to year. Data from 1991–2011 show a gradient in improving water quality from the eastern part of the sound, where population and anthropogenic stressors are lower and water quality was most often rated “good,” to the western side where population and development pressure are both higher and water quality was consistently rated “fair” ([LISS, 2017](#)).

The Chesapeake Bay Monitoring Program established in 1984 is a regional partnership that monitors 19 physical, chemical, and biological characteristics, including nutrients and DO, enabling the study of the bay and long-term trends ([Testa et al., 2017](#)). The original Chesapeake Bay Program agreement of 1983 included Maryland, Virginia, Pennsylvania, Washington, D.C., the U.S. EPA, and regional partners. In 2014, the Chesapeake Watershed Agreement was signed to include representatives from the entire watershed and accelerate restoration of the bay.

The NPS also conducts estuarine water quality monitoring to monitor “Park Vital Signs,” which are elements and processes of park ecosystems that can serve as indicators of the overall health of the park. The Estuarine Nutrient Enrichment Monitoring (ENEM) program monitors nitrogen loading inputs as well as overall water quality and seagrass distribution in park estuaries within the Northeast Coastal and Barrier Network (NCBN) region (covering Massachusetts to Virginia) of the NPS. In this region, the Park Vital Signs are all related to nutrient enrichment, which is considered the stressor with the ability to cause the greatest potential impacts on park health ([USGS US Department of the Interior, 2015](#)). Water quality indicators are defined with the same criteria as U.S. EPA's NCCA methods, and data are available on the program's website for each park in the NCBN region of the NPS at <https://www.nps.gov/im/ncbn/what-we-monitor.htm>.

The National Oceanic and Atmospheric Administration (NOAA) conducts several monitoring programs in estuaries and coastal waters. The National Estuarine Research Reserves System (NERRS) is a federal-state partnership network of 29 coastal sites encompassing 1.3 million acres designated to protect and study estuarine systems. Estuarine water quality monitoring data are collected by the NERRS System-Wide Monitoring Program (SWMP), which identifies and tracks short-term variability and long-term changes in estuarine ecosystems and coastal watersheds. Data are housed in a central online database available at <http://cdmo.baruch.sc.edu/>.

Many NERRS sites work with other groups to analyze and report their overall findings about water quality indicators. In the Great Bay estuary in New Hampshire and Maine, NERR's SWMP collects nitrogen, DO, and temperature data, which is used by the Piscataqua Region Estuaries Partnership (a NEP site) to assess the environmental status and trends in the Bay. The most recent State of the Estuaries report found that total N load to the estuary in 2009–2011 was 1,225 tons per year, which appeared to be strongly influenced by rainfall amounts ([PREP, 2013](#)).

NOAA's Gulf of Mexico Ecosystems and Hypoxia Assessment (NGOMEX) is a large study focusing on a single geographic region in the Gulf of Mexico. NGOMEX has been collecting data and conducting research for more than 30 years to investigate the spatial and temporal dynamics of the hypoxia zone in the Gulf of Mexico, especially with regards to the link between the hypoxia zone size and the amount of nutrient loading, primarily from the Mississippi River watershed ([Appendix 10.2.4](#)). In 2017, work funded by NGOMEX measured the largest Gulf of Mexico hypoxia zone since mapping of the area began in 1985 ([U.S. EPA, 2017f](#)). The size of the 2017 hypoxia zone was accurately forecasted by Mississippi River spring discharge levels and nutrient data, gathered by the USGS and analyzed with NOAA-sponsored models, and clearly indicates that nutrient pollution from the Mississippi River watershed is affecting the health of the coastal Gulf ecosystem.

NOAA also conducts the Monitoring and Event Response for Harmful Algal Blooms (MERHAB) program which helps identify when beaches, shellfisheries, and marine animals are at risk from harmful algae and cyanobacteria. It allows local stakeholders to react as quickly as possible to any human health risk. MERHAB largely funds research projects, but also aims to help routine water quality and shellfish monitoring studies upgrade to better HAB detection methods and technologies. NOAA's Center for Operational Oceanographic Products and Services (CO-OPS) produces HAB forecasts for the Gulf of Mexico to help communities plan for and mitigate the effects of potentially harmful algal blooms. Data for these forecasts come from many sources. The National Aeronautics and Space Administration (NASA) Moderate Resolution Imaging Spectroradiometer (MODIS) satellite collects ocean color data which are processed by NOAA CoastWatch ([NOAA, 2017a](#)). The satellite sensors measure visible light at specific wavelengths to determine the color of the ocean. These color data can be used to estimate chlorophyll concentrations; however, in coastal areas, interpretation can be complicated by the presence of other biota, compounds, and minerals ([NOAA, 2017b](#)). The HAB forecasts prepared by CO-OPS also integrate other data about factors that may affect algal and cyanobacterial bloom formation and intensity such as water temperature, ocean currents, and weather conditions ([NOAA, 2017b](#)). The forecasts also note cell counts of the toxic dinoflagellate *Karenia brevis* (commonly called a "red tide" species)

taken from specific locations along the coast. Another NOAA product called the Harmful Algal Bloom Observing System (HABSOS) integrates these data sources, including cell counts and other environmental information into an interactive mapping application available online at <https://habsos.noaa.gov/> (NOAA, 2017c). HABSOS can map recent satellite data and cell counts to depict areas that may be at risk of HABs in the near future. Trends in HABs and responses to N are discussed further in [Appendix 10.2.2](#) and [Appendix 10.3.3](#).

---

### 7.2.7.2 Coastal Acidification

Coastal acidification monitoring programs are developing around the world. In the U.S., ocean acidification has been documented from the New England region, California, Oregon, Washington, and the northern Gulf of Mexico (Laurent et al., 2017; Gledhill et al., 2015; Gruber et al., 2012; Hauri et al., 2009; Feely et al., 2008; Yang, 1998). In a series of sampling cruises and analysis of water sampling data, Wallace et al. (2014) identified concurrent low pH conditions and declining DO in four Northeast estuaries (Long Island Sound, NY; Jamaica Bay, NY; Narragansett Bay, RI; Hempstead Bay, NY). Observed conditions in eutrophic estuaries during late summer were such that marine biota, especially calcifying organisms, may be affected (Appendix 10.5). Analysis of historical (from the late 1960s to 2010) alkalinity and pH data from bays along the northwestern coast of Texas indicated that 16 of 27 systems showed long-term decreases in alkalinity and 22 systems showed decreased pH (Hu et al., 2015a). Cai et al. (2017b) showed that redox reactions and weak buffering capacity are leading to the acidification of Chesapeake Bay. A recent study by Baumann and Smith (2018) of long-term databases of pH and trophic state on numerous EPA-NEP and NOAA-National Estuarine Research Reserve System estuarine sites show no clear relationship between trophic state and acidification including for Chesapeake Bay; however, they did not evaluate within bay spatial patterns.

---

### 7.2.8 Modeling Estuaries and Near-Coastal Areas

Since the 2008 ISA, several new applications of existing models have quantified eutrophication processes in estuaries and near-coastal marine ecosystems. These have included studies that focused primarily on N cycling or hypoxia.

---

### 7.2.8.1 Models

There are several models that track the sources and movement of N through the landscape and stream network to estuary and near-coastal marine ecosystems. These models vary in scope, level of spatial and temporal resolution, forms of N considered, complexity, and empirical versus deterministic construction ([Alexander et al., 2008](#)). They can be structured as statistical models ([Howarth et al., 2012](#); [Peierls et al., 1991](#)), empirical models ([Caraco and Cole, 1999](#)), export coefficient models ([Johnes, 1996](#)), deterministic models such as SWAT ([Gassman et al., 2007](#); [Nietsch et al., 2002](#)), Generalized Watershed Loading Function [GWLF; [Haith and Shoenaker \(1987\)](#)], and hybrid approaches (SPARROW, NEWS). The principal ecosystem models applied to U.S. waters to assess N enrichment were reviewed in the 2008 ISA and are briefly summarized here ([U.S. EPA, 2008a](#)).

Some of these models have been applied at national or large regional scales to examine N loading to rivers and the coastal zone. SPARROW is a hybrid statistical-mechanistic model that can attribute pollutant sources and contaminant transport to surface waters ([Smith et al., 1997](#)). SWAT is a mechanistic model developed by the U.S. Department of Agriculture, Agricultural Research Service ([Gassman et al., 2007](#); [Nietsch et al., 2002](#)). WATERS-N is a mass balance model that has been used to evaluate N inputs to estuaries ([Castro et al., 2003](#); [Castro et al., 2001](#)).

Since the 2008 ISA, there have been new applications of SPARROW and SWAT, as well as development and application of new models and approaches such as NEWS, Net Anthropogenic Nitrogen Inputs (NANI), and the Dynamic Land Ecosystem Model [DLEM; [Tian et al. \(2012\)](#)]. SPARROW has been used to estimate total N loads within watersheds to estimate sources of N to streams and rivers. It has also been applied at regional and national scales ([Schwarz et al., 2011](#); [Alexander et al., 2008](#)). SPARROW operates on an annual time step, usually integrating several decades of data to develop load relationships and then simulating conditions for 1 year. NEWS is a similar hybrid model. It has been used to estimate the magnitudes and sources of different forms of N (particulate, dissolved inorganic, and organic) to coastal waters ([Glibert et al., 2010a](#)). Recent work with NEWS included a global, seasonal version ([McCrackin et al., 2014](#)). It has been used for scenario comparisons, including predictions about reductions in air deposition resulting from Clean Air Act regulations and other policy actions ([McCrackin et al., 2015](#)). NANI is a simple mass balance model for calculating net anthropogenic nitrogen inputs that takes information about inputs and outputs of nitrogen within a basin and estimates the riverine flux from the landscape to the ocean ([Howarth et al., 2012](#)). It was developed for watersheds across the contiguous U.S. at the county level ([Hong et al., 2013, 2011](#)). Using NANI, [Howarth et al. \(2012\)](#) demonstrated larger N fluxes (larger

percentage delivery of human N inputs) in wetter climates with more discharge, across 154 different watersheds in the U.S. and Europe. The NANI Calculator Toolbox takes into consideration fertilizer N application, agricultural N fixation, net food and feed imports, and atmospheric sources of N. The DLEM is a process-based ecosystem model that couples major biogeochemical cycles, water cycle, and land use and land cover change to make spatially explicit estimates of water, carbon, and N fluxes. and has the advantage of being able to simulate temporal variability of N loads ([Tian et al., 2012](#)).

Deterministic models of N flux are based on mechanistic relationships that simulate N transformations, transport, and removal, often at relatively fine temporal and spatial resolution. SWAT has been recently applied at the regional scale of the Mississippi River basin ([Santhi et al., 2014](#)). It allows examination of the effects of changes in cropland management on delivery of N to coastal waters. Recent SWAT publications do not explicitly include atmospheric deposition as a source of N, but have produced similar overall results as SPARROW and NEWS in terms of load and attribution to agriculture in the Mississippi River basin [ $\approx 54\text{--}61\%$ ; [McCrackin et al. \(2013\)](#); [White et al. \(2014\)](#)].

The watershed models described above route N from the landscape to estuaries and the coastal zone, but generally do not model the contribution of N directly to the estuary surface from the atmosphere. These models also deal with the freshwater components of watersheds and do not predict N fate within estuaries or N effects on estuarine processes or functions. The following sections describe new applications of several models that operate within estuaries.

Additional models and tools that have been applied to assess atmospheric contributions of N to U.S. estuaries since the 2008 ISA included the watershed N Loading Model [NLM; [Latimer and Charpentier \(2010\)](#)] and the Watershed Deposition Tool [WDT; [Poor et al. \(2013b\)](#)]. The latter was developed by the U.S. EPA to map atmospheric deposition estimates to watersheds using wet and dry deposition data from the Community Multiscale Air Quality Model [CMAQ; [Schwede et al. \(2009\)](#)]. This tool links air and water quality modeling data for use in TMDL determinations and analysis of nonpoint-source impacts. The NLM has been used for New England estuaries to estimate total N loading and the relative contributions of the various N sources ([Table 7-9](#)) and develop load response relationships among N inputs and seagrass extent ([Latimer and Rego, 2010](#)).

---

### **7.2.8.2 Predicted Response to Nitrogen Loading**

Many of the models that estimate N loads to the coastal zone from the landscape and freshwater inflow have been compared, and there is a good deal of knowledge about their

limitations and uncertainties ([McCrackin et al., 2013](#); [Alexander et al., 2008](#)). In a 2000 National Research Council review, it was determined that these models are hydrodynamically complex and tend to be specific to particular sites. Thus, they are difficult to apply broadly ([NRC, 2000](#)).

The range of coastal ecosystem responses to changing N loads reflect changes in DO, productivity, SAV cover, and impacts on other organisms. Water residence time can influence the response of estuaries to nutrient loading because of the effects of flushing on nutrients, water temperature, plankton, and light penetration. Capturing these dynamics in a model is challenging ([Swaney et al., 2008](#)).

A recent review of hypoxia modeling described trade-offs between details of complex models and the need for simpler, more broadly applicable models ([Peña et al., 2010](#)). [Greene et al. \(2009\)](#) developed a set of multiple regression models to simulate relationships between river loads and concentrations of N and P compared with the extent of hypoxic bottom water. A Bayesian approach was used in combination with a model of hypoxia to project the O<sub>2</sub> demand and extent of hypoxia ([Liu et al., 2010](#)). Estuarine models have been important to policy decision making and formulation of nutrient reduction goals ([Scavia et al., 2006](#); [Scavia et al., 2004](#)). There is an increased interest in developing coupled models that connect physical-chemical-biological nutrient loading and fate models ([Fennel et al., 2011](#)) and that connect chemical eutrophication models to fisheries response models ([Cercio et al., 2010](#)).

The responses of estuaries to N loading is partly determined by environmental characteristics. Nutrient-phytoplankton-zooplankton (NPZ) models examine biological responses including the effects of nutrient limitation and zooplankton predation on phytoplankton dynamics and fish production. The NPZ model described by [Swaney et al. \(2008\)](#) can assess complex responses of estuaries to different climate variables, land use, atmospheric loading, and other stressors ([Appendix 10.3.8](#)).

New studies have focused on increasing understanding of spatial variation in DIN export from the watershed to coastal zones. Seasonal patterns of DIN export influence impacts of coastal eutrophication, including HABs and the development of seasonal hypoxic zones. [McCrackin et al. \(2014\)](#) predicted seasonal DIN export to coastal regions, using the NEWS2 model calibrated to measured DIN yield in 77 rivers distributed globally. The DIN transport efficiency was positively correlated with runoff and negatively correlated with temperature. [McCrackin et al. \(2014\)](#) concluded that because of landscape N attenuation, a better representation of land-to-river N transfers, in particular, might improve models of nutrient cycling.

[Eldridge and Morse \(2008\)](#) developed a combined water-column and sediment model to investigate sediment and water-column metabolism and their impacts on development of hypoxia on the Louisiana shelf. They found that sediment O<sub>2</sub> demand was the primary sink for O<sub>2</sub> at the beginning and end of a hypoxic event. Once hypoxia has developed, however, sediments became isolated from O<sub>2</sub> rich upper waters.

Key drivers of hypoxia in coastal waters include nutrient loading, mainly from anthropogenic sources, C supply, and processes that contribute to thermal stratification. Complex hypoxia models are difficult to validate, however, and this limits the confidence that can be placed on simulation results. [Eldridge and Roelke \(2011\)](#) recommended the use of multiple models and identification of similarities in qualitative model behavior. They provided a brief overview of recent hypoxia models and identified the need for a meta-analysis of simulations produced by these models in search of qualitative similarities. They concluded that more complex models of hypoxia need to be developed that include three-dimensional hydrology. [Sturdivant et al. \(2013\)](#) developed a model of hypoxia impact on macrobenthic production in the lower Rappahannock River, a tributary of the Chesapeake Bay that experiences seasonal hypoxia. Simulation results suggested that macrobenthic biomass was strongly linked with dissolved O<sub>2</sub> concentration. Biomass fluctuations reflected the duration and severity of hypoxia. Results suggested that hypoxia had a negative effect on biomass, with longer duration and greater severity resulting in increased loss of biomass.

[Glibert et al. \(2010a\)](#) reviewed modeling approaches to improve understanding of HABs and their relationship with nutrient inputs. They recommended that predictive capabilities will likely improve if a suite of modeling approaches is used. This might include site-specific loading models of nutrient sources and models that couple nutrient discharge to biological responses.

[Dale et al. \(2011\)](#) investigated biogeochemical processes that affect N cycling in the sediment of Eckernförde Bay in the southwestern portion of the Baltic Sea, where severe bottom water hypoxia (and sometimes anoxia) commonly occurs during late summer. Sediments acted as net sinks for NO<sub>3</sub><sup>-</sup>, of which three-fourths was characterized as derived from reduction of NO<sub>3</sub><sup>-</sup> to NH<sub>4</sub><sup>+</sup>. The other 25% was characterized as derived from denitrification of NO<sub>3</sub><sup>-</sup> to NO<sub>2</sub><sup>-</sup>. The NH<sub>4</sub><sup>+</sup> flux was high (1.74 mmol/m<sup>2</sup>/day), in response to degradation of organic N at the sediment interface and was directed out of the sediment.

---

## 7.2.9 National-Scale Sensitivity

Characteristics of coastal systems sensitive to eutrophication are described in [Appendix 10.1.4](#). In the 2008 ISA and the National Estuarine Eutrophication Assessment (NEEA), a comprehensive survey of eutrophic conditions in the Nation's estuaries conducted by the National Oceanic and Atmospheric Administration (NOAA), the most eutrophic estuaries in the U.S. occurred in the mid-Atlantic region, and the estuaries with the lowest degree of eutrophication were in the North Atlantic [[Figure 10-2](#); [Bricker et al. \(2007\)](#)]. Areas of eutrophication-related hypoxia are found on the U.S. East and West coasts and the Gulf of Mexico ([Figure 10-5](#)). During the summer of 2017 the extent of hypoxia in the Gulf of Mexico was the largest ever recorded in the U.S. ([U.S. EPA, 2017f](#)). The most recent NCCA report, based on 2010 data and released by U.S. EPA in 2016, analyzed survey data from 1,104 sites, representing 35,400 square miles of U.S. coastal waters ([U.S. EPA, 2016g](#)). In this most recent NCCA report, water quality was rated good in 36% of coastal and Great Lakes nearshore waters, fair in 48%, and poor in 14%, based on measures of the eutrophication parameters that make up the water quality index (P, N, water clarity, chlorophyll *a*, and DO concentrations; [Figure 7-10](#)).

In the U.S., Chesapeake Bay is perhaps the best-documented case study of the effects of human activities on estuarine eutrophication. Other impacted estuaries identified in the 2008 ISA included Long Island Sound, the Pamlico Estuary in North Carolina, and along the continental shelf adjacent to the Mississippi and the Atchafalaya River discharges to the Gulf of Mexico ([U.S. EPA, 2008a](#)). In many parts of the U.S., especially the Southeast, Midwest, and Mid-Atlantic deposition of reduced N has increased relative to oxidized N in last few decades ([Appendix 2](#) and [Appendix 10.1.2](#)). Since the 2008 ISA, additional evidence has shown that reduced forms of atmospheric N play an increasingly important role in estuarine and coastal eutrophication ([Appendix 10.3.3](#)). The form of N delivered to some coastal areas of the U.S. is shifting from primarily  $\text{NO}_3^-$  to an increase in reduced forms of N.

Coastal acidification was not discussed in the 2008 ISA yet acidification trends reported in some locations has resulted in recent research and monitoring efforts in the U.S. ([Appendix 7.2.7.2](#)). Ocean acidification has been documented from the Gulf of Maine, California, Oregon, Washington, and the northern Gulf of Mexico ([Laurent et al., 2017](#); [Gledhill et al., 2015](#); [Gruber et al., 2012](#); [Hauri et al., 2009](#); [Feely et al., 2008](#); [Salisbury et al., 2008](#); [Yang, 1998](#)) while other long-term monitoring efforts, such as in Chesapeake Bay, have shown no trend of trophic state with pH ([Baumann and Smith, 2018](#)).

Unlike freshwaters where chemical recovery linked to decreased atmospheric deposition of N and S is observed in some systems ([Appendix 7.1.5.1](#)), N inputs from atmospheric and other sources contribute to the continued water quality degradation in U.S. coastal

waters. There are only a few cases of documented recovery of biological indicators in U.S. estuaries such as SAV in Tampa Bay ([Appendix 16](#)) and Chesapeake Bay ([Figure 10-6](#)).

---

## 7.2.10 Water Quality Criteria for Estuaries

As discussed for fresh water in [Appendix 7.1.6](#), the U.S. EPA develops WQC using the latest scientific knowledge to determine when water is unsafe for people and wildlife. State and tribal governments may adopt these criteria or use them as guidance in developing their own. Numeric nutrient criteria are critical tools for protecting and restoring a water body's designated uses related to N and P nutrient pollution. These criteria enable effective monitoring of a water body for attaining its designated uses, facilitate formulation of the National Pollutant Discharge Elimination System (NPDES) discharge permits, and simplify development of TMDLs for restoring impaired waters.

Generally, it has been considered more complicated to determine appropriate nutrient criteria for estuaries than for many freshwater systems because estuaries are influenced by so many variable factors such as tidal fluctuations, salinity gradients, and other widely varying physical and chemical conditions which impact water quality. The designation of water bodies within which similar ambient conditions are expected to occur is much more difficult in estuaries, as the ambient values often fluctuate widely under natural conditions within the same estuary. Nevertheless, several states have made progress in the development of numeric nutrient criteria for estuaries. One of the first states to implement its own criteria for estuaries, Florida designated 62 different estuary segments and adopted a TN target value for each segment based on extensive monitoring and modeling studies.

The U.S. EPA is continuing to work with the states to develop numeric nutrient criteria to better define levels of N that affect U.S. marine and estuarine waters. WQC for TN are now available statewide in American Samoa, Florida, Hawaii, and the Northern Marianas Islands ([Figure 7-11](#)). Guam has statewide criteria for  $\text{NO}_3^-$  as N, and Puerto Rico has statewide criteria for DIN. Delaware has criteria for DIN as N in some estuaries. Massachusetts has not developed N criteria for estuaries but there is a TMDL in place that limits N loading to select estuaries on Cape Cod, Martha's Vineyard, Nantucket, and the Buzzards Bay/South Coastal area. California has made progress toward numeric nutrient criteria. Currently, the state has numeric criteria for water clarity in all estuaries statewide, but specific N criteria currently exist only for one location based on a TMDL for nutrient compounds (including N) for the Malibu Creek watershed, which includes the estuarine waters of Malibu Lagoon. By 2020, the following additional states are

---

## 7.2.11 Estuary and Near-Coastal Biogeochemistry Summary
