Table of Contents

List of Tables	i
List of Figures	iii
Abbreviations and Acronyms	v
Annex 1. Framework for Review	1-1
AX1.1. Literature Selection and Retrieval	1-1
AX1.1.1. General Criteria for Study Selection	1-3
AX1.1.2. Criteria for Selecting Epidemiology Studies	1-3
AX1.1.3. Criteria for Selecting Toxicology Studies	1-4
AX1.2. Guidelines for the Determination of Causality	1-4
AX1.2.1. Surgeon General's Report: The Health Consequences of Smoking	1-4
AX1.2.2. The EPA Guidelines for Carcinogen Risk Assessment	1-6
AX1.2.3. Improving Presumptive Disability Decision-Making Process for Veterans	1-9
AX1.2.4. Formulation of Scientific Findings for Policy Purposes	1-13
AX1.2.5. IARC Cancer Guidelines for Scientific Review and Evaluation	1-14
AX1.2.6. National Toxicology Program Criteria	1-21
Annex 2. Atmospheric Chemistry of NO_x	2-1
AX2.1. Introduction	2-1
AX2.2. Chemistry of NO _x in the Troposphere	2-2
AX2.2.1. Basic Chemistry	2-2
AX2.2.2. NO _x Concentrations and O ₃ Formation	2-6
AX2.2.3. Multiphase Chemistry Involving NO _x	2-8
AX2.2.4. Formation of Nitro-PAHs	2-10
AX2.2.5. Multiphase Chemical Processes Involving NO _x and Halogens	2-13
AX2.3. Transport of NO _x in the Atmosphere	2-16
AX2.3.1. Convective Transport	2-16
AX2.3.2. Observations of the Effects of Convective Transport	2-16
AX2.3.3. Effects on Photolysis Rates and Wet Scavenging	2-17
AX2.4. Sources and Emissions of NO _x	2-18
AX2.4.1. Interactions of NO _x with the Biosphere	2-18
AX2.4.1.1. NO ₂ and HNO ₃ Flux Data from Harvard Forest	2-21
AX2.4.2. Emissions of NO _x	2-27
AX2.4.2.1. Emissions of NO ₂ from Motor Vehicles	2-27
AX2.4.2.2. NO _x Emissions from Natural Sources	2-29
AX2.4.2.3. Uses of Satellite Data to Derive Emissions	2-30
AX2.4.2.4. Field Studies Evaluating Emissions Inventories	2-31
AX2.5. Methods for Calculating NO _x Concentrations in the Atmosphere	2-32
AX2.5.1. Chemistry-Transport Models	2-32
AX2.5.1.1. Regional Scale Chemistry Transport Models	2-33
AX2.5.1.2. Intra-urban Scale Dispersion Modeling	2-37
AX2.5.1.3. Global Scale CTMs	2-37
AX2.5.1.4. Modeling the Effects of Convection	2-39
AX2.5.2. CTM Evaluation	2-40
AX2.6. Sampling and Analysis of NO _x	2-49
AX2.6.1. Availability and Accuracy of Ambient NO _y Measurements	2-49
AX2.6.1.1. Measurement of NO	2-49
AX2.6.1.2. Measurements of NO ₂	2-50
AX2.6.1.3. Monitoring for NO ₂ Compliance Versus Monitoring for O ₃ Formation	2-52
AX2.6.2. Summary of Methods for Measuring NO ₂	2-52
AX2.6.3. Measurements of HNO ₃	2-52
AX2.6.4. Techniques for Measuring Other NO _y Species	2-54
AX2.6.5. Remote Sensing of Tropospheric NO ₂ Columns for Surface NO _x Emissions and Surface NO ₂ Concentrations	2-54
AX2.7. Policy-relevant Background NO _x Concentrations	2-57
AX2.7.1. Analysis of PRB Contribution to U.S. NO _x Concentrations and Deposition	2-57

Annex 3. Ambient Concentrations and Exposures	3-66
AX3.1. Introduction	3-66
AX3.1.1. Characterizing Ambient NO ₂ Concentrations	3-66
AX3.1.2. Relationship to the 1993 AQCD for NO _x	3-66
AX3.2. Ambient Concentrations of NO _x	3-66
AX3.2.1. Temporal Variability in Ambient NO _x Concentrations in Urban Areas	3-67
AX3.2.1.1. Diurnal Variability in NO ₂ Concentrations	3-67
AX3.2.1.2. Seasonal Variability in NO ₂ Concentrations	3-67
AX3.2.1.3. Urban Sites	3-67
AX3.2.1.4. Regional Background Sites	3-68
AX3.2.2. Relationships between NO ₂ and Other Pollutants	3-76
AX3.2.3. Abundance of NO _y Species	3-78
AX3.2.3.1. PANs	3-78
AX3.2.3.2. HONO	3-81
AX3.2.3.3. HNO ₃ and NO ₃	3-81
AX3.2.3.4. Nitro-PAHs	3-83
AX3.3. Measuring Personal and Indoor NO ₂ Concentrations	3-84
AX3.3.1. Issues in Measuring Personal/Indoor NO ₂	3-84
AX3.3.1.1. Active (Pumped) Sampling	3-85
AX3.3.1.2. Passive (Diffusive) Sampling	3-85
AX3.3.1.3. Tube Type Samplers	3-87
AX3.3.1.4. Badge-Types Samplers	3-88
AX3.3.1.5. Radial Sampler Types	3-88
AX3.4. NO _x in Indoor Air	3-89
AX3.4.1. Indoor Sources and Concentrations of NO _x	3-89
AX3.4.1.1. Gas Cooking Appliances	3-89
AX3.4.1.2. Other Combustion Sources	3-90
AX3.4.1.3. Other Indoor Environments	3-92
AX3.4.2. Reactions of NO ₂ in Indoor Air	3-92
AX3.5. Personal Exposure	3-96
AX3.5.1. Personal Exposure in the Residential Indoor Environment	3-96
AX3.5.1.1. School and Office	3-99
AX3.5.1.2. Exposure Reconstruction	3-100
AX3.5.2. Factors Affecting Exposure	3-100
AX3.5.3. Associations between HONO and NO ₂	3-101
AX3.6. Modeling Human Exposures to NO ₂	3-102
AX3.6.1. Exposure Models	3-102
AX3.6.1.1. Population Exposure Models	3-106
AX3.6.1.2. Ambient Concentrations of NO ₂ and Related Air Pollutants	3-108
AX3.6.1.3. Characterization of Microenvironmental Concentrations	3-109
AX3.6.1.4. Characterization of Outdoor Microenvironments Concentrations	3-110
AX3.6.1.5. Characterization of Indoor Microenvironments	3-111
AX3.6.1.6. Characterization of Activity Events	3-113
AX3.6.1.7. Characterization of Inhalation Intake and Uptake	3-113
AX3.6.1.8. Issues to be Addressed in Future Exposure Modeling Efforts	3-114
Annex 4. Toxicological Effects of NO_x	4-1
AX4.1. Pulmonary Effects of NO _x	4-1
AX4.1.1. Effects of NO ₂ on Oxidant and Antioxidant Metabolism	4-1
AX4.1.2. Lipid Metabolism and Content of the Lung	4-2
AX4.1.3. Lung Host Defense, Lung Permeability and Inflammation, Immune Responses, and Infectious Agents	4-3
AX4.1.4. Emphysema Following NO ₂ Exposure	4-3
AX4.1.5. Lung Function	4-4
AX4.1.6. Nitrates (NO ₃)	4-4
AX4.2. Dosimetry of Inhaled NO _x	4-4
AX4.2.1. Mechanisms of NO ₂ Absorption	4-5
AX4.2.2. Regional and Total Respiratory Absorption of NO ₂	4-6
AX4.2.2.1. Dosimetry Models	4-7
AX4.3. Experimental Studies of NO ₂ Uptake	4-8
AX4.3.1. Upper Respiratory Tract Absorption	4-8
AX4.3.2. Lower Respiratory Tract Absorption	4-9
AX4.3.3. Total Respiratory Tract Absorption	4-9

AX4.4. Metabolism, Distribution and Elimination of NO ₂	4-9
AX4.5. Extra-Pulmonary Effects of NO ₂ and NO	4-10
AX4.5.1. Body Weight, Hepatic, Renal, and Miscellaneous Effects	4-10
AX4.5.2. Brain Effects	4-11
AX4.5.3. NO	4-11
AX4.5.4. Effects of Mixtures Containing NO ₂	4-11
AX4.5.5. Simple Mixtures Containing NO ₂	4-12
AX4.5.6. Complex Mixtures Containing NO ₂	4-12
Annex 5. Clinical Studies: Exposure to NO_x	5-1
AX5.1. Introduction	5-1
AX5.1.1. Considerations in Controlled Human Clinical Studies	5-2
AX5.2. Effects of NO ₂ in Healthy Subjects	5-2
AX5.3. Effects of NO _x Exposure in Sensitive Subjects	5-3
AX5.4. Effects of Mixtures Containing NO _x	5-3
Annex 6. Epidemiologic Studies Related to Ambient Exposure to NO_x	6-2
AX6.1. Interpretation of Epidemiologic Studies	6-2
AX6.1.1. Exposure Assessment and Measurement Error	6-2
AX6.1.2. NO ₂ Exposure Indices Used	6-4
AX6.1.3. Lag Time: Period between Exposure and Health Effect	6-4
AX6.1.4. Model Specification for Temporal Trends and Meteorological Effects	6-5
AX6.1.5. Confounding Effects of Copollutants	6-6
AX6.1.6. Generalized Estimating Equations	6-6
AX6.1.7. Hypothesis Testing and Model Selection	6-6
AX6.1.8. Generalized Additive Models	6-7
AX6.2. Cardiovascular Effects Related to Short-Term NO ₂ Exposure	6-8
AX6.2.1. Hospital Admissions and ED Visits: All CVD	6-8
AX6.2.2. Hospital Admissions and ED Visits: Myocardial Infarction (MI)	6-13
AX6.2.3. Hospital Admissions and ED Visits: Arrhythmia and Congestive Heart Failure (CHF)	6-13
AX6.2.4. Hospital Admissions and ED Visits: Cerebrovascular Disease	6-13
AX6.2.4.1. Vaso-Occlusion in Sickle Cell	6-13
AX6.2.5. Hospital Admissions and ED Visits: Multipollutant Modeling Results	6-14
AX6.2.6. Heart Rate Variability	6-16
AX6.2.7. Repolarization Changes	6-17
AX6.2.8. Arrhythmias Recorded on Implantable Cardioverter Defibrillators (ICDs)	6-17
AX6.2.9. Markers of Cardiovascular Disease	6-18
AX6.3. Epidemiologic Studies	6-19

List of Tables

Table AX2.6-1.	Satellite Instruments Used to Retrieve Tropospheric NO ₂ Columns. _____	2-55
Table AX2.4-1.	Emissions of nitrogen oxides and ammonia in the United States in 2002 _____	2-61
Table AX3.2-1.	NO _x and NO _y concentrations at regional background sites in the Eastern United States. Concentrations are given in ppb. _____	3-115
Table AX3.3-1.	Passive samplers used in NO ₂ measurements. _____	3-115
Table AX3.3-2.	The performance of sampler/sampling method for NO ₂ measurements in the air. _____	3-116
Table AX3.4-1.	NO ₂ concentrations (ppb) in homes in Latrobe Valley, Victoria, Australia. _____	3-116
Table AX3.4-2.	NO ₂ concentrations (ppb) in homes in Connecticut. _____	3-117
Table AX3.4-3.	NO ₂ concentrations near indoor sources – short-term averages. _____	3-117
Table 3.5-1a.	Indoor/outdoor ratio and the indoor vs. outdoor regression slope. _____	3-118
Table 3.5-1b.	Summary of regression models of personal exposure to ambient/outdoor NO ₂ . _____	3-120
Table AX3.5-2.	NO ₂ concentrations (ppb) in different rooms. _____	3-122
Table AX3.5-3a.	Average ambient and nonambient contributions to population exposure _____	3-123
Table AX3.5-3b.	Indoor and outdoor contributions to indoor concentrations. _____	3-123
Table AX3.5-4.	The association between indoor, outdoor, and personal NO ₂ . _____	3-124
Table AX3.5-5.	Indoor, outdoor, and personal NO ₂ levels stratified by exposure factors (concentrations are in ppb and slopes are dimensionless) _____	3-127
Table AX3.5-6.	Personal NO ₂ levels stratified by demographic and socioeconomic factors (concentrations are in ppb and slopes are dimensionless). _____	3-133
Table AX3.6-1.	The essential attributes of the pNEM, HAPEM, APEX, SHEDS, and MENTOR-1A. _____	3-134
Table AX4.1.	Oxidant and antioxidant homeostasis. _____	4-13
Table AX4.2.	Lung amino acids, proteins, lipids, and enzymes. _____	4-15
Table AX4.3.	Alveolar macrophages and lung host defense. _____	4-18
Table AX4.4.	Lung permeability and inflammation. _____	4-22
Table AX4.5.	Immune responses. _____	4-25
Table AX4.6.	Infectious agents. _____	4-28
Table AX4.7.	Lung structure. _____	4-31
Table AX4.8.	Pulmonary function. _____	4-34
Table AX4.9.	Hematological parameters. _____	4-34
Table AX4.10.	Iron, enzymes, and nucleic acids. _____	4-35
Table AX4.11.	Genotoxicity in vitro and in plants. _____	4-36
Table AX4.12.	Genotoxicity in vivo. _____	4-37
Table AX4.13.	Genotoxicity. _____	4-37
Table AX5.2-1.	Clinical studies – healthy subjects. _____	5-3
Table AX5.3-1.	Subjects with respiratory disease. _____	5-6
Table AX5.3-2.	Inhaled allergen. _____	5-7
Table AX5.4-1.	NO ₂ and other pollutants. _____	5-8
Table AX6.3-1.	Studies examining exposure to indoor NO ₂ and respiratory symptoms. _____	6-19

Table AX6.3-2.	Studies examining exposure to ambient NO ₂ and acute respiratory symptoms using generalized estimating equations (GEE) in the analysis method _____	6-22
Table AX6.3-3.	Respiratory health effects of oxides of nitrogen: hospital admissions. _____	6-24
Table AX6.3-4.	Respiratory Health Effects of Oxides of Nitrogen: Emergency Department Visits _____	6-56
Table AX6.3-5.	Respiratory Health Effects of Oxides of Nitrogen: General Practitioner/Clinic Visits _____	6-73
Table AX6.3-6.	Human Health Effects of Oxides of Nitrogen: CVD Hospital Admissions and Visits: United States and Canada _____	6-78
Table AX6.3-7.	Human Health Effects of Oxides of Nitrogen: CVD Hospital Admissions and Visits: Australia and New Zealand _____	6-88
Table AX6.3-8.	Human health effects of oxides of nitrogen: cvd hospital admissions and visits: Europe _____	6-92
Table AX6.3-9.	Human health effects of oxides of nitrogen: cvd hospital admissions and visits: Asia _____	6-100
Table AX6.3-10.	Studies examining exposure to ambient NO ₂ and heart rate variability as measured by standard deviation of normal-to-normal intervals (SDNN). _____	6-104
Table AX6.3-11.	Studies examining exposure to ambient NO ₂ and heart rate variability as measured by variables recorded on implantable cardioverter defibrillators (ICDs). _____	6-105
Table AX6.3-12.	Birth weight and long-term NO ₂ exposure studies _____	6-106
Table AX6.3-13.	Preterm delivery and long-term NO ₂ exposure studies _____	6-109
Table AX6.3-14.	Fetal growth and long-term NO ₂ exposure studies _____	6-111
Table AX6.3-15.	Lung function and long-term NO ₂ exposure. _____	6-112
Table AX6.3-16.	Asthma and long-term NO ₂ exposure. _____	6-114
Table AX6.3-17.	Respiratory symptoms and long-term NO ₂ exposure. _____	6-118
Table AX6.3-18.	Lung cancer. _____	6-124
Table AX6.3-19.	Effects of acute NO _x exposure on mortality. Risk estimates are standardized for per 20 ppb 24-h avg NO ₂ increment. _____	6-125

List of Figures

Figure AX1.1-1.	Selection process for studies included in ISA. _____	1-2
Figure AX1.2-1.	Focusing on unmeasured confounders/covariates, or other sources of spurious association from bias. _____	1-11
Figure AX1.2-2.	Example posterior distribution for the determination of <i>Sufficient</i> . _____	1-12
Figure AX1.2-3.	Example posterior distribution for the determination of <i>Equipose and Above</i> . _____	1-12
Figure AX1.2-4.	Example posterior distribution for the determination of <i>Against</i> . _____	1-12
Figure AX2.2-1.	Schematic diagram of the cycle of reactive nitrogen species in the atmosphere. _____	2-2
Figure AX2.2-2.	Measured values of O ₃ and NO _z (NO _y – NO _x). _____	2-8
Figure AX2.2-3.	Structures of same nitro-polycyclic aromatic hydrocarbons. _____	2-10
Figure AX2.2-4.	Formation of 2-nitropyrene (2NP) from the reaction of OH with gaseous pyrene (PY). _____	2-11
Figure AX2.4-1.	Diel cycles of median concentrations (upper panels) and fluxes (lower panels). _____	2-22
Figure AX2.4-2.	Simple NO _x photochemical canopy model outputs. _____	2-23
Figure AX2.4-3.	Hourly (dots) and median nightly (pluses) NO ₂ flux vs. concentration. _____	2-24
Figure AX2.4-4.	Averaged profiles at Harvard Forest. _____	2-25
Figure AX2.4-5.	Summer (June-August) 2000 median concentrations (upper panels), fractions of NO _y (middle panels), and fluxes (lower panels) of NO _y and component species. _____	2-26
Figure AX2.5-1.	Time series for measured gas-phase species in comparison with results from aphotochemical model. _____	2-41
Figure AX2.5-2.	Time series for measured gas-phase species in comparison with results from a photochemical model. _____	2-42
Figure AX2.5-3.	Correlations for O ₃ versus NO _z (NO _y –NO _x) in ppb from chemical transport models for the northeast corridor, Lake Michigan, Nashville, the San Joaquin Valley, and Los Angeles. _____	2-44
Figure AX.2.5-4.	Evaluation of model versus measured O ₃ versus NO _y for two model scenarios for Atlanta. _____	2-45
Figure AX2.5-5.	Evaluation of model versus: (a) measured O ₃ versus NO _z and (b) O ₃ versus the sum 2H ₂ O ₂ + NO _z for Nashville, TN. _____	2-46
Figure AX2.5-6.	Time series of concentrations of RO ₂ , HO ₂ , and OH radicals, local O ₃ photochemical production rate and concentrations of NO _x . _____	2-48
Figure AX2.6-1.	Tropospheric NO ₂ columns (molecules NO ₂ /cm ²) retrieved from the SCIAMACHY satellite instrument for 2004-2005. _____	2-56
Figure AX2.7-1.	Annual mean concentrations of NO ₂ (ppb) in surface air over the United States in the present-day (upper panel) and policy relevant background (middle panel) MOZART-2 simulations. _____	2-58
	The bottom panel shows the percentage contribution of the background to the present-day concentrations. Please see text for details. _____	2-58
Figure AX2.7-2.	Same as for Figure AX2.7-1 but for wet and dry deposition of HNO ₃ , NH ₄ NO ₃ , NO _x , HO ₂ NO ₂ , and organic nitrates (mg N m ² /y). _____	2-59
Figure AX2.7-3.	July mean soil NO emissions (upper panels; 1 H 10 ⁹ molecules cm ⁻² s ⁻¹) and surface PRB NO _x concentrations (lower panels; ppt). _____	2-60
Figure AX3.2-1.	Time series of 24-h avg NO ₂ concentrations at individual sites in New York City from 2003 through 2006. _____	3-69
Figure AX3.2-2.	Time series of 24-h average NO ₂ concentrations at individual sites in Chicago, IL from 2003 through 2005. _____	3-70

Figure AX3.2-3.	Time series of 24-h avg NO ₂ concentrations at individual sites in Baton Rouge, LA from 2003 through 2005.	3-71
Figure AX3.2-4.	Time series of 24-h avg NO ₂ concentrations at individual sites in Houston, TX from 2003 through 2005.	3-72
Figure AX3.2-5.	Time series of 24-h avg NO ₂ concentrations at individual sites in Los Angeles, CA from 2003 through 2005.	3-73
Figure AX3.2-5.	(Continued) Time series of 24-h avg NO ₂ concentrations at individual sites in Los Angeles, CA from 2003 through 2006.	3-74
Figure AX3.2-6.	Time series of 24-h avg NO ₂ concentrations at individual sites in Riverside, CA from 2003 through 2006.	3-75
Figure AX3.2-6.	(Continued) Time series of 24-h avg NO ₂ concentrations at individual sites in Riverside, CA from 2003 through 2006.	3-76
Figure AX3.2-7.	Relationship between O ₃ , NO, and NO ₂ as a function of NO _x concentration.	3-77
Figure AX3.2-8.	Variation of odd oxygen (= O ₃ + NO ₂) with NO _x .	3-78
Figure AX3.2-9.	Measured O ₃ (ppb) versus PAN (ppt) in Tennessee, including (a) aircraft measurements, and (b, c, and d) suburban sites near Nashville.	3-79
Figure AX3.2-10.	Relationship between benzene and NO _γ at a measurement site in Boulder, CO.	3-80
Figure AX3.2-11.	Ratios of PAN to NO ₂ observed at Silwood Park, Ascot, Berkshire, U.K. from July 24 to August 12 1999.	3-82
Figure AX3.2-12.	Ratios of HONO to NO ₂ observed in a street canyon (Marylebone Road) in London, U.K. from 11 a.m. to midnight during October 1999. Data points reflect 15-min avg concentrations of HONO and NO ₂ .	3-82
Figure AX3.2-13.	Concentrations of particulate nitrate measures as part of the EPA's speciation network.	3-84
Figure AX3.6-1.	Schematic description of a general framework identifying the processes (steps or components) involved in assessing inhalation exposures and doses for individuals and populations.	3-104
Figure AX6.2-1.	Relative risks (95% CI) for associations of 24-h NO ₂ (per 20 ppb) and daily 1-h max NO ₂ * with hospitalizations or emergency department visits for all cardiovascular diseases (CVD).	6-9
Figure AX6.2-2.	Relative risks (95% CI) for associations of 24-h NO ₂ (per 20 ppb) and daily 1-h max NO ₂ * (per 30 ppb) with hospitalizations for Ischemic Heart Disease (IHD).	6-10
Figure AX6.2-3.	Relative risks (95% CI) for associations between 24-h avg NO ₂ (per 20 ppb) and hospitalizations for myocardial infarction (MI).	6-11
Figure AX6.2-4.	Relative risks (95% CI) for associations of 24-h avg NO ₂ (per 20 ppb) and 1-h max NO ₂ * with hospitalizations for congestive heart failure (CHF).	6-12
Figure AX6.2-5.	Relative risks (95% CI) for associations of 24-h avg NO ₂ exposure (per 20 ppb) and daily 1-h max NO ₂ * (per 30 ppb) with hospitalizations or emergency department visits for CVD.	6-15

Abbreviations and Acronyms

8-OHdG	8-hydroxy-2N-deoxyguanosine
5-HETE	5-hydroxyeicosatebrachoic
AA	arachidonic acid
ACP	accumulation mode particle
AHH	aryl hydrocarbon hydroxylase
ALT	alanine-amino-transferase
AM	alveolar macrophages
AMMN	N-nitroso-acetoxymethylmethylamine
AP	alkaline phosphatase
ARIC	Atherosclerosis Risk in Communities (Study)
AST	aspartate-amino-transferase
B[a]P	benzo[a]pyrene
BAL	bronchoalveolar lavage
BALF	bronchoalveolar lavage fluid
BC	black carbon
BHPN	N-bis(2-hydroxypropyl) nitrosamine
BLF	bronchial lavage fluid
bpm	beats per minute
bw	body weight
C	carbon or carbon black particles
CA	chromosome aberrations
CAT	catalase
CHD	coronary heart disease
CHF	congestive heart failure
Chol	cholesterol
CMD	count median diameter
CO	carbon monoxide
COPD	Chronic obstructive pulmonary disease
CRP	C-reactive protein
CVD	cardiovascular disease
CYP	Cytochrome P450
Dae	aerodynamic diameter
DEcCBP	DEP extract coated carbon black particles
DEN	diethylnitrosamine
DEP	diesel exhaust particles
DEP+C	diesel exhaust particle extract adsorbed to C
dG	2N-deoxyguanosine
DMBA	7, 12-dimethylbenzanthracene
DMSO	dimethyl sulfoxide
EC	elemental carbon
ED	emergency department

ELF	epithelial lining fluid
FHLC	fetal hamster lung cells
GAM	generalized additive models
γ GCS	γ -glutamylcysteine synthetase
GPx	glutathione peroxidase
GPx	Se-dependent glutathione peroxidase
GPx	glutathione peroxidase
GRed	glutathione reductase
GS	glutathione synthetase
GSD	geometric standard deviation
GSH	glutathione
GSSG	glutathione disulfide
GSSO ₃ H	glutathione S-sulfonate
GST	glutathione-S-transferase
γ GT	γ -glutamyl transpeptidase
HF	heart failure
HNO ₂	nitrous acid
HNO ₃	nitric acid
HP	hydrolyzed protein
HR	heart rate
HRV	heart rate variability
GT	γ -glutamyl transpeptidase
HVA-ICa	high-voltage activated calcium currents
ICAM-1	intercellular adhesion molecule
ICD	implantable cardioverter defibrillators
IgG	immunoglobulin
IHD	ischemic heart disease
IQR	interquartile range
LDH	lactate dehydrogenase
LOESS	locally estimated smoothing splines
LTB ₄	leukotrine B4
MAD	median aerodynamic diameter
MI	myocardial infraction
MMAD	mass median aerodynamic density
MMD	mass median diameter
MN	micronuclei
MNPCE	micronucleated PCE
Mo	molybdenum
NADPH	nicotinamide adenine dinucleotide phosphate
NDMA	nitrosodimethylamine
NHANES III	Third National Health and Nutrition Examination Survey
NHLBI	National Heart, Lung, and Blood Institute
NMBzA	N-nitrosomethylbenzylamine
NO	nitric oxide

NO ₂	nitrogen dioxide
NO _x	oxides of nitrogen; mono-nitrogen oxides (e.g. NO, NO ₂)
NO _y	total reactive nitrogen (all oxidized forms of nitrogen) [Sum of NO _x and NO _z]
NO _z	other oxides of nitrogen (e.g. HNO ₃ and PAN)
NR	Not Reported
O ₃	ozone
OC	organic carbon
PAF	paroxysmal atrial fibrillation
PAH	polycyclic aromatic hydrocarbons
PAR	proximal alveolar region
PCE	polychromatic erythrocytes
PEC	pulmonary endocrine cells
PKA	cyclic AMP-dependent protein kinase A
PKI	synthetic peptide inhibitor of PKA
PL	phospholipids
PM _{2.5}	particulate matter particles equal to or smaller than 2.5 µm
PM ₁₀	particulate matter particles between 2.5 µm and 10 µm
PNC	particle number concentration
ppb	parts per billion
ppm	parts per million
RBC	red blood cell or erythrocyte
RH	relative humidity
r-MSSD	root mean square successive difference (in heart period series) a time domain measurement of heart period variability
SCE	sister chromatid exchanges
SDNN	standard deviation of all normal-to-normal R-R intervals
SEPs	somatosensory-evoked potentials
SO ₂	sodium dioxide
SOD	superoxide dismutase
SP-A	surfactant protein A
SPF	specific pathogen free
SPM	suspended particulate matter extract
SQCA	squamous cell carcinoma
SSO	seabuckthorn seed oil
SV40	simian virus 40
TBA	thiobarbituric acid
TBARS	thiobarbituric acid-reactive substance
TOC	potassium channel transient outward currents
TTX	tetrodotoxin
TTX-R	tetrodotoxin-resistant
TTX-S	tetrodotoxin-sensitive
TxB ₂	thromboxane B ₂
UFP	ultrafine particles
µm	micon, micrometer: 10 ⁻⁶ meter or (1/1000 of a millimeter)

\dot{V}_E	ventilation rate
VEPs	visual-evoked potentials
V_T	tidal volume
VWF	von Willibrand factor
W	tungsten
WBC	white blood cell

Annex 1. Framework for Review

This Integrated Science Assessment (ISA) presents a concise synthesis of the most policy-relevant science to form the scientific foundation for the review of the primary (health-based) National Ambient Air Quality Standards (NAAQS) for nitrogen dioxide (NO₂). The Annexes: (1) provide more details of the most pertinent scientific literature relative to the review of the NO₂ NAAQS in the areas of atmospheric sciences, air quality analyses, exposure assessment, dosimetry, controlled human exposure studies, toxicology, and epidemiology; and (2) focus on the key policy relevant questions and studies published since the last NAAQS review.

Annex AX1 details the methods used to identify and select studies; and frameworks for evaluating scientific evidence relative to causality determination. The overarching framework for evaluation of evidence for causality is outlined in Chapter 1 of this ISA, and this Annex provides supporting information for that framework, including excerpts from decision frameworks or criteria developed by other organizations.

Annex AX2 presents evidence related to the physical and chemical processes controlling the production, destruction, and levels of reactive nitrogen compounds in the atmosphere, including both oxidized and reduced species. Annex AX3 presents information on environmental concentrations, patterns, and human exposure to ambient oxides of nitrogen; however, most information relates to NO₂. Annex AX4 presents results from toxicological studies as well as information on dosimetry of oxides of nitrogen. Annex AX5 discusses results from controlled human exposure studies, and Annex AX6 presents evidence from epidemiologic studies. These Annexes include more detailed information on health or exposure studies that is summarized in tabular form, as well as more extensive discussion of atmospheric chemistry, source, exposure, and dosimetry information. Annex tables for health studies are generally organized to include information about (1) concentrations of oxides of nitrogen levels or doses and exposure times, (2) description of study methods employed, (3) results and comments, and (4) quantitative outcomes for oxides of nitrogen measures.

AX1.1. Literature Selection and Retrieval

Literature searches were conducted routinely to identify studies published since the last review. The review included publications from 1-2 years prior to the publication of 1993 AQCD for Oxides of Nitrogen (U.S. Environmental Protection Agency, 1993). Search strategies were iteratively modified in an effort to optimize the identification of pertinent publications. Additional papers were identified for inclusion in several ways: review of pre-publication tables of contents for journals in which relevant papers may be published; independent identification of relevant literature by expert authors; and identification by public and CASAC during the external review process. Generally, only information that had undergone scientific peer review and had been published or accepted for publication was considered. The following sections briefly summarize criteria for selection of studies for this ISA.

The selection process for studies included in this ISA is shown in Figure AX1.1-1. Studies were evaluated by EPA staff and outside experts to determine if the studies merited inclusion. Criteria used for study selection are summarized below.

Identification of Studies for Inclusion in the ISA

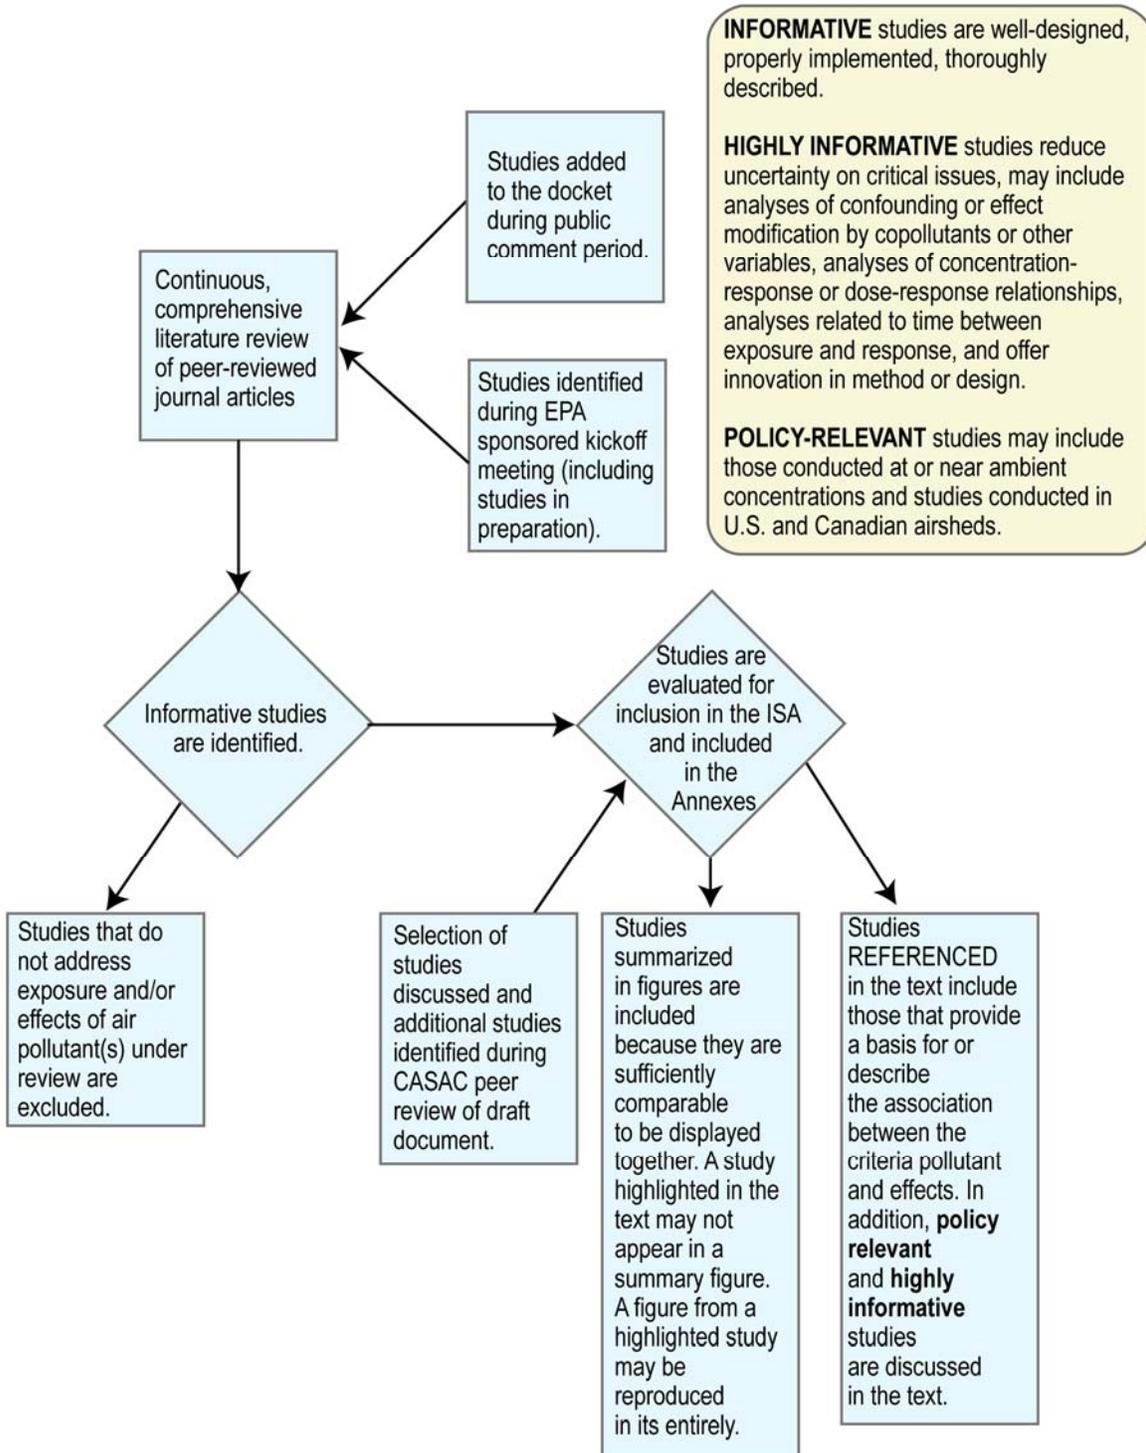

Figure AX1.1-1. Selection process for studies included in ISA.

AX1.1.1. General Criteria for Study Selection

In assessing the scientific quality and relevance of epidemiological and human or animal toxicological studies, the following considerations have been taken into account.

- Are the study populations adequately selected and are they sufficiently well defined to allow for meaningful comparisons between study groups?
- Are the statistical analyses appropriate, properly performed, and properly interpreted?
- Are likely covariates (i.e., potential confounders or effect modifiers) adequately controlled or taken into account in the study design and statistical analysis?
- Are the reported findings internally consistent, biologically plausible, and coherent in terms of consistency with other known facts?
- To what extent are the aerometric data, exposure, or dose metrics of adequate quality and sufficiently representative to serve as indicators of exposure to ambient NO_x?

Consideration of these issues informs the judgments on the relative quality of individual studies and allows the most pertinent studies to be the focus of the assessment.

AX1.1.2. Criteria for Selecting Epidemiology Studies

In selecting epidemiological studies, EPA considered whether a given study contained information on (1) associations with measured oxides of nitrogen concentrations using short- or long-term exposures at or near ambient levels of oxides of nitrogen, (2) health effects of specific oxides of nitrogen species or indicators related to oxides of nitrogen sources (e.g., motor vehicle emissions, combustion-related particles), (3) health endpoints and populations not previously extensively researched, (4) multiple pollutant analyses and other approaches to address issues related to potential confounding and modification of effects, and/or (5) important methodology issues (e.g., lag of effects, model specifications, thresholds, mortality displacement) related to interpretation of the health evidence. Among the epidemiological studies, particular emphasis was placed on those studies most relevant to the review of the NAAQS. Specifically, studies conducted in the United States or Canada were discussed in more detail than those from other geographical regions. Particular emphasis was placed on: (1) recent multicity studies that employ standardized analyses methods for evaluating effects of oxides of nitrogen and that provide overall estimates for effects based on combined analyses of information pooled across multiple cities, (2) new studies that provide quantitative effect estimates for populations of interest, and (3) studies that consider oxides of nitrogen as a component of a complex mixture of air pollutants.

Not all studies are accorded equal weight in the overall interpretive assessment of evidence regarding NO₂-associated health effects. Among well-conducted studies with adequate control for confounding, increasing scientific weight is accorded in proportion to the precision of their effect estimates. Small-scale studies without a wide range of exposures generally produced less precise estimates compared to larger studies with a broad exposure gradient. For time-series studies, the size of the study, as indicated by the length of the study period and total number of events, and the variability of NO₂ exposures are important components to determine the precision of the health effect estimates. In evaluating the epidemiologic evidence in this chapter, more weight is accorded to estimates from studies with narrow confidence bands.

The goal was to perform a balanced and objective evaluation that summarized, interpreted, and synthesized the most important studies and issues in the epidemiologic database pertaining to oxides of nitrogen exposure. For each study presented, the quality of the exposure and outcome data, as well as the quality of the statistical analysis methodology were discussed. The framework for evaluation of evidence is further described below.

AX1.1.3. Criteria for Selecting Toxicology Studies

Criteria for the selection of research evaluating animal toxicological or controlled human exposure studies included a focus on studies conducted within an order of a magnitude of ambient NO₂ concentrations and those studies that approximated expected human exposure conditions in terms of concentration and duration. Studies that elucidated mechanisms of action and/or susceptibility, particularly if the studies were conducted under atmospherically relevant conditions, were emphasized whenever possible.

The selection of research evaluating controlled human exposures to oxides of nitrogen is mainly limited to studies in which subjects are exposed to <5 ppm NO₂. For these controlled human exposures, emphasis is placed on studies that (1) investigate potentially susceptible populations such as asthmatics, particularly studies that compare responses in susceptible individuals with those in age-matched healthy controls; (2) address issues such as concentration-response or time-course of responses; (3) investigate exposure to NO₂ separately and in combination with other pollutants such as O₃ and SO₂; (4) include control exposures to filtered air; and (5) have sufficient statistical power to assess findings.

AX1.2. Guidelines for the Determination of Causality

The following sections include excerpts from several reports that have documented approaches for the determination of causality, or related decision-making processes. These sections provide supplementary documentation of approaches that are similar in nature to EPA's framework for evaluation of health evidence.

AX1.2.1. Surgeon General's Report: The Health Consequences of Smoking

The Surgeon General's Report (CDC, 2004) evaluates the health effects of smoking; it builds upon the first Surgeon General's report published in 1964 (USDEHW, 1964). It also updates the methodology for evaluating evidence that was first presented in the 1964 report. The 2004 report acknowledges the effectiveness of the previous methodology, but attempts to standardize the language surrounding causality of associations.

The Surgeon General's Reports on Smoking played a central role in the translation of scientific evidence into policy. As such, it was important that scientific evidence was presented in a manner that conveyed most succinctly the link between smoking and a health effect. Specifically, the report stated:

The statement that an exposure "causes" a disease in humans represents a serious claim, but one that carries with it the possibility of prevention. Causal determinations may also carry substantial economic implications for society and for those who might be held responsible for the exposure or for achieving its prevention.

To address the issue of identifying causality, the 2004 report provided the following summary of the earlier 1964 report:

When a relationship or an association between smoking...and some condition in the host was noted, the significance of the association was assessed.

The characterization of the assessment called for a specific term. ...The word *cause* is the one in general usage in connection with matters considered in this study, and it is capable of conveying the notion of a significant, effectual relationship between an agent and an associated disorder or disease in the host.

No member was so naive as to insist upon mono-etiology in pathological processes or in vital phenomena. All were thoroughly aware... that the end results are the net effect of many actions and counteractions.

Granted that these complexities were recognized, it is to be noted clearly that the Committee's considered decision to use the words "a cause," or "a major cause," or "a significant cause," or "a causal association" in certain conclusions about smoking and health affirms their conviction (USDHEW, 1964, p. 21).

This 2004 report created uniformly labeled conclusions that were used throughout the document. The following excerpts from the report included a description of the methodology and the judgments used to reach a conclusion:

Terminology of Conclusions and Causal Claims

The first step in introducing this revised approach is to outline the language that will be used for summary conclusions regarding causality, which follows hierarchical language used by Institute of Medicine committees (Institute of Medicine, 1999) to couch causal conclusions, and by IARC to classify carcinogenic substances (IARC, 1986). These entities use a four-level hierarchy for classifying the strength of causal inferences based on available evidence as follows:

Evidence is **sufficient** to infer a causal relationship.

Evidence is suggestive but not sufficient to infer a causal relationship.

Evidence is inadequate to infer the presence or absence of a causal relationship (which encompasses evidence that is sparse, of poor quality, or conflicting).

Evidence is suggestive of no causal relationship.

For this report, the summary conclusions regarding causality are expressed in this four-level classification. Use of these classifications should not constrain the process of causal inference, but rather bring consistency across chapters and reports, and greater clarity as to what the final conclusions are actually saying. As shown in Table 1.1 [see original document], without a uniform classification the precise nature of the final judgment may not always be obvious, particularly when the judgment is that the evidence falls below the "sufficient" category. Experience has shown that the "suggestive" category is often an uncomfortable one for scientists, since scientific culture is such that any evidence that falls short of causal proof is typically deemed inadequate to make a causal determination. However, it is very useful to distinguish between evidence that is truly inadequate versus that which just falls short of sufficiency.

There is no category beyond “suggestive of no causal relationship” as it is extraordinarily difficult to prove the complete absence of a causal association. At best, “negative” evidence is suggestive, either strongly or weakly. In instances where this category is used, the strength of evidence for no relationship will be indicated in the body of the text. In this new framework, conclusions regarding causality will be followed by a section on implications. This section will separate the issue of causal inference from recommendations for research, policies, or other actions that might arise from the causal conclusions. This section will assume a public health perspective, focusing on the population consequences of using or not using tobacco and also a scientific perspective, proposing further research directions. The proportion of cases in the population as a result of exposure (the population attributable risk), along with the total prevalence and seriousness of a disease, are more relevant for deciding on actions than the relative risk estimates typically used for etiologic determinations. In past reports, the failure to sharply separate issues of inference from policy issues resulted in inferential statements that were sometimes qualified with terms for action. For example, based on the evidence available in 1964, the first Surgeon General’s report on smoking and health contained the following statement about the relationship between cardiovascular diseases and smoking:

It is established that male cigarette smokers have a higher death rate from coronary artery disease than non-smoking males. Although the causative role of cigarette smoking in deaths from coronary disease is not proven, the Committee considers it more prudent from the public health viewpoint to assume that the established association has causative meaning, than to suspend judgment until no uncertainty remains (USDHEW, 1964, p. 32).

Using this framework, this conclusion would now be expressed differently, probably placing it in the “suggestive” category and making it clear that although it falls short of proving causation, this evidence still makes causation more likely than not. The original statement makes it clear that the 1964 committee judged that the evidence fell short of proving causality but was sufficient to justify public health action. In this report, the rationale and recommendations for action will be placed in the implications section, separate from the causal conclusions. This separation of inferential from action-related statements clarifies the degree to which policy recommendations are driven by the strength of the evidence and by the public health consequences acting to reduce exposure. In addition, this separation appropriately reflects the differences between the processes and goals of causal inference and decision making.

AX1.2.2. The EPA Guidelines for Carcinogen Risk Assessment

The EPA Guidelines for Carcinogen Risk Assessment, published in 2005 (U.S. Environmental Protection Agency, 2005), was an update to the previous risk assessment document published in 1986. This document served to guide EPA staff and public about the Agency’s risk assessment development and methodology. In the 1986 Guidelines, a step-wise approach was used to evaluate the scientific findings. However, this newer document was similar to the Surgeon General’s Report on Smoking in that it used a single integrative step after assessing all of the individual lines of evidence. Five standard descriptors are used to evaluate the weight of evidence:

1. Carcinogenic to Humans
2. Likely to Be Carcinogenic to Humans
3. Suggestive Evidence of Carcinogenic Potential
4. Inadequate Information to Assess Carcinogenic Potential
5. Not Likely to Be Carcinogenic to Humans.

The 2005 Guidelines recommended that a separate narrative be prepared on the weight of evidence and the descriptor. The Guidelines further recommended that the descriptors should only be used in the context of a weight of evidence discussion.

The following excerpt describes how a weight of evidence narrative should be developed and how a descriptor should be selected (U.S. Environmental Protection Agency, 2005):

The weight of the evidence should be presented as a narrative laying out the complexity of information that is essential to understanding the hazard and its dependence on the quality, quantity, and type(s) of data available, as well as the circumstances of exposure or the traits of an exposed population that may be required for expression of cancer. For example, the narrative can clearly state to what extent the determination was based on data from human exposure, from animal experiments, from some combination of the two, or from other data. Similarly, information on mode of action can specify to what extent the data are from *in vivo* or *in vitro* exposures or based on similarities to other chemicals. The extent to which an agent's mode of action occurs only on reaching a minimum dose or a minimum duration should also be presented. A hazard might also be expressed disproportionately in individuals possessing a specific gene; such characterizations may follow from a better understanding of the human genome. Furthermore, route of exposure should be used to qualify a hazard if, for example, an agent is not absorbed by some routes. Similarly, a hazard can be attributable to exposures during a susceptible lifestage on the basis of our understanding of human development.

The weight of evidence narrative should highlight:

- the quality and quantity of the data;
- all key decisions and the basis for these major decisions; and
- any data, analyses, or assumptions that are unusual for or new to EPA.

To capture this complexity, a weight of evidence narrative generally includes

- conclusions about human carcinogenic potential (choice of descriptor(s), described below)
- a summary of the key evidence supporting these conclusions (for each descriptor used), including information on the type(s) of data (human and/or animal, *in vivo* and/or *in vitro*) used to support the conclusion(s)
- available information on the epidemiologic or experimental conditions that characterize expression of carcinogenicity (e.g., if carcinogenicity is possible only by one exposure route or only above a certain human exposure level),
- a summary of potential modes of action and how they reinforce the conclusions,

- indications of any susceptible populations or lifestages, when available, and
- a summary of the key default options invoked when the available information is inconclusive.

To provide some measure of clarity and consistency in an otherwise free-form narrative, the weight of evidence descriptors are included in the first sentence of the narrative. Choosing a descriptor is a matter of judgment and cannot be reduced to a formula. Each descriptor may be applicable to a wide variety of potential data sets and weights of evidence. These descriptors and narratives are intended to permit sufficient flexibility to accommodate new scientific understanding and new testing methods as they are developed and accepted by the scientific community and the public. Descriptors represent points along a continuum of evidence; consequently, there are gradations and borderline cases that are clarified by the full narrative. Descriptors, as well as an introductory paragraph, are a short summary of the complete narrative that preserves the complexity that is an essential part of the hazard characterization. **Users of these cancer guidelines and of the risk assessments that result from the use of these cancer guidelines should consider the entire range of information included in the narrative rather than focusing simply on the descriptor.**

In borderline cases, the narrative explains the case for choosing one descriptor and discusses the arguments for considering but not choosing another. For example, between “suggestive” and “likely” or between “suggestive” and “inadequate,” the explanation clearly communicates the information needed to consider appropriately the agent's carcinogenic potential in subsequent decisions.

Multiple descriptors can be used for a single agent, for example, when carcinogenesis is dose- or route-dependent. For example, if an agent causes point-of-contact tumors by one exposure route but adequate testing is negative by another route, then the agent could be described as likely to be carcinogenic by the first route but not likely to be carcinogenic by the second. Another example is when the mode of action is sufficiently understood to conclude that a key event in tumor development would not occur below a certain dose range. In this case, the agent could be described as likely to be carcinogenic above a certain dose range but not likely to be carcinogenic below that range.

Descriptors can be selected for an agent that has not been tested in a cancer bioassay if sufficient other information, e.g., toxicokinetic and mode of action information, is available to make a strong, convincing, and logical case through scientific inference. For example, if an agent is one of a well-defined class of agents that are understood to operate through a common mode of action and if that agent has the same mode of action, then in the narrative the untested agent would have the same descriptor as the class. Another example is when an untested agent's effects are understood to be caused by a human metabolite, in which case in the narrative the untested agent could have the same descriptor as the metabolite. As new testing methods are developed and used, assessments may increasingly be based on inferences from toxicokinetic and mode of action information in the absence of tumor studies in animals or humans.

When a well-studied agent produces tumors only at a point of initial contact, the descriptor generally applies only to the exposure route producing tumors unless

the mode of action is relevant to other routes. The rationale for this conclusion would be explained in the narrative.

When tumors occur at a site other than the point of initial contact, the descriptor generally applies to all exposure routes that have not been adequately tested at sufficient doses. An exception occurs when there is convincing information, e.g., toxicokinetic data that absorption does not occur by another route.

When the response differs qualitatively as well as quantitatively with dose, this information should be part of the characterization of the hazard. In some cases reaching a certain dose range can be a precondition for effects to occur, as when cancer is secondary to another toxic effect that appears only above a certain dose. In other cases exposure duration can be a precondition for hazard if effects occur only after exposure is sustained for a certain duration. These considerations differ from the issues of relative absorption or potency at different dose levels because they may represent a discontinuity in a dose-response function.

When multiple bioassays are inconclusive, mode of action data are likely to hold the key to resolution of the more appropriate descriptor. When bioassays are few, further bioassays to replicate a study's results or to investigate the potential for effects in another sex, strain, or species may be useful.

When there are few pertinent data, the descriptor makes a statement about the database, for example, "Inadequate Information to Assess Carcinogenic Potential," or a database that provides "Suggestive Evidence of Carcinogenic Potential." With more information, the descriptor expresses a conclusion about the agent's carcinogenic potential to humans. If the conclusion is positive, the agent could be described as "Likely to Be Carcinogenic to Humans" or, with strong evidence, "Carcinogenic to Humans." If the conclusion is negative, the agent could be described as "Not Likely to Be Carcinogenic to Humans."

Although the term "likely" can have a probabilistic connotation in other contexts, its use as a weight of evidence descriptor does not correspond to a quantifiable probability of whether the chemical is carcinogenic. This is because the data that support cancer assessments generally are not suitable for numerical calculations of the probability that an agent is a carcinogen. Other health agencies have expressed a comparable weight of evidence using terms such as "Reasonably Anticipated to Be a Human Carcinogen" (NTP) or "Probably Carcinogenic to Humans" (International Agency for Research on Cancer).

AX1.2.3. Improving Presumptive Disability Decision-Making Process for Veterans

A recent publication by the Institute of Medicine (IOM) also provided the foundation for the causality framework adapted in this ISA (IOM, 2007). The Committee on Evaluation of the Presumptive Disability Decision-Making Process for Veterans was charged by the Veterans Association to describe how presumptive decisions are made for veterans with health conditions arising from military service currently, as well as recommendations for how such decisions could be made in the future. The committee proposed a multiple-element approach that included a quantification of the extent of disease attributable to an exposure. This process involved a review of all relevant data to decide the strength of evidence for causation, using one of four categories:

- *Sufficient*: the evidence is sufficient to conclude that a causal relationship exists.
- *Equipoise and Above*: the evidence is sufficient to conclude that a causal relationship is at least as likely as not, but not sufficient to conclude that a causal relationship exists.
- *Below Equipoise*: the evidence is not sufficient to conclude that a causal relationship is at least as likely as not, or is not sufficient to make a scientifically informed judgment.
- *Against*: the evidence suggests the lack of a causal relationship.

The following is an excerpt from this report and describes these four categories in detail:

In light of the categorizations used by other health organizations and agencies as well as considering the particular challenges of the presumptive disability decision-making process, we propose a four-level categorization of the strength of the *overall evidence* for or against a *causal relationship* from exposure to disease.

We use the term “equipoise” to refer to the point at which the evidence is in balance between favoring and not favoring causation. The term “equipoise” is widely used in the biomedical literature, is a concept familiar to those concerned with evidence-based decision-making and is used in VA processes for rating purposes as well as being a familiar term in the veterans’ community.

Below we elaborate on the four-level categorization which the Committee recommends.

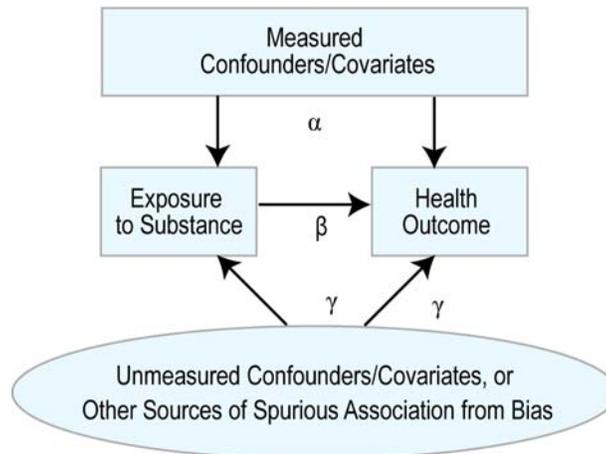

Sufficient

If the overall evidence for a causal relationship is categorized as Sufficient, then it should be scientifically compelling. It might include:

- replicated and consistent evidence of a causal association: that is, evidence of an association from several high-quality epidemiologic studies that cannot be explained by plausible noncausal alternatives (e.g., chance, bias, or confounding)
- evidence of causation from animal studies and mechanistic knowledge
- compelling evidence from animal studies and strong mechanistic evidence from studies in exposed humans, consistent with (i.e., not contradicted by) the epidemiologic evidence.

Using the Bayesian framework to illustrate the evidential support and the resulting state of communal scientific opinion needed for reaching the Sufficient category (and the lower categories that follow), consider again the causal diagram in Figure AX1.2-1. In this model, used to help clarify matters conceptually, the observed association between exposure and health is the result of: (1) measured confounding, parameterized by α ; (2) the causal relation, parameterized by β ; and (3) other, unmeasured sources such as bias or unmeasured confounding, parameterized by γ . The belief of interest, after all the evidence has been weighed, is in the size of the causal parameter β . Thus, for decision making, what matters is how strongly the evidence supports the proposition that β is above 0. As it is extremely unlikely that the types of exposures considered for presumptions reduce the risk of developing disease, we

exclude values of β below 0. If we consider the evidence as supporting degrees of belief about the size of β , and we have a posterior distribution over the possible size of β , then a posterior like Figure AX1.2-2 illustrates a belief state that might result when the evidence for causation is considered Sufficient.

Source: IOM (2007).

Figure AX1.2-1. Focusing on unmeasured confounders/covariates, or other sources of spurious association from bias.

Equipoise and Above

To be categorized as Equipoise and Above, the scientific community should categorize the overall evidence as making it more confident in the existence of a causal relationship than in the non-existence of a causal relationship, but not sufficient to conclude causation.

For example, if there are several high-quality epidemiologic studies, the preponderance of which show evidence of an association that cannot readily be explained by plausible noncausal alternatives (e.g., chance, bias, or confounding), and the causal relationship is consistent with the animal evidence and biological knowledge, then the overall evidence might be categorized as Equipoise and Above. Alternatively, if there is strong evidence from animal studies or mechanistic evidence, not contradicted by human or other evidence, then the overall evidence might be categorized as Equipoise and Above. Equipoise is a common term employed by VA and the courts in deciding disability claims.

Again, using the Bayesian model to illustrate the idea of Equipoise and Above, Figure AX1.2-3 shows a posterior probability distribution that is an example of belief compatible with the category Equipoise and Above.

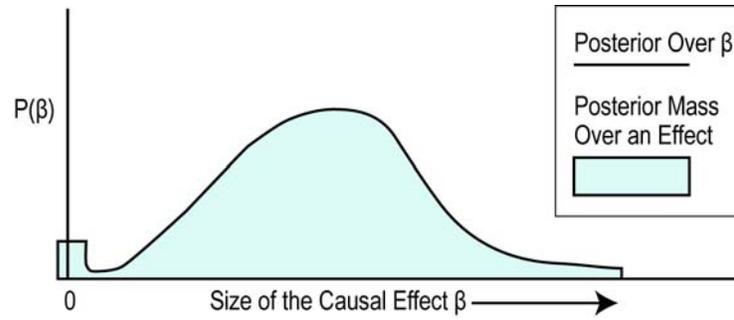

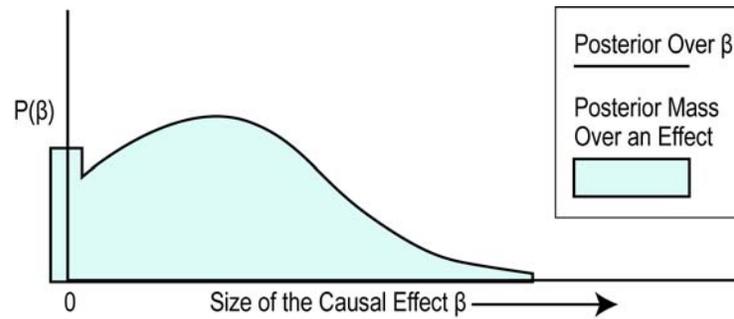

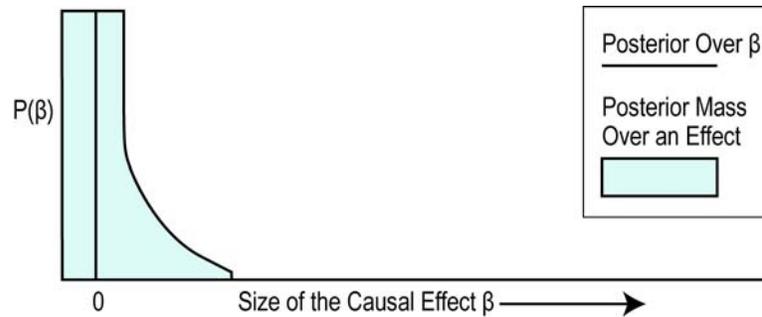

Figure AX1.2-2. Example posterior distribution for the determination of *Sufficient*.

Source: IOM (2007).

Figure AX1.2-3. Example posterior distribution for the determination of *Equipoise and Above*.

Source: IOM (2007).

Figure AX1.2-4. Example posterior distribution for the determination of *Against*.

In this figure, unlike the one for evidence classified as *Sufficient*, there is considerable mass over zero, which means that the scientific community has considerable uncertainty as to whether exposure causes disease at all; that is, whether β is greater than zero. At *least* half of the mass is to the right of the zero,

however, so the community judges causation to be at least as likely as not, after they have seen and combined all the evidence available.

Below Equipoise

To be categorized as Below Equipoise, the overall evidence for a causal relationship should either be judged not to make causation at least as likely as not, or not sufficient to make a scientifically informed judgment.

This might occur:

- when the human evidence is consistent in showing an association, but the evidence is limited by the inability to rule out chance, bias, or confounding with confidence, and animal or mechanistic evidence is weak
- when animal evidence suggests a causal relationship, but human and mechanistic evidence is weak or inconsistent
- when mechanistic evidence is suggestive but animal and human evidence is weak or inconsistent
- when the evidence base is very thin.

Against

To be categorized as Against, the overall evidence should favor belief that there is no causal relationship from exposure to disease. For example, if there is human evidence from multiple studies covering the full range of exposures encountered by humans that are consistent in showing no causal association, or there are animal or mechanistic evidence supporting the lack of a causal relationship, and combining all of the evidence results in a posterior resembling Figure AX1.2-4 then the scientific community should categorize the evidence as *Against* causation.

AX1.2.4. Formulation of Scientific Findings for Policy Purposes

The following guidelines in the form of questions were developed and published in 1991 by the National Acid Precipitation Assessment Program (NAPAP) Oversight Review Board for NAPAP to assist scientists in formulating presentations of research results to be used in policy decision processes.

Is the statement sound? Have the central issues been clearly identified? Does each statement contain the distilled essence of present scientific and technical understanding of the phenomenon or process to which it applies? Is the statement consistent with all relevant evidence – evidence developed either through NAPAP research or through analysis of research conducted outside of NAPAP? Is the statement contradicted by any important evidence developed through research inside or outside of NAPAP? Have apparent contradictions or interpretations of available evidence been considered in formulating the statement of principal findings?

Is the statement directional and, where appropriate, quantitative? Does the statement correctly quantify both the direction and magnitude of trends and relationships in the phenomenon or process to which the statement is relevant? When possible, is a range of uncertainty given for each quantitative result? Have various sources of uncertainty been identified and quantified, for

example, does the statement include or acknowledge errors in actual measurements, standard errors of estimate, possible biases in the availability of data, extrapolation of results beyond the mathematical, geographical, or temporal relevancy of available information, etc. In short, are there numbers in the statement? Are the numbers correct? Are the numbers relevant to the general meaning of the statement?

Is the degree of certainty or uncertainty of the statement indicated clearly? Have appropriate statistical tests been applied to the data used in drawing the conclusion set forth in the statement? If the statement is based on a mathematical or novel conceptual model, has the model or concept been validated? Does the statement describe the model or concept on which it is based and the degree of validity of that model or concept?

Is the statement correct without qualification? Are there limitations of time, space, or other special circumstances in which the statement is true? If the statement is true only in some circumstances, are these limitations described adequately and briefly?

Is the statement clear and unambiguous? Are the words and phrases used in the statement understandable by the decision makers of our society? Is the statement free of specialized jargon? Will too many people misunderstand its meaning?

Is the statement as concise as it can be made without risk of misunderstanding? Are there any excess words, phrases, or ideas in the statement which are not necessary to communicate the meaning of the statement? Are there so many caveats in the statement that the statement itself is trivial, confusing, or ambiguous?

Is the statement free of scientific or other biases or implications of societal value judgments? Is the statement free of influence by specific schools of scientific thought? Is the statement also free of words, phrases, or concepts that have political, economic, ideological, religious, moral, or other personal-, agency-, or organization-specific values, overtones, or implications? Does the choice of how the statement is expressed rather than its specific words suggest underlying biases or value judgments? Is the tone impartial and free of special pleading? If societal value judgments have been discussed, have these judgments been identified as such and described both clearly and objectively?

Have societal implications been described objectively? Consideration of alternative courses of action and their consequences inherently involves judgments of their feasibility and the importance of effects. For this reason, it is important to ask if a reasonable range of alternative policies or courses of action have been evaluated? Have societal implications of alternative courses of action been stated in the following general form?

“If this [particular option] were adopted then that [particular outcome] would be expected.”

Have the professional biases of authors and reviewers been described openly? Acknowledgment of potential sources of bias is important so that readers can judge for themselves the credibility of reports and assessments.

AX1.2.5. IARC Cancer Guidelines for Scientific Review and Evaluation

The following is excerpted from the International Agency for Research on Cancer (IARC) Monographs on the evaluation of carcinogenic risks to humans (IARC, 2006).

The available studies are summarized by the Working Group, with particular regard to the qualitative aspects discussed below. In general, numerical findings are indicated as they appear in the original report; units are converted when necessary for easier comparison. The Working Group may conduct additional analyses of the published data and use them in their assessment of the evidence; the results of such supplementary analyses are given in square brackets. When an important aspect of a study that directly impinges on its interpretation should be brought to the attention of the reader, a Working Group comment is given in square brackets.

The scope of the *IARC Monographs* programme has expanded beyond chemicals to include complex mixtures, occupational exposures, physical and biological agents, lifestyle factors and other potentially carcinogenic exposures. Over time, the structure of a *Monograph* has evolved to include the following sections:

1. Exposure data
2. Studies of cancer in humans
3. Studies of cancer in experimental animals
4. Mechanistic and other relevant data
5. Summary
6. Evaluation and rationale

In addition, a section of General Remarks at the front of the volume discusses the reasons the agents were scheduled for evaluation and some key issues the Working Group encountered during the meeting.

This part of the Preamble discusses the types of evidence considered and summarized in each section of a *Monograph*, followed by the scientific criteria that guide the evaluations.

Evaluation and rationale

Evaluations of the strength of the evidence for carcinogenicity arising from human and experimental animal data are made, using standard terms. The strength of the mechanistic evidence is also characterized.

It is recognized that the criteria for these evaluations, described below, cannot encompass all of the factors that may be relevant to an evaluation of carcinogenicity. In considering all of the relevant scientific data, the Working Group may assign the agent to a higher or lower category than a strict interpretation of these criteria would indicate.

These categories refer only to the strength of the evidence that an exposure is carcinogenic and not to the extent of its carcinogenic activity (potency). A classification may change as new information becomes available.

An evaluation of the degree of evidence is limited to the materials tested, as defined physically, chemically or biologically. When the agents evaluated are considered by the Working Group to be sufficiently closely related, they may be grouped together for the purpose of a single evaluation of the degree of evidence.

(a) Carcinogenicity in humans

The evidence relevant to carcinogenicity from studies in humans is classified into one of the following categories:

Sufficient evidence of carcinogenicity: The Working Group considers that a causal relationship has been established between exposure to the agent and human cancer. That is, a positive relationship has been observed between the exposure and cancer in studies in which chance, bias and confounding could be ruled out with reasonable confidence. A statement that there is *sufficient evidence* is followed by a separate sentence that identifies the target organ(s) or tissue(s) where an increased risk of cancer was observed in humans. Identification of a specific target organ or tissue does not preclude the possibility that the agent may cause cancer at other sites.

Limited evidence of carcinogenicity: A positive association has been observed between exposure to the agent and cancer for which a causal interpretation is considered by the Working Group to be credible, but chance, bias or confounding could not be ruled out with reasonable confidence.

Inadequate evidence of carcinogenicity: The available studies are of insufficient quality, consistency or statistical power to permit a conclusion regarding the presence or absence of a causal association between exposure and cancer, or no data on cancer in humans are available.

Evidence suggesting lack of carcinogenicity: There are several adequate studies covering the full range of levels of exposure that humans are known to encounter, which are mutually consistent in not showing a positive association between exposure to the agent and any studied cancer at any observed level of exposure. The results from these studies alone or combined should have narrow confidence intervals with an upper limit close to the null value (e.g. a relative risk of 1.0). Bias and confounding should be ruled out with reasonable confidence, and the studies should have an adequate length of follow-up. A conclusion of *evidence suggesting lack of carcinogenicity* is inevitably limited to the cancer sites, conditions and levels of exposure, and length of observation covered by the available studies. In addition, the possibility of a very small risk at the levels of exposure studied can never be excluded.

In some instances, the above categories may be used to classify the degree of evidence related to carcinogenicity in specific organs or tissues.

When the available epidemiological studies pertain to a mixture, process, occupation or industry, the Working Group seeks to identify the specific agent considered most likely to be responsible for any excess risk. The evaluation is focused as narrowly as the available data on exposure and other aspects permit.

(b) Carcinogenicity in experimental animals

Carcinogenicity in experimental animals can be evaluated using conventional bioassays, bioassays that employ genetically modified animals, and other in-vivo bioassays that focus on one or more of the critical stages of carcinogenesis. In the absence of data from conventional long-term bioassays or from assays with neoplasia as the end-point, consistently positive results in several models that address several stages in the multistage process of carcinogenesis should be considered in evaluating the degree of evidence of carcinogenicity in experimental animals.

The evidence relevant to carcinogenicity in experimental animals is classified into one of the following categories:

Sufficient evidence of carcinogenicity: The Working Group considers that a causal relationship has been established between the agent and an increased incidence of malignant neoplasms or of an appropriate combination of benign and malignant neoplasms in (a) two or more species of animals or (b) two or more independent studies in one species carried out at different times or in different laboratories or under different protocols. An increased incidence of tumours in both sexes of a single species in a well-conducted study, ideally conducted under Good Laboratory Practices, can also provide *sufficient evidence*.

A single study in one species and sex might be considered to provide *sufficient evidence of carcinogenicity* when malignant neoplasms occur to an unusual degree with regard to incidence, site, type of tumour or age at onset, or when there are strong findings of tumours at multiple sites.

Limited evidence of carcinogenicity: The data suggest a carcinogenic effect but are limited for making a definitive evaluation because, e.g. (a) the evidence of carcinogenicity is restricted to a single experiment; (b) there are unresolved questions regarding the adequacy of the design, conduct or interpretation of the studies; (c) the agent increases the incidence only of benign neoplasms or lesions of uncertain neoplastic potential; or (d) the evidence of carcinogenicity is restricted to studies that demonstrate only promoting activity in a narrow range of tissues or organs.

Inadequate evidence of carcinogenicity: The studies cannot be interpreted as showing either the presence or absence of a carcinogenic effect because of major qualitative or quantitative limitations, or no data on cancer in experimental animals are available.

Evidence suggesting lack of carcinogenicity: Adequate studies involving at least two species are available which show that, within the limits of the tests used, the agent is not carcinogenic. A conclusion of *evidence suggesting lack of carcinogenicity* is inevitably limited to the species, tumour sites, age at exposure, and conditions and levels of exposure studied.

(c) Mechanistic and other relevant data

Mechanistic and other evidence judged to be relevant to an evaluation of carcinogenicity and of sufficient importance to affect the overall evaluation is highlighted. This may include data on preneoplastic lesions, tumour pathology, genetic and related effects, structure–activity relationships, metabolism and toxicokinetics, physicochemical parameters and analogous biological agents.

The strength of the evidence that any carcinogenic effect observed is due to a particular mechanism is evaluated, using terms such as ‘weak’, ‘moderate’ or ‘strong’. The Working Group then assesses whether that particular mechanism is likely to be operative in humans. The strongest indications that a particular mechanism operates in humans derive from data on humans or biological specimens obtained from exposed humans. The data may be considered to be especially relevant if they show that the agent in question has caused changes in exposed humans that are on the causal pathway to carcinogenesis. Such data may, however, never become available, because it is at least conceivable that certain compounds may be kept from human use solely on the basis of evidence of their toxicity and/or carcinogenicity in experimental systems.

The conclusion that a mechanism operates in experimental animals is strengthened by findings of consistent results in different experimental systems, by the demonstration of biological plausibility and by coherence of the overall database. Strong support can be obtained from studies that challenge the hypothesized mechanism experimentally, by demonstrating that the suppression of key mechanistic processes leads to the suppression of tumour development. The Working Group considers whether multiple mechanisms might contribute to tumour development, whether different mechanisms might operate in different dose ranges, whether separate mechanisms might operate in humans and experimental animals and whether a unique mechanism might operate in a susceptible group. The possible contribution of alternative mechanisms must be considered before concluding that tumours observed in experimental animals are not relevant to humans. An uneven level of experimental support for different mechanisms may reflect that disproportionate resources have been focused on investigating a favoured mechanism.

For complex exposures, including occupational and industrial exposures, the chemical composition and the potential contribution of carcinogens known to be present are considered by the Working Group in its overall evaluation of human carcinogenicity. The Working Group also determines the extent to which the materials tested in experimental systems are related to those to which humans are exposed.

(d) Overall evaluation

Finally, the body of evidence is considered as a whole, in order to reach an overall evaluation of the carcinogenicity of the agent to humans.

An evaluation may be made for a group of agents that have been evaluated by the Working Group. In addition, when supporting data indicate that other related agents, for which there is no direct evidence of their capacity to induce cancer in

humans or in animals, may also be carcinogenic, a statement describing the rationale for this conclusion is added to the evaluation narrative; an additional evaluation may be made for this broader group of agents if the strength of the evidence warrants it.

The agent is described according to the wording of one of the following categories, and the designated group is given. The categorization of an agent is a matter of scientific judgement that reflects the strength of the evidence derived from studies in humans and in experimental animals and from mechanistic and other relevant data.

Group 1: The agent is *carcinogenic to humans*.

This category is used when there is *sufficient evidence of carcinogenicity* in humans. Exceptionally, an agent may be placed in this category when evidence of carcinogenicity in humans is less than *sufficient* but there is *sufficient evidence of carcinogenicity* in experimental animals and strong evidence in exposed humans that the agent acts through a relevant mechanism of carcinogenicity.

Group 2.

This category includes agents for which, at one extreme, the degree of evidence of carcinogenicity in humans is almost *sufficient*, as well as those for which, at the other extreme, there are no human data but for which there is evidence of carcinogenicity in experimental animals. Agents are assigned to either Group 2A (*probably carcinogenic to humans*) or Group 2B (*possibly carcinogenic to humans*) on the basis of epidemiological and experimental evidence of carcinogenicity and mechanistic and other relevant data. The terms *probably carcinogenic* and *possibly carcinogenic* have no quantitative significance and are used simply as descriptors of different levels of evidence of human carcinogenicity, with probably carcinogenic signifying a higher level of evidence than possibly carcinogenic.

Group 2A: The agent is probably carcinogenic to humans.

This category is used when there is *limited evidence of carcinogenicity* in humans and *sufficient evidence of carcinogenicity* in experimental animals. In some cases, an agent may be classified in this category when there is *inadequate evidence of carcinogenicity* in humans and *sufficient evidence of carcinogenicity* in experimental animals and strong evidence that the carcinogenesis is mediated by a mechanism that also operates in humans. Exceptionally, an agent may be classified in this category solely on the basis of *limited evidence of carcinogenicity* in humans. An agent may be assigned to this category if it clearly belongs, based on mechanistic considerations, to a class of agents for which one or more members have been classified in Group 1 or Group 2A.

Group 2B: The agent is *possibly carcinogenic to humans*.

This category is used for agents for which there is *limited evidence of carcinogenicity* in humans and less than *sufficient evidence of carcinogenicity* in experimental animals. It may also be used when there is *inadequate evidence of*

carcinogenicity in humans but there is *sufficient evidence of carcinogenicity* in experimental animals. In some instances, an agent for which there is *inadequate evidence of carcinogenicity* in humans and less than *sufficient evidence of carcinogenicity* in experimental animals together with supporting evidence from mechanistic and other relevant data may be placed in this group. An agent may be classified in this category solely on the basis of strong evidence from mechanistic and other relevant data.

Group 3: The agent is *not classifiable as to its carcinogenicity to humans*.

This category is used most commonly for agents for which the evidence of carcinogenicity is *inadequate* in humans and *inadequate* or *limited* in experimental animals.

Exceptionally, agents for which the evidence of carcinogenicity is *inadequate* in humans but *sufficient* in experimental animals may be placed in this category when there is strong evidence that the mechanism of carcinogenicity in experimental animals does not operate in humans.

Agents that do not fall into any other group are also placed in this category.

An evaluation in Group 3 is not a determination of non-carcinogenicity or overall safety. It often means that further research is needed, especially when exposures are widespread or the cancer data are consistent with differing interpretations.

Group 4: The agent is probably not carcinogenic to humans.

This category is used for agents for which there is *evidence suggesting lack of carcinogenicity* in humans and in experimental animals. In some instances, agents for which there is *inadequate evidence of carcinogenicity* in humans but *evidence suggesting lack of carcinogenicity* in experimental animals, consistently and strongly supported by a broad range of mechanistic and other relevant data, may be classified in this group.

(e) Rationale

The reasoning that the Working Group used to reach its evaluation is presented and discussed. This section integrates the major findings from studies of cancer in humans, studies of cancer in experimental animals, and mechanistic and other relevant data. It includes concise statements of the principal line(s) of argument that emerged, the conclusions of the Working Group on the strength of the evidence for each group of studies, citations to indicate which studies were pivotal to these conclusions, and an explanation of the reasoning of the Working Group in weighing data and making evaluations. When there are significant differences of scientific interpretation among Working Group Members, a brief summary of the alternative interpretations is provided, together with their scientific rationale and an indication of the relative degree of support for each alternative.

AX1.2.6. National Toxicology Program Criteria

The criteria for listing an agent, substance, mixture, or exposure circumstance in the National Toxicology Program's Report on Carcinogens (NTP, 2005) are as follows:

Known To Be Human Carcinogen:

There is sufficient evidence of carcinogenicity from studies in humans*, which indicates a causal relationship between exposure to the agent, substance, or mixture, and human cancer.

Reasonably Anticipated To Be Human Carcinogen:

There is limited evidence of carcinogenicity from studies in humans*, which indicates that causal interpretation is credible, but that alternative explanations, such as chance, bias, or confounding factors, could not adequately be excluded,

or

there is sufficient evidence of carcinogenicity from studies in experimental animals, which indicates there is an increased incidence of malignant and/or a combination of malignant and benign tumors (1) in multiple species or at multiple tissue sites, or (2) by multiple routes of exposure, or (3) to an unusual degree with regard to incidence, site, or type of tumor, or age at onset,

or

there is less than sufficient evidence of carcinogenicity in humans or laboratory animals; however, the agent, substance, or mixture belongs to a well-defined, structurally related class of substances whose members are listed in a previous Report on Carcinogens as either known to be a human carcinogen or reasonably anticipated to be a human carcinogen, or there is convincing relevant information that the agent acts through mechanisms indicating it would likely cause cancer in humans.

Conclusions regarding carcinogenicity in humans or experimental animals are based on scientific judgment, with consideration given to all relevant information. Relevant information includes, but is not limited to, dose response, route of exposure, chemical structure, metabolism, pharmacokinetics, sensitive sub-populations, genetic effects, or other data relating to mechanism of action or factors that may be unique to a given substance. For example, there may be substances for which there is evidence of carcinogenicity in laboratory animals, but there are compelling data indicating that the agent acts through mechanisms which do not operate in humans and would therefore not reasonably be anticipated to cause cancer in humans.

*This evidence can include traditional cancer epidemiology studies, data from clinical studies, and/or data derived from the study of tissues or cells from humans exposed to the substance in question that can be useful for evaluating whether a relevant cancer mechanism is operating in people.

Annex 2. Atmospheric Chemistry of NO_x

AX2.1. Introduction

Nitrogen oxides (NO_x) along with volatile organic compounds (VOCs) including anthropogenic and biogenic hydrocarbons, aldehydes, etc. and carbon monoxide (CO) serve as precursors in the formation of ozone (O₃) and other elements of photochemical smog. Nitrogen dioxide is an oxidant and can further react to form other photochemical oxidants, in particular the organic nitrates, including peroxy acetyl nitrates (PAN) and higher PAN analogues. It can also react with toxic compounds such as polycyclic aromatic hydrocarbons (PAHs) to form nitro-PAHs, which may be even more toxic than the precursors.

The role of NO_x in O₃ formation was reviewed in Chapter 2 (Section 2.2) of the 2006 AQCD for Ozone and Other Photochemical Oxidants (U.S. Environmental Protection Agency, 2006), and in numerous texts (e.g., Seinfeld and Pandis, 1998; Jacob, 2000; Jacobson, 2002). Mechanisms for transporting O₃ precursors, the factors controlling the efficiency of O₃ production from NO_x, methods for calculating O₃ from its precursors, and methods for measuring NO_x were all reviewed in Section 2.6 of the 2006 O₃ AQCD. The main points from those discussions in the 2006 O₃ AQCD and updates, based on new materials will be presented here.

The overall chemistry of reactive nitrogen compounds in the atmosphere is summarized in Figure AX2.2-1 and is described in greater detail in the following sections. Nitrogen oxides are emitted primarily as NO with smaller quantities of NO₂. Emissions of NO_x are spatially distributed vertically with some occurring at or near ground level (e.g., mobile sources) and others aloft (e.g., electric generating utility (EGUs) stacks) as indicated in Figure AX2.2-1. Because of atmospheric chemical reactions, the relative abundance of different compounds contributed by different sources varies with location. Both anthropogenic and natural (biogenic) processes emit NO_x. In addition to gas phase reactions, multiphase processes are important for forming aerosol-phase pollutants, including aerosol NO₃⁻.

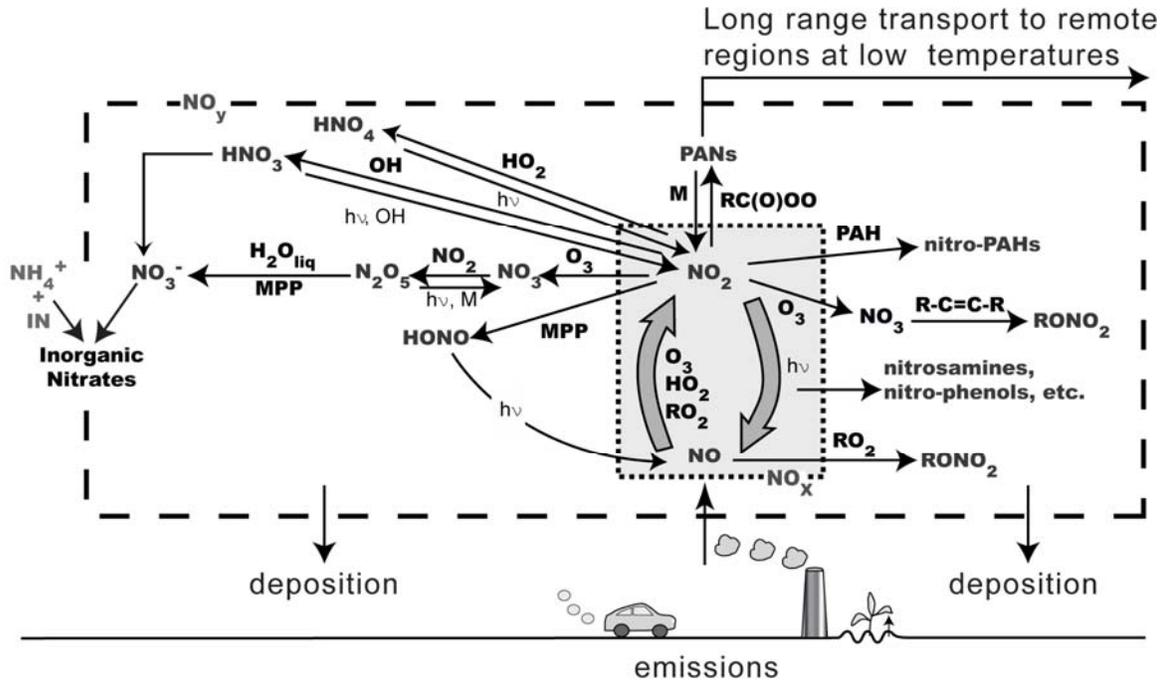

Figure AX2.2-1. Schematic diagram of the cycle of reactive nitrogen species in the atmosphere. MPP refers to multi-phase process; $h\nu$ to a photon of solar energy.

AX2.2. Chemistry of NO_x in the Troposphere

AX2.2.1. Basic Chemistry

There is a rapid photochemical cycle in the troposphere that involves photolysis of NO_2 by solar UV-A radiation to yield NO and a ground-state oxygen atom, $\text{O}(^3\text{P})$

This ground-state oxygen atom can then combine with molecular oxygen (O_2) to form O_3 ; and, colliding with any molecule from the surrounding air ($M = \text{N}_2, \text{O}_2$, etc.), the newly formed O_3 molecule transfers excess energy and is stabilized

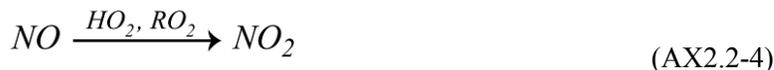

where $M = \text{N}_2, \text{O}_2$. Reaction AX2.2-2 is the only significant reaction forming O_3 in the troposphere.

NO and O_3 react to reform NO_2

Reaction AX2.2-3 is responsible for O₃ decreases and NO₂ increases found near sources of NO (e.g., highways). The falloff of NO₂ from a road depends on wind speed and direction and the local structure of turbulent mixing, temperature (through the temperature dependence of Reaction AX2.2-3) and the amount of sunlight (through Reaction AX2.2-1). Oxidation of reactive VOCs leads to formation of reactive radical species that allow the conversion of NO to NO₂ without participation of O₃ as in Reaction AX2.2-3

O₃, therefore, can accumulate as NO₂ photolyzes as in Reaction AX2.2-1, followed by Reaction AX2.2-2. Specific mechanisms for the oxidation of a number of VOCs were discussed in the O₃ AQCD (U.S. Environmental Protection Agency, 2006).

It is often convenient to speak about families of chemical species defined in terms of members that interconvert rapidly among themselves on time scales that are shorter than those for formation or destruction of the family as a whole. For example, an “odd oxygen” (*O_x*) family can be defined as

$$O_x = \sum(O(^3P) + O(^1D) + O_3 + NO_2) \quad (\text{AX2.2-5})$$

In much the same way, NO_x is sometimes referred to as “odd nitrogen”. Hence, we see that production of *O_x* occurs by the schematic Reaction AX2.2-5, and that the sequence of reactions given by reactions AX2.2-1 through AX2.2-3 represents no net production of *O_x*. Definitions of species families and methods for constructing families are discussed in Jacobson (1999) and references therein. Other families that include nitrogen-containing species, and which will be referred to later in this chapter, are:

$$NO_z = \sum HNO_3 + HNO_4 + NO_3 + 2NO_2O_5 + PAN(CH_3CHO - OO - NO_2) + \text{other organic nitrates} + \text{halogen nitrates} + \text{particulate nitrate}$$

$$NO_Y = NO_X + NO_Z + HONO; \\ \text{and } NH_X = NH_3 + NH_4^+ \quad (\text{AX2.2-6})$$

In this equation, *NO_Z* refers to the sum of the oxidation products of *NO_X*. The reaction of NO₂ with O₃ leads to the formation of NO₃· radical

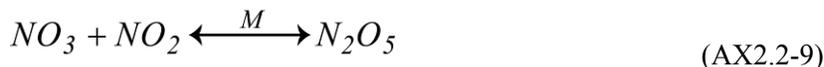

However, because the NO₃ radical photolyzes rapidly (lifetime of ~5 s during the photochemically most active period of the day around local solar noon (Atkinson et al., 1992),

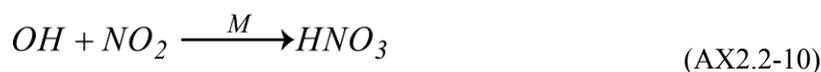

its concentration remains low during daylight hours, but can increase after sunset to nighttime concentrations of $<5 \times 10^7$ to 1×10^{10} molecules/cm³ (<2 to 430 parts per trillion (ppt)) over continental areas influenced by anthropogenic emissions of NO_x (Atkinson et al., 1986). At night, NO₃, rather than the hydroxyl radical (OH), is the primary oxidant in the system.

Nitrate radicals can combine with NO₂ to form dinitrogen pentoxide (N₂O₅)

and N₂O₅ both photolyzes and thermally decomposes back to NO₂ and NO₃ during the day; however, N₂O₅ concentrations can accumulate during the night to parts per billion (ppb) levels in polluted urban atmospheres.

The tropospheric chemical removal processes for NO_x include reaction of NO₂ with the OH radical and hydrolysis of N₂O₅ in aqueous aerosol solutions if there is no organic coating. Both of these reactions produce HNO₃

The gas-phase reaction of OH radical with NO₂ (Reaction AX2.2-11) initiates one of the major and ultimate removal processes for NO_x in the troposphere. This reaction removes OH and NO₂ radicals and competes with hydrocarbons for OH radicals in areas characterized by high NO_x concentrations, such as urban centers (see Section AX2.2.2). The timescale (τ) for conversion of NO_x to HNO₃ in the planetary boundary layer at 40 N latitude ranges from about 4 h in July to about 16 h in January. The corresponding range in τ at 25 N latitude is between 4 and 5 h, while at 50 N latitude, HNO₃ τ ranges from about 4 to 20 h (Martin et al., 2003). In addition to gas-phase HNO₃, Golden and Smith (2000) have shown on the basis of theoretical studies that pernitrous acid (HOONO) is also produced by the reaction of NO₂ and OH radicals. However, this channel of production most likely represents a minor yield approximately 15% at the surface (Jet Propulsion Laboratory, 2003).

Pernitrous acid will thermally decompose and can photolyze. Gas-phase HNO₃ formed from Reactions AX2.2-10 and AX2.2-11 undergoes wet and dry deposition to the surface, and uptake by ambient aerosol particles. Reaction AX2.2-10 limits NO_x τ to a range of hours to days. Geyer and Platt (2002) concluded that Reaction AX2.2-10 constituted about 10% of the removal of NO_x at a site near Berlin, Germany during spring and summer. However, other studies found a larger contribution to HNO₃ production from Reaction AX2.2-10. Dentener and Crutzen (1993) estimated 20% in summer and 80% of HNO₃ production in winter is from Reaction AX2.2-10. Tonnesen and Dennis (2000) found 16 to 31% of summer HNO₃ production was from Reaction AX2.2-10. The contribution of Reaction AX2.2-11 to HNO₃ formation is highly uncertain during both winter and summer. The importance of Reaction AX2.2-11 could be much higher during winter than during summer because of the much lower concentration of OH radicals and the enhanced stability of N₂O₅ due to lower temperatures and less sunlight. Note that Reaction AX2.2-11 proceeds as a heterogeneous reaction. Recent work in the northeastern United States indicates that this reaction proceeds at a faster rate in power plant plumes than in urban plumes (Brown et al., 2006a,b; Frost et al., 2006).

In addition to the uptake of HNO₃ on particles and in cloud drops, it photolyzes and reacts with OH radicals via

and

The lifetime of HNO_3 with respect to these two reactions is long enough for HNO_3 to act as a reservoir species for NO_x during long-range transport.

OH radicals also can react with NO to produce nitrous acid (HONO or HNO_2)

In the daytime, HNO_2 is rapidly photolyzed back to the original reactants.

Reaction AX2.2-15 is, however, a negligible source of HONO, which is formed mainly by multiphase processes (see Section AX2.2.3). At night, heterogeneous reactions of NO_2 in aerosols or at the earth's surface result in accumulation of HONO (Lammel and Cape, 1996; Jacob, 2000; Sakamaki et al., 1983; Pitts et al., 1984; Svensson et al., 1987; Jenkin et al., 1988; Lammel and Perner, 1988; Notholt et al., 1992a,b). Harris et al. (1982) suggested that photolysis of this HNO_2 at sunrise could provide an important early-morning source of OH radicals to drive O_3 formation.

Hydroperoxy (HO_2) radicals can react with NO_2 to produce pernitric acid (HNO_4)

which then can thermally decompose and photolyze back to its original reactants. The acids formed in these gas-phase reactions are all water soluble. Hence, they can be incorporated into cloud drops and in the aqueous phase of particles.

Although the lifetimes of HNO_4 and N_2O_5 are short (minutes to hours) during typical summer conditions, they can be much longer at the lower temperatures and darkness found during the polar night. Under these conditions, species such as PAN, HNO_3 , HNO_4 , and N_2O_5 serve as NO_x reservoirs that can liberate NO_2 upon the return of sunlight during the polar spring.

A broad range of organic nitrogen compounds can be directly emitted by combustion sources or formed in the atmosphere from NO_x emissions. Organic nitrogen compounds include the PANs, nitrosamines, nitro-PAHs, and the more recently identified nitrated organics in the quinone family. Oxidation of VOCs produces organic peroxy radicals (RO_2), as discussed in the 2006 AQCD for Ozone. Reaction of RO_2 radicals with NO and NO_2 produces organic nitrates ($RONO_2$) and peroxy nitrates (RO_2NO_2)

Reaction (AX2.2-17) is a minor branch for the reaction of RO_2 with NO; the major branch involves NO_2 as in Reaction AX2.2-18. Note, however, that organic nitrate yields increase with carbon number (Atkinson, 2000).

The most important of these organic nitrates is PAN, the dominant member of the broader family of peroxyacetyl nitrates which includes peroxypropionyl nitrate (PPN) of anthropogenic origin and

peroxymethacrylic nitrate (MPAN) produced from isoprene oxidation. The PANs are formed by the combination reaction of acetyl peroxy radicals with NO₂

where the acetyl peroxy radicals are formed mainly during the oxidation of ethane (C₂H₆). Acetaldehyde (CH₃CHO) is formed as an intermediate species during the oxidation of ethane. Acetaldehyde can be photolyzed or react with OH radicals to yield acetyl radicals.

Acetyl radicals then react with O₂ to yield acetyl peroxy radicals.

However, acetyl peroxy radicals will react with NO in areas of high NO concentrations

and the acetyl-oxy radicals will then decompose

Thus, the formation of PAN is favored at conditions of high ratios of NO₂ to NO which are most typically found under low NO_x conditions. The PANs both thermally decompose and photolyze back to their reactants on timescales of a few hours during warm sunlit conditions, having lifetimes with respect to thermal decomposition ranging from ~1 hour at 298 K to ~2.5 days at 273 K, up to several weeks at 250 K. Thus, they can provide an effective sink of NO_x at cold temperatures and high solar zenith angles, allowing release of NO₂ as air masses warm, in particular by subsidence. The PANs are also removed by uptake to vegetation (Sparks et al., 2003; Teklemariam and Sparks, 2004).

The organic nitrates may react further, depending on the functionality of the R group, but they will typically not return NO_x and can therefore be viewed mainly as a permanent sink for NO_x as alkyl nitrates are sparingly soluble and will photolyze. This sink is usually small compared to HNO₃ formation although the formation of isoprene nitrates may be a significant sink for NO_x in the United States in summer (Liang et al., 1998).

The peroxy nitrates produced by AX2.2-19 are thermally unstable and most have very short lifetimes (less than a few minutes) owing to thermal decomposition back to the original reactants. They are thus not effective sinks of NO_x.

AX2.2.2. NO_x Concentrations and O₃ Formation

Ozone is unlike some other species whose rates of formation vary directly with the emissions of their precursors in that O₃ production (P(O₃)) changes nonlinearly with the concentrations of its precursors. At the low NO_x concentrations found in most environments ranging from remote continental areas to rural and suburban areas downwind of urban centers, the net production of O₃ increases with

increasing NO_x . At the high NO_x concentrations found in downtown metropolitan areas especially near busy streets and roadways and in power plant plumes, there is net destruction of O_3 by (titration) reaction with NO . Between these two regimes is a transition stage in which O_3 shows only a weak dependence on NO_x concentrations. In the high NO_x regime, NO_2 scavenges OH radicals which would otherwise oxidize VOCs to produce peroxy radicals, which in turn would oxidize NO to NO_2 . In the low NO_x regime, VOC oxidation generates, or at least does not consume, free radicals, and O_3 production varies directly with NO_x . Sometimes the terms ‘VOC-limited’ and ‘ NO_x -limited’ are used to describe these two regimes; also, the terms NO_x -limited and NO_x -saturated are used, e.g., by Jaeglé et al., 2001. The chemistry of OH radicals, which are responsible for initiating the oxidation of hydrocarbons, shows behavior similar to that for O_3 with respect to NO_x concentrations (Hameed et al., 1979; Pinto et al., 1993; Poppe et al., 1993; Zimmerman and Poppe, 1993). These considerations introduce a high degree of uncertainty into attempts to relate changes in O_3 concentrations to emissions of precursors. It should also be noted at the outset that in a NO_x -limited (or NO_x -sensitive) regime, O_3 formation is not insensitive to radical production or the flux of solar UV photons, just that O_3 formation is more sensitive to NO_x . For example, global tropospheric O_3 is sensitive to the concentration of CH_4 even though the troposphere is predominantly NO_x -limited.

Various analytical techniques have been proposed that use ambient NO_x and VOC measurements to derive information about O_3 production and O_3 - NO_x -VOC sensitivity. Previously (e.g., National Research Council, 1991), it was suggested that O_3 formation in individual urban areas could be understood in terms of measurements of ambient NO_x and VOC concentrations during the early morning. In this approach, the ratio of summed VOC to NO_x concentrations (unweighted by chemical reactivity) is used to determine whether conditions are NO_x -sensitive or VOC sensitive. This technique is inadequate to characterize O_3 formation because it omits many factors recognized as important for $\text{P}(\text{O}_3)$, including: the effect of biogenic VOCs (which are not present in urban centers during early morning); important individual differences in the ability of VOCs to generate free radicals, rather than just from total VOC concentration and other differences in O_3 -forming potential for individual VOCs (Carter, 1995); the effect of multiday transport; and general changes in photochemistry as air moves downwind from urban areas (Milford et al., 1994).

Jacob et al. (1995) used a combination of field measurements and a chemical transport model (CTM) to show that the formation of O_3 changed from NO_x -limited to NO_x -saturated as the season changed from summer to fall at a monitoring site in Shenandoah National Park, VA. Photochemical production of O_3 generally occurs together with production of other species including HNO_3 , organic nitrates, and hydrogen peroxide (H_2O_2). The relative rates of $\text{P}(\text{O}_3)$ and the production of other species varies depending on photochemical conditions and can be used to provide information about O_3 -precursor sensitivity.

There are no hard and fast rules governing the levels of NO_x at which the transition from NO_x -limited to NO_x -saturated conditions occurs. The transition between these two regimes is highly spatially and temporally dependent. In the upper troposphere, responses to NO_x additions from commercial aircraft have been found which are very similar to these in the lower troposphere (Brühl et al., 2000). Brühl et al. (2000) found that the NO_x levels for O_3 production versus loss are highly sensitive to the radical sources included in model calculations. They found that inclusion of only CH_4 and CO oxidation leads to a decrease in net O_3 production in the North Atlantic flight corridor due to NO emissions from aircraft. However, the additional inclusion of acetone photolysis was found to shift the maximum in O_3 production to higher NO_x mixing ratios, thereby reducing or eliminating areas in which O_3 production rates decreased due to aircraft emissions.

Trainer et al. (1993) suggested that the slope of the regression line between O_3 and NO_z can be used to estimate the rate of $\text{P}(\text{O}_3)$ per NO_x , also known as the O_3 production efficiency or OPE. Ryerson et al. (1998, 2001) used measured correlations between O_3 and NO_z to identify different rates of O_3 production in plumes from large point sources.

Sillman (1995) and Sillman and He (2002) identified several secondary reaction products that show different correlation patterns for NO_x -limited conditions and NO_x -saturated conditions. The most

important correlations are for O_3 versus NO_Y , O_3 versus NO_Z , O_3 versus HNO_3 , and H_2O_2 versus HNO_3 . The correlations between O_3 and NO_Y , and O_3 and NO_Z are especially important because measurements of NO_Y and NO_X are widely available. Measured O_3 versus NO_Z (Figure AX2.2-2) shows distinctly different patterns in different locations. In rural areas and in urban areas such as Nashville, TN, O_3 shows a strong correlation with NO_Z and a relatively steep slope to the regression line. By contrast, in Los Angeles O_3 also increases with NO_Z , but the rate of increase of O_3 with NO_Z is lower and the O_3 concentrations for a given NO_Z value are generally lower.

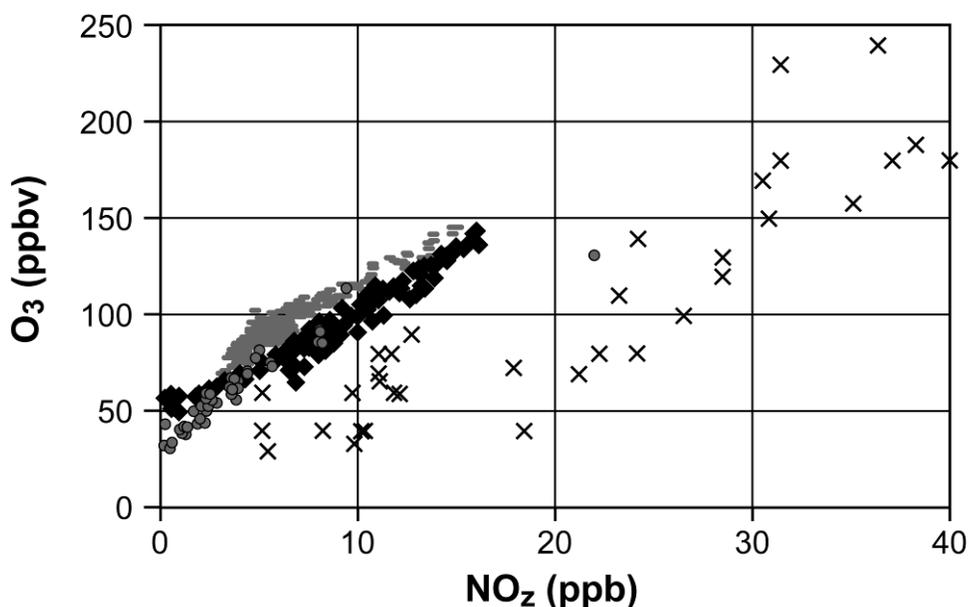

Figure AX2.2-2. Measured values of O_3 and NO_z ($NO_Y - NO_X$). Measured during the afternoon at rural sites in the eastern United States (gray circle) and in urban areas and urban plumes associated with Nashville, TN (gray dash), Paris, FR (black diamond) and Los Angeles, CA (X)

The difference between NO_X -limited and NO_X -saturated regimes is also reflected in measurements of H_2O_2 . Formation of H_2O_2 takes place by self-reaction of photochemically generated HO_2 radicals, so that there is large seasonal variation of H_2O_2 concentrations, and values in excess of 1 ppb are mainly limited to the summer months when photochemistry is more active (Kleinman, 1991). Hydrogen peroxide is produced in abundance only when O_3 is produced under NO_X -limited conditions. When the photochemistry is NO_X -saturated, much less H_2O_2 is produced. In addition, increasing NO_X tends to slow the formation of H_2O_2 under NO_X -limited conditions. Differences between these two regimes are also related to the preferential formation of sulfate during summer and to the inhibition of sulfate and hydrogen peroxide during winter (Stein and Lamb, 2003). Measurements in the rural eastern United States (Jacob et al., 1995), at Nashville (Sillman et al., 1998), and at Los Angeles (Sakugawa and Kaplan, 1989) show large differences in H_2O_2 concentrations likely due to differences in NO_X availability at these locations.

AX2.2.3. Multiphase Chemistry Involving NO_X

Recent laboratory studies on sulfate and organic aerosols indicate that the reaction probability $\gamma_{N_2O_5}$ is in the range of 0.01 to 0.05 (Kane et al., 2001; Hallquist et al., 2003; Thornton et al., 2003). Tie

et al. (2003) found that a value of 0.04 in their global model gave the best simulation of observed NO_x concentrations over the Arctic in winter.

Using aircraft measurements over the northeastern United States, Brown et al. (2006b) found that the uptake coefficient for N_2O_5 , $\gamma\text{N}_2\text{O}_5$, on the surfaces of particles depends strongly on their sulfate content. They found that $\gamma\text{N}_2\text{O}_5$ was highest (0.017) in regions where the aerosol sulfate concentration was highest and lower elsewhere (<0.0016). This result contrasts with that of Dentener and Crutzen (1993) who concluded that $\gamma\text{N}_2\text{O}_5$ would be independent of aerosol composition, based on a value for $\gamma\text{N}_2\text{O}_5$ of 0.1, implying that the heterogeneous hydrolysis of N_2O_5 would be saturated for typical ambient aerosol surface areas. The importance of this reaction to tropospheric chemistry depends on the value of $\gamma\text{N}_2\text{O}_5$. If it is 0.01 or lower, there may be difficulty explaining the loss of NO_y and the formation of aerosol nitrate, especially during winter. A decrease in N_2O_5 slows down removal of NO_x by leaving more NO_2 available for reaction and thus increases O_3 production. Based on the consistency between measurements of NO_y partitioning and gas-phase models, Jacob (2000) considered it unlikely that HNO_3 is recycled to NO_x in the lower troposphere in significant concentrations. However, only one of the reviewed studies (Schultz et al., 2000) was conducted in the marine troposphere and none was conducted in the MBL. An investigation over the equatorial Pacific reported discrepancies between observations and theory (Singh et al., 1996) which might be explained by HNO_3 recycling. It is important to recognize that both Schultz et al. (2000) and Singh et al. (1996) involved aircraft sampling at altitude which, in the MBL, can significantly under-represent sea salt aerosols and thus most total NO_3 (defined to be $\text{HNO}_3 + \text{NO}_3^-$) and large fractions of NO_y in marine air (see Huebert et al., 1996). Consequently, some caution is warranted when interpreting constituent ratios and NO_y budgets based on such data.

Recent work in the Arctic has quantified significant photochemical recycling of NO_3^- to NO_x and attendant perturbations of OH chemistry in snow (Honrath et al., 2000; Dibb et al., 2002; Dominé and Shepson, 2002) which suggest the possibility that similar multiphase pathways could occur in aerosols. As mentioned above, NO_3^- is photolytically reduced to NO_2^- (Zafiriou and True, 1979) in acidic sea salt solutions (Anastasio et al., 1999). Further photolytic reduction of NO_2^- to NO (Zafiriou and True, 1979) could provide a possible mechanism for HNO_3 recycling. Early experiments reported production of NO_x during the irradiation of artificial seawater concentrates containing NO_3^- (Petriconi and Papee, 1972). Based on the above, HNO_3 recycling in sea salt aerosols is potentially important and warrants further investigation. Other possible recycling pathways involving highly acidic aerosol solutions and soot are reviewed by Jacob (2000).

Stemmler et al. (2006) studied the photosensitized reduction of NO_2 to HONO on humic acid films using radiation in the UV-A through the visible spectral regions. They also found evidence for reduction occurring in the dark, reactions which may occur involving surfaces containing partly oxidized aromatic structures. For example, Simpson et al. (2006) found that aromatic compounds constituted ~20% of organic films coating windows in downtown Toronto. They calculated production rates of HONO that are compatible with observations of high HONO levels in a variety of environments. The photolysis of HONO formed this way could account for up to 60% of the integrated source of OH radicals in the inner planetary boundary layer. A combination of high NO_2 levels and surfaces of soil and buildings and other man-made structures exposed to diesel exhaust would then be conducive to HONO formation and, hence, to high OH concentrations.

Ammann et al. (1998) reported the efficient conversion of NO_2 to HONO on fresh soot particles in the presence of water. They suggested that interaction between NO_2 and soot particles may account for high concentrations of HONO observed in urban environments. Conversion of NO_2 to HONO and the subsequent photolysis of HONO to $\text{NO} + \text{OH}$ would constitute a NO_x -catalyzed O_3 sink involving snow. High concentrations of HONO can lead to the rapid growth in OH concentrations shortly after sunrise, giving a “jump start” to photochemical smog formation. Prolonged exposure to ambient oxidizing agents appears to deactivate this process. Bröske et al. (2003) studied the interaction of NO_2 on secondary organic aerosols and concluded that the uptake coefficients were too low for this reaction to be an important source of HONO in the troposphere.

Choi and Leu (1998) evaluated the interactions of HNO₃ on model black carbon soot (FW2), graphite, hexane, and kerosene soot. They found that HNO₃ decomposed to NO₂ and H₂O at higher HNO₃ surface coverages, i.e., P(HNO₃) ≥ 10⁻⁴ Torr. None of the soot models used were reactive at low HNO₃ coverages, at P(HNO₃) = 5 × 10⁻⁷ Torr or at temperatures below 220 K. They concluded that it is unlikely that aircraft soot in the upper troposphere/lower stratosphere reduces HNO₃.

Heterogeneous production on soot at night is believed to be the mechanism by which HONO accumulates to provide an early morning source of HO_x in high NO_x environments (Harrison et al., 1996; Jacob, 2000). HONO has been frequently observed to accumulate to levels of several ppb overnight, and this has been attributed to soot chemistry (Harris et al., 1982; Calvert et al., 1994; Jacob, 2000).

Longfellow et al. (1999) observed the formation of HONO when methane, propane, hexane, and kerosene soots were exposed to NO₂. They suggested that this reaction may account for some part of the unexplained high levels of HONO observed in urban areas. They commented that without details about the surface area, porosity, and amount of soot available for this reaction, reactive uptake values cannot be estimated reliably. They further commented that soot and NO₂ are produced in close proximity during combustion, and that large quantities of HONO have been observed in aircraft plumes.

Saathoff et al. (2001) studied the heterogeneous loss of NO₂, HNO₃, NO₃/N₂O₅, HO₂/HO₂NO₂ on soot aerosol using a large aerosol chamber. Reaction periods of up to several days were monitored and results used to fit a detailed model. Saathoff et al. derived reaction probabilities at 294 K and 50% relative humidity (RH) for NO₂, NO₃, HO₂, and HO₂NO₂ deposition to soot; HNO₃ reduction to NO₂; and N₂O₅ hydrolysis. When these probabilities were included in photochemical box model calculations of a 4-day smog event, the only noteworthy influence of soot was a 10% reduction in the second day O₃ maximum, for a soot loading of 20 μg/m³, i.e., roughly a factor of 10 times observed black carbon loadings seen in U.S. urban areas, even during air pollution episodes.

Muñoz and Rossi (2002) conducted Knudsen cell studies of HNO₃ uptake on black and grey decane soot produced in lean and rich flames, respectively. They observed HONO as the main species released following HNO₃ uptake on grey soot, and NO and traces of NO₂ from black soot. They concluded that these reactions would only have relevance in special situations in urban settings where soot and HNO₃ are present in high concentrations simultaneously.

AX2.2.4. Formation of Nitro-PAHs

Nitro-polycyclic aromatic hydrocarbons (nitro-PAHs) (see Figure AX2.2-3 for some example nitro-PAHs) are generated from incomplete combustion processes through electrophilic reactions of polycyclic aromatic hydrocarbons (PAHs) in the presence of NO₂ (International Agency for Research on Cancer [IARC], 1989; World Health Organization [WHO], 2003). Among combustion sources, diesel emissions have been identified as the major source of nitro-PAHs in ambient air (Bezabeh et al., 2003; Gibson, 1983; Schuetzle, 1983; Tokiwa and Ohnishi, 1986). Direct emissions of nitro-PAHs in PM vary with type of fuel, vehicle maintenance, and ambient conditions (Zielinska et al., 2004).

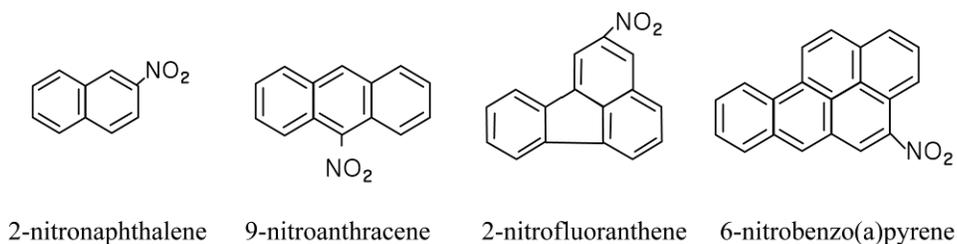

Figure AX2.2-3. Structures of some nitro-polycyclic aromatic hydrocarbons.

In addition to being directly emitted, nitro-PAHs can also be formed from both gaseous and heterogeneous reactions of PAHs with gaseous nitrogenous pollutants in the atmosphere (Arey et al., 1986, 1989, Arey, 1998; Perrini, 2005; Pitts, 1987; Sasaki et al., 1997; Zielinska et al., 1989). Different isomers of nitro-PAHs are formed through different formation processes. For example, the most abundant nitro-PAH in diesel particles is 1-nitropyrene (1NP), followed by 3-nitrofluoranthene (3NF) and 8-nitrofluoranthene (8NF) (Bezabeh et al., 2003; Gibson, 1983; Schuetzle, 1983; Tokiwa and Ohnishi, 1986). However, in ambient particulate organic matter (POM), 2-nitrofluoranthene (2NF) is the dominant compound, followed by 1NP and 2-nitropyrene (2NP) (Arey et al., 1989; Bamford et al., 2003; Reisen and Arey, 2005; Zielinska et al., 1989), although 2NF and 2NP are not directly emitted from primary combustion emissions. The reaction mechanisms for the different nitro-PAH formation processes have been well documented and are presented in Figure AX2.2-4.

The dominant process for the formation of nitro-PAHs in the atmosphere is gas-phase reaction of PAHs with OH radicals in the presence of NO_x (Arey et al., 1986, Arey, 1998; Atkinson and Arey, 1994; Ramdahl et al., 1986; Sasaki et al., 1997). Hydroxyl radicals can be generated photochemically or at night through ozone-alkene reactions, (Finlayson-Pitts and Pitts, 2000). The postulated reaction mechanism of OH with PAHs involves the addition of OH at the site of highest electron density of the aromatic ring, for example, the 1-position for pyrene (PY) and the 3-position for fluoranthene (FL). This reaction is followed by the addition of NO_2 to the OH-PAH adduct and elimination of water to form the nitroarenes (Figure AX2.2-4) (Arey et al., 1986; Atkinson et al., 1990; Pitts, 1987). After formation, nitro-PAHs with low vapor pressures (such as 2NF and 2NP) immediately migrate to particles under ambient conditions (Fan et al., 1995; Feilberg et al., 1999). The second order rate-constants for the reactions of OH with most PAHs range from 10^{-10} to 10^{-12} $\text{cm}^3/\text{molecule}/\text{s}$ at 298 K with the yields ranging from ~ 0.06 to $\sim 5\%$ (Atkinson and Arey, 1994). 2NF and 2NP have been found as the most abundant nitro-PAHs formed via reactions of OH with gaseous FL and PY, respectively, in ambient air.

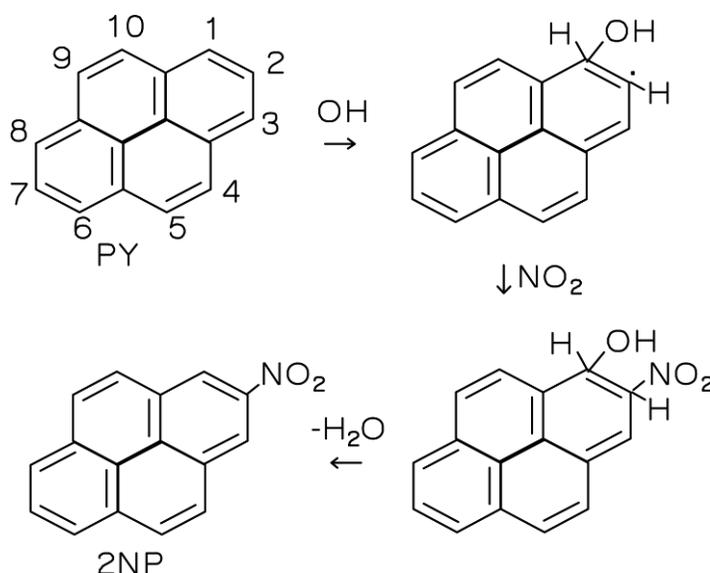

Figure AX2.2-4. Formation of 2-nitropyrene (2NP) from the reaction of OH with gaseous pyrene (PY).

The second important process for the formation of nitro-PAHs in the atmosphere is the nitration of PAHs by NO_3^- in the presence of NO_x at night (Atkinson et al., 1990; Atkinson and Arey, 1994; Sasaki et al., 1997). Nitrate radicals can be generated by reaction of ozone (O_3) with NO_2 in the atmosphere by Reaction AX2.2-25.

Similar to the mechanism of OH reactions with PAHs, NO₃ initially adds to the PAH ring to form an NO₃-PAH adduct, followed by loss of HNO₃ to form nitro-PAHs (Atkinson et al., 1990; Atkinson and Arey, 1994; Sasaki et al., 1997). For example, in the mixture of naphthalene and N₂O₅-NO₃-NO₂, the major products formed through the NO₃ reaction are 1- and 2-nitro-naphthalene (1NN and 2NN) (Atkinson et al., 1990; Feilberg et al., 1999; Sasaki et al., 1997). 2NF and 4NP were reported as the primary products of the gas-phase reactions of FL and PY with NO₃ radical, respectively (Atkinson et al., 1990; Atkinson and Arey, 1994).

The reaction with NO₃ is of minor importance in the daytime because NO₃ radical is not stable in sunlight. In addition, given the rapid reactions of NO with NO₃ and with O₃ in the atmosphere (Finlayson-Pitts and Pitts 2000), concentrations of NO₃ at ground level are low during daytime. However, at night, concentrations of NO₃ radicals formed in polluted ambient air are expected to increase. According to Atkinson (1991), the average NO₃ concentration is about 20 ppt in the lower troposphere at night and can be as high as 430 ppt. It is also worth noting that significant NO₃ radical concentrations are found at elevated altitudes where O₃ is high but NO is low (Reissell and Arey, 2001; Stutz et al., 2004a). When NO₃ reaches high concentrations, the formation of nitro-PAHs by the reaction of gaseous PAHs with NO₃ may be of environmental significance. At 10⁻¹⁷ to 10⁻¹⁸ cm³/molecule/s, the rate constants of NO₃ with most PAHs are several orders of magnitude lower than those of OH with the same PAHs; however, the yields of nitro-PAHs from NO₃ reactions are generally much higher than those of OH reactions. For example, the yields of 1-NN and 2NF are 0.3% and 3%, respectively from OH reactions, but the yields are 17% and 24% for these two compounds generated from the NO₃ radical reactions (Atkinson and Arey, 1994). Therefore, formation of nitro-PAHs via reactions of NO₃ at nighttime under certain circumstances can be significant.

The third process of nitro-PAH formation in the atmosphere is nitration of PAHs by NO₂/N₂O₅ in the presence of trace amounts of HNO₃ in both gas and particle phases. This mechanism could be operative throughout the day and night (Pitts, 1983, 1985a,b; Grosjean et al., 1983; Ramdahl et al., 1984; Kamens et al., 1990). The formation of nitro-fluoranthenes was observed when adsorbed FL was exposed to gaseous N₂O₅, and the distribution of product NF isomers was 3- > 8- > 7- > 1- NF (Pitts et al., 1985a,b). The proposed mechanism for this reaction was an ionic electrophilic nitration by nitronium ion (NO₂⁺). It was speculated that N₂O₅ became ionized prior to the reaction with FL (Zielinska et al., 1986). Only 1NP was observed for the reaction of PY with N₂O₅ on filters (Pitts et al., 1985b). Compared to the reactions of OH and NO₃, nitration of PAHs by NO₂/N₂O₅ is less important.

Measurements of nitro-PAHs in ambient air provide evidence for the proposed reaction mechanism, i.e. the reactions of OH and NO₃ radicals with PAHs are the major sources of nitro-PAHs (Bamford and Baker, 2003; Reisen and Arey, 2005; and references therein). 2NF is a ubiquitous component of ambient POM, much higher than 1NP, itself a marker of combustion sources. Nitro-PAH isomer ratios show strong seasonality. For instance, the mean ratios of 2NF/1NP were higher in summer than in winter (Bamford et al., 2003; Reisen and Arey, 2005), indicating that reactions of OH and NO₃ with FL are the major sources of nitro-PAHs in ambient air in summer. The ratio of 2NF/1NP was lower in winter than in summer because of lower OH concentrations and, therefore, less production of 2NF via atmospheric reactions. A ratio of 1NP/2NF greater than 1 was observed in locations with major contributions from vehicle emissions (Dimashki et al., 2000; Feilberg et al., 2001). In addition, the ratio of 2NF/2NP was also used to evaluate the contribution of OH and NO₃ initiated reactions to the ambient nitro-PAHs (Bamford et al., 2003; Reisen and Arey, 2005).

The concentrations for most nitro-PAHs found in ambient air are much lower than 1 pg/m³, except NNs, 1NP, and 2NF, which can be present at several pg/m³. These levels are much lower (~2 to ~1000 times lower) than their parent PAHs. However, nitro-PAHs are much more toxic than PAHs (Durant et al., 1996; Grosinsky et al., 1999; Salmeen et al., 1982; Tokiwa et al., 1998; Tokiwa and Ohnishi, 1986). Moreover, most nitro-PAHs are present in particles with a mass median diameter <0.1 μm.

Esteve et al. (2006) examined the reaction of gas-phase NO₂ and OH radicals with various PAHs adsorbed onto model diesel particulate matter (SRM 1650a, NIST). Using pseudo second order rate coefficients, they derived lifetimes for conversion of the particle-bound PAHs to nitro-PAHs of a few days (for typical urban NO₂ levels of 20 ppb). They also found that the rates of reaction of OH with the PAHs were about four orders of magnitude larger than for the reactions involving NO₂. However, since the concentrations of NO₂ used above are more than four orders of magnitude larger than those for OH (10⁶-10⁷/cm³), they concluded that the pathway involving NO₂ is expected to be favored over that involving OH radicals. Consistent with the importance of the gas-phase formation of NPAHs, both the mutagenic potency of PM and the content of NPAHs in PM vary by particle size, and are higher in the submicron size range (Xu and Lee, 2000; Kawanaka et al., 2004).

The major loss process of nitro-PAHs is photodecomposition (Fan et al., 1996; Feilberg et al., 1999; Feilberg and Nielsen, 2001), with lifetimes on the order of hours. However, lacking direct UV light sources indoors, nitro-PAHs are expected have a longer lifetimes (days) indoors than outdoors; and may therefore pose increased health risks. Many nitro-PAHs are semi- or nonvolatile organic compounds. As stated above, indoor environments have much greater surface areas than outdoors. Thus, it is expected that gas/particle distribution of nitro-PAHs indoors will be different from those in ambient air. A significant portion of nitro-PAHs will probably be adsorbed by indoor surfaces, such as carpets, leading to different potential exposure pathways to nitro-PAHs in indoor environments. The special characteristics of indoor environments, which can affect the indoor chemistry and potential exposure pathways significantly, should be taken into consideration when conducting exposure studies of nitro-PAHs.

Reaction with OH and NO₃ radicals is a major mechanism for removing gas-phase PAHs, with OH radical initiated reactions predominating depending on season (Vione et al., 2004; Bamford et al., 2003). Particle-bound PAH reactions occur but tend to be slower. Nitronaphthalenes tend to remain in the vapor phase, but because phase partitioning depends on ambient temperature, in very cold regions these species can condense (Castells et al., 2003) while the higher molecular weight PAHs such as the nitroanthracenes, nitrophenantrenes and nitrofluoranthenes condense in and on PM (Ciganek et al., 2004; Cecinato, 2003).

AX2.2.5. Multiphase Chemical Processes Involving NO_x and Halogens

Four decades of observational data on O₃ in the troposphere have revealed numerous anomalies not easily explained by gas-phase HO_x-NO_x photochemistry. The best-known example is the dramatic depletion of ground-level O₃ during polar sunrise due to multiphase catalytic cycles involving inorganic Br and Cl radicals (Barrie et al., 1988; Martinez et al., 1999; Foster et al., 2001). Other examples of anomalies in tropospheric O₃ at lower latitudes include low levels of O₃ (<10 ppb) in the marine boundary layer (MBL) and overlying free troposphere (FT) at times over large portions of the tropical Pacific (Kley et al., 1996), as well as post-sunrise O₃ depletions over the western subtropical Pacific Ocean (Nagao et al., 1999), the temperate Southern Ocean (Galbally et al., 2000), and the tropical Indian Ocean (Dickerson et al., 1999). The observed O₃ depletions in near-surface marine air are generally consistent with the model-predicted volatilization of Br₂, BrCl, and Cl₂ from sea salt aerosols through autocatalytic halogen “activation” mechanisms (e.g., Vogt et al., 1996; Von Glasow et al., 2002a) involving these aqueous phase reactions.

In polluted marine regions at night, the heterogeneous reaction

may also be important (Finlayson-Pitts et al., 1989; Behnke et al., 1997; Erickson et al., 1999). Diatomic bromine, BrCl, Cl₂, and ClNO₂ volatilize and photolyze in sunlight to produce atomic Br and Cl. The acidification of sea salt aerosol via incorporation of HNO₃ (and other acids) leads to the volatilization of HCl (Erickson et al., 1999), e.g.

and the corresponding shift in phase partitioning can accelerate the deposition flux to the surface of total NO₃ (Russell et al., 2003; Fischer et al., 2006). However, Pryor and Sorensen (2000) have shown that the dominant form of nitrate deposition is a complex function of wind speed. In polluted coastal regions where HCl from Reaction AX2.2-30 often exceeds 1 ppb, significant additional atomic Cl is produced via

(Singh and Kasting, 1988; Keene et al., 2007). Following production, Br and Cl atoms catalytically destroy O₃ via

where (X = Br and Cl).

Formation of Br and Cl nitrates via

and the subsequent reaction of XNO₃ with sea salt and sulfate aerosols via

and

(where $Y = \text{Cl, Br, or I}$) accelerates the conversion of NO_x to particulate NO_3^- and thereby contributes indirectly to net O_3 destruction (Sander et al., 1999; Vogt et al., 1999; Pszenny et al., 2004).

Most XNO_3 reacts via Reaction AX2.2-36 on sea salt whereas reaction AX2.2-37 is more important on sulfate aerosols. Partitioning of HCl on sulfate aerosols following Henry's Law provides Cl⁻ for Reaction AX2.2-37 to form BrCl. Product NO_3^- from both Reactions AX2.2-36 and AX2.2-37 partitions with the gas-phase HNO_3 following Henry's Law. Because most aerosol size fractions in the MBL are near equilibrium with respect to HNO_3 (Erickson et al., 1999; Keene et al., 2004), both sulfate and sea salt aerosol can sustain the catalytic removal of NO_x and re-activation of Cl and Br with no detectable change in composition. The photolytic reduction of NO_3^- in sea salt aerosol solutions recycles NO_x to the gas phase (Pszenny et al., 2004). Halogen chemistry also impacts O_3 indirectly by altering OH/ HO_2 ratios through the steps of Reactions AX2.2-33 and AX2.2-34 (e.g., Stutz et al., 1999; Bloss et al., 2005).

In addition to O_3 destruction via Reaction AX2.2-32, atomic Cl oxidizes hydrocarbons (HCs) primarily via hydrogen abstraction to form HCl vapor and organic products (Jobson et al., 1994; Pszenny et al., 2006). The enhanced supply of odd-H radicals from HC oxidation leads to net O_3 production in the presence of sufficient NO_x (Pszenny et al., 1993). Available evidence suggests that Cl⁻ radical chemistry may be a significant net source for O_3 in polluted coastal/urban air (e.g., Tanaka et al., 2003; Finley and Saltzman, 2006).

An analogous autocatalytic O_3 destruction cycle involving multiphase iodine (I) chemistry also operates in the marine atmosphere (Alicke et al., 1999; Vogt et al., 1999; McFiggans et al., 2000; Ashworth et al., 2002). In this case, the primary source of I is believed to be either photolysis of CH_2I_2 , other I-containing gases (Carpenter et al., 1999; Carpenter, 2003), or perhaps I_2 (McFiggans et al., 2004; Saiz-Lopez and Plane, 2004; McFiggans, 2005) emitted by micro-and macro flora. Sea salt and sulfate aerosols provide substrates for multiphase reactions that sustain the catalytic I-IO cycle. The IO radical has been measured by long-path (LP) and multi axis (MAX) differential optical absorption spectroscopy (DOAS) at Mace Head, Ireland; Tenerife, Canary Islands; Cape Grim, Tasmania; and coastal New England, USA. These studies have established that the IO radical has average daytime levels of about 1 ppt with maxima up to 7 ppt (e.g., Allan et al., 2000; Pikelnaya et al., 2006). Modeling suggests that up to 13% per day of O_3 in marine air may be destroyed via multiphase iodine chemistry (McFiggans et al., 2000). The reaction of IO with NO_2 followed by uptake of INO_3 into aerosols (analogous to Reactions AX2.2-32 through AX2.2-34) accelerates the conversion of NO_x to particulate NO_3^- and thereby contributes to net O_3 destruction. The reaction $\text{IO} + \text{NO} \rightarrow \text{I} + \text{NO}_2$ also influences NO_x cycling.

Most of the above studies focused on halogen-radical chemistry and related influences on NO_x cycling in coastal and urban air. However, available evidence suggests that similar chemical transformations proceed in other halogen-rich tropospheric regimes. For example, Cl, Br, and/or I oxides have been measured at significant concentrations in near-surface air over the Dead Sea, Israel, the Great Salt Lake, Utah (e.g., Hebestreit et al., 1999; Stutz et al., 1999, 2002; Zingler and Platt, 2005), and the Salar de Uyuni salt pan in the Andes mountains (U. Platt, unpublished data, 2006); high column densities of halogenated compounds have also been observed from satellites over the northern Caspian Sea (Wagner et al., 2001; Hollwedel et al., 2004). The primary source of reactive halogens in these regions is thought to be from activation along the lives of that in Reactions AX2.2-26 through AX2.2-28 involving concentrated salt deposits on surface evaporative pans. High concentrations of BrO have also been measured in volcanic plumes (Bobrowski et al., 2003; Gerlach, 2004). Although virtually unexplored, the substantial emissions of inorganic halogens during biomass burning (Lobert et al., 1999; Keene et al., 2006) and in association with crustal dust (Keene et al., 1999; Sander et al., 2003) may also support active halogen-radical chemistry and related transformations involving NO_x downwind of sources. Finally, observations from satellites, balloons, and aircraft indicate that BrO is present in the free troposphere at levels sufficient to significantly influence photochemistry (e.g., Von Glasow et al., 2004).

AX2.3. Transport of NO_x in the Atmosphere

Major episodes of high O₃ concentrations in the eastern United States and in Europe are associated with slow moving high-pressure systems. High-pressure systems during the warmer seasons are associated with subsidence, resulting in warm, generally cloudless conditions with light winds. The subsidence results in stable conditions near the surface, which inhibit or reduce the vertical mixing of O₃ precursors (NO_x, VOCs, and CO). Photochemical activity is enhanced because of higher temperatures and the availability of sunlight. However, it is becoming increasingly apparent that transport of O₃ and NO_x and VOC from distant sources can provide significant contributions to local [O₃] even in areas where there is substantial photochemical production. There are a number of transport phenomena occurring either in the upper boundary layer or in the free troposphere which can contribute to high O₃ values at the surface. These phenomena include stratospheric-tropospheric exchange (STE), deep and shallow convection, low-level jets, and the so-called “conveyor belts” that serve to characterize flows around frontal systems.

AX2.3.1. Convective Transport

Crutzen and Gidel (1983), Gidel (1983), and Chatfield and Crutzen (1984) hypothesized that convective clouds played an important role in rapid atmospheric vertical transport of trace species and first tested simple parameterizations of convective transport in atmospheric chemical models. At nearly the same time, evidence was shown of venting the boundary layer by shallow, fair weather cumulus clouds (e.g., Greenhut et al., 1984; Greenhut, 1986). Field experiments were conducted in 1985 which resulted in verification of the hypothesis that deep convective clouds are instrumental in atmospheric transport of trace constituents (Dickerson et al., 1987). Once pollutants are lofted to the middle and upper troposphere, they typically have a much longer chemical lifetime and with the generally stronger winds at these altitudes, they can be transported large distances from their source regions. Transport of NO_x from the boundary layer to the upper troposphere by convection tends to dilute the higher in the boundary layer concentrations and extend the NO_x lifetime from less than 24 h to several days. Photochemical reactions occur during this long-range transport. Pickering et al. (1990) demonstrated that venting of boundary layer NO_x by convective clouds (both shallow and deep) causes enhanced O₃ production in the free troposphere. Dilution of NO_x at the surface can often increase O₃ production efficiency. Therefore, convection aids in the transformation of local pollution into a contribution to global atmospheric pollution. Downdrafts within thunderstorms tend to bring air with less NO_x from the middle troposphere into the boundary layer. Lightning produces NO which is directly injected chiefly into the middle and upper troposphere. The total global production of NO by lightning remains uncertain, but is on the order of 10% of the total.

AX2.3.2. Observations of the Effects of Convective Transport

The first unequivocal observations of deep convective transport of boundary layer pollutants to the upper troposphere were documented by Dickerson et al. (1987). Instrumentation aboard three research aircraft measured CO, O₃, NO, NO_x, NO_y, and hydrocarbons in the vicinity of an active mesoscale convective system near the Oklahoma/Arkansas border during the 1985 PRE-STORM experiment. Anvil penetrations about 2 h after maturity found greatly enhanced mixing ratios inside the cloud of all of the aforementioned species compared with outside it. NO mixing ratios in the anvil averaged 3 to 4 ppb, with individual 3-min observations reaching 6 ppb; boundary layer NO_x was typically 1.5 ppb or less outside the cloud. Therefore, the anvil observations represent a mixture of boundary layer NO_x and NO_x contributed by lightning. Luke et al. (1992) summarized the air chemistry data from all 18 flights during PRE-STORM by categorizing each case according to synoptic flow patterns. Storms in the maritime

tropical flow regime transported large amounts of CO, O₃, and NO_y into the upper troposphere with the midtroposphere remaining relatively clean. During frontal passages a combination of stratiform and convective clouds mixed pollutants more uniformly into the middle and upper levels.

Prather and Jacob (1997) and Jaegle et al. (1997) noted that precursors of HO_x are also transported to the upper troposphere by deep convection, in addition to primary pollutants (e.g., NO_x, CO, VOCs). The HO_x precursors of most importance are water vapor, HCHO, H₂O₂, CH₃OOH, and acetone. The hydroperoxyl radical is critical for oxidizing NO to NO₂ in the O₃ production process as described above.

Over remote marine areas, the effects of deep convection on trace gas distributions differ from those over moderately polluted continental regions. Chemical measurements taken by the NASA ER-2 aircraft during the Stratosphere-Troposphere Exchange Project (STEP) off the northern coast of Australia show the influence of very deep convective events. Between 14.5 and 16.5 km on the February 2-3, 1987 flight, chemical profiles that included pronounced maxima in CO, water vapor, and CCN, and minima of NO_y, and O₃ (Pickering et al., 1993). Trajectory analysis showed that these air parcels likely were transported from convective cells 800-900 km upstream. Very low marine boundary layer mixing ratios of NO_y and O₃ in this remote region were apparently transported upward in the convection. A similar result was noted in Central Equatorial Pacific Experiment (CEPEX) (Kley et al., 1996) and in Indian Ocean Experiment (INDOEX) (DeLaat et al., 1999) where a series of ozonesonde ascents showed very low upper tropospheric O₃ following deep convection. It is likely that similar transport of low-ozone tropical marine boundary layer air to the upper troposphere occurs in thunderstorms along the east coast of Florida. Deep convection occurs frequently over the tropical Pacific. Low-ozone and low-NO_x convective outflow likely will descend in the subsidence region of the subtropical eastern Pacific, leading to some of the cleanest air that arrives at the west coast of the United States.

The discussion above relates to the effects of specific convective events. Observations have also been conducted by NASA aircraft in survey mode, in which the regional effects of many convective events can be measured. The Subsonic Assessment Ozone and Nitrogen Oxides Experiment (SONEX) field program in 1997 conducted primarily upper tropospheric measurements over the North Atlantic. The regional effects of convection over North America and the Western Atlantic on upper tropospheric NO_x were pronounced (Crawford et al., 2000; Allen et al., 2000). A discussion of the results of model calculations of convection and its effects can be found in Section AX2.7.

AX2.3.3. Effects on Photolysis Rates and Wet Scavenging

Thunderstorm clouds are optically very thick, and, therefore, have major effects on radiative fluxes and photolysis rates. Madronich (1987) provided modeling estimates of the effects of clouds of various optical depths on photolysis rates. In the upper portion of a thunderstorm anvil, photolysis is likely to be enhanced by a factor of 2 or more due to multiple reflections off the ice crystals. In the lower portion and beneath the cloud, photolysis is substantially decreased. With enhanced photolysis rates, the NO/NO₂ ratio in the upper troposphere is driven to larger values than under clear-sky conditions.

Thunderstorm updraft regions, which contain copious amounts of water, are regions where efficient scavenging of soluble species can occur (Balkanski et al., 1993). NO₂ itself is not very soluble and therefore wet scavenging is not a major removal process for it. However, a major NO_x reservoir species, HNO₃ is extremely soluble. Very few direct field measurements of the amounts of specific trace gases that are scavenged in storms are available. Pickering et al. (2001) used a combination of model estimates of soluble species that did not include wet scavenging and observations of these species from the upper tropospheric outflow region of a major line of convection observed near Fiji. Over 90% of the NO_x in the outflow air appeared to have been removed by the storm; about 50% of CH₃OOH and about 80% of HCHO had been lost.

Convective processes and small-scale turbulence transport pollutants both upward and downward throughout the planetary boundary layer and the free troposphere. Ozone and its precursors (NO_x, CO, and VOCs) can be transported vertically by convection into upper part of the mixed layer on one day,

then transported overnight as a layer of elevated mixing ratios, perhaps by a nocturnal low-level jet, and then entrained into a growing convective boundary layer downwind and brought back to the surface.

Because NO and NO₂ are only slightly soluble, they can be transported over longer distances in the gas phase than can more soluble species which can be depleted by deposition to moist surfaces, or taken up more readily on aqueous surfaces of particles. During transport, they can be transformed into reservoir species such as HNO₃, PANs, and N₂O₅. These species can then contribute to local NO_x concentrations in remote areas. For example, it is now well established that PAN decomposition provides a major source of NO_x in the remote troposphere (Staudt et al., 2003). PAN decomposition in subsiding air masses from Asia over the eastern Pacific could make an important contribution to O₃ and NO_x enhancement in the United States (Kotchenruther et al., 2001; Hudman et al., 2004). Further details about mechanisms for transporting ozone and its precursors were described at length in the 2006 AQCD for Ozone.

AX2.4. Sources and Emissions of NO_x

NO_x has natural and anthropogenic sources. In Section AX2.4.1, interactions of NO_x with the terrestrial biosphere are discussed. Because of the tight coupling between processes linking emissions and deposition, they are discussed together. Additional sources are described in Section AX2.4.2. Field studies evaluating emissions inventories are discussed in Section AX2.4.2.4.

AX2.4.1. Interactions of NO_x with the Biosphere

NO_x affect vegetated ecosystems, and in turn the atmospheric chemistry of NO_x is influenced by vegetation. Extensive research on nitrogen inputs from the atmosphere to forests was conducted in the 1980s as part of the Integrated Forest Study, and is summarized by Johnson and Lindberg (1992). The following sections discuss sources of NO_x from soil, deposition of NO_x to foliage, reactions with biogenic hydrocarbons, and ecological effects of nitrogen deposition.

NO from soil metabolism is the dominant but not exclusive source of NO_x from the biosphere to the atmosphere. As noted below, our understanding of NO₂ exchange with vegetation suggests that there should be emission of NO₂ from foliage when ambient concentrations are less than about 1 ppb. However, Lerdaun et al. (2000) have pointed out that present understanding of the global distribution of NO_x is not consistent with a large source that would be expected in remote forests if NO₂ emission was important when atmospheric concentrations were below the compensation point.

The pathways for nitrification and denitrification include two gas-phase intermediates, NO and N₂O, some of which can escape. While N₂O is of interest for its greenhouse gas potential and role in stratospheric chemistry it is not considered among the reactive NO_x species important for urban and regional air quality and will not be discussed further. Temperature and soil moisture are critical factors that control the rates of reaction and importantly the partitioning between NO and N₂O which depend on oxygen levels: in flooded soils where oxygen levels are low, N₂O is the dominant soil nitrogen gas; as soil dries, allowing more O₂ to diffuse, NO emissions increase. In very dry soils, microbial activity is inhibited and emissions of both N₂O and NO decrease. Nitrogen metabolism in soil is strongly dependent on the substrate concentrations. Where nitrogen is limiting, nitrogen is efficiently retained and little gaseous nitrogen is released. Where nitrogen is in excess of demand, gaseous nitrogen emissions increase; consequently, soil NO emissions are highest in fertilized agriculture and tropical soils (Davidson and Kingerlee, 1997; Williams et al., 1992).

Several reactive nitrogen species are deposited to vegetation, among them, HNO₃, NO₂, PAN, and organic nitrates. Deposition of HNO₃ appears to be relatively simple. Field observations based on concentration gradients and recently using eddy covariance demonstrate rapid deposition that approaches the aerodynamic limit (as constrained by atmospheric turbulence) in the Wesely (1989) formulation based

on analogy to resistance. Surface resistance for HNO₃ uptake by vegetation is negligible. Deposition rates are independent of leaf area or stomatal conductance, implying that deposition occurs to branches, soil, and leaf cuticle as well as internal leaf surfaces.

Deposition velocities (V_d) typically exceed 1 cm/s and exhibit a daily pattern controlled by turbulence characteristics such that midday maximum and lower values at night when there is stable boundary layer.

Nitrogen dioxide interaction with vegetation is more complex. Application of ¹⁵N-labeled NO₂ demonstrates that NO₂ is absorbed and metabolized by foliage (Siegwolf et al., 2001; Möcker et al., 1998; Segschneider et al., 1995; Weber, et al., 1995). Exposure to NO₂ induces nitrate reductase (Weber et al., 1995, 1998), a necessary enzyme for assimilating oxidized nitrogen. Understanding NO₂ interactions with foliage is largely based on leaf cuvette and growth chamber studies, which expose foliage or whole plants to controlled levels of NO₂ and measure the fraction of NO₂ removed from the chamber air. A key finding is that the fit of NO₂ flux to NO₂ concentration, has a non-zero intercept, implying a compensation point or internal concentration. In studies at very low NO₂ concentrations emission from foliage is observed (Teklemariam and Sparks, 2006). Evidence for a compensation point is not solely based on the fitted intercept. NO₂ uptake rate to foliage is clearly related to stomatal conductance. Internal resistance is variable, and may be associated with concentrations of reactive species such as ascorbate in the plant tissue that react with NO₂ (Teklemariam and Sparks, 2006). Foliar NO₂ emissions show some dependence on nitrogen content (Teklemariam and Sparks, 2006). Internal NO₂ appears to derive from plant nitrogen metabolism.

Two approaches to modeling NO₂ uptake by vegetation are the resistance-in-series analogy which considers flux (F) as the product of concentration (C) and V_d , where is related to the sum of aerodynamic, boundary layer, and internal resistances (R_a , R_b , and R_c ; positive fluxes are from atmosphere to foliage)

$$F = CV_d \quad (\text{AX2.4-1})$$

$$V_d = (R_a + R_b + R_c)^{-1} \quad (\text{AX2.4-2})$$

R_a and R_b and controlled by turbulence in the mixed layer; R_c is dependent on characteristics of the foliage and other elements of the soil, and may be viewed as 2 combination of resistance internal to the foliage and external on the cuticle, soils, and bark. This approach is amenable to predicting deposition in regional air quality models (Wesely, 1989). Typically, the NO₂, V_d is less than that for O₃, due to the surface's generally higher resistance to NO₂ uptake, consistent with NO₂'s lower reactivity.

Alternatively, NO₂ exchange with foliage can be modeled from a physiological viewpoint where the flux from the leaf is related to the stomatal conductance and a concentration gradient between the ambient air and interstitial air in the leaf. This approach best describes results for exchange with individual foliage elements, and is expressed per unit leaf (needle) area. While this approach provides linkage to leaf physiology, it is not straightforward to scale up from the leaf to ecosystem scale

$$J = g_s(C_a - C_i) \quad (\text{AX2.4-3})$$

This model implicitly associates the compensation point with a finite internal concentration. Typically observed compensation points are around 1 ppb. Finite values of internal NO₂ concentration are consistent with metabolic pathways that include oxides of nitrogen. In this formulation, the uptake will be linear with NO₂ concentration, which is typically observed with foliar chamber studies.

Several studies have shown the UV dependence of NO₂ emission, which implies some photo-induced surface reactions that release NO₂. Rather than model this as a UV-dependent internal concentration, it would be more realistic to add an additional term to account for emission that is dependent on light levels and other surface characteristics

$$J = g_s(C_a - C_i) = J_s(UV) \quad (\text{AX2.4-4})$$

The mechanisms for surface emission are discussed below. Measurement of NO₂ flux is confounded by the rapid interconversion of NO, NO₂, and O₃ (Gao et al., 1991).

PAN is phytotoxic, absorbed largely at the leaf. Observations based on inference from concentration gradients and rates of decline at night (Shepson et al., 1992; Schrimpf et al., 1996) and leaf chamber studies (Teklemariam and Sparks, 2004) have indicated that PAN uptake is slower than that of O₃; however, recent work in coniferous canopy with direct eddy covariance PAN flux measurements indicated a V_d more similar to that of O₃. Uptake of PAN is under stomatal control, has a non-zero deposition at night, and is influenced by leaf wetness (Turnipseed et al., 2006). On the other hand, flux measurements determined by gradient methods over a grass surface showed a V_d closer to 0.1 cm/s, with large uncertainty (Doskey et al., 2004). Whether the discrepancies are methodological or indicate intrinsic differences between different vegetation is unknown. Uptake of PAN is smaller than its thermal decomposition in all cases.

The biosphere also interacts with NO_x through hydrocarbon emissions and their subsequent reactions to form multi-functional organic nitrates. Isoprene nitrates are an important class of these. Isoprene reacts with OH to form a radical that adds NO₂ to form a hydroxyalkyl nitrate. The combination of hydroxyl and nitrate functional group makes these compounds especially soluble with low vapor pressures; they likely deposit rapidly (Shepson et al., 1996; Treves et al., 2000). Many other unsaturated hydrocarbons react by analogous routes. Observations at Harvard Forest show a substantial fraction of total NO_y not accounted for by NO, NO₂ and PAN, which is attributed to the organic nitrates (Horii et al., 2006; Munger et al., 1998). Furthermore, the total NO_y flux exceeds the sum of HNO₃, NO_x, and PAN, which implies that the organic nitrates are a substantial fraction of nitrogen deposition. Other observations that show evidence of hydroxyalkyl nitrates include those of Grossenbacher et al. (2001) and Day et al. (2003).

Formation of the hydroxyalkyl nitrates occurs following OH attack on VOCs. In some sense, this mechanism is just an alternate pathway for OH to react with NO_x to form a rapidly depositing species, because if VOC were not present, OH would be available to react with any NO₂ present to form HNO₃.

HNO₂ formation on vegetative surfaces at night has long been observed based on measurements of positive gradients (Harrison and Kitto, 1994). Surface reactions of NO₂ enhanced by moisture were proposed to explain these results. Production was evident at sites with high ambient NO₂; at low concentration, uptake of HONO exceeded the source. Daytime observations of HONO when rapid photolysis is expected to deplete ambient concentrations to very low levels implies a substantial source of photo-induced HONO formation at a variety of forested sites where measurements have been made. Estimated source strengths are 200-1800/ppt-h in the surface layer (Zhou et al., 2002a, 2003), which is about 20 times faster than all nighttime sources. HNO₂ sources could be important to OH/HO₂ budgets as HONO is rapidly photolyzed by sunlight to OH and NO. Additional evidence of light-dependent reactions to produce HONO comes from discovery of a HONO artifact in pyrex sample inlet lines exposed to ambient light. Either covering the inlet or washing it eliminated the HONO formation (Zhou et al., 2002b). Similar reactions might serve to explain observations of UV-dependent production of NO_x in empty foliar cuvettes that had been exposed to ambient air (Hari et al., 2003; Raivonen et al., 2003).

Production of HONO in the dark is currently believed to occur via a heterogeneous reaction involving NO₂ on wet surfaces (Jenkin et al., 1988; Pitts et al., 1984; He et al., 2006; Sakamaki et al., 1983), and it is proposed that the mechanism has first-order dependence in both NO₂ and H₂O (Kleffmann et al., 1998; Svensson et al., 1987) despite the stoichiometry. However, the molecular pathway of the mechanism is still under debate. Jenkin et al. (1988) postulated a H₂O·NO₂ water complex reacting with gas phase NO₂ to produce HONO, which is inconsistent with the formation of an N₂O₄ intermediate leading to HONO as proposed by Finlayson-Pitts et al. (2003). Another uncertainty is whether the reaction forming HONO is dependent on water vapor (Svensson et al., 1987; Stutz et al., 2004b) or water adsorbed on surfaces (Kleffmann et al., 1998). Furthermore, the composition of the surface and the

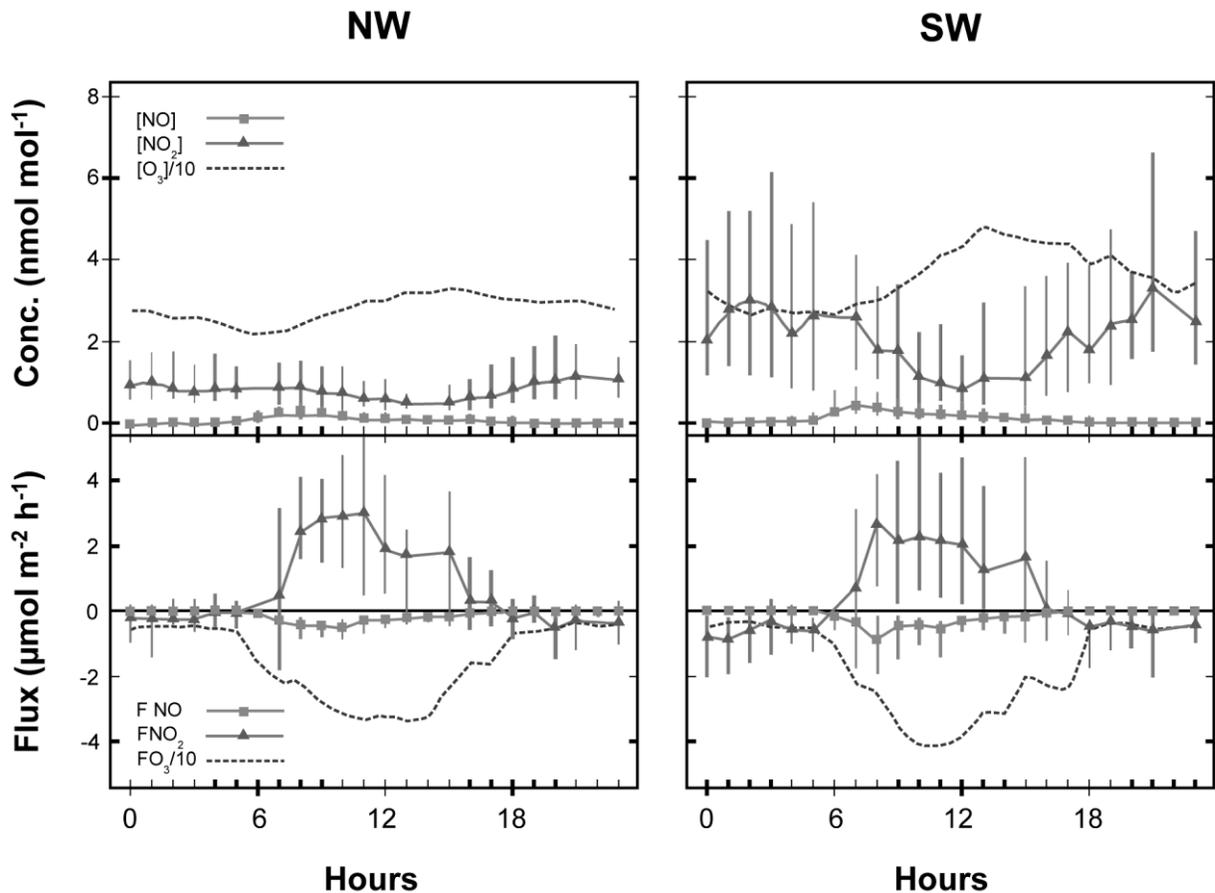

available amount of surface or surface-to-volume ratio can significantly influence the HONO production rates (Kaiser and Wu, 1977; Kleffmann et al., 1998; Svensson et al., 1987), which may explain the difference in the rates observed between laboratory and atmospheric measurements.

There is no consensus on a chemical mechanism for photo-induced HONO production. Photolysis of HNO₃ or NO₃⁻ absorbed on ice or in surface water films has been proposed (Honrath et al., 2002; Ramazan et al., 2004; Zhou et al., 2001, 2003); but alternative pathways include NO₂ interaction with organic surfaces such as humic substances (George et al., 2005; Stemmler et al., 2006). Note that either NO₃⁻ photolysis or heterogeneous reaction of NO₂ are routes for recycling deposited NO_x back to the atmosphere in an active form. NO₃ photolysis would return nitrogen that heretofore was considered irreversibly deposited, surface reactions between NO₂ and water films or organic molecules would decrease the effectiveness of observed NO₂ deposition if the HONO were re-emitted.

AX2.4.1.1. NO₂ and HNO₃ Flux Data from Harvard Forest

Harvard Forest is a rural site in central Massachusetts, where ambient NO_x, NO_y, and other pollutant concentrations and fluxes of total NO_y have been measured since 1990 (Munger et al., 1996). An intensive study in 2000 utilized a Tunable Diode Laser Absorption Spectrometer (TDLAS) to measure NO₂ and HNO₃. TDLAS has an inherently fast response, and for species such as NO₂ and HNO₃ with well-characterized spectra it provides an absolute and specific measurement. Absolute concentrations of HNO₃ were measured, and the flux inferred based on the dry deposition inferential method that uses momentum flux measurements to compute a deposition velocity and derives an inferred flux (Wesely and Hicks, 1977; Hicks et al., 1987). Direct eddy covariance calculations for HNO₃ were not possible because the atmospheric variations were attenuated by interaction with the inlet walls despite very short residence time and use of fluorinated silane coatings to make the inlet walls more hydrophobic. Nitrogen oxide response was adequate to allow both concentration and eddy covariance flux determination. Simultaneously, NO and NO_y eddy covariance fluxes were determined with two separate O₃ chemiluminescence detectors, one equipped with a H₂-gold catalyst at the inlet to convert all reactive nitrogen compounds to NO. Additionally, the measurements include concentration gradients for NO, NO₂, and O₃ over several annual cycles to examine their vertical profiles in the forest canopy.

Overall, the results show typical NO₂ concentrations of 1 ppb under clean-air conditions and mean concentrations up to 3 ppb at night and 1 ppb during daytime for polluted conditions. Net positive fluxes (emission) of NO₂ were evident in the daytime and negative fluxes (deposition) were observed at night (Figure AX2.4-1). Nitric oxide fluxes were negative during the daytime and near zero at night.

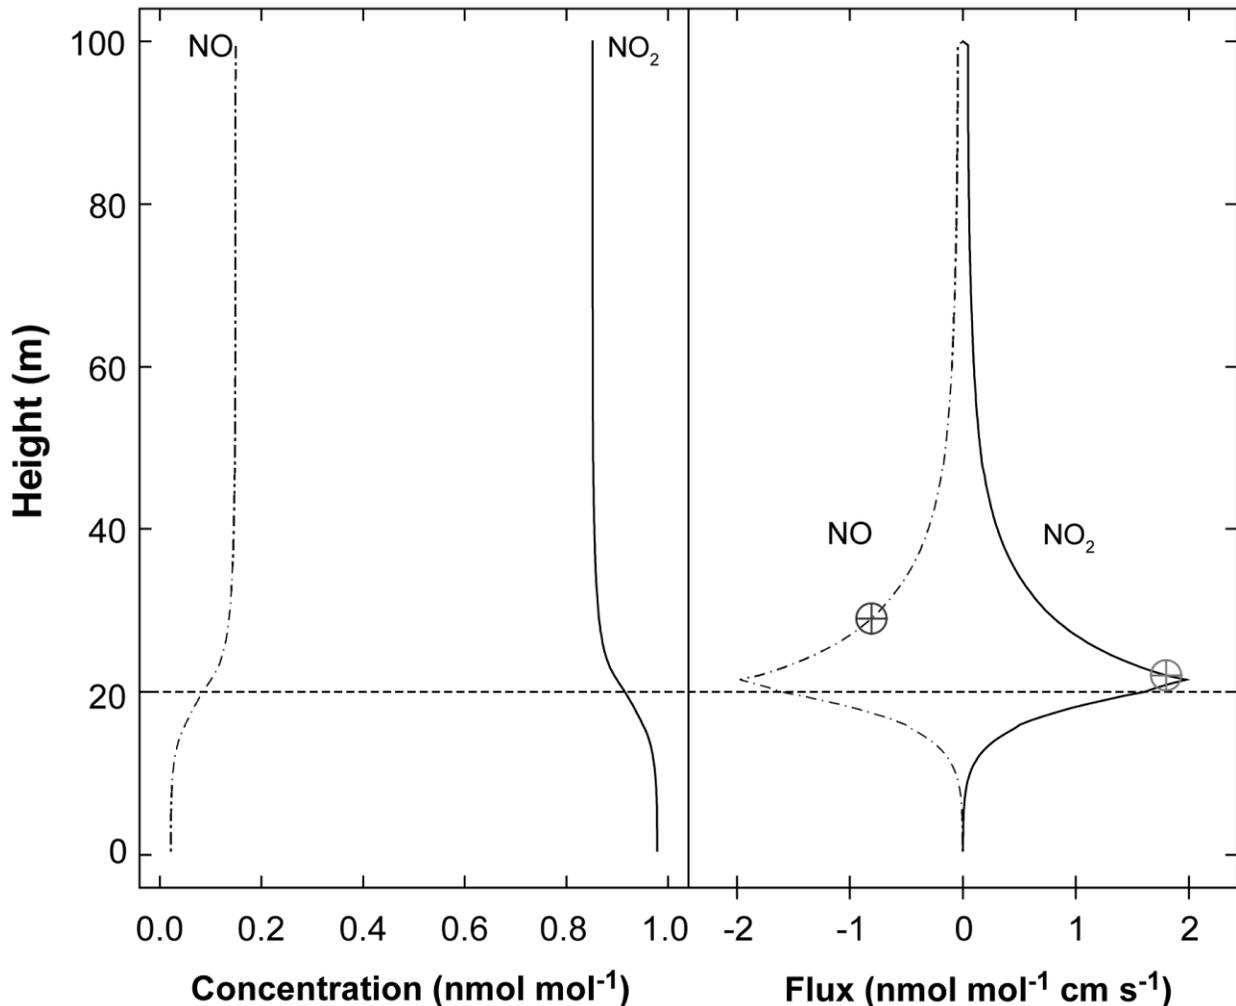

Source: Horii et al. (2004).

Figure AX2.4-1. Diel cycles of median concentrations (upper panels) and fluxes (lower panels). These are for the Northwest (clean sector, left panels) and Southwest (polluted sector, right panels) wind sectors at Harvard Forest, April-November, 2000, for NO, NO₂, and O₃/10. NO and O₃ were sampled at a height of 29 m, and NO₂ at 22 m. Vertical bars indicate 25th and 27th quartiles for NO and NO₂ measurements. NO₂ concentration and nighttime deposition are enhanced under southwesterly conditions, as are O₃ and the morning NO maximum.

In part the opposite NO and NO₂ fluxes are simply consequences of variable NO/NO₂ distributions responding to vertical gradients in light intensity and O₃ concentration, which resulted in no net flux of NO_x (Gao et al., 1993). In the Harvard Forest situation, the NO and NO₂ measurements were not at the same height above the canopy, and the resulting differences derive at least in part from the gradient in flux magnitude between the two inlets (Figure AX2.4-2).

Simple Model

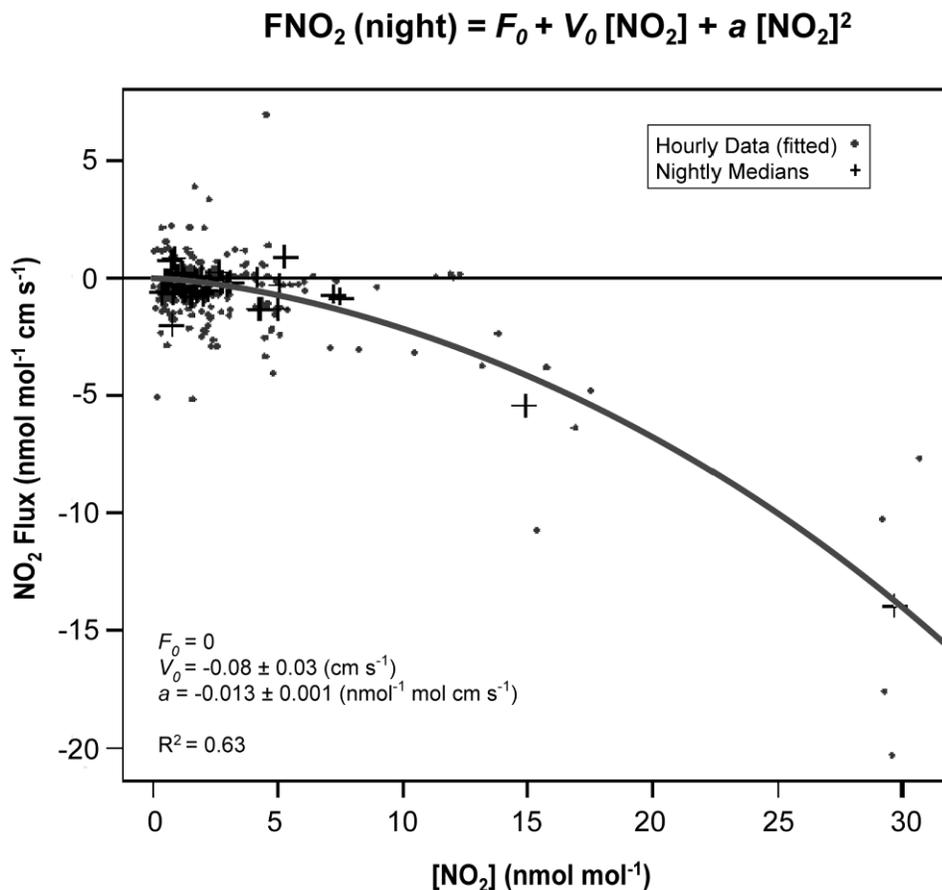

Source: Horii (2002).

Figure AX2.4-2. Simple NO_x photochemical canopy model outputs. Left panel, concentrations of NO (dashed) and NO₂ (solid); right, fluxes of NO (dashed) and NO₂ (solid). Symbols indicate measurement heights for NO (29m) and NO₂ (22m) at Harvard Forest. The model solves the continuity equation for NO concentration at 200 levels, $d/dz(-Kc(dNO/dz)) = PNO - LNO$, where $PNO = [NO]/t1$, $LNO = [NO]/t2$, and zero net deposition or emission of NO_x is allowed. NO_x (NO + NO₂) is normalized to 1ppb. $t1 = 70s$ in this example. Due to the measurement height difference, observed upward NO₂ flux due to photochemical cycling alone should be substantially larger than observed downward NO flux attributable to the same process.

At night, when NO concentrations are near 0 due to titration by ambient O₃ there is not a flux of NO to offset NO₂ fluxes. Nighttime data consistently show NO₂ deposition (Figure AX2.4-3), which increases with increasing NO₂ concentrations. Concentrations above 10 ppb were rare at this site, but the few high NO₂ observations suggest a nonlinear dependence on concentration. The data fit a model with V_d of -0.08 plus an enhancement term that was second order in NO₂ concentration. The second order

term implies that NO₂ deposition rates to vegetation in polluted urban sites would be considerably larger than what was observed at this rural site.

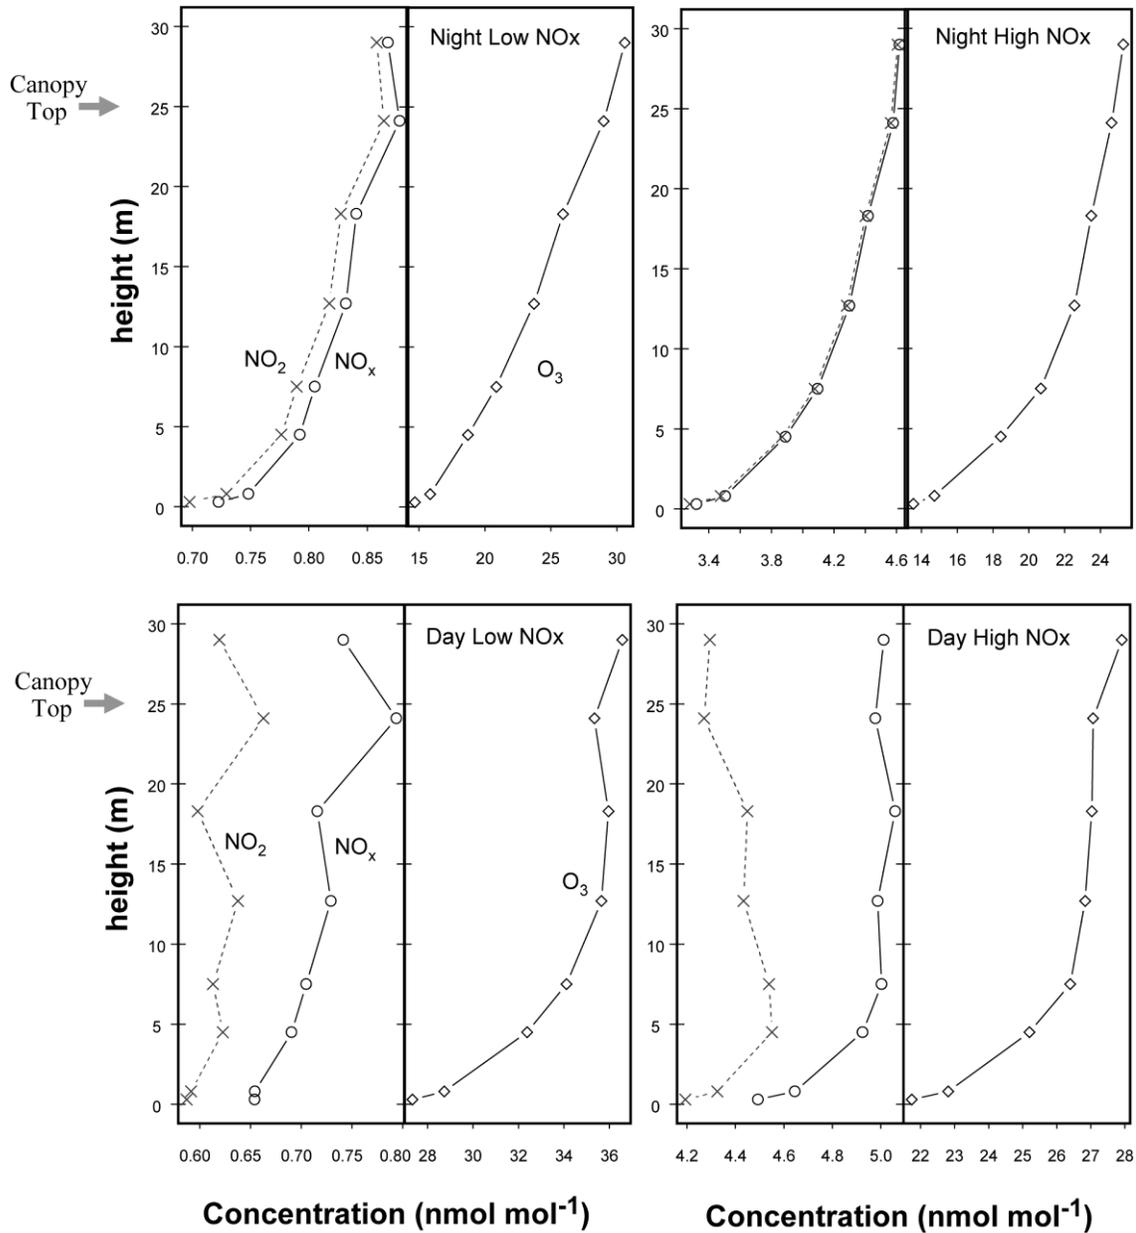

Source: Horii et al. (2004).

Figure AX2.4-3. Hourly (dots) and median nightly (pluses) NO₂ flux vs. concentration. The results of least-squares fit on the hourly data (curve). The flux is expressed in units of concentration times velocity (nmol/mol·cm·s) in order to simplify the interpretation of the coefficients in the least-squares fit. Pressure and temperature corrections have been taken into account in the conversion from density to mixing ratio.

After accounting for the NO-NO₂ null cycle the net NO_x flux could be derived. Overall, there was a net deposition of NO_x during the night and essentially zero flux in the day, with large variability in the magnitude and sign of individual flux observations. For the periods with [NO₂] > 2 ppb, deposition was always observed. These canopy-scale field observations are consistent with a finite compensation point for NO₂ in the canopy that offsets foliar uptake or even reverses it when concentrations are especially low. At concentrations above the compensation point, NO_x is absorbed by the canopy. Examination of concentration profiles corroborates the flux measurements (Figure AX2.4-4). During daytime for low-NO_x conditions, there is a local maximum in the concentration profile near the top of the canopy where O₃ has a local minimum, which is consistent with foliar emission or light-dependent production of NO_x in the upper canopy. Depletion is evident for both NO_x and O₃ near the forest floor. Air reaching the ground

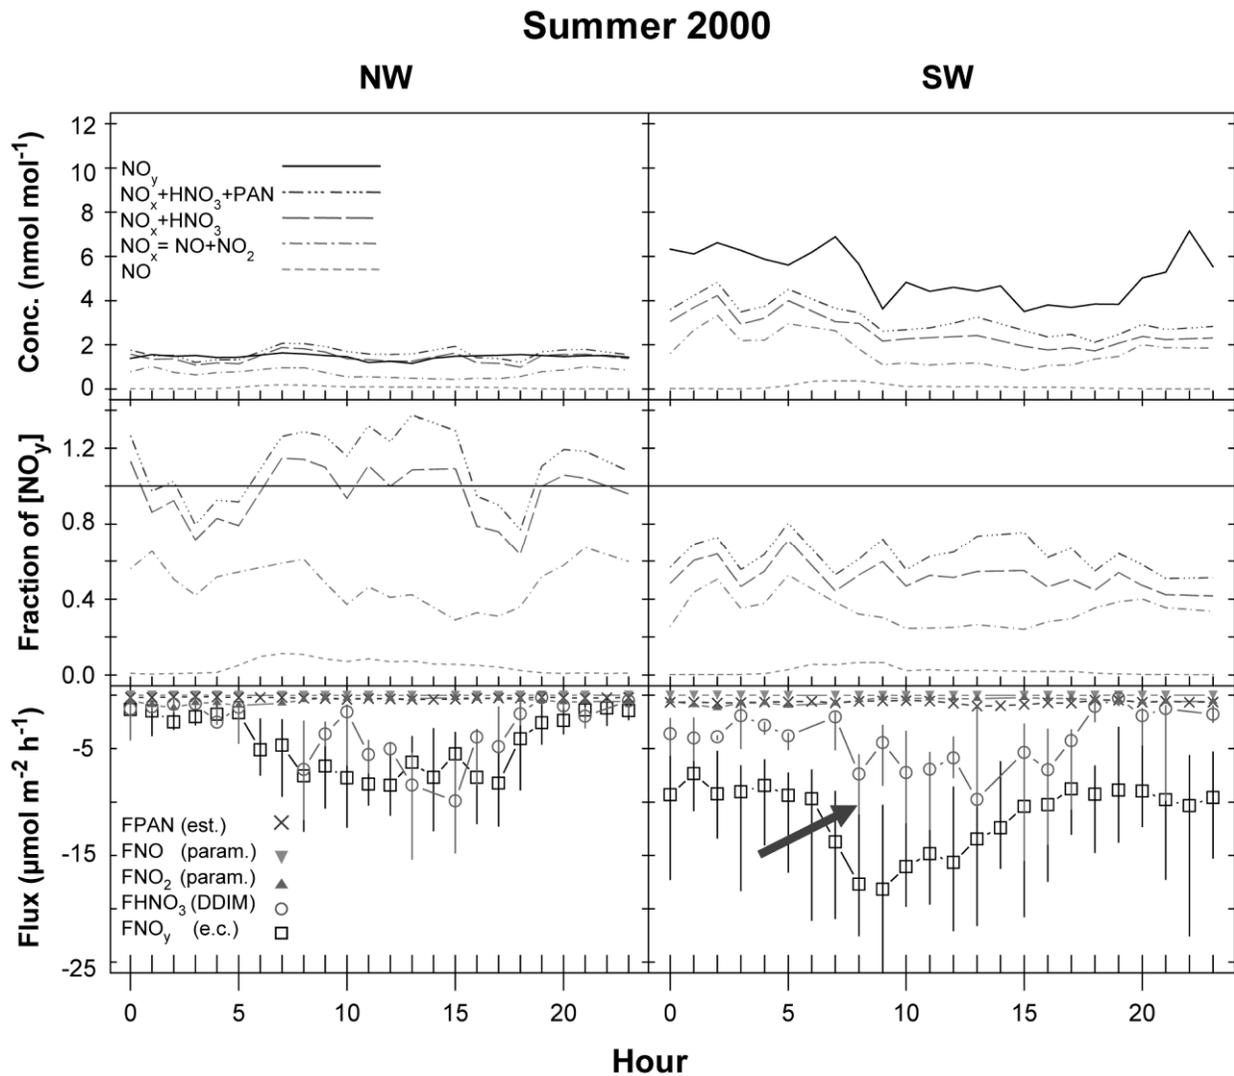

has passed through the canopy where uptake is efficient and the vertical exchange rates near the ground are slow. At night, the profiles generally decrease with decreasing height above the ground, showing only uptake. At higher concentrations, the daytime NO_x concentrations are nearly constant through the canopy; no emission is evident from the sunlit leaves.

NO_x PROFILES

Figure AX2.4-4. Averaged profiles at Harvard Forest. These give some evidence of some NO_2 input near the canopy top from light-mediated ambient reactions, or emission from open stomates.

Source: Horii et al. (2006).

Figure AX2.4-5. Summer (June-August) 2000 median concentrations (upper panels), fractions of NO_Y (middle panels), and fluxes (lower panels) of NO_Y and component species. These are separated by wind direction (Northwest on the left and Southwest on the right). Vertical lines in the flux panels show 25th and 75th quartiles of $F(\text{NO}_Y)$ and $F(\text{HNO}_3)$; negative fluxes represent deposition; $F(\text{NO}_X)$ is derived from eddy covariance $F(\text{NO})$ and $F(\text{NO}_2)$ measurements (corrected for photochemical cycling), $F(\text{HNO}_3)$ is inferred, and $F(\text{NO}_Y)$ was measured by eddy covariance. The sum of NO_X , HNO_3 , and PAN accounts for all of the NO_Y concentration and flux for Northwesterly (unpolluted background) flows, whereas up to 50% of NO_Y and $F(\text{NO}_Y)$ under Southwesterly flows are in the form of reactive nitrogen species whose fluxes are not measured or estimated here.

Figure AX2.4-5 compares observed fluxes of all the observed species. The measured NO_X and estimated PAN fluxes are small relative to the observed total NO_Y flux. In clean air, HNO_3 accounts for nearly all the NO_Y flux and the sum of all measured species is about equal to the NO_Y concentration. However, in polluted conditions, unmeasured species are up to 25% of the NO_Y , and HNO_3 fluxes cannot

account for all the total NO_Y flux observed. Likely these unmeasured NO_Y species are hydroxyalkyl nitrates and similar compounds and are rapidly deposited. Although NO_2 uptake may be important to the plant, because it is an input directly to the interior of foliage that can be used immediately in plant metabolism, it is evidently not a significant part of overall nitrogen deposition to rural sites. The deposition of HNO_3 and multifunctional organic nitrates are the largest elements of the nitrogen dry deposition budget. Two key areas of remaining uncertainty are the production of HONO over vegetation and the role of very reactive biogenic VOCs. HONO is important because its photolysis is a source of OH radicals, and its formation may represent an unrecognized mechanism to regenerate photochemically active NO_X from nitrate that had been considered terminally removed from the atmosphere.

AX2.4.2. Emissions of NO_X

Estimated annual emissions of NO_X for 2002 (U.S. Environmental Protection Agency, 2006) are shown at end of Annex AX2, in Table AX2.4-1. Information relevant for estimating emissions of criteria pollutants is given in U.S. Environmental Protection Agency (1999). Discussions of uncertainties in current emissions inventories and strategies for improving them can be found in NARSTO (2005).

As can be seen from the table, combustion by stationary sources, such as electrical utilities and various industries, accounts for roughly half of total anthropogenic emissions of NO_X . Mobile sources account for the other half, with highway vehicles representing the major mobile source component. Approximately half the mobile source emissions are contributed by diesel engines, the remainder are emitted by gasoline-fueled vehicles and other sources.

Emissions of NO_X associated with combustion arise from contributions from both fuel nitrogen and atmospheric nitrogen. Combustion zone temperatures greater than about 1300 K are required to fix atmospheric N_2

Otherwise, NO can be formed from fuel N according to this reaction

In addition to NO formation by the schematic reactions given above, some NO_2 and CO are also formed depending on temperatures, concentrations of OH and HO_2 radicals and O_2 levels. Fuel nitrogen is highly variable in fossil fuels, ranging from 0.5 to 2.0 percent by weight (wt %) in coal to 0.05% in light distillates (e.g., diesel fuel), to 1.5 wt % in heavy fuel oils (UK AQEG, 2004).

AX2.4.2.1. Emissions of NO_2 from Motor Vehicles

NO_2 in exhaust gasoline-powered engines generally comprises <1-3% of total NO_X (Heeb et al., 2008; Hilliard and Wheeler, 1979), according to dynamometer studies. Some European studies have reported NO_2/NO_X ratios of 15% or higher from gasoline vehicles based on integrated measurements from Tedlar bags (Lenner, 1987; Soltic and Weilenmann, 2003). However, subsequent studies suggesting that NO-to- NO_2 conversion can occur within bag sample of a diluted exhaust have led the groups performing these measurement to revise their measurement techniques and avoid the use of Tedlar bag samples (Alvarez et al., 2007; Heeb et al., 2008). As a result, dynamometer-based measurements generally indicate that in the absence of post-tailpipe transformation, NO_2 comprises, at most, a few percent of total NO_X in gasoline exhaust.

Emission control devices for diesel engines can increase the fraction of exhaust NO_x emitted as NO_2 . The two major types that can increase NO_2/NO_x ratios include diesel oxidation catalysts (DOCs) and catalyzed diesel particle filters (CDPFs). Both are considered “after treatment” devices, in that they affect exhaust after it leaves an engine. In both DOCs and CDPFs, the effect on NO_2/NO_x ratios depends on the composition of the catalytic washcoats.

DOCs are flow-through devices consisting of porous ceramic with a catalytic washcoat. Catalysis within the DOC reduces exhaust concentrations of organic material, including PM and hydrocarbons. In doing so, DOCs convert NO to NO_2 , the excess of which may be emitted through the tailpipe.

Like DOCs, CDPFs also may be a part of the emission control system for diesel vehicles. CDPFs can reduce PM emissions from a diesel vehicle by $\geq 90\%$. They commonly consist of a DOC and a particle trapping filter or a particle trap with a catalytic wash coat, generally containing noble metals. As exhaust gases pass through a CDPF, soot and organic material in the exhaust becomes trapped in the filter. The DOC or the filter’s catalytic washcoat converts exhaust NO to NO_2 to use in oxidizing the particulate matter trapped by the filter. Excess NO_2 is emitted through the tailpipe.

Widespread use of CDPFs in European cities has been identified as a cause for increasing NO_2/NO_x ratios at urban air quality monitors. Carslaw et al. (2007a) report upward trends in roadside concentrations of NO_2 between 2002 and 2006 at Marylebone Road, site on the edge of central London, UK. Using ambient data analysis methods developed in earlier publications (Carslaw et al., 2005a), Carslaw et al. (2007b) estimated the NO_2/NO_x emission ratio from the London vehicle fleet over time. NO_2/NO_x emission ratios increased significantly along Marylebone Road between 2002 and 2006, from approximately 10% by volume to over 20% by volume. Using multivariate regression, Carslaw et al. (2005b) estimated that the largest contributor to the increasing NO_2/NO_x emission ratios was the retrofit of London transit buses with catalyzed diesel particle filters (CDPF).

Kessler et al. (2006) employed the methods developed by Carslaw et al. (2005a) to estimate the NO_2/NO_x ratio from traffic in Baden-Württemberg, Germany between 1995 and 2005. The estimates increase from approximately 5% in 1995 to over 20% in 2005. The investigators attributed the increase to an increase in the use of oxidation catalysts in diesel-fueled passenger cars.

Ayala et al. (2002) compared NO_2/NO_x ratios in a bus before and after installation of a CDPF. NO_2 emissions before retrofit were 0.92-2.14 g/mi across different test cycles, comprising 3-9% of total NO_x . After retrofit, NO_2 emissions were 9.0-24.0 g/mi, comprising 39-49% of total NO_x .

Two U.S. studies where investigators sampled the plumes of heavy-duty diesel vehicles found that, vehicles retrofitted with CDPFs had lower PM emissions and higher NO_2/NO_x ratios compared to diesel vehicles without CDPFs. Shorter et al. (2005) conducted a “chase” experiment of vehicles in New York City, including metropolitan transit buses equipped with CDPFs. Overall, while following CDPF-equipped buses, approximately one-third of exhaust NO_x was NO_2 . In contrast, less than 10% of NO_x was NO_2 behind city buses lacking a CDPF. Kittleson et al. (2006) used an on-road laboratory to sample the exhaust plumes of a truck under highway cruise conditions, equipped with one of two different CDPFs. NO_2/NO_x ratios for CDPF-treated exhaust under highway cruise conditions ranged from 59-70%. The comparison of these two studies illustrates the role that temperature can play in increasing CDPF catalytic activity.

The ratio of NO_2 to NO_x in primary emissions ranges from 3 to 5 % from gasoline engines, 5 to 12% from heavy-duty diesel trucks, 5 to 10% from vehicles fueled by compressed natural gas and from 5 to 10% from stationary sources. In addition to NO_x , motor vehicles also emit HONO, with ratios of HONO to NO_x ranging from 0.3% in the Caldecott Tunnel, San Francisco Bay (Kirchstetter and Harley, 1996) to 0.5 to 1.0% in studies in the United Kingdom (UK AQEG, 2004).

The NO_2 to NO_x ratios in emissions from turbine jet engines are as high as 32 to 35 % during taxi and takeoff (1993 AQCD for NO_x). Sawyer et al. (2000) have reviewed the factors associated with NO_x emissions by mobile sources. Marine transport represents a minor source of NO_x , but constitutes a larger source in the EU where it is expected to represent about two-thirds of land-based sources (UK AQEG, 2004).

AX2.4.2.2. NO_x Emissions from Natural Sources

Soil

Emission rates of NO from cultivated soil depend mainly on fertilization levels and soil temperature. About 60% of the total NO_x emitted by soils occurs in the central corn belt of the United States. The oxidation of NH₃, emitted mainly by livestock and soils, leads to the formation of NO, as do NH₄⁺ and NO₃⁻ fertilizers on soils. Estimates of emissions from natural sources are less certain than those from anthropogenic sources. On a global scale, the contribution of soil emissions to the oxidized nitrogen budget is on the order of 10% (Van Aardenne et al., 2001; Finlayson-Pitts and Pitts, 2000; Seinfeld and Pandis, 1998), but NO_x emissions from fertilized fields are highly variable. Soil NO emissions can be estimated from the fraction of the applied fertilizer nitrogen emitted as NO_x, but the flux varies strongly with land use and temperature. Estimated globally averaged fractional applied nitrogen loss as NO varies from 0.3% (Skiba et al., 1997) to 2.5% (Yienger and Levy, 1995). Variability within biomes to which fertilizer is applied, such as shortgrass versus tallgrass prairie, accounts for a factor of three in uncertainty (Williams et al., 1992; Yienger and Levy, 1995; Davidson and Kinglerlee, 1997).

The local contribution can be much greater than the global average, particularly in summer and especially where corn is grown extensively. Williams et al. (1992) estimated that contributions to NO budgets from soils in Illinois are about 26% of the emissions from industrial and commercial processes in that State. In Iowa, Kansas, Minnesota, Nebraska, and South Dakota, all states with smaller human populations, soil emissions may dominate the NO budget. Conversion of NH₃ to NO₃ (nitrification) in aerobic soils appears to be the dominant pathway to NO. The mass and chemical form of nitrogen (reduced or oxidized) applied to soils, the vegetative cover, temperature, soil moisture, and agricultural practices such as tillage all influence the amount of fertilizer nitrogen released as NO.

Emissions of NO from soils peak in summer when O₃ formation is also at a maximum. An NRC panel report (NRC, 2002) outlined the role of agriculture in emissions of air pollutants including NO and NH₃. That report recommends immediate implementation of best management practices to control these emissions, and further research to quantify the magnitude of emissions and the impact of agriculture on air quality. Civerolo and Dickerson (1998) report that use of the no-till cultivation technique on a fertilized cornfield in Maryland reduced NO emissions by a factor of seven.

NO_x from Biomass Burning

During biomass burning, nitrogen is derived mainly from fuel N and not from atmospheric N₂, since temperatures required to fix atmospheric N₂ are likely to be found only in the flaming crowns of the most intense boreal forest fires. Nitrogen is present mainly in plants as amino (NH₂) groups in amino acids. During combustion, nitrogen is released mainly in unidentified forms, presumably as N₂, with very little remaining in fuel ash. Apart from N₂, the most abundant species in biomass burning plumes is NO. Emissions of NO account for only about 10 to 20% relative to fuel N (Lobert et al., 1991). Other species such as NO₂, nitriles, ammonia, and other nitrogen compounds account for a similar amount. Emissions of NO_x are about 0.2 to 0.3% relative to total biomass burned (e.g., Andreae, 1991; Radke et al., 1991). Westerling et al. (2006) have noted that the frequency and intensity of wildfires in the western United States have increased substantially since 1970.

Lightning Production of NO

Annual global production of NO by lightning is the most uncertain source of reactive nitrogen. In the last decade, literature values of the global average production rate range from 2 to 20 Tg N per year. However, the most likely range is from 3 to 8 Tg N per year, because the majority of the recent estimates fall in this range. The large uncertainty stems from several factors: (1) a large range of NO production rates per meter of flash length (as much as two orders of magnitude); (2) the open question of whether

cloud-to-ground (CG) flashes and intracloud flashes (IC) produce substantially different amounts of NO; (3) the global flash rate; and (4) the ratio of the number of IC flashes to the number of CG flashes. Estimates of the amount of NO produced per flash have been made based on theoretical considerations (e.g., Price et al., 1997), laboratory experiments (e.g., Wang et al., 1998); field experiments (e.g., Stith et al., 1999; Huntrieser et al., 2002, 2007); and through a combination of cloud-resolving model simulations, observed lightning flash rates, and anvil measurements of NO (e.g., DeCaria et al., 2000, 2005; Ott et al., 2007). The latter method was also used by Pickering et al. (1998), who showed that only ~5 to 20% of the total NO produced by lightning in a given storm exists in the boundary layer at the end of a thunderstorm. Therefore, the direct contribution to boundary layer O₃ production by lightning NO is thought to be small. However, lightning NO production can contribute substantially to O₃ production in the middle and upper troposphere. DeCaria et al. (2005) estimated that up to 10 ppb of O₃ was produced in the upper troposphere in the first 24 h following a Colorado thunderstorm due to the injection of lightning NO. A series of midlatitude and subtropical thunderstorm events have been simulated with the model of DeCaria et al. (2005), and the derived NO production per CG flash averaged 500 moles/flash while average production per IC flash was 425 moles/flash (Ott et al., 2006).

A major uncertainty in mesoscale and global chemical transport models is the parameterization of lightning flash rates. Model variables such as cloud top height, convective precipitation rate, and upward cloud mass flux have been used to estimate flash rates. Allen and Pickering (2002) have evaluated these methods against observed flash rates from satellite, and examined the effects on O₃ production using each method.

AX2.4.2.3. Uses of Satellite Data to Derive Emissions

Satellite data have been shown to be useful for optimizing estimates of emissions of NO₂ (Leue et al., 2001; Martin et al., 2003; Jaeglé et al., 2005). Satellite-borne instruments such as Global Ozone Monitoring Experiment (GOME) (Martin et al., 2003; and references therein) and Scanning Imaging Absorption Spectrometer for Atmospheric Chartography (SCIAMACHY) (Bovensmann et al., 1999) retrieve tropospheric columns of NO₂, which can then be combined with model-derived chemical lifetimes of NO_x to yield emissions of NO_x.

Top-down inference of the NO_x emission inventory from the satellite observations of NO₂ columns by mass balance requires at minimum three pieces of information: the retrieved tropospheric NO₂ column, the ratio of tropospheric NO_x to NO₂ columns, and the NO_x lifetime against loss to stable reservoirs. A photochemical model has been used to provide information on the latter two pieces of information. The method is generally applied exclusively to land surface emissions, excluding lightning. Tropospheric NO₂ columns are insensitive to lightning NO_x emissions since most of the lightning NO_x in the upper troposphere is present as NO at the local time of the satellite measurements (Ridley et al., 1996), owing to the slower reactions of NO with O₃ there.

Jaeglé et al. (2005) applied additional information on the spatial distribution of emissions and on fire activity to partition NO_x emissions into sources from fossil fuel combustion, soils, and biomass burning. Global a posteriori estimates of soil NO_x emissions are 68% larger than the a priori estimates. Large increases are found for the agricultural region of the western United States during summer, increasing total U.S. soil NO_x emissions by a factor of 2 to 0.9 Tg N/yr. Bertram et al. (2005) found clear signals in the SCIAMACHY observations of short intense NO_x pulses following springtime fertilizer application and subsequent precipitation over agricultural regions of the western United States. For the agricultural region in North-Central Montana, they calculate a yearly SCIAMACHY top-down estimate that is 60% higher than a commonly used model of soil NO_x emissions by Yienger and Levy (1995).

Martin et al. (2006) retrieved tropospheric NO₂ columns for May 2004 to April 2005 from the SCIAMACHY satellite instrument to derive top-down NO_x emissions estimates via inverse modeling with a global chemical transport model (GEOS-Chem). The top-down emissions were combined with a priori information from a bottom-up emission inventory with error weighting to achieve an improved a

posteriori estimate of the global distribution of surface NO_x emissions. Their a posteriori inventory improves the GEOS-Chem simulation of NO_x , PAN, and HNO_3 with respect to airborne in situ measurements over and downwind of New York City. Their a posteriori inventory shows lower NO_x emissions from the Ohio River valley during summer than during winter, reflecting recent controls on NO_x emissions from electric utilities. Their a posteriori inventory is highly consistent ($R^2 = 0.82$, bias = 3%) with the NEI99 inventory for the United States. In contrast, their a posteriori inventory is 68% larger than a recent inventory by Streets et al. (2003) for East Asia for the year 2000.

AX2.4.2.4. Field Studies Evaluating Emissions Inventories

Comparisons of emissions model predictions with observations have been performed in a number of environments. A number of studies of ratios of concentrations of CO to NO_x and NMOC to NO_x during the early 1990s in tunnels and ambient air (summarized in Air Quality Criteria for Carbon Monoxide (U.S. Environmental Protection Agency, 2000)) indicated that emissions of CO and NMOC were systematically underestimated in emissions inventories. However, the results of more recent studies have been mixed in this regard, with many studies showing agreement to within $\pm 50\%$ (U.S. Environmental Protection Agency, 2000). Improvements in many areas have resulted from the process of emissions model development, evaluation, and further refinement. It should be remembered that the conclusions from these reconciliation studies depend on the assumption that NO_x emissions are predicted correctly by emissions factor models. Roadside remote sensing data indicate that $> 50\%$ of NMHC and CO emissions are produced by less than about 10% of the vehicles (Stedman et al., 1991). These “super-emitters” are typically poorly maintained vehicles. Vehicles of any age engaged in off-cycle operations (e.g., rapid accelerations) emit much more than if operated in normal driving modes. Bishop and Stedman (1996) found that the most important variables governing CO emissions are fleet age and owner maintenance.

Emissions inventories for North America can be evaluated by comparison to measured long-term trends and or ratios of pollutants in ambient air. A decadal field study of ambient CO at a rural site in the eastern United States (Hallock-Waters et al., 1999) indicates a downward trend consistent with the downward trend in estimated emissions over the period 1988 to 1999 (U.S. Environmental Protection Agency, 1997), even when a global downward trend is accounted for. Measurements at two urban areas in the United States confirmed the decrease in CO emissions (Parrish et al., 2002). That study also indicated that the ratio of CO to NO_x emissions decreased by a factor of almost three over 12 years. (Such a downward trend was noted in the 1996 O_3 AQCD). Emissions estimates (U.S. Environmental Protection Agency, 1997) indicate a much smaller decrease in this ratio, suggesting that NO_x emissions from mobile sources may be underestimated and/or increasing. Parrish et al. (2002) conclude that O_3 photochemistry in U.S. urban areas may have become more NO_x -limited over the past decade.

Pokharel et al. (2002) employed remotely sensed emissions from on-road vehicles and fuel use data to estimate emissions in Denver. Their calculations indicate a continual decrease in CO, HC, and NO emissions from mobile sources over the 6-year study period. Inventories based on the ambient data were 30 to 70% lower for CO, 40% higher for HC, and 40 to 80% lower for NO than those predicted by the MOBILE6 model.

Stehr et al. (2000) reported simultaneous measurements of CO, SO_2 , and NO_y at an East Coast site. By taking advantage of the nature of mobile sources (they emit NO_x and CO but little SO_2) and power plants (they emit NO_x and SO_2 but little CO), the authors evaluated emissions estimates for the eastern United States. Results indicated that coal combustion contributes 25 to 35% of the total NO_x emissions in rough agreement with emissions inventories (U.S. Environmental Protection Agency, 1997).

Parrish et al. (1998) and Parrish and Fehsenfeld (2000) proposed methods to derive emission rates by examining measured ambient ratios among individual VOC, NO_x and NO_y . There is typically a strong correlation among measured values for these species because emission sources are geographically collocated, even when individual sources are different. Correlations can be used to derive emissions ratios

between species, including adjustments for the impact of photochemical aging. Investigations of this type include correlations between CO and NO_y (e.g., Parrish et al., 1991), between individual VOC species and NO_y (Goldan et al., 1995, 1997, 2000) and between various individual VOC (Goldan et al., 1995, 1997; McKeen and Liu, 1993; McKeen et al., 1996). Buhr et al. (1992) derived emission estimates from principal component analysis (PCA) and other statistical methods. Many of these studies are summarized in Trainer et al. (2000), Parrish et al. (1998), and Parrish and Fehsenfeld (2000). Goldstein and Schade (2000) also used species correlations to identify the relative impacts of anthropogenic and biogenic emissions. Chang et al. (1996, 1997) and Mendoza-Dominguez and Russell (2000, 2001) used the more quantitative technique of inverse modeling to derive emission rates, in conjunction with results from chemistry-transport models.

AX2.5. Methods for Calculating NO_x Concentrations in the Atmosphere

Atmospheric chemistry and transport models are the major tools used to calculate the relations among O₃, other oxidants, and their precursors, the transport and transformation of air toxics, the production of secondary organic aerosol, the evolution of the particle size distribution, and the production and deposition of pollutants affecting ecosystems. Chemical transport models are driven by emissions inventories for primary species such as the precursors for O₃ and PM and by meteorological fields produced by other numerical models. Emissions of precursor compounds can be divided into anthropogenic and natural source categories. Natural sources can be further divided into biotic (vegetation, microbes, animals) and abiotic (biomass burning, lightning) categories. However, the distinction between natural sources and anthropogenic sources is often difficult to make because human activities can affect directly or indirectly emissions from what would have been considered natural sources during the preindustrial era. Moreover, emissions from plants and animals used in agriculture have been referred to as anthropogenic or natural in different applications. Wildfire emissions may be considered to be natural, except that forest management practices may have led to the buildup of fuels on the forest floor, thereby altering the frequency and severity of forest fires. Needed meteorological quantities such as winds and temperatures are taken from operational analyses, reanalyses, or circulation models. In most cases, these are off-line analyses, i.e., they are not modified by radiatively active species such as O₃ and particles generated by the model.

A brief overview of atmospheric chemistry-transport models is given in Section AX2.5.1. A discussion of emissions inventories of precursors used by these models is given in Section AX2.5. Uncertainties in emissions estimates have also been discussed in the AQCD for PM (U.S. Environmental Protection Agency, 2004). Chemistry-transport model evaluation and an evaluation of the reliability of emissions inventories are presented in Section AX2.5.4.

AX2.5.1. Chemistry-Transport Models

Atmospheric CTMs have been developed for application over a wide range of spatial scales ranging from neighborhood to global. Regional scale CTMs are used chiefly for four purposes: (1) to obtain better understanding of the processes controlling the formation, transport, and destruction of gas-and particle-phase criteria and hazardous air pollutants; (2) to understand the relations between O₃ concentrations and concentrations of its precursors such as NO_x and VOCs, the factors leading to acid deposition, and hence to possible damage to ecosystems; (3) to understand relations among the concentration patterns of various pollutants that may exert adverse health effects; (4) for determining control strategies for O₃ precursors. However, this last application has met with varying degrees of success because of the highly nonlinear

relations between O₃ and emissions of its precursors, and uncertainties in emissions, parameterizations of transport, and chemical production and loss terms. Uncertainties in meteorological variables and emissions can be large enough to lead to significant errors in developing control strategies (e.g., Russell and Dennis, 2000; Sillman et al., 1995).

Global scale CTMs are used to address issues associated with climate change, stratospheric ozone depletion, and to provide boundary conditions for regional scale models. CTMs include mathematical (and often simplified) descriptions of atmospheric transport, the transfer of solar radiation through the atmosphere, chemical reactions, and removal to the surface by turbulent motions and precipitation for pollutants emitted into the model domain. Their upper boundaries extend anywhere from the top of the mixing layer to the mesopause (about 80 km in height), to obtain more realistic boundary conditions for problems involving stratospheric dynamics. There is a trade-off between the size of the modeling domain and the grid resolution used in the CTM that is imposed by computational resources.

There are two major formulations of CTMs in current use. The first approach, grid-based or Eulerian air quality models subdivide the region to be modeled (the modeling domain) into a three-dimensional array of grid cells. Spatial derivatives in the species continuity equations are cast in finite-difference form over this grid and a system of equations for the concentrations of all the chemical species in the model are solved numerically at each grid point. Finite element Eulerian models also exist and have been applied, but less frequently. Time dependent continuity (mass conservation) equations are solved for each species including terms for transport, chemical production and destruction, and emissions and deposition (if relevant), in each cell. Chemical processes are simulated with ordinary differential equations, and transport processes are simulated with partial differential equations. Because of a number of factors such as the different time scales inherent in different processes, the coupled, nonlinear nature of the chemical process terms, and computer storage limitations, all of the terms in the equations are not solved simultaneously in three dimensions. Instead, operator splitting, in which terms in the continuity equation involving individual processes are solved sequentially, is used. In the second CTM formulation, trajectory or Lagrangian models, a number of hypothetical air parcels are specified as following wind trajectories. In these models, the original system of partial differential equations is transformed into a system of ordinary differential equations.

A less common approach is to use a hybrid Lagrangian/Eulerian model, in which certain aspects of atmospheric chemistry and transport are treated with a Lagrangian approach and others are treated in an Eulerian manner (e.g., Stein et al., 2000). Each approach has its advantages and disadvantages. The Eulerian approach is more general in that it includes processes that mix air parcels and allows integrations to be carried out for long periods during which individual air parcels lose their identity. There are, however, techniques for including the effects of mixing in Lagrangian models such as FLEXPART (e.g., Zanis et al., 2003), ATTILA (Reithmeier and Sausen, 2002), and CLaMS (McKenna et al., 2002).

AX2.5.1.1. Regional Scale Chemistry Transport Models

Major modeling efforts within the U.S. Environmental Protection Agency center on the Community Multiscale Air Quality modeling system (CMAQ) (Byun and Ching, 1999; Byun and Schere, 2006). A number of other modeling platforms using Lagrangian and Eulerian frameworks have been reviewed in the 96 AQCD for O₃ (U.S. Environmental Protection Agency, 1997), and in Russell and Dennis (2000). The capabilities of a number of CTMs designed to study local- and regional-scale air pollution problems were summarized by Russell and Dennis (2000). Evaluations of the performance of CMAQ are given in Arnold et al. (2003), Eder and Yu (2005), Appel et al. (2005), and Fuentes and Raftery (2005). The domain of CMAQ and other Eulerian CTMs can extend from several hundred km to the entire hemisphere. In addition, both of these classes of models allow resolution of the calculations over specified areas to vary. CMAQ is most often driven by the MM5 mesoscale meteorological model (Seaman, 2000), though it may be driven by other meteorological models including RAMS. Simulations of pollution episodes over regional domains have been performed with a horizontal resolution as low as 1

km, and smaller calculations over limited domains have been accomplished at even finer scales. However, simulations at such high resolutions require better parameterizations of meteorological processes such as boundary layer fluxes, deep convection and clouds (Seaman, 2000), as well as finer-scale emissions. Finer spatial resolution is necessary to resolve features such as urban heat island circulation; sea, bay, and land breezes; mountain and valley breezes, and the nocturnal low-level jet, all of which can affect pollutant concentrations.

The most common approach to setting up the horizontal domain is to nest a finer grid within a larger domain of coarser resolution. However, there are other strategies such as the stretched grid (e.g., Fox-Rabinovitz et al., 2002) and the adaptive grid. In a stretched grid, the grid's resolution continuously varies throughout the domain, thereby eliminating any potential problems with the sudden change from one resolution to another at the boundary. Caution should be exercised in using such a formulation, because certain parameterizations (such as for convection) valid on a relatively coarse grid scale may not be valid on finer scales. Adaptive grids are not fixed at the start of the simulation, but instead adapt to the needs of the simulation as it evolves (e.g., Hansen et al., 1994). They have the advantage that they can resolve processes at relevant spatial scales. However, they can be very slow if the situation to be modeled is complex. Additionally, if adaptive grids are used for separate meteorological, emissions, and photochemical models, there is no reason a priori why the resolution of each grid should match, and the gains realized from increased resolution in one model will be wasted in the transition to another model. The use of finer horizontal resolution in CTMs will necessitate finer-scale inventories of land use and better knowledge of the exact paths of roads, locations of factories, and, in general, better methods for locating sources and estimating their emissions.

The vertical resolution of these CTMs is variable, and usually configured to have higher resolution near the surface and decreasing aloft. Because the height of the boundary layer is of critical importance in simulations of air quality, improved resolution of the boundary layer height would likely improve air quality simulations. Additionally, current CTMs do not adequately resolve fine scale features such as the nocturnal low-level jet in part because little is known about the nighttime boundary layer.

CTMs require time-dependent, three-dimensional wind fields for the period of simulation. The winds may be generated either by a model using initial fields alone or with four-dimensional data assimilation to improve the model's performance; (i.e., model equations can be updated periodically "nudged" to bring results into agreement with observations). Modeling efforts typically focus on simulations of several days' duration, the typical time scale for individual O₃ episodes; but longer term modeling series of several months or multiple seasons of the year are now common. The current trend in modeling applications is towards annual simulations. This trend is driven in part by the need to better understand observations of periods of high wintertime PM (e.g., Blanchard et al., 2002) and the need to simulate O₃ episodes occurring outside of summer.

Chemical kinetics mechanisms (a set of chemical reactions) representing the important reactions occurring in the atmosphere are used in CTMs to estimate the rates of chemical formation and destruction of each pollutant simulated as a function of time. Unfortunately, chemical mechanisms that explicitly treat the reactions of individual reactive species are too computationally demanding to be incorporated into CTMs for regulatory use. So, for example, one very extensive "master mechanism" (Derwent et al., 2001) includes approximately 10,500 reactions involving 3603 chemical species (Derwent et al., 2001), but "lumped" mechanisms that group compounds of similar chemistry together may be used. The chemical mechanisms used in existing photochemical O₃ models contain significant uncertainties that may limit the accuracy of their predictions; the accuracy of each of these mechanisms is also limited by missing chemistry. Because of different approaches to the lumping of organic compounds into surrogate groups, chemical mechanisms can produce somewhat different results under similar conditions. The CB-IV chemical mechanism (Gery et al., 1989), the RADM II mechanism (Stockwell et al., 1990), the SAPRC (e.g., Wang et al., 2000a,b; Carter, 1990) and the RACM mechanisms can be used in CMAQ. Jimenez et al. (2003) provide brief descriptions of the features of the main mechanisms in use and they compared concentrations of several key species predicted by seven chemical mechanisms in a box model simulation over 24 h. The average deviation from the average of all mechanism predictions for O₃ and NO over the

daylight period was less than 20%, and was 10% for NO₂ for all mechanisms. However, much larger deviations were found for HNO₃, PAN, HO₂, H₂O₂, ethylene (C₂H₄), and isoprene (C₅H₈). An analysis for OH radicals was not presented. The large deviations shown for most species imply differences between the calculated lifetimes of atmospheric species and the assignment of model simulations to either NO_x-limited or radical quantity limited regimes between mechanisms. Gross and Stockwell (2003) found small differences between mechanisms for clean conditions, with differences becoming more significant for polluted conditions, especially for NO₂ and organic peroxy radicals. Faraji et al. (2005) found differences of 40% in peak 1-h O₃ in the Houston-Galveston-Brazoria area between simulations using SAPRAC and CB-IV. They attributed differences in predicted O₃ concentrations to differences in the mechanisms of oxidation of aromatic hydrocarbons.

CMAQ and other CTMs (e.g., PM-CAMx) incorporate processes and interactions of aerosol-phase chemistry (Mebust et al., 2003). There have also been several attempts to study the feedbacks of chemistry on atmospheric dynamics using meteorological models, like MM5 (e.g., Grell et al., 2000; Liu et al., 2001a; Lu et al., 1997; Park et al., 2001). This coupling is necessary to simulate accurately feedbacks such as may be caused by the heavy aerosol loading found in forest fire plumes (Lu et al., 1997; Park et al., 2001), or in heavily polluted areas. Photolysis rates in CMAQ can now be calculated interactively with model produced O₃, NO₂, and aerosol fields (Binkowski et al., 2007).

Spatial and temporal characterizations of anthropogenic and biogenic precursor emissions must be specified as inputs to a CTM. Emissions inventories have been compiled on grids of varying resolution for many hydrocarbons, aldehydes, ketones, CO, NH₃, and NO_x. Emissions inventories for many species require the application of algorithms for calculating the dependence of emissions on physical variables such as temperature and to convert the inventories into formatted emission files which can be used by a CTM. For example, preprocessing of emissions data for CMAQ is done by the Spare-Matrix Operator Kernel Emissions (SMOKE) system. For many species, information concerning the temporal variability of emissions is lacking, so long-term (e.g., annual or O₃-season) averages are used in short-term, episodic simulations. Annual emissions estimates are often modified by the emissions model to produce emissions more characteristic of the time of day and season. Significant errors in emissions can occur if an inappropriate time dependence or a default profile is used. Additional complexity arises in model calculations because different chemical mechanisms can include different species, and inventories constructed for use with another mechanism must be adjusted to reflect these differences. This problem also complicates comparisons of the outputs of these models because one chemical mechanism may produce some species not present in another mechanism yet neither prediction may agree with the measurements.

In addition to wet deposition, dry deposition (the removal of chemical species from the atmosphere by interaction with ground-level surfaces) is an important removal process for pollutants on both urban and regional scales and must be included in CTMs. The general approach used in most models is the resistance in series method, in which where dry deposition is parameterized with a deposition velocity (V_d), which is represented as

$$V_d = (r_a + r_b + r_c)^{-1} \quad \text{AX2.5-1}$$

where r_a , r_b , and r_c represent the resistance due to atmospheric turbulence, transport in the fluid sublayer very near the elements of surface such as leaves or soil, and the resistance to uptake of the surface itself. This approach works for a range of substances, although it is inappropriate for species with substantial emissions from the surface or for species whose deposition to the surface depends on its concentration at the surface itself. The approach is also modified somewhat for aerosols: the terms r_b and r_c are replaced with a surface V_d to account for gravitational settling. In their review, Wesely and Hicks (2000) pointed out several shortcomings of current knowledge of dry deposition. Among those shortcomings are difficulties in representing dry deposition over varying terrain where horizontal advection plays a

significant role in determining the magnitude of r_a and difficulties in adequately determining a V_d for extremely stable conditions such as those occurring at night (e.g., Mahrt, 1998). Under the best of conditions, when a model is exercised over a relatively small area where dry deposition measurements have been made, uncertainties as large as $\pm 30\%$ (e.g., Massman et al., 1994; Brook et al., 1996; Padro, 1996) persist. Wesely and Hicks (2000) stated that an important result of these comparisons is that the current level of sophistication of most dry deposition models is relatively low, and that deposition estimates therefore must rely heavily on empirical data. Still larger uncertainties exist when the surface features in the built environment are not well known or when the surface comprises a patchwork of different surface types, as is common in the eastern U.S.

The initial conditions, i.e., the starting concentration fields of all species computed by a model, and the boundary conditions, i.e., the concentrations of species along the horizontal and upper boundaries of the model domain throughout the simulation must be specified at the beginning of the simulation. Both initial and boundary conditions can be estimated from models or data or, more generally, model-data hybrids. Because data for vertical profiles of most species of interest are sparse, results of model simulations over larger, usually global, domains are often used. As may be expected, the influence of boundary conditions depends on the lifetime of the species under consideration and the time scales for transport from the boundaries to the interior of the model domain (Liu et al., 2001b).

Each of the model components described above has associated uncertainties and the relative importance of these uncertainties varies with the modeling application. The largest errors in photochemical modeling are still thought to arise from the meteorological and emissions inputs to the model (Russell and Dennis, 2000). Within the model itself, horizontal advection algorithms are still thought to be significant source of uncertainty (e.g., Chock and Winkler, 1994), though more recently, those errors are thought to have been reduced (e.g., Odman and Ingram, 1996). There are also indications that problems with mass conservation continue to be present in photochemical and meteorological models (e.g., Odman and Russell, 1999), and can result in significant simulation errors. The effects of errors in initial conditions can be minimized by including several days "spin-up" time in a simulation to allow the model to be driven by emitted species before the simulation of the period of interest begins.

While the effects of poorly specified boundary conditions propagate through the model's domain, the effects of these errors remain undetermined. Because many meteorological processes occur on spatial scales which are smaller than the model grid spacing (either horizontally or vertically) and thus are not calculated explicitly, parameterizations of these processes must be used and these introduce additional uncertainty.

Uncertainty also arises in modeling the chemistry of O_3 formation because it is highly nonlinear with respect to NO_x concentrations. Thus, the volume of the grid cell into which emissions are injected is important because the nature of O_3 chemistry (i.e., O_3 production or titration) depends in a complicated way on the concentrations of the precursors and the OH radical as noted earlier. The use of ever-finer grid spacing allows regions of O_3 titration to be more clearly separated from regions of O_3 production. The use of grid spacing fine enough to resolve the chemistry in individual power-plant plumes is too demanding of computer resources for this to be attempted in most simulations. Instead, parameterizations of the effects of sub-grid-scale processes such as these must be developed, else serious errors can result if emissions are allowed to mix through an excessively large grid volume before the chemistry step in a model calculation is performed. In light of the significant differences between atmospheric chemistry taking place within and without of a power plant plume (e.g., Ryerson et al., 1998 and Sillman, 2000), inclusion of a separate, meteorological module for treating large, tight plumes can be useful. Because the photochemistry of O_3 and many other atmospheric species is nonlinear, emissions correctly modeled in a tight plume may be incorrectly modeled in a more dilute plume. Fortunately, it appears that the chemical mechanism used to follow a plume's development need not be as detailed as that used to simulate the rest of the domain, as the inorganic reactions are the most important in the plume see (e.g., Kumar and Russell, 1996). The need to include explicit plume-in-grid chemistry only down to the level of the smallest grid disappears if one uses the adaptive grid approach mentioned previously, though such grids

are more computationally intensive. These differences in simulations may be significant for calculated sensitivity of O₃ to its precursors (e.g., Sillman et al., 1995).

Because the chemical production and loss terms in the continuity equations for individual species are coupled, the chemical calculations must be performed iteratively until calculated concentrations converge to within some preset criterion. The number of iterations and the convergence criteria chosen also can introduce error.

AX2.5.1.2. Intra-urban Scale Dispersion Modeling

The grid spacing in regional chemistry transport models between 1 and 12 km², is usually too coarse to resolve spatial variations on the neighborhood scale. The interface between regional scale models and models of personal exposure described in Annex 3, Section AX3.5 is provided by smaller scale dispersion models. Several models could be used to simulate concentration fields near roads, each with its own set of strengths and weaknesses. For example, AERMOD (http://www.epa.gov/scram001/dispersion_prefrec.htm) is a steady-state plume model that was formulated as a replacement to the ISC3 dispersion model. In the stable boundary layer (SBL), it assumes the concentration distribution to be Gaussian in both the vertical and horizontal. In the convective boundary layer, the horizontal distribution is also assumed to be Gaussian, but the vertical distribution is described with a bi-Gaussian probability density function (pdf). AERMOD has provisions to be applied to flat and complex terrain, and multiple source types (including, point, area and volume sources) in both urban and rural areas. It incorporates air dispersion based on planetary boundary layer turbulence structure and scaling concepts, and is meant to treat both surface and elevated sources and simple and complex terrain in rural and urban areas. The dispersion of emissions from line sources like highways is treated as the sum of emissions from a number of point sources placed side by side. However, emissions are usually not in steady state and there are different functional relationships between buoyant plume rise in point and line sources. It should be remembered that NO₂ is largely secondary in nature as it is produced by Reaction AX 2.2-3. However, AERMOD does not have provision for including secondary sources. The more appropriate use of AERMOD would be to simulate the total of NO and NO₂, or NO_x.

There are models that are non-steady state and can incorporate plume rise explicitly from different types of sources. For example, CALPUFF (<http://www.src.com/calpuff/calpuff1.htm>) is a non-steady-state puff dispersion model that simulates the effects of time- and space-varying meteorological conditions on pollution transport, transformation, and removal and has provisions for calculating dispersion from surface sources. However, it should be noted that neither model was designed to treat the dispersion of emissions from roads or to include secondary sources. In using either model, the user would have to specify dispersion parameters that are specific to traffic. The distinction between a steady-state and time varying model might not be important for long time scales; however for short time scales, the temporal variability in traffic emissions could result in underestimation of peak concentration and exposures.

AX2.5.1.3. Global Scale CTMs

The importance of global transport of O₃ and O₃ precursors and their contribution to regional O₃ levels in the United States is now apparent. There are at present on the order of 20 three-dimensional global models developed by various groups to address problems in tropospheric chemistry. These models resolve synoptic meteorology, O₃-NO_x-CO-hydrocarbon photochemistry, have parameterizations for wet and dry deposition, and parameterize sub-grid scale vertical mixing processes such as convection. Global models have proven useful for testing and advancing scientific understanding beyond what is possible with observations alone. For example, they can calculate quantities of interest that cannot be measured

directly, such as the export of pollution from one continent to the global atmosphere or the response of the atmosphere to future perturbations to anthropogenic emissions.

Global simulations are typically conducted at a horizontal resolution of 200 km² or more. Simulations of the effects of transport from long-range transport link multiple horizontal resolutions from the global to the local scale. Finer resolution will only improve scientific understanding to the extent that the governing processes are more accurately described at that scale. Consequently, there is a critical need for observations at the appropriate scales to evaluate the scientific understanding represented by the models.

During the recent IPCC-AR4 tropospheric chemistry study coordinated by the European Union Atmospheric Composition Change: the European Network of excellence (ACCENT), 26 atmospheric CTMs were used to estimate the impacts of three emissions scenarios on global atmospheric composition, climate, and air quality in 2030 (Dentener et al., 2006a). All models were required to use anthropogenic emissions developed at IIASA (Dentener et al., 2005) and GFED version 1 biomass burning emissions (Van der Werf et al., 2003) as described in Stevenson et al. (2006). The base simulations from these models were evaluated against a suite of present-day observations. Most relevant to this assessment report are the evaluations with ozone, NO₂, and nitrogen deposition (Stevenson et al., 2006; Van Noije et al., 2006; Dentener et al., 2006a), which are summarized briefly below.

An analysis of the standard deviation of zonal mean and tropospheric column O₃ reveals large inter-model variability in the tropopause region and throughout the polar troposphere, likely reflecting differences in model tropopause levels and the associated stratospheric injection of O₃ to the troposphere (Stevenson et al., 2006). Ozone distributions in the tropics also exhibit large standard deviations (~30%), particularly as compared to the mid-latitudes (~20%), indicating larger uncertainties in the processes that influence ozone in the tropics: deep tropical convection, lightning NO_x, isoprene emissions and chemistry, and biomass burning emissions (Stevenson et al., 2006).

Stevenson et al., (2006) found that the model ensemble mean (MEM) typically captures the observed seasonal cycles to within one standard deviation. The largest discrepancies between the MEM and observations include: (1) an underestimate of the amplitude of the seasonal cycle at 30°-90°N with a 10 ppb overestimate of winter ozone, possibly due to the lack of a seasonal cycle in anthropogenic emissions or to shortcomings in the stratospheric influx of O₃, and (2) an overestimate of O₃ throughout the northern tropics. However, the MEM was found to capture the observed seasonal cycles in the southern hemisphere, suggesting that the models adequately represent biomass burning and natural emissions.

The mean present-day global ozone budget across the current generation of CTMs differs substantially from that reported in the IPCC Third Assessment Report (TAR), with a 50% increase in the mean chemical production (to 5100 Tg O₃/yr), a 30% increase in the chemical and deposition loss terms (to 4650 and 1000 Tg O₃/yr, respectively) and a 30% decrease in the mean stratospheric input flux (to 550 Tg O₃/yr) (Stevenson et al., 2006). The larger chemical terms as compared to the IPCC TAR are attributed mainly to higher NO_x (as well as an equatorward shift in distribution) and isoprene emissions, although more detailed schemes and/or improved representations of photolysis, convection, and stratospheric-tropospheric exchange may also contribute (Stevenson et al., 2006).

A subset of 17 of the 26 models used in the Stevenson et al. (2006) study was used to compare with three retrievals of NO₂ columns from the GOME instrument (van Noije et al., 2006) for the year 2000. The higher resolution models reproduce the observed patterns better, and the correlation among simulated and retrieved columns improved for all models when simulated values are smoothed to a 5° H 5° grid, implying that the models do not accurately reproduce the small-scale features of NO₂ (Van Noije et al., 2006). Van Noije et al. (2006) suggest that variability in simulated NO₂ columns may reflect model differences in OH distributions and the resulting NO_x lifetimes, as well as differences in vertical mixing which strongly affect partitioning between NO and NO₂. Overall, the models tend to underestimate concentrations in the retrievals in industrial regions (including the eastern United States) and overestimate them in biomass burning regions (Van Noije et al., 2006).

Over the eastern United States and in industrial regions more generally, the spread in absolute column abundances is generally larger among the retrievals than among the models, with the discrepancy among the retrievals particularly pronounced in winter (Van Noije et al., 2006), suggesting that the models are biased low, or that the European retrievals may be biased high as the Dalhousie/SAO retrieval is closer to the model estimates. The lack of seasonal variability in fossil fuel combustion emissions may contribute to a wintertime model underestimate (Van Noije et al., 2006) manifested most strongly over Asia. In biomass burning regions, the models generally reproduce the timing of the seasonal cycle of the retrievals, but tend to overestimate the seasonal cycle amplitude, partly due to lower values in the wet season, which may reflect an underestimate in wet season soil NO emissions (Van Noije et al., 2006, Jaeglé et al., 2004, 2005).

AX2.5.1.4. Modeling the Effects of Convection

The effects of deep convection can be simulated using cloud-resolving models, or in regional or global models in which the convection is parameterized. The Goddard Cumulus Ensemble (GCE) model (Tao and Simpson, 1993) has been used by Pickering et al. (1991, 1992a,b, 1993, 1996), Scala et al. (1990), and Stenchikov et al. (1996) in the analysis of convective transport of trace gases. The cloud model is nonhydrostatic and contains a detailed representation of cloud microphysical processes. Two- and three-dimensional versions of the model have been applied in transport analyses. The initial conditions for the model are usually from a sounding of temperature, water vapor and winds representative of the region of storm development. Model-generated wind fields can be used to perform air parcel trajectory analyses and tracer advection calculations.

Such methods were used by Pickering et al. (1992b) to examine transport of urban plumes by deep convection. Transport of an Oklahoma City plume by the 10-11 June 1985 PRE-STORM squall line was simulated with the 2-D GCE model. This major squall line passed over the Oklahoma City metropolitan area, as well as more rural areas to the north. Chemical observations ahead of the squall line were conducted by the PRE-STORM aircraft. In this event, forward trajectories from the boundary layer at the leading edge of the storm showed that almost 75% of the low level inflow was transported to altitudes exceeding 8 km. Over 35% of the air parcels reached altitudes over 12 km. Tracer transport calculations were performed for CO, NO_x, O₃, and hydrocarbons. Rural boundary layer NO_x was only 0.9 ppb, whereas the urban plume contained about 3 ppb. In the rural case, mixing ratios of 0.6 ppb were transported up to 11 km. Cleaner air descended at the rear of the storm lowering NO_x at the surface from 0.9 to 0.5 ppb. In the urban plume, mixing ratios in the updraft core reached 1 ppb between 14 and 15 km. At the surface, the main downdraft lowered the NO_x mixing ratios from 3 to 0.7 ppb.

Regional chemical transport models have been used for applications such as simulations of photochemical O₃ production, acid deposition, and fine PM. Walcek et al. (1990) included a parameterization of cloud-scale aqueous chemistry, scavenging, and vertical mixing in the chemistry model of Chang et al. (1987). The vertical distribution of cloud microphysical properties and the amount of sub-cloud-layer air lifted to each cloud layer are determined using a simple entrainment hypothesis (Walcek and Taylor, 1986). Vertically integrated O₃ formation rates over the northeast U. S. were enhanced by ~50% when the in-cloud vertical motions were included in the model.

Wang et al. (1996) simulated the 10-11 June 1985 PRE-STORM squall line with the NCAR/Penn State Mesoscale Model (MM5) (Grell et al., 1994; Dudhia, 1993). Convection was parameterized as a sub-grid-scale process in MM5 using the Kain and Fritsch (1993) scheme. Mass fluxes and detrainment profiles from the convective parameterization were used along with the 3-D wind fields in CO tracer transport calculations for this convective event.

Convective transport in global chemistry and transport models is treated as a sub-grid-scale process that is parameterized typically using cloud mass flux information from a general circulation model or global data assimilation system. While GCMs can provide data only for a “typical” year, data assimilation systems can provide “real” day-by-day meteorological conditions, such that CTM output can be compared

directly with observations of trace gases. The NASA Goddard Earth Observing System Data Assimilation System (GEOS-1 DAS and successor systems; Schubert et al., 1993; Bloom et al., 1996; Bloom et al., 2005) provides archived global data sets for the period 1980 to present, at 2E H 2.5E or better resolution with 20 layers or more in the vertical. Deep convection is parameterized with the Relaxed Arakawa-Schubert scheme (Moorthi and Suarez, 1992) in GEOS-1 and GEOS-3 and with the Zhang and McFarlane (1995) scheme in GEOS-4. Pickering et al. (1995) showed that the cloud mass fluxes from GEOS-1 DAS are reasonable for the 10-11 June 1985 PRE-STORM squall line based on comparisons with the GCE model (cloud-resolving model) simulations of the same storm. In addition, the GEOS-1 DAS cloud mass fluxes compared favorably with the regional estimates of convective transport for the central United States presented by Thompson et al. (1994). However, Allen et al. (1997) have shown that the GEOS-1 DAS overestimates the amount and frequency of convection in the tropics and underestimates the convective activity over midlatitude marine storm tracks.

Global models with parameterized convection and lightning have been run to examine the roles of these processes over North America. Lightning contributed 23% of upper tropospheric NO_x over the SONEX region according to the UMD-CTM modeling analysis of Allen et al. (2000). During the summer of 2004 the NASA Intercontinental Chemical Transport Experiment - North America (INTEX-NA) was conducted primarily over the eastern two-thirds of the United States, as a part of the International Consortium for Atmospheric Research on Transport and Transformation (ICARTT). Deep convection was prevalent over this region during the experimental period. Cooper et al. (2006) used a particle dispersion model simulation for NO_x to show that 69-84% of the upper tropospheric O_3 enhancement over the region in Summer 2004 was due to lightning NO_x . The remainder of the enhancement was due to convective transport of O_3 from the boundary layer or other sources of NO_x . Hudman et al. (2007) used a GEOS-Chem model simulation to show that lightning was the dominant source of upper tropospheric NO_x over this region during this period. Approximately 15% of North American boundary layer NO_x emissions were shown to have been vented to the free troposphere over this region based on both the observations and the model.

AX2.5.2. CTM Evaluation

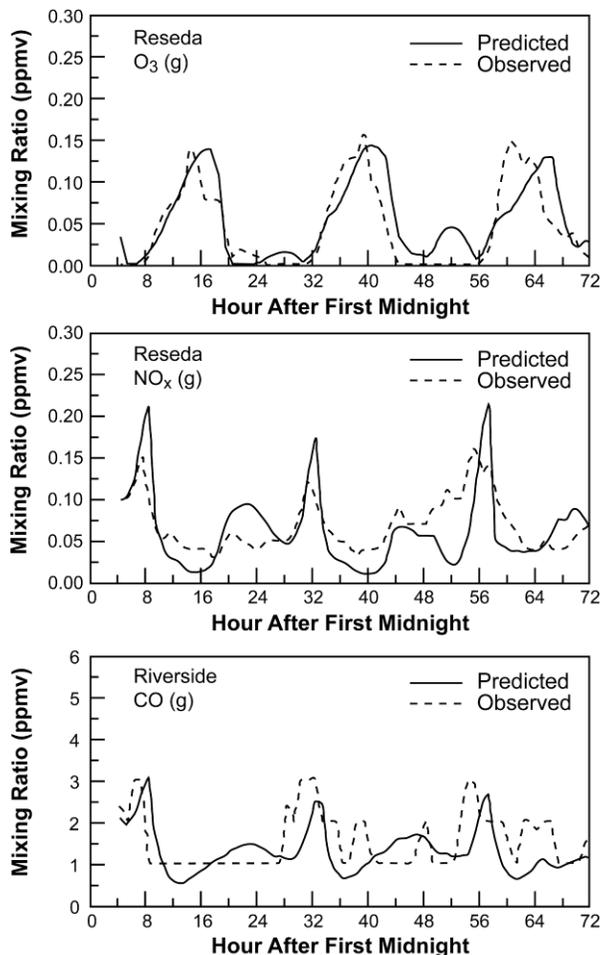

The comparison of model predictions with ambient measurements represents a critical task for establishing the accuracy of photochemical models and evaluating their ability to serve as the basis for making effective control strategy decisions. The evaluation of a model's performance, or its adequacy to perform the tasks for which it was designed can only be conducted within the context of measurement errors and artifacts. Not only are there analytical problems, but there are also problems in assessing the representativeness of monitors at ground level for comparison with model values which represent typically an average over the volume of a grid box.

Global-scale CTMs have generally been evaluated by comparison with measurements for a wide array of species, rather than just for O_3 (e.g., Wang et al., 1998; Emmons et al., 2000; Bey et al., 2001; Hess, 2001; Fiore et al., 2002). These have included evaluation of major primary species (NO_x , CO, and selected VOCs) and an array of secondary species (HNO_3 , PAN, H_2O_2) that are often formed concurrently with O_3 . Models for urban and regional O_3 have also been evaluated against a broader ensemble of measurements in a few cases, often associated with measurement intensives (e.g., Jacobson et al., 1996; Lu et al., 1997; Sillman et al., 1998). The results of a comparison between observed and computed concentrations from Jacobson et al. (1996) for the Los Angeles Basin are shown in Figures AX2.5-1 and AX2.5-2.

The highest concentrations of primary species usually occur in close proximity to emission sources (typically in urban centers) and at times when dispersion rates are low. The diurnal cycle includes high concentrations at night, with maxima during the morning rush hour, and low concentrations during the afternoon (Figure AX2.5-1). The afternoon minima are driven by the much greater rate of vertical mixing at that time. Primary species also show a seasonal maximum during winter, and are often high during fog

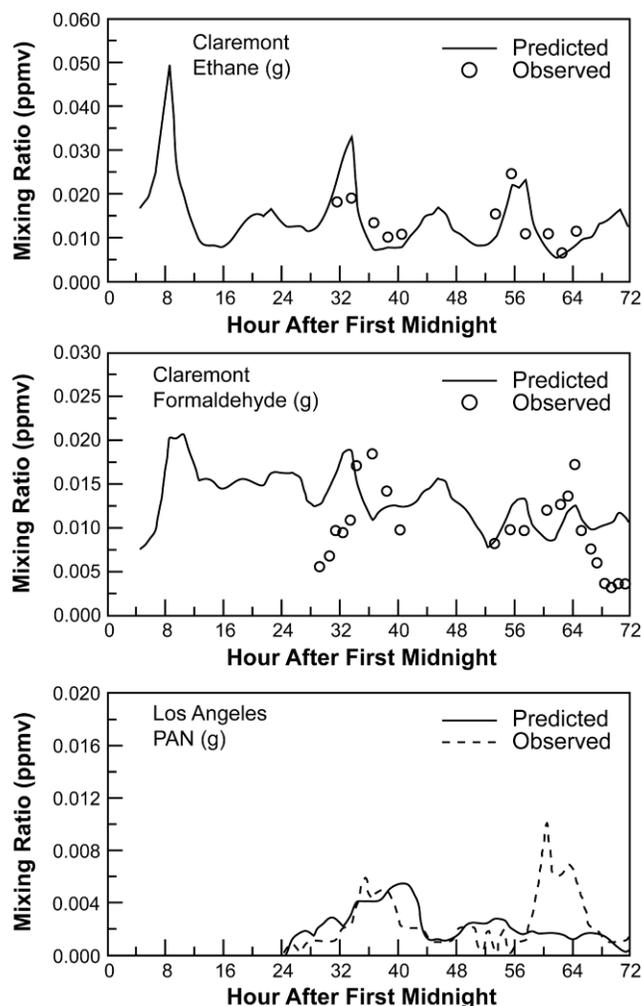

episodes in winter when vertical mixing, is suppressed. By contrast, secondary species such as O_3 are typically highest during the afternoon (the time of greatest photochemical activity), on sunny days and during summer.

During these conditions, concentrations of primary species may be relatively low. Strong correlations between primary and secondary species are generally observed only in downwind rural areas where all anthropogenic species are simultaneously elevated. The difference in the diurnal cycles of primary species (CO , NO_x and ethane) and secondary species (O_3 , PAN, and HCHO) is evident in Figure AX2.5-2.

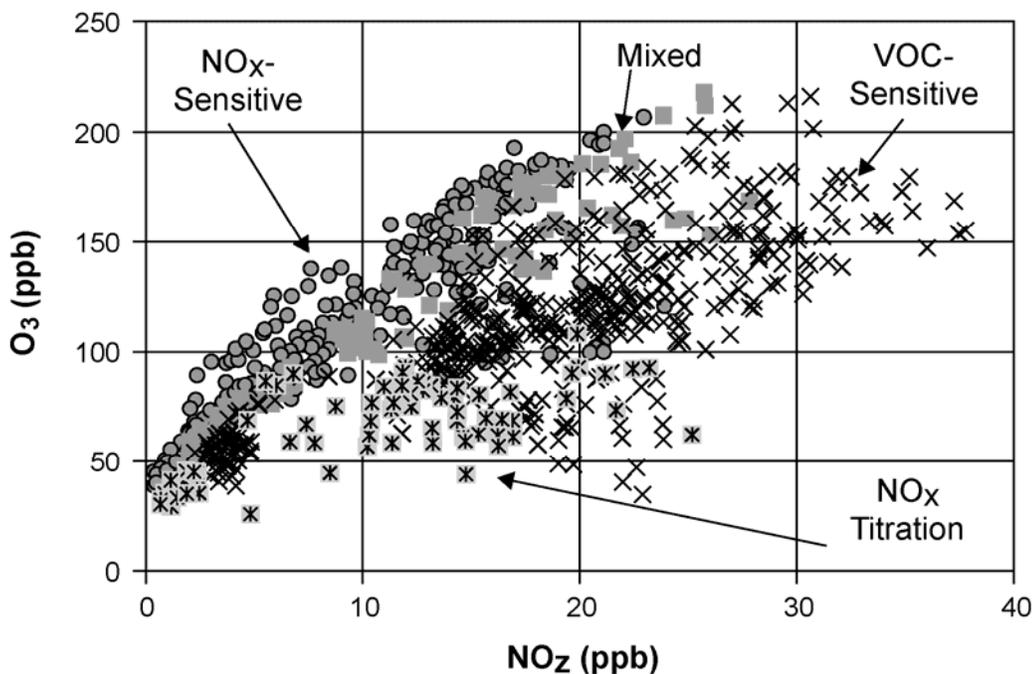

Figure AX2.5-2. Time series for measured gas-phase species in comparison with results from a photochemical model. The circles represent measurements, and solid lines represent model predictions (in parts per million, ppmv) for August 26–28, 1988 at sites in southern California. The horizontal axis represents hours past midnight, August 25. Results represent ethane and formaldehyde at Claremont, and PAN at Los Angeles.

Models for urban and regional chemistry have been evaluated less extensively than global-scale models in part because the urban/regional context presents a number of difficult challenges. Global-scale models typically represent continental-scale events and can be evaluated effectively against a sparse network of measurements. By contrast, urban/regional models are critically dependent on the accuracy of local emission inventories and event-specific meteorology, and must be evaluated separately for each urban area that is represented.

The evaluation of urban/regional models is also limited by the availability of data. Measured NO_x and speciated VOC concentrations are widely available through the regulatory networks of the U.S. EPA. Evaluation of urban/regional models versus measurements has generally relied on results from a limited number of field studies in the United States. Short-term, research-grade measurements for species relevant to O_3 formation, including VOCs, NO_x , PAN, HNO_3 , and H_2O_2 are also available at selected

rural and remote sites (e.g., Daum et al., 1990, 1996; Martin et al., 1997; Young et al., 1997; Thompson et al., 2000; Hoell et al., 1997, 1999; Fehsenfeld et al., 1996; Emmons et al., 2000; Hess, 2001; Carroll et al., 2001). The equivalent measurements are available for some polluted rural sites in the eastern United States, but only at a few urban locations (Meagher et al., 1998; Hübler et al., 1998; Kleinman et al., 2000, 2001; Fast et al., 2002; Lu et al., 1997). Extensive measurements have also been made in Vancouver (Steyn et al., 1997) and in several European cities (Staffelbach et al., 1997; Prévôt et al., 1997, Dommen et al., 1999; Geyer et al., 2001; Thielman et al., 2001; Martilli et al., 2002; Vautard et al., 2002).

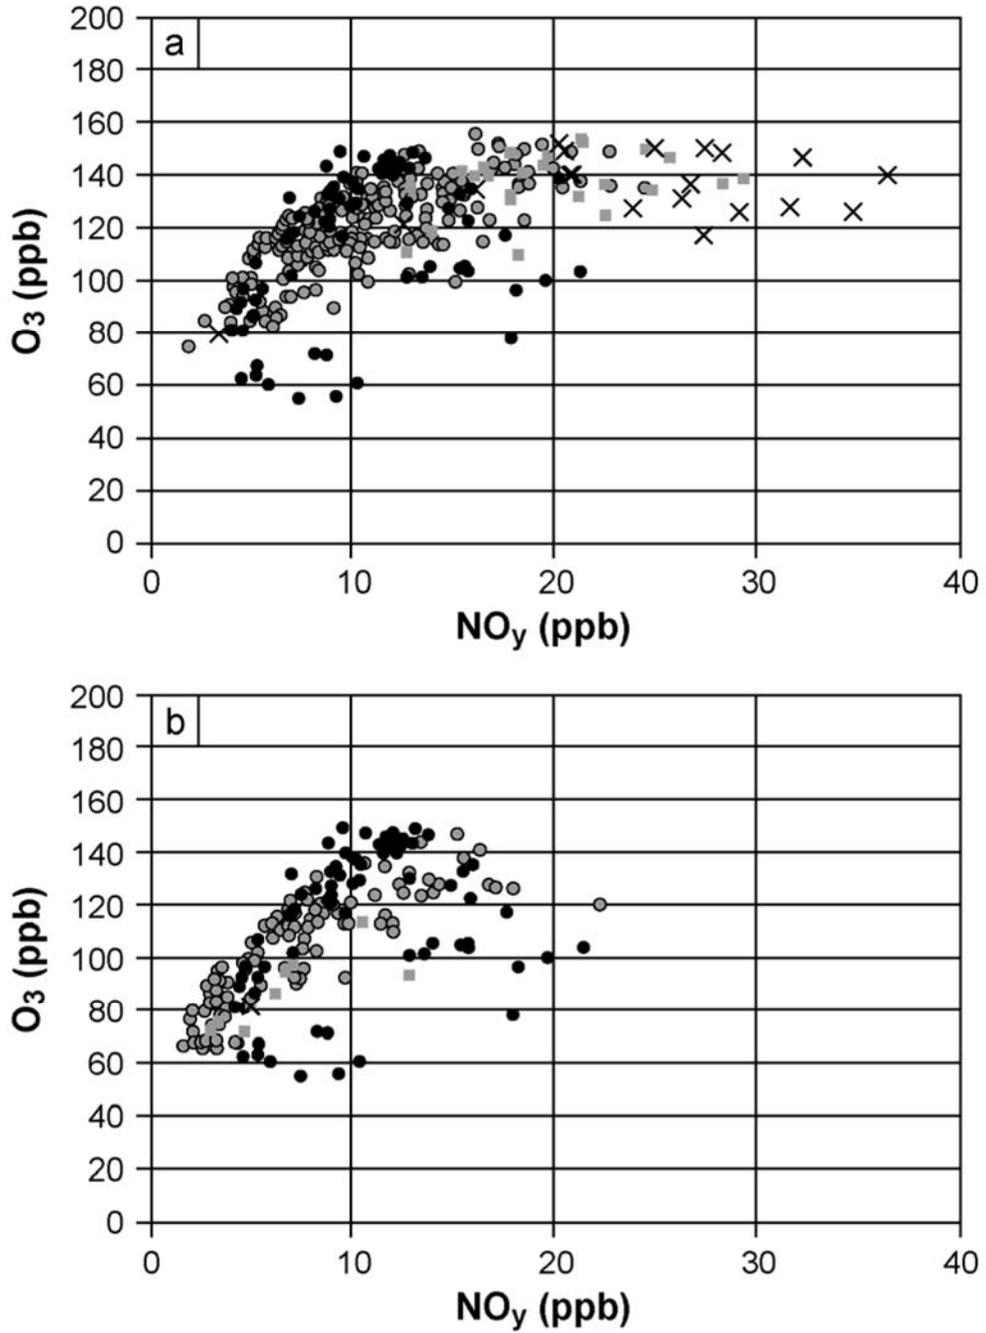

The results of straightforward comparisons between observed and predicted concentrations of O₃ can be misleading because of compensating errors, although this possibility is diminished when a number of species are compared. Ideally, each of the main modules of a CTM system (for example, the meteorological model and the chemistry and radiative transfer routines) should be evaluated separately. However, this is rarely done in practice. To better indicate how well physical and chemical processes are being represented in the model, comparisons of relations between concentrations measured in the field and concentrations predicted by the model can be made. These comparisons could involve ratios and correlations between species. For example, correlation coefficients could be calculated between primary species as a means of evaluating the accuracy of emission inventories or between secondary species as a means of evaluating the treatment of photochemistry in the model. In addition, spatial relations involving individual species (correlations, gradients) can also be used as a means of evaluating the accuracy of transport parameterizations. Sillman and He (2002) examined differences in correlation patterns between O₃ and NO_Z in Los Angeles, CA, Nashville, TN, and various sites in the rural United States. Model calculations (Figure AX2.5-3) show differences in correlation patterns associated with differences in the sensitivity of O₃ to NO_X and VOCs. Primarily NO_X-sensitive (NO_X-limited) areas in models show a strong correlation between O₃ and NO_Z with a relatively steep slope, while primarily VOC-sensitive (NO_X-saturated) areas in models show lower O₃ for a given NO_Z and a lower O₃-NO_Z slope. They found that differences found in measured data ensembles were matched by predictions from chemical transport models. Measurements in rural areas in the eastern United States show differences in the pattern of correlations for O₃ versus NO_Z between summer and autumn (Jacob et al., 1995; Hirsch et al., 1996), corresponding to the transition from NO_X-limited to NO_X-saturated patterns, a feature which is also matched by CTMs.

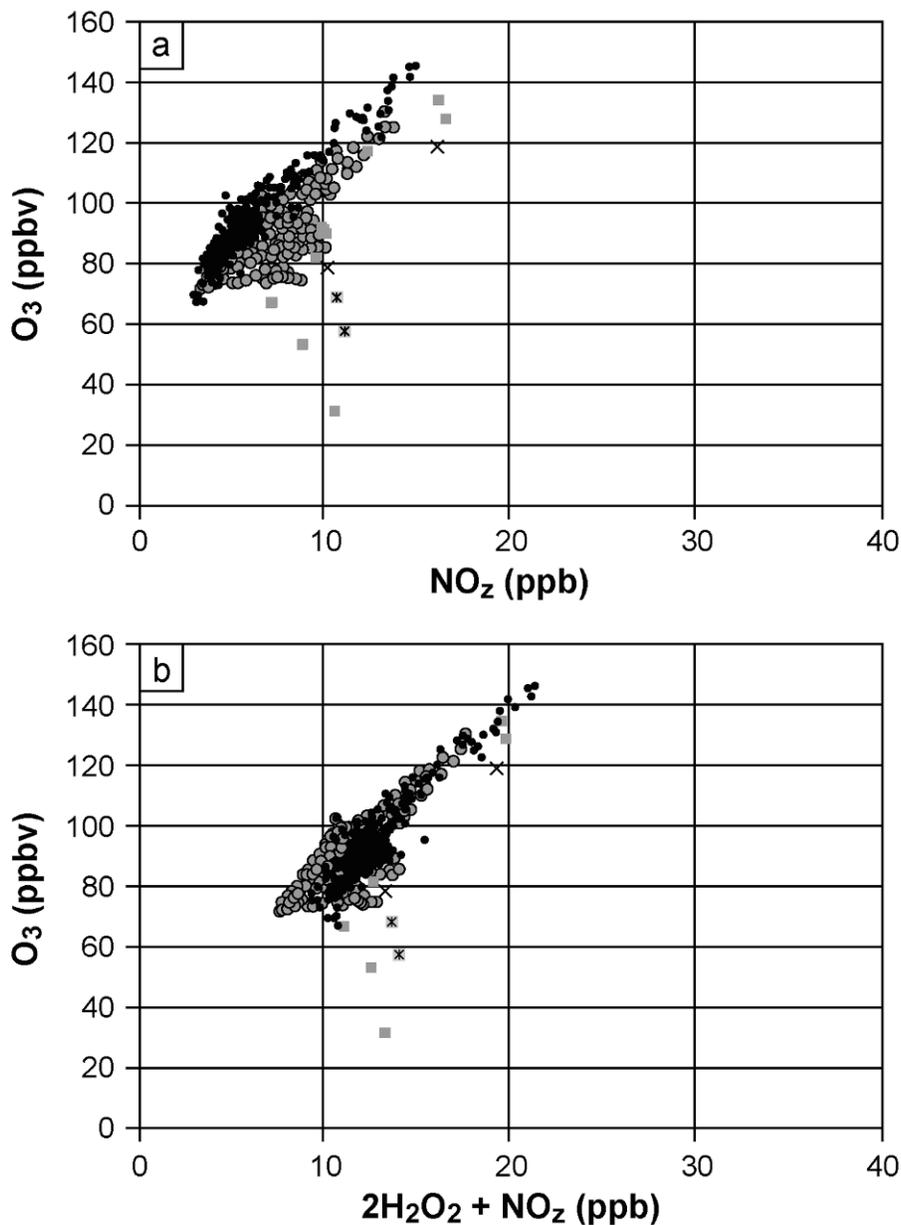

Figure AX2.5-3. Correlations for O₃ versus NO_z (NO_y-NO_x) in ppb from chemical transport models for the northeast corridor, Lake Michigan, Nashville, the San Joaquin Valley, and Los Angeles. Each location is classified as NO_x-limited or NO_x-sensitive (circles), NO_x-saturated or VOC-sensitive (crosses), mixed or with near-zero sensitivity (squares), and dominated by NO_x titration (asterisks) based on the model response to reduced NO_x and VOC.

The difference in correlations between secondary species in NO_x-limited to NO_x-saturated environments can also be used to evaluate the accuracy of model predictions in individual applications. Figures AX2.5-4, show results for two different model scenarios for Atlanta. As shown in the figures, the first model scenario predicts an urban plume with high NO_y and O₃ formation apparently suppressed by high NO_y. Measurements show much lower NO_y in the Atlanta plume. This error was especially significant because the model locations sensitive to NO_x. The second model scenario (with primarily NO_x sensitive conditions) shows much better agreement with measured values. Figure AX2.5-5 shows model-measurement comparison for secondary species in Nashville, showing better agreement with measured conditions. Greater confidence in the predictions made by CTMs will be gained by the application of techniques such as these on a more routine basis.

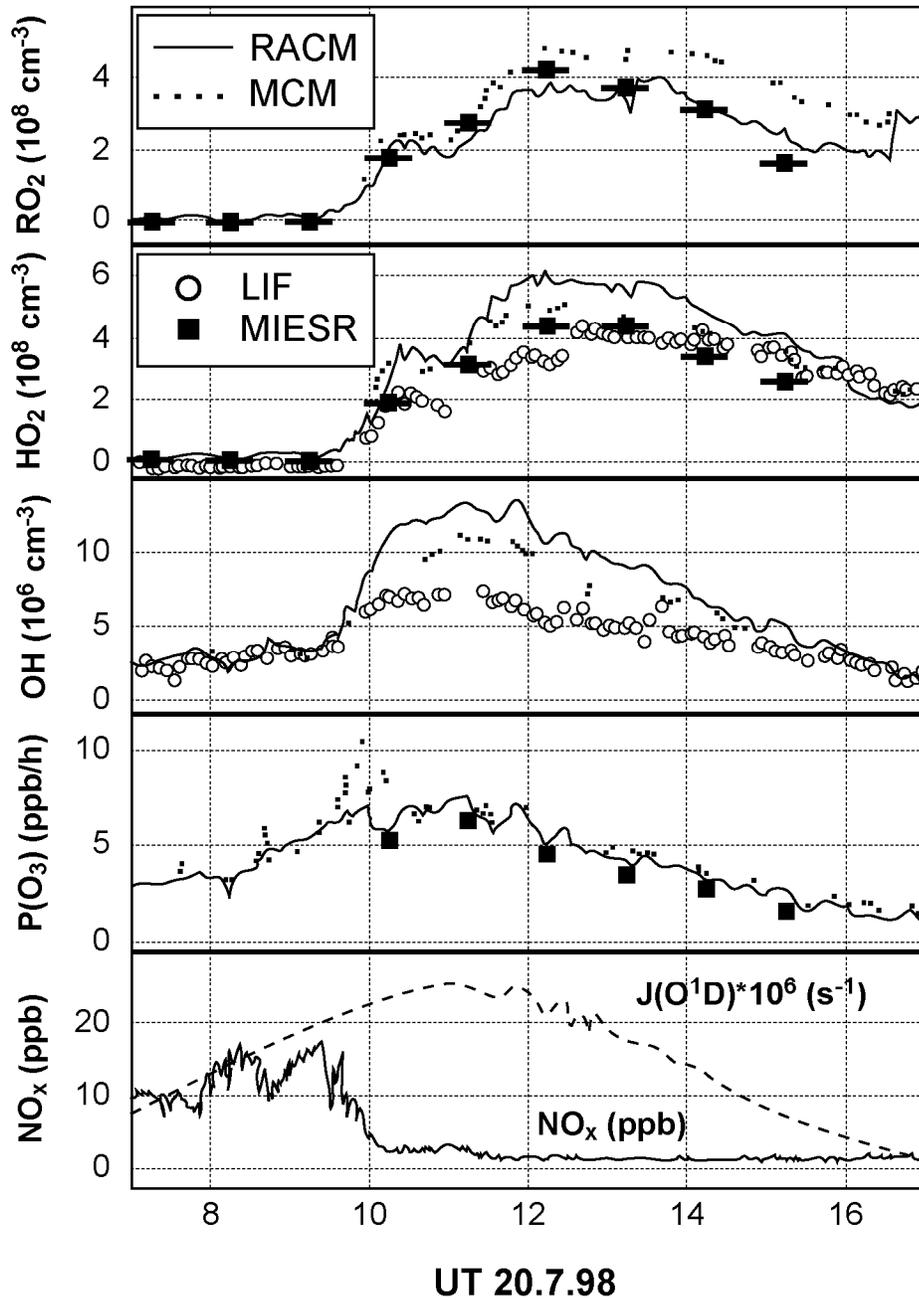

Figure AX2.5-5. Evaluation of model versus: (a) measured O_3 versus NO_z and (b) O_3 versus the sum $2H_2O_2 + NO_z$ for Nashville, TN. The model values are classified as NO_x -limited (gray circles), NO_x -saturated (X's), mixed or near-zero sensitivity (squares), or dominated by NO_x titration (filled circles). Diamonds represent aircraft measurements.

The ability of chemical mechanisms to calculate the concentrations of free radicals under atmospheric conditions was tested in the Berlin Ozone Experiment, BERLIOZ (Volz-Thomas et al., 2003) during July and early August at a site located about 50 km NW of Berlin. (This location was chosen because O_3 episodes in central Europe are often associated with SE winds.)

Concentrations of major compounds such as O_3 , hydrocarbons, etc., were fixed at observed values. Figure AX2.5-6 compares the concentrations of RO_2 , HO_2 , and OH radicals predicted by RACM and

MCM with observations made by the laser-induced fluorescence (LIF) technique and by matrix isolation ESR spectroscopy (MIESR). Also shown are the production rates of O₃ calculated using radical concentrations predicted by the mechanisms and those obtained by measurements, and measurements of NO_x concentrations. As can be seen, there is good agreement between measurements of RO₂, HO₂, OH, radicals with values predicted by both mechanisms at high concentrations of NO_x (>10 ppb). However, at lower NO_x concentrations, both mechanisms substantially overestimate OH concentrations and moderately overestimate HO₂ concentrations. Agreement between models and measurements is generally better for organic peroxy radicals, although the MCM appears to overestimate their concentrations somewhat. In general, the mechanisms reproduced the HO₂ to OH and RO₂ to OH ratios better than the individual measurements. The production of O₃ was found to increase linearly with NO (for NO < 0.3 ppb) and to decrease with NO (for NO > 0.5 ppb).

OH and HO₂ concentrations measured during the PM_{2.5} Technology Assessment and Characterization Study conducted at Queens College in New York City in the summer of 2001 were also compared with those predicted by RACM (Ren et al., 2003). The ratio of observed to predicted HO₂ concentrations over a diurnal cycle was 1.24 and the ratio of observed to predicted OH concentrations was about 1.10 during the day, but the mechanism significantly underestimated OH concentrations during the night.

Source: Volz-Thomas et al. (2003).

Figure AX2.5-6. Time series of concentrations of RO₂, HO₂, and OH radicals, local O₃ photochemical production rate and concentrations of NO_x. These are from measurements made during BERLIOZ. Also shown are comparisons with results of photochemical box model calculations using the RACM and MCM chemical mechanisms.

AX2.6. Sampling and Analysis of NO_x

AX2.6.1. Availability and Accuracy of Ambient NO_y Measurements

Sections AX2.6.1-AX2.6.4 focus on current methods and on promising new technologies, but no attempt is made here to cover the extensive development of these methods or of methods such as wet chemical techniques no longer in widespread use. More detailed discussions of these methods may be found elsewhere (U.S. Environmental Protection Agency, 1993, 1996). McClenny (2000), Parrish and Fehsenfeld (2000), and Clemitshaw (2004) reviewed methods for measuring NO_x and NO_y compounds. Discussions in Sections 2.6.1-2.6.4 center on chemiluminescence and optical Federal Reference and Equivalent Methods (FRM and FEM, respectively).

The use of methods such as observationally based methods or source apportionment models, either as stand-alone methods or as a basis for evaluating chemical transport models, is often limited by the availability and accuracy of measurements. Measured NO_x and speciated VOC concentrations are widely available in the United States through the Photochemical Assessment Monitoring Stations (PAMS) network. The PAMS network currently includes measured NO and NO_x. However, Cardelino and Chameides (2000) reported that measured NO during the afternoon was frequently at or below the detection limit of the instruments (1 ppb), even in large metropolitan regions (Washington, DC; Houston, TX; New York, NY). NO₂ measurements are made with commercial chemiluminescent detectors with hot molybdenum converters. However, these measurements typically include a wide variety of other reactive N species, such as organic nitrates in addition to NO_x, and cannot be interpreted as a “pure” NO_x measurement (see summary in Parrish and Fehsenfeld, 2000).

Total reactive nitrogen (NO_y) is included in the PAMS network only at a few sites. The possible expansion of PAMS to include more widespread NO_y measurements has been suggested (McClenny, 2000). NO_y measurements are also planned for inclusion in the NCore network (U.S. Environmental Protection Agency, 2005). A major issue to be considered when measuring NO_x and NO_y is the possibility that HNO₃, a major component of NO_y, is sometimes lost in inlet tubes and not measured (Luke et al., 1998; Parrish and Fehsenfeld, 2000). This problem is especially critical if measured NO_y is used to identify NO_x-limited versus NO_x-saturated conditions. The problem is substantially alleviated although not necessarily completely solved by using much shorter inlets on NO_y monitors than on NO_x monitors and by the use of surfaces less likely to take up HNO₃. The correlation between O₃ and NO_y differs for NO_x-limited versus NO_x-saturated locations, but this difference is driven primarily by differences in the ratio of O₃ to HNO₃. If HNO₃ were omitted from the NO_y measurements, then the measurements would represent a biased estimate and their use would be problematic.

AX2.6.1.1. Measurement of NO

Gas-phase Chemiluminescence (CL) Methods

Nitric oxide can be measured reliably using the principle of gas-phase chemiluminescence induced by the reaction of NO with O₃ at low pressure. Modern commercial NO_x analyzers have sufficient sensitivity and specificity for adequate measurement in urban and many rural locations (U.S. Environmental Protection Agency, 1993, 1996, 2006). Research grade CL instruments have been compared under realistic field conditions to spectroscopic instruments, and the results indicate that both methods are reliable (at concentrations relevant to smog studies) to better than 15 percent with 95 percent confidence. Response times are on the order of 1 minute. For measurements meaningful for understanding O₃ formation, emissions modeling, and N deposition, special care must be taken to zero and calibrate the instrument frequently. A chemical zero, obtained by reacting the NO up-stream and out of view of the photomultiplier tube, is preferred because it accounts for interferences such as light emitting reactions

with unsaturated hydrocarbons. Standard additions of NO at the inlet will account for NO loss or conversion to NO₂ in the lines. In summary, CL methods, when operated carefully in an appropriate manner, can be suitable for measuring or monitoring NO (e.g., Crosley, 1996).

Spectroscopic Methods for NO_x

NO has also been successfully measured in ambient air with direct spectroscopic methods; these include two-photon laser-induced fluorescence (TPLIF), tunable diode laser absorption spectroscopy (TDLAS), and two-tone frequency-modulated spectroscopy (TTFMS). These were reviewed thoroughly in the previous AQCD and will be only briefly summarized here. The spectroscopic methods demonstrate excellent sensitivity and selectivity for NO with detection limits on the order of 10 parts per trillion (ppt) for integration times of 1 min. Spectroscopic methods compare well with the CL method for NO in controlled laboratory air, ambient air, and heavily polluted air (e.g., Walega et al., 1984; Gregory et al., 1990; Kireev et al., 1999). These spectroscopic methods remain in the research arena due to their complexity, size, and cost, but are essential for demonstrating that CL methods are reliable for monitoring NO concentrations involved in O₃ formation, from around 20 ppt to several hundred of ppb.

Atmospheric pressure laser ionization followed by mass spectroscopy has also been deployed for detection of NO and NO₂. Garnica et al. (2000) describe a technique involving selective excitation at one wavelength followed by ionization at a second wavelength. They report good selectivity and detection limits well below 1 ppb. The practicality of the instrument for ambient monitoring, however, has yet to be demonstrated.

AX2.6.1.2. Measurements of NO₂

Gas-Phase Chemiluminescence Methods

Reduction of NO₂ to NO on the surface of a heated (to 300 to 400°C) molybdenum oxide (MoO_x) substrate followed by detection of the chemiluminescence produced during the reaction of NO with O₃ at low pressure as described earlier for measurement of NO serves as the basis of the FRM for measurement of ambient NO₂. However, the substrate used in the reduction of NO₂ to NO is not specific to NO₂; hence the chemiluminescence analyzers are subject to interference from nitrogen oxides other than NO₂ produced by oxidized NO_y compounds or NO_z. Thus, this technique will overestimate NO₂ concentrations particularly in areas downwind of sources of NO and NO₂ as NO_x is oxidized to NO_z in the form of PANs and other organic nitrates, and HNO₃ and HNO₄. Many of these compounds are reduced at the catalyst with nearly the same efficiency as NO₂. Interferences have also been found from a wide range of other compounds as described in the latest AQCD for NO₂.

Other Methods

NO₂ can be selectively converted to NO by photolysis. For example, Ryerson et al. (2000) developed a gas-phase chemiluminescence method using a photolytic converter based on a Hg lamp with increased radiant intensity in the region of peak NO₂ photolysis (350 to 400 nm) and producing conversion efficiencies of 70% or more in less than 1 s. Metal halide lamps with conversion efficiency of about 50% and accuracy on the order of 20% (Nakamura et al., 2003) have been used. Because the converter produces little radiation at wavelengths less than 350 nm, interferences from HNO₃ and PAN are minimal. Alternative methods to photolytic reduction followed by CL are desirable to test the reliability of this widely used technique. Any method based on a conversion to measured species presents potential for interference a problem. Several atmospheric species, PAN and HO₂NO₂ for example, dissociate to NO₂ at higher temperatures.

Laser induced fluorescence for NO₂ detection involves excitation of atmospheric NO₂ with laser light emitted at wavelengths too long to induce photolysis. The resulting excited molecules relax in a photoemissive mode and the fluorescing photons are counted. Because collisions would rapidly quench the electronically excited NO₂, the reactions are conducted at low pressure. Matsumi et al. (2001) describe a comparison of LIF with a photofragmentation chemiluminescence instrument. The LIF system involves excitation at 440 nm with a multiple laser system. They report sensitivity of 30 ppt in 10 s and good agreement between the two methods under laboratory conditions at mixing ratios up to 1.0 ppb. This high-sensitivity LIF system has yet to undergo long-term field tests. Cleary et al. (2002) describe field tests of a system that uses continuous, supersonic expansion followed by excitation at 640 nm with a commercial tunable diode laser. More recently, LIF has been successfully used to detect NO₂ with accuracy of about 15% and detection limits well below 1 ppb. When coupled with thermal dissociation, the technique also measures peroxy nitrates such as PAN, alkyl nitrates, HNO₄ and HNO₃ (Cohen, 1999; Day et al., 2002; Farmer et al., 2006; Pérez et al., 2007; Thornton et al., 2003). This instrument can have very fast sampling rates (>1 Hz) and shows good correlation with chemiluminescent techniques but remains a research-grade device.

NO₂ can be detected by differential optical absorption spectroscopy (DOAS) in an open, long-path system by measuring narrow band absorption features over a background of broad band extinction (e.g., Stutz et al., 2000; Kim and Kim, 2001). A DOAS system manufactured by OPSIS is designated as a Federal Equivalent Method for measuring NO₂. DOAS systems can also be configured to measure NO, HONO, and NO₃ radicals. Typical detection limits are 0.2 to 0.3 ppb for NO, 0.05 to 0.1 ppb for NO₂, 0.05 to 0.1 ppb for HONO, and 0.001 to 0.002 ppb for NO₃, at path lengths of 0.2, 5, 5, and 10 km, respectively. The obvious advantage compared to fixed point measurements is that concentrations relevant to a much larger area are obtained, especially if multiple targets are used. At the same time, any microenvironmental artifacts are minimized over the long path integration. However, comparisons to other measurements made at point not a real location are difficult. A major limitation in this technique had involved inadequate knowledge of absorption cross sections. Harder et al. (1997) conducted an experiment in rural Colorado involving simultaneous measurements of NO₂ by DOAS and by photolysis followed by chemiluminescence. They found differences of as much as 110% in clean air from the west, but for NO₂ mixing ratios in excess of 300 ppt, the two methods agreed to better than 10%. Stutz et al. (2000) cites two intercomparisons of note. NO was measured by DOAS, by photolysis of NO₂ followed by chemiluminescence, and by LIF during July 1999 as part of the SOS in Nashville, TN. On average, the three methods agreed to within 2%, with some larger differences likely caused by spatial variability over the DOAS path. In another study in Europe, and a multi-reflection set-up over a 15 km path, negated the problem of spatial averaging here agreement with the chemiluminescence detector following photolytic conversion was excellent (slope = 1.006 ± 0.005 ; intercept = 0.036 ± 0.019 ; $r = 0.99$) over a concentration range from about 0.2 to 20 ppb.

NO₂ can also be detected from space with DOAS-like UV spectroscopy techniques (Kim et al., 2006; Ma et al., 2006). These measurements appear to track well with emissions estimates and can be a useful indicator of column content as well as for identifying hot spots in sources. See also Richter et al., 2005. Leigh (2006) report on a DOAS method that uses the sun as a light source and compares well with an in situ chemiluminescence detector in an urban environment.

Chemiluminescence on the surface of liquid luminol has also been used for measurement of NO₂ (Gaffney et al., 1998; Kelly et al., 1990; Marley et al., 2004; Nikitas et al., 1997; Wendel et al., 1983). This technique is sensitive and linear and more specific than hot MoO_x. Luminol does not emit light when exposed to HNO₃ or alkyl nitrates, but does react with PAN. This interference can be removed by chromatographic separation prior to detection and the resulting measurement compares well with more specific techniques for moderate to high (≥ 1 ppb) mixing ratios of NO₂.

Several tunable diode laser spectroscopy techniques have been used successfully for NO₂ detection (Eisele et al., 2003; Osthoff et al., 2006). These devices remain research grade instruments, not yet practical for urban monitoring.

Measurements of NO_Y

Gold catalyzed CO or H₂ reduction for conversion on hot MoO_x catalyst has been used to reduce NO_Y to NO before then detection by chemiluminescence (Fehsenfeld et al., 1987; Crosley, 1996). Both techniques offer generally reliable measurements, with response times on the order of 60 s and a linear dynamic range demonstrated in field intercomparisons from about 10 ppt to 10s of ppb. Under certain conditions, HCN, NH₃, RNO₂, and CH₃CN can be converted to NO, but at normal concentrations and humidity these are minor interferences. Thermal decomposition followed by LIF has also been used for NO_Y detection, as described above. In field comparisons, instruments based on these two principles generally showed good agreement (Day et al., 2002). The experimental uncertainty is estimated to be of 15-30%.

AX2.6.1.3. Monitoring for NO₂ Compliance Versus Monitoring for O₃ Formation

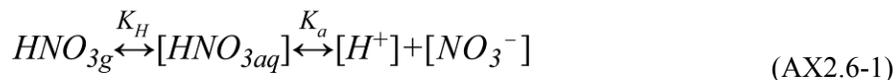

Regulatory measurements of NO₂ have been focused on demonstrating compliance with the NAAQS for NO₂. Today, few locations violate that standard, but NO₂ and related NO_Y compounds remain among the most important atmospheric trace gases to measure and understand. Unfortunately, with an internal MoO_x converter for NO_x to NO conversion, the instruments may not give a faithful indication of total NO_Y either; reactive species such as HNO₃ will adhere to the walls of the inlet system. Most recently, commercial vendors such as Thermo Environmental (Franklin, MA) have offered NO/NO_Y detectors with external MoO_x converters. If such instruments are calibrated through the inlet with a reactive nitrogen species such as propyl nitrate, they give accurate measurements of total NO_Y suitable for evaluation of photochemical models. (Crosley, 1996; Fehsenfeld et al., 1987; Nunnermacker et al., 1998; Rodgers and Davis, 1989). Under conditions of fresh emissions, such as in urban areas during the rush hour, NO_Y ~ NO_x and these monitors can be used for testing emissions inventories (Dickerson, et al., 1995; Parrish, 2006).

AX2.6.2. Summary of Methods for Measuring NO₂

A variety of techniques exist for reliable monitoring of atmospheric NO₂ and related reactive nitrogen species. For demonstration of compliance with the NAAQS for NO₂, commercial chemiluminescence instruments are adequate. For certain conditions, luminol chemiluminescence is adequate. Precise measurements of NO₂ can be made with research grade instruments such as LIF and TDLS. For path-integrated concentration determinations UV spectroscopic methods provide useful information. Commercial NO_x instruments are sensitive to other NO_Y species, but do not measure NO_Y quantitatively. NO_Y instruments with external converters offer measurements more useful for comparison to chemical transport model calculations.

AX2.6.3. Measurements of HNO₃

Accurate measurement of HNO₃, has presented a long-standing analytical challenge to the atmospheric chemistry community. In this context, it is useful to consider the major factors that control HNO₃ partitioning between the gas and deliquesced-particulate phases in ambient air. In equation form,

where K_H is the Henry's Law constant in M atm⁻¹ and K_a is the acid dissociation constant in M.

Thus, the primary controls on HNO₃ phase partitioning are its thermodynamic properties (K_H , K_a , and associated temperature corrections), aerosol liquid water content (LWC), solution pH, and kinetics. Aerosol LWC and pH are controlled by the relative mix of different acids and bases in the system, hygroscopic properties of condensed compounds, and meteorological conditions such as RH, temperature, and pressure. It is evident from relationship AX2.6-1 that, in the presence of chemically distinct aerosols of varying acidities (e.g., supermicron predominantly sea salt and submicron predominantly S aerosol), HNO₃ will partition preferentially with the less-acidic particles; and this is consistent with observations (e.g., Huebert et al., 1996; Keene and Savoie, 1998; Keene et al., 2002). Kinetics are controlled by atmospheric concentrations of HNO₃ vapor and particulate NO₃⁻ and the size distribution and corresponding atmospheric lifetimes of particles against deposition. Submicron diameter aerosols typically equilibrate with the gas phase in seconds to minutes while supermicron aerosols require hours to a day or more (e.g., Meng and Seinfeld, 1996; Erickson et al., 1999). Consequently, smaller aerosol size fractions are typically close to thermodynamic equilibrium with respect to HNO₃ whereas larger size fractions (for which atmospheric lifetimes against deposition range from hours to a few days) are often undersaturated (e.g., Erickson et al., 1999; Keene and Savoie, 1998).

Many sampling techniques for HNO₃ (e.g., annular denuder, standard filterpack and mist-chamber samplers) employ upstream prefilters to remove particulate species from sample air. However, when chemically distinct aerosols with different pHs (e.g., sea salt and S aerosols) mix together on a bulk filter, the acidity of the bulk mixture will be greater than that of the less acidic aerosols with which most NO₃⁻ is associated. This change in pH may cause the bulk mix to be supersaturated with respect to HNO₃ leading to volatilization and, thus, positive measurement bias in HNO₃ sampled downstream. Alternatively, when undersaturated supermicron size fractions (e.g., sea salt) accumulate on a bulk filter and chemically interact over time with HNO₃ in the sample air stream, scavenging may lead to negative bias in HNO₃ sampled downstream. Because the magnitude of both effects will vary as functions of the overall composition and thermodynamic state of the multiphase system, the combined influence can cause net positive or net negative measurement bias in resulting data. Pressure drops across particle filters can also lead to artifact volatilization and associated positive bias in HNO₃ measured downstream.

Widely used methods for measuring HNO₃ include standard filterpacks configured with nylon or alkaline-impregnated filters (e.g., Goldan et al., 1983; Bardwell et al., 1990), annular denuders (EPA Method IP-9), and standard mist chambers (Talbot et al., 1990). Samples from these instruments are typically analyzed by ion chromatography. Intercomparisons of these measurement techniques (e.g., Hering et al., 1988; Tanner et al., 1989; Talbot et al., 1990) report differences on the order of a factor of two or more.

More recently, sensitive HNO₃ measurements based on the principle of Chemical Ionization Mass Spectroscopy (CIMS) have been reported (e.g., Huey et al., 1998; Mauldin et al., 1998; Furutani and Akimoto, 2002; Neuman et al., 2002). CIMS relies on selective formation of ions such as SiF₅⁻≡HNO₃ or HSO₄⁻≡HNO₃ followed by detection via mass spectroscopy. Two CIMS techniques and a filter pack technique were intercompared in Boulder, CO (Fehsenfeld et al., 1998). Results indicated agreement to within 15% between the two CIMS instruments and between the CIMS and filterpack methods under relatively clean conditions with HNO₃ mixing ratios between 50 and 400 ppt. In more polluted air, the filterpack technique generally yielded higher values than the CIMS suggesting that interactions between chemically distinct particles on bulk filters is a more important source of bias in polluted continental air. Differences were also greater at lower temperature when particulate NO₃⁻ corresponded to relatively greater fractions of total NO₃⁻.

Three semi-continuous methods for detecting nitric acid (HNO₃) were tested against the annular denuder filter pack (ADS) integrated collection technique at the Tampa Bay Regional Atmospheric Chemistry Experiment (BRACE) Sydney research station ~20 km downwind of the Tampa, Florida, urban core. The semi-continuous instruments included: two slightly differing implementations of the NO_y -- NO_y* (total oxides of nitrogen minus that total denuded of HNO₃) denuder difference technique, one from the NOAA Air Resources Lab (ARL), and one from Atmospheric Research and Analysis, Inc. (ARA); the parallel plate wet diffusion scrubber online ion chromatography technique from Texas Tech

University (TTU); and the chemical ionization mass spectrometer from the Georgia Institute of Technology (GIT). Twelve hour ADS samples were collected by the University of South Florida (USF). Results for 10 min samples computed from the various higher sampling frequencies of each semi-continuous instrument showed good agreement ($R^2 > 0.7$) for afternoon periods of the highest production and accumulation of HNO_3 . Further, agreement was within $\pm 30\%$ for these instruments even at HNO_3 concentrations 0.30 ppb. The USF ADS results were biased low, however, by 44%, on average, compared to the corporate 12-h aggregated means from the semi-continuous methods, and by 460% for the nighttime samples; ADS results were below the corporate mean maximum HNO_3 concentration by 430% as well. The four instruments using semi-continuous methods, by contrast, were all within 10% of each other's 12-h mean mixing ratios. While only ARA employed a formal minimum detection limit at 0.050 ppb, error analysis with the other techniques established that at the same level of precision, TTU's effective limit was approximately the same as ARA's and that ARL's limit was 0.030 ppb; analysis for GIT showed no apparent effective limit at the levels of HNO_3 encountered in this field study. The importance of sample inlet height for HNO_3 measurements was indirectly shown through comparison to previous field work at this site when sample inlet heights ranged from 1.5–10 m and produced systematic discrepancies in HNO_3 concentrations correlated with height of more than a factor of 2 (Arnold et al., 2007).

AX2.6.4. Techniques for Measuring Other NO_y Species

Methods for sampling and analysis of alkyl nitrates in the atmosphere have been reviewed by Parrish and Fehsenfeld (2000). Peroxyacetylnitrate, PPN, and MPAN are typically measured using a chromatograph followed by electron capture detectors or GC/ECD (e.g., Gaffney et al., 1998), although other techniques such as FTIR could also be used. Field measurements are made using GC/ECD with a total uncertainty of $\pm 5 \text{ ppt} + 15\%$ (Roberts et al., 1998).

In the IMPROVE network and in the EPA Chemical Speciation Network (CSN), particulate nitrate in the $\text{PM}_{2.5}$ size range is typically collected on nylon filters downstream of annular denuders coated with a basic solution capable of removing acidic gases such as HNO_3 , HNO_2 , and SO_2 . Filter extracts are then analyzed by ion chromatography (IC) for nitrate, sulfate, and chloride. Nitrite ions are also measured by this technique but their concentrations are almost always beneath detection limits. However, both of these networks measure nitrate only in the $\text{PM}_{2.5}$ fraction. Because of interactions with more highly acidic components on filter surfaces, there could be volatilization of nitrate in PM_{10} samples. These effects are minimized if separate aerosol size fractions are collected, i.e., the more acidic $\text{PM}_{2.5}$ and the more alkaline $\text{PM}_{10-2.5}$ as in a dichotomous sampler or multistage impactor.

AX2.6.5. Remote Sensing of Tropospheric NO_2 Columns for Surface NO_x Emissions and Surface NO_2 Concentrations

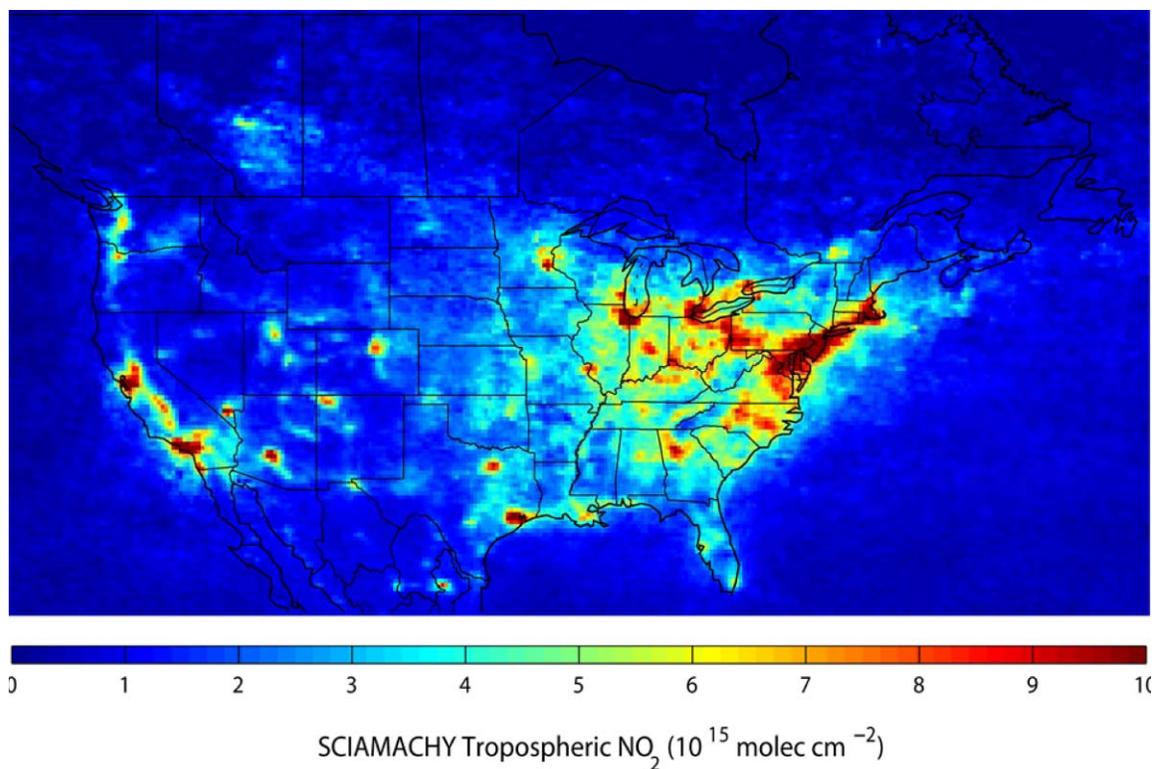

Table AX2.6-1 contains an overview of the three satellite instruments that are used retrieve tropospheric NO_2 columns from measurements of solar backscatter. All three instruments are in polar sun-synchronous orbits with global measurements in the late morning and early afternoon. The spatial resolution of the measurement from SCIAMACHY is 7 times better than that from Ozone Monitoring Instrument (GOME), and that from Ozone Monitoring Instrument (OMI) is 40 times better than that from GOME.

Table AX2.6-1. Satellite Instruments Used to Retrieve Tropospheric NO₂ Columns.

INSTRUMENT	COVERAGE	TYPICAL U.S. MEASUREMENT TIME	TYPICAL RESOLUTION (KM)	RETURN TIME (DAYS) ¹	INSTRUMENT OVERVIEW
GOME	1995-2002	10:30-11:30 AM	320 H 40	3	Burrows et al. (1999)
SCIAMACHY	2002-	10:00-11:00 AM	30 H 60	6	Bovensmann et al. (1999)
OMI	2004-	12:45-1:45 PM	13 H 24	1	Levelt et al. (2006)

¹ Return time is reported here for cloud free conditions. Note that due to precession of the satellite's orbit, return measurements are close to but not made over the same location. In practice, clouds decrease observation frequency by a factor of 2.

Figure AX2.6-1 shows tropospheric NO₂ columns retrieved from SCIAMACHY. Pronounced enhancements are evident over major urban and industrial emissions. The high degree of spatial heterogeneity over the southwestern United States provides empirical evidence that most of the tropospheric NO₂ column is concentrated in the lower troposphere. Tropospheric NO₂ columns are more sensitive to NO_x in the lower troposphere than in the upper troposphere (Martin et al., 2002). This sensitivity to NO_x in the lower troposphere is due to the factor of 25 decrease in the NO₂/NO ratio from the surface to the upper troposphere (Bradshaw et al., 1999) that is driven by the temperature dependence of the NO + O₃ reaction. Martin et al. (2004a) integrated in situ airborne measurements of NO₂ and found that during summer the lower mixed layer contains 75% of the tropospheric NO₂ column over Houston and Nashville. However, it should be noted that these measurements are also sensitive to surface albedo and aerosol loading.

Source: Martin et al. (2006).

Figure AX2.6-1. Tropospheric NO₂ columns (molecules NO₂/cm²) retrieved from the SCIAMACHY satellite instrument for 2004-2005.

The retrieval involves three steps: (1) determining total NO₂ line-of-sight (slant) columns by spectral fitting of solar backscatter measurements, (2) removing the stratospheric columns by using data from remote regions where the tropospheric contribution to the column is small, and (3) applying an air mass factor (AMF) for the scattering atmosphere to convert tropospheric slant columns into vertical columns. The retrieval uncertainty is determined by (1) and (2) over remote regions where there is little tropospheric NO₂, and by (3) over regions in regions of elevated tropospheric NO₂ (Martin et al., 2002; Boersma et al., 2004).

The paucity of in situ NO₂ measurements motivates the inference of surface NO₂ concentrations from satellite measurements of tropospheric NO₂ columns. This prospect would take advantage of the greater sensitivity of tropospheric NO₂ columns to NO_x in the lower troposphere than in the upper troposphere as discussed earlier. Tropospheric NO₂ columns show a strong correlation with in situ NO₂ measurements in northern Italy (Ordóñez et al., 2006).

Quantitative calculation of surface NO₂ concentrations from a tropospheric NO₂ column would require information on the relative vertical profile. Comparison of vertical profiles of NO₂ in a chemical transport model (GEOS-Chem) versus in situ measurements over and downwind of North America shows a high degree of consistency (Martin et al., 2004b, 2006), suggesting that chemical transport models could be used to infer the relationship between surface NO₂ concentrations and satellite observations of the tropospheric NO₂ column.

However, the satellites carrying the spectrometer (GOME/SCIAMACHY/OMI) are in near polar, sun-synchronous orbits. As a result, these measurements are made only once per day, typically between

about 10:00 to 11:00 a.m. or 1 p.m. local time, during a brief overflight. Thus the utility of these measurements is limited as they would likely miss short-term features.

AX2.7. Policy-relevant Background NO_x Concentrations

Background concentrations of nitrogen oxides used for purposes of informing decisions about NAAQS are referred to as Policy-relevant Background (PRB) concentrations. Policy Relevant Background concentrations are those concentrations that would occur in the United States in the absence of anthropogenic emissions in continental North America (defined here as the United States, Canada, and Mexico). Concentrations include contributions from natural sources everywhere in the world and from anthropogenic sources outside these three countries. Background levels so defined facilitate separation of pollution levels that can be controlled by U.S. regulations (or through international agreements with neighboring countries) from levels that are generally uncontrollable by the United States. EPA assesses risks to human health and environmental effects from NO₂ levels in excess of PRB concentrations.

Contributions to PRB concentrations include natural emissions of NO₂ and photochemical reactions involving natural emissions of reduced nitrogen compounds, as well as their long-range transport from outside North America. Natural sources of NO₂ and its precursors include biogenic emissions, wildfires, lightning, and the stratosphere. Natural sources of reduced nitrogen compounds, mainly NH₃, include biogenic emissions and wildfires. Biogenic emissions from agricultural activities are not considered in the formation of PRB concentrations. Discussions of the sources and estimates of emissions are given in Section AX2.4.2.

AX2.7.1. Analysis of PRB Contribution to U.S. NO_x Concentrations and Deposition

The MOZART-2 global model of tropospheric chemistry (Horowitz et al., 2003) was used to diagnose the PRB contribution to nitrogen oxide concentrations, as well as to total (wet plus dry) deposition. The model setup for the present-day simulation has been published in a series of papers from a recent model intercomparison (Dentener et al., 2006a,b; Shindell et al., 2006; Stevenson et al., 2006; Van Noije et al., 2006). MOZART-2 is driven by National Center for Environmental Prediction meteorological fields and IIASA 2000 emissions at a resolution of 1.9° H 1.9° with 28 sigma levels in the vertical, and it includes gas- and aerosol phase chemistry. Results shown in Figures AX2.7-1 to AX2.7-3 are for the meteorological year 2001. Note that color images are available on the web. An additional PRB simulation was conducted in which continental North American anthropogenic emissions were set to zero.

We first examine the role of PRB in contributing to NO₂ concentrations in surface air. Figure AX2.7-1 shows the annual mean NO₂ concentrations in surface air in the base case simulation (top panel) and the PRB simulation (middle panel), along with the percentage contribution of the background to the total base case NO₂ (bottom panel). Maximum concentrations in the base case simulation occur along the Ohio River Valley and in the Los Angeles basin. While present-day concentrations are often above 5 ppb, PRB is less than 300 ppt over most of the continental United States, and less than 100 ppt in the eastern United States. The distribution of PRB (middle panel of Figure AX2.7-1) largely reflects the distribution of soil NO emissions, with some local enhancements due to biomass burning such as is seen in western Montana. In the northeastern United States, where present-day NO₂ concentrations are highest, PRB contributes <1% to the total.

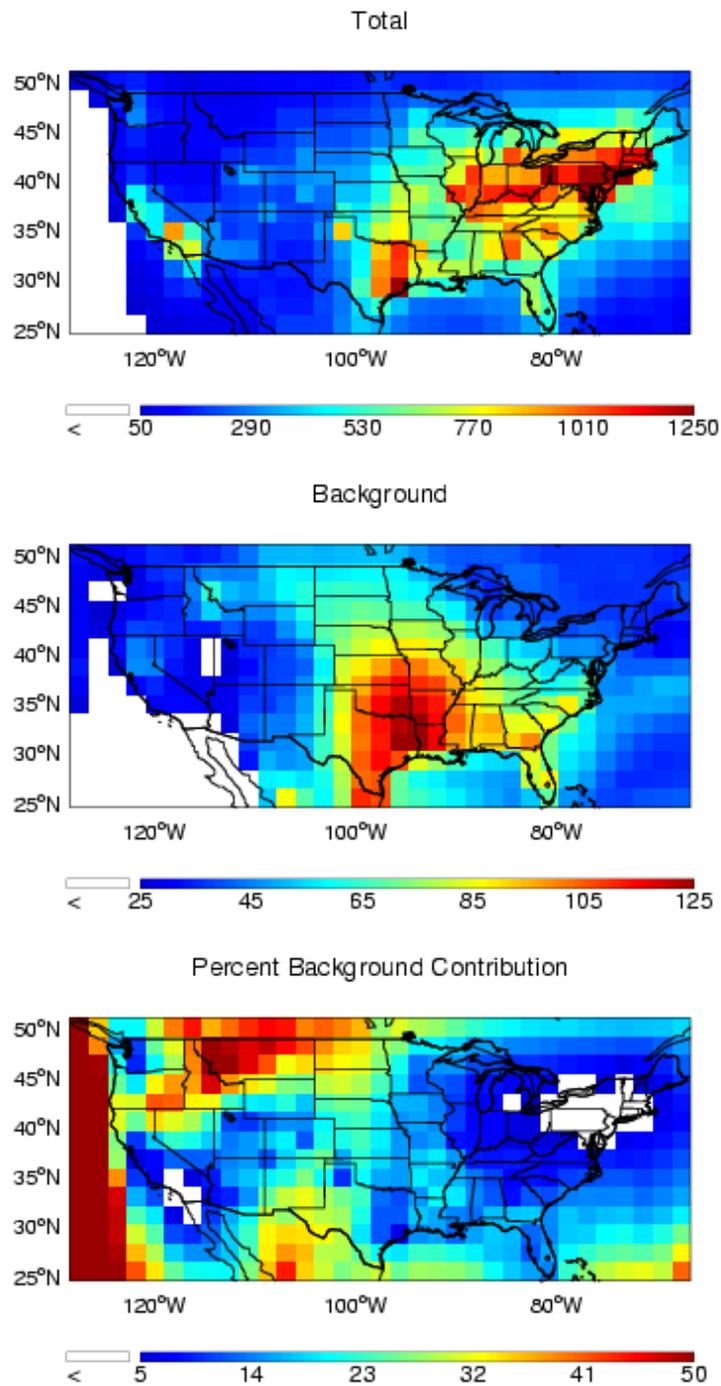

Figure AX2.7-1. Annual mean concentrations of NO₂ (ppb) in surface air over the United States in the present-day (upper panel) and policy relevant background (middle panel) MOZART-2 simulations. The bottom panel shows the percentage contribution of the background to the present-day concentrations. Please see text for details.

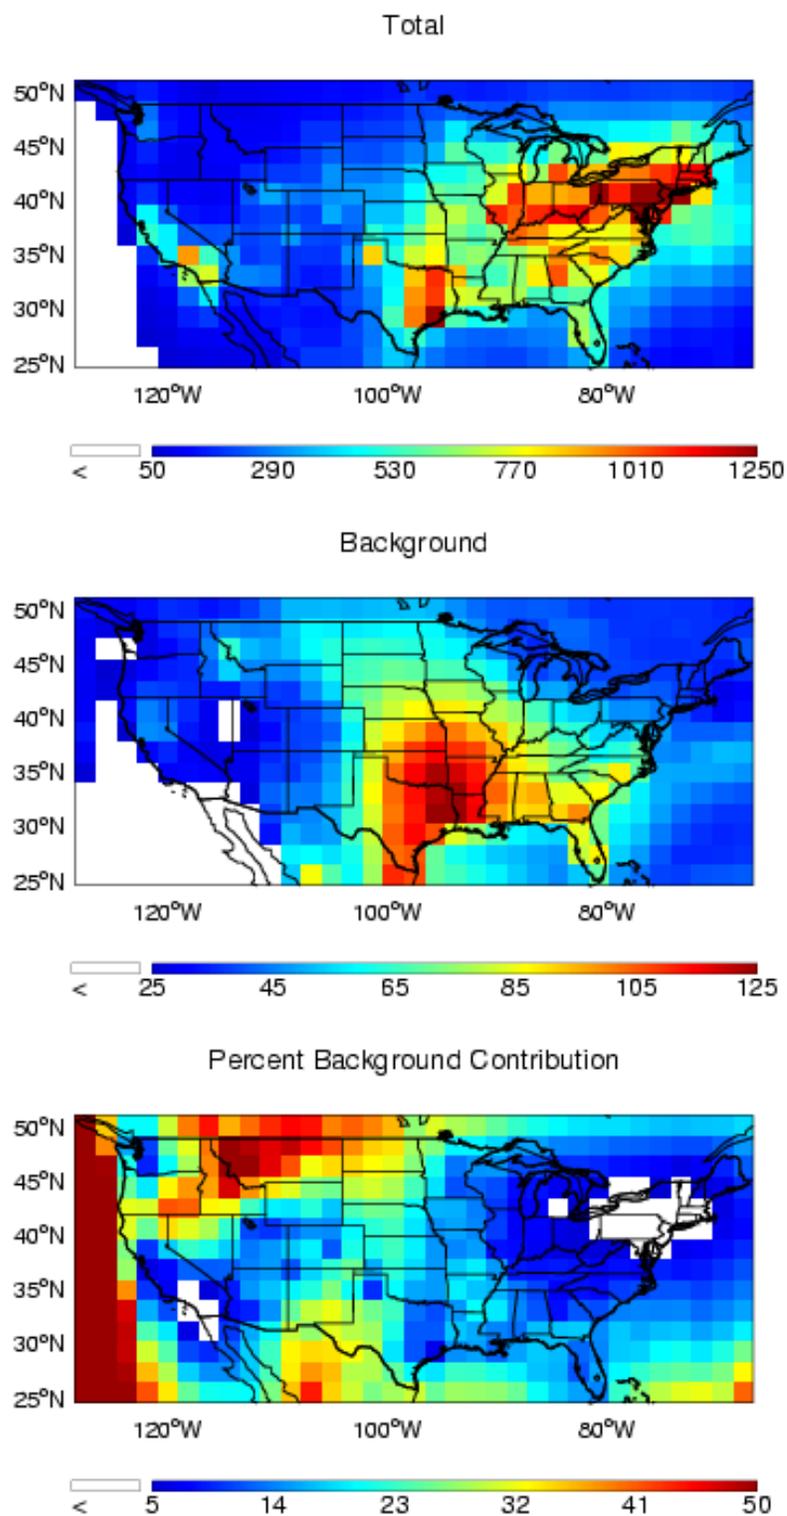

Figure AX2.7-2. Same as for Figure AX2.7-1 but for wet and dry deposition of HNO_3 , NH_4NO_3 , NO_x , HO_2NO_2 , and organic nitrates ($\text{mg N m}^{-2}/\text{y}$).

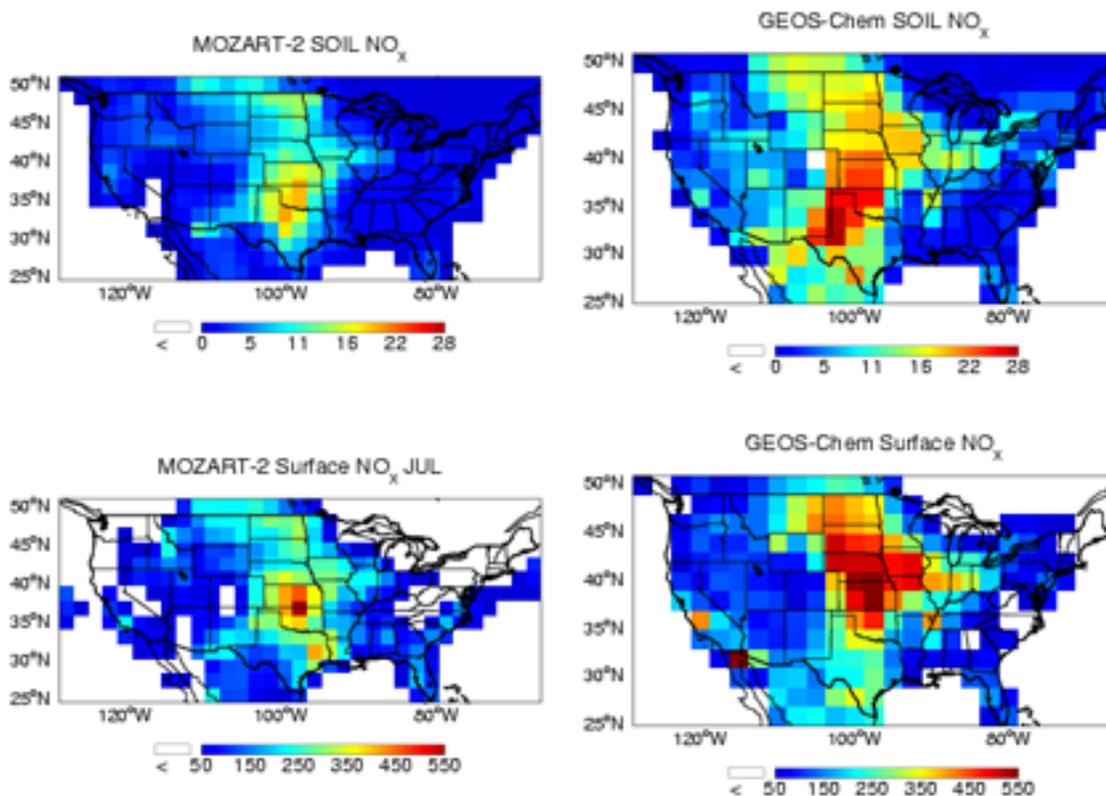

Figure AX2.7-3. July mean soil NO emissions (upper panels; $1 \text{ H } 10^9 \text{ molecules cm}^{-2} \text{ s}^{-1}$) and surface PRB NO_x concentrations (lower panels; ppt). These are over the United States from MOZART-2 (left) and GEOS-Chem (right) model simulations in which anthropogenic O_3 precursor emissions were set to zero in North America.

The spatial pattern of NO_y (defined here as HNO_3 , NH_4NO_3 , NO_x , HO_2NO_2 , and organic nitrates) wet and dry deposition is shown in Figure AX2.7-2. Figure AX2.7-2 (upper panel) shows that highest values are found in the eastern United States in and downwind of the Ohio River Valley. The pattern of nitrogen deposition in the PRB simulation (Figure AX2.7-2, middle panel), however, shows maximum deposition centered over Texas and in the Gulf Coast region, reflecting a combination of nitrogen emissions from lightning in the Gulf region, biomass burning in the Southeast, and from microbial activity in soils (maximum in central Texas and Oklahoma). The bottom panel of Figure AX2.7-2 shows that the PRB contribution to nitrogen deposition is less than 20% over the eastern United States, and typically less than 50% in the western United States where NO_y deposition is low ($25\text{-}50 \text{ mg N/m}^2/\text{yr}$).

Thus far, the discussion has focused on results from the MOZART-2 tropospheric chemistry model. In Figure AX2.7-3, results from MOZART-2 are compared with those from another tropospheric chemistry model, GEOS-Chem (Bey et al., 2001), which was previously used to diagnose PRB O_3 (Fiore et al., 2003; U.S. Environmental Protection Agency, 2006). In both models, the surface PRB NO_x concentrations tend to mirror the distribution of soil NO emissions, which are highest in the Midwest. The higher soil NO emissions in GEOS-Chem (by nearly a factor of 2) as compared to MOZART-2 reflect different assumptions regarding the contribution to soil NO emissions largely through fertilizer, since GEOS-Chem total soil NO emissions are actually higher than MOZART-2 (0.07 versus 0.11 Tg N) over

the United States in July. Even with the larger PRB soil NO emissions, surface NO_x concentrations in GEOS-Chem are typically below 500 ppt.

Annex 3. Ambient Concentrations and Exposures

AX3.1. Introduction

Topics discussed in this chapter include the characterization of ambient air quality for nitrogen dioxide (NO₂), the uses of these data in assessing human exposures to NO₂; concentrations and sources of NO₂ in different microenvironments, and personal exposures to NO₂. The NO₂ data contained in this chapter are taken mainly from the U.S. Environmental Protection Agency's Air Quality System (AQS) database (formerly the AIRS database) (U.S. Environmental Protection Agency, 2007).

AX3.1.1. Characterizing Ambient NO₂ Concentrations

The “concentration” of a specific air pollutant is typically defined as the amount (mass) of that material per unit volume of air. However, most of the data presented in this chapter are expressed as “mixing ratios” in terms of a volume-to-volume ratio (e.g., parts per million [ppm] or parts per billion [ppb]). Data expressed this way are often referred to as concentrations, both in the literature and in the text, following common usage. Human exposures are expressed in units of mixing ratio times time.

AX3.1.2. Relationship to the 1993 AQCD for NO_x

The 1993 AQCD for Oxides of Nitrogen emphasized NO₂ indoor sources (gas stoves) and the relationship between personal total exposure and indoor or outdoor NO₂ concentrations (U.S. Environmental Protection Agency, 1993). At that time, only few personal exposure studies had been conducted with an emphasis on residential indoor NO₂ sources and concentrations. Although the concept of microenvironment had been introduced in the document, NO₂ concentrations were seldom reported for microenvironments other than residences. Exposure measurements at that time relied on Palmes tubes and Yanagisawa badges; and exposure-modeling techniques were limited mainly to simple linear regression. In the 1993 AQCD, NO₂ was treated as an independent risk factor, and confounding issues were not mentioned in the human environmental exposure chapters.

The current chapter summarizes and discusses the state-of-the-science and technology regarding NO₂ human exposures since 1993. Since then, numerous human exposure studies have been conducted with new measurement and modeling techniques. Microenvironmental measurements were not limited to residential indoor environments; NO₂ concentrations were also measured in vehicles, schools and offices, and microenvironments close to traffic. More indoor sources have been identified and more NO₂ formation and transformation mechanisms in the indoor environment have been reported.

AX3.2. Ambient Concentrations of NO_x

As discussed in Chapter 2 of the ISA, most measurements of NO_x are made by instruments that convert NO₂ to NO, which is then measured by chemiluminescence. However, the surface converters that reduce NO₂ to NO also reduce other reactive NO_y species. As indicated in Chapter 2, NO_y compounds consist of NO_x, gas phase inorganic nitrates, such as chlorine nitrate (ClNO₃); organic nitrates, such as

PANs; inorganic acids, given by the formulas HNO_Y ($Y = 2$ to 4); and particulate nitrate. In urban areas or in rural areas where there are large local sources, NO and NO_2 are expected to be the major forms of NO_Y . Thus, interference from PANs and other NO_Y species near sources are expected to be minor; in most rural and remote areas, interference may be substantial as concentrations of other NO_Y species may be much larger than those for NO and NO_2 (National Research Council, 1991).

Because of their short lifetime with respect to oxidation to PANs and HNO_3 , NO_X concentrations are highly spatially and temporally variable. Average concentrations range from tens of ppt in remote areas of the globe to tens of ppb in urban cores, i.e., by three orders of magnitude. Median NO, NO_X , and NO_Y concentrations at the surface are typically below 0.01, 0.05, and 0.3 ppb, respectively, in remote areas such as Alaska, northern Canada, and the eastern Pacific; median NO_Y concentrations range from about 0.7 to about 4.3 ppb at regional background sites in the eastern United States (Emmons et al., 1997). Note that the last two values, especially, contain a substantial contribution from pollution. Maximum short-term average (1-h) NO_X concentrations near heavy traffic (e.g., in Los Angeles, CA) approach 1 ppm, but these levels decrease rapidly away from sources. Even at sites where such high hourly values are found, 24-h avg concentrations are much lower. For example, the maximum 24-h average NO_X concentration at any site in Los Angeles in 2004 was 82 ppb.

AX3.2.1. Temporal Variability in Ambient NO_X Concentrations in Urban Areas

AX3.2.1.1. Diurnal Variability in NO_2 Concentrations

As might be expected from a pollutant having a major traffic source, the diurnal cycle of NO_2 in typical urban areas is characterized by traffic emissions, with peaks in emissions occurring during morning and evening rush hour traffic. Motor vehicle emissions consist mainly of NO, with only about 10% of primary emissions in the form of NO_2 . The diurnal pattern of NO and NO_2 concentrations is also strongly influenced by the diurnal variation in the mixing layer height. Thus, during the morning rush hour when mixing layer heights are still low, traffic produces a peak in NO and NO_2 concentrations. As the mixing layer height increases during the day, dilution of emissions occurs. During the afternoon rush hour, mixing layer heights are at or are near their daily maximum values resulting in dilution of traffic emissions through a larger volume than in the morning. Starting near sunset, the mixing layer height drops and conversion of NO to NO_2 occurs without photolysis of NO_2 recycling NO.

The composite diurnal variability of NO_2 in selected urban areas with multiple sites (New York, NY; Atlanta, GA; Baton Rouge, LA; Chicago, IL; Houston, TX; Riverside, CA; and Los Angeles, CA) shows that lowest hourly median concentrations are typically found at around midday and that highest hourly median concentrations are found either in the early morning or in mid-evening. Median values range by about a factor of two from about 13 ppb to about 25 ppb (Figures AX3.2-1 to AX3.2-6). However, individual hourly concentrations can be considerably higher than these typical median values, and hourly NO_2 concentrations > 0.10 ppm can be found at any time of day.

AX3.2.1.2. Seasonal Variability in NO_2 Concentrations

AX3.2.1.3. Urban Sites

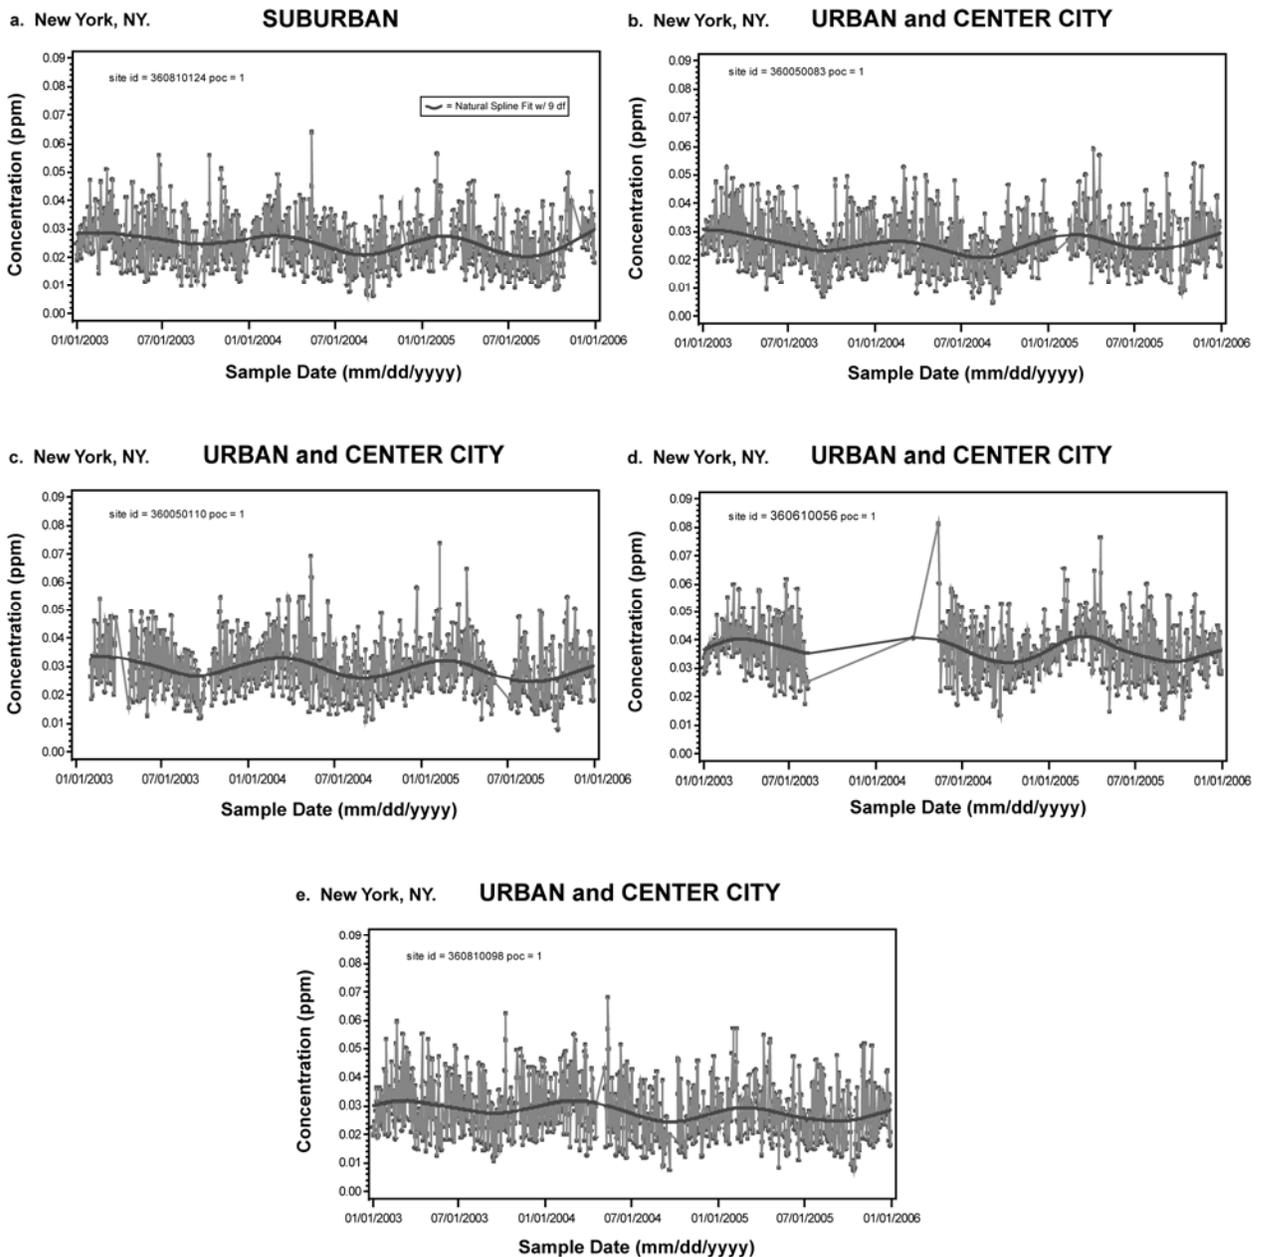

As might be expected from an atmospheric species that behaves essentially like a primary pollutant emitted from surface sources, there is strong seasonal variability in NO_X and NO_2 concentrations. Highest concentrations are found during winter, consistent with lowest mixing layer heights found during the year.

Mean and peak concentrations in winter can be up to a factor of two larger than in the summer at several sites in Los Angeles County.

The month-to-month variability in NO₂ at individual sites in selected urban areas is illustrated in Figures AX3.2-1 to AX3.2-6. Seasonal patterns can be found at some sites but not in others. There appears to be a somewhat regular pattern for the southern cities with winter maxima and summer minima. Monthly maxima tend to be found from late winter to early spring in Chicago and New York with minima occurring from summer through the fall. However, in Los Angeles and Riverside, monthly maxima tend to occur from autumn through early winter with minima occurring from spring through early summer.

AX3.2.1.4. Regional Background Sites

Surface NO_x and NO_y data obtained in Shenandoah National Park, VA from 1988 to 1989 show wintertime maxima and summertime minima (Doddridge et al., 1991, 1992; Poulida et al., 1991). NO_x and NO_y data collected in Harvard Forest, MA from 1990 to 1993 show a similar seasonal pattern (Munger et al., 1996). In addition the within-season variability was found to be smaller in the summer than in the winter as shown in Table AX3.2-1.

Source: U.S. Environmental Protection Agency (2003)

AX3.2.2. Relationships between NO₂ and Other Pollutants

Relationships between O₃, NO, and NO₂ are shown in Figures AX3.2-7 and AX3.2-8. Figure AX3.2-7 shows daylight average concentrations based on data collected from November 1998 and 1999 at several sites in the United Kingdom representing a wide range of pollution conditions (open symbols). The solid lines represent calculations of photostationary state values subject to the constraint that O_X =

$31.1 + 0.104 (\text{NO}_x)$, where $\text{O}_x = \text{O}_3 + \text{NO}_2$. Note that O_x is defined in the UK AQG report as oxidant, as used in this document, and in the latest AQCD for Ozone and other Photochemical Oxidants (U.S. Environmental Protection Agency, 2006a) it is taken to refer to “odd oxygen” as defined in Section 2.2. The reason is that oxidants also include PANs, peroxides, and reactive oxygen species in particles etc., in addition to O_3 and NO_2 . The concentrations of NO_2 (an oxidant and a component of odd oxygen) varying linearly with emissions of NO_x , especially after NO has reacted with O_3 to form NO_2 as shown in Figure AX3.2-7. Thus the concentration of O_x (and not O_3 , as is often stated) can be taken to be the sum of regional and local contributions.

Figure AX3.2-8 shows that primary emissions from motor vehicles are major sources of oxidant in the form of NO_2 , as evidenced by the high values of O_x at elevated NO_x .

Source: Clapp and Jenkin (2001).

Figure AX3.2-7. Relationship between O_3 , NO , and NO_2 as a function of NO_x concentration. Open circles represent data collected at a number of sites in the United Kingdom. Lines represent calculated relationships based on photostationary state.

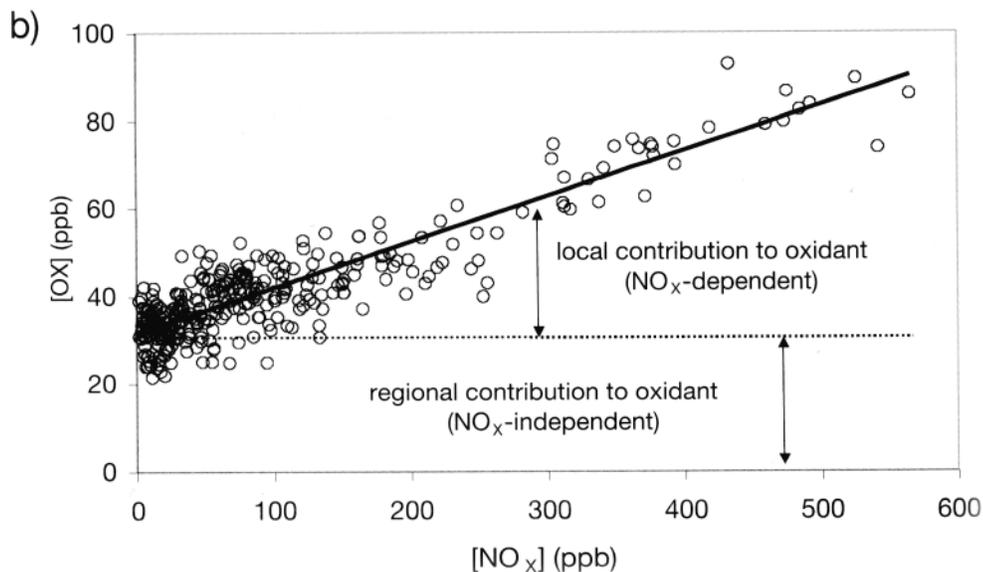

Figure AX3.2-8. Variation of odd oxygen ($= O_3 + NO_2$) with NO_x . The figure shows the “regional” and the “local” contributions. Note that O_x refers to odd oxygen in the document and the latest O_3 AQCD.

AX3.2.3. Abundance of NO_y Species

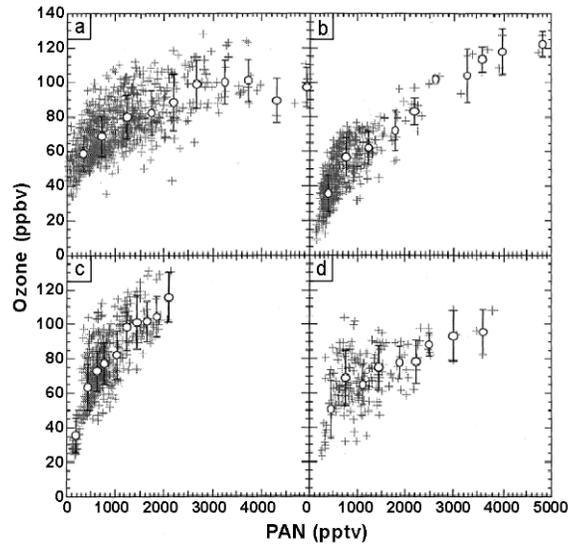

Data for individual NO_y species are much less abundant than for either oxides of nitrogen or for total NO_y . Data for several NO_y species are collected typically only as part of research field studies, e.g., the Southern Oxidant Study (SOS), Texas Air Quality Study (TexAQS I and TexAQS II) in the United States. As a result, this information is simply not available for a large number of areas in the United States.

AX3.2.3.1. PANs

Organic nitrates consist of PAN, a number of higher-order species with photochemistry similar to PAN (e.g., PPN), and species such as alkyl nitrates with somewhat different photochemistry. These species are produced by a photochemical process very similar to that of O_3 . Photochemical production is initiated by the reaction of primary and secondary VOCs with OH radicals, the resulting organic radicals subsequently react with NO_2 (producing Source: Clapp and Jenkin (2001). PAN and analogous species) or with NO (producing alkyl nitrates). The same sequence (with organic radicals reacting with NO) leads to the formation of O_3 .

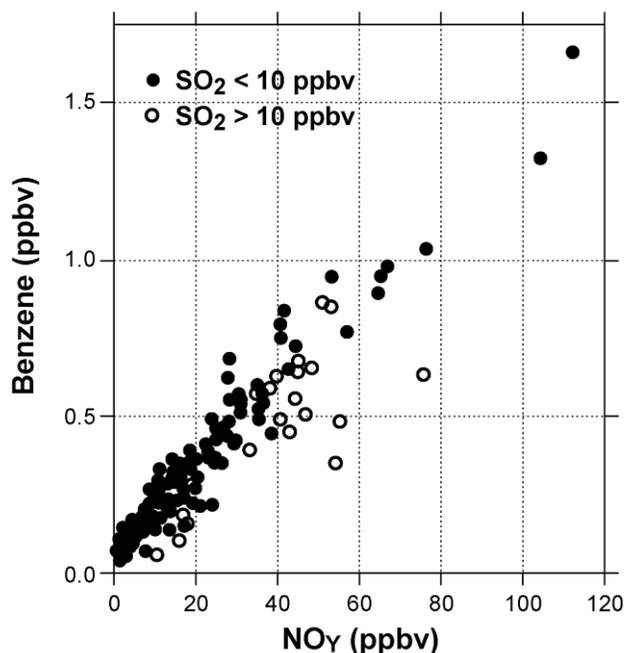

In addition, at warm temperatures, the concentration of PAN forms a photochemical steady state with its radical precursors on a timescale of roughly 30 min. This steady state value increases with the ambient concentration of O_3 (Sillman et al., 1990). O_3 and PAN may show different seasonal cycles, because they are affected differently by temperature. Ambient O_3 increases with temperature, driven in part by the photochemistry of PAN (see description in Chapter 2). The atmospheric lifetime of PAN decreases rapidly with increasing temperature due to thermal decomposition. Based on the above, the

ratio of O_3 to PAN is expected to show seasonal changes, with highest ratios in summer, although there is no evidence from measurements. Measured ambient concentrations (Figure AX3.2-9) show a strong nonlinear association between O_3 and PAN, and between O_3 and other organic nitrates (Pippin et al., 2001; Roberts et al., 1998). Moreover, uncertainty in the relationship between O_3 and PAN grows as the level of PAN increases. Individual primary VOCs are generally highly correlated with each other and with NO_x (Figure AX3.2-10).

Source: Roberts et al. (1998).

Figure AX3.2-9. Measured O_3 (ppb) versus PAN (ppt) in Tennessee, including (a) aircraft measurements, and (b, c, and d) suburban sites near Nashville.

Source: Goldan et al. (1995).

Figure AX3.2-10. Relationship between benzene and NO_y at a measurement site in Boulder, CO. Instances with $\text{SO}_2 > 10$ ppb are identified separately (open circles), because these may reflect different emission sources.

Measurements and models show that PAN in the United States includes major contributions from both anthropogenic and biogenic VOC precursors (Horowitz et al., 1998; Roberts et al., 1998). Measurements in Nashville during the 1999 summertime Southern Oxidants Study (SOS) showed PPN and MPAN amounting to 14% and 25% of PANs, respectively (Roberts et al., 2002). Measurements during the TexAQS 2000 study in Houston indicated PAN concentrations of up to 6.5 ppb (Roberts et al., 2003). PAN measurements in southern California during the SCOS97-NARSTO study indicated peak concentrations of 5-10 ppb, which can be contrasted to values of 60-70 ppb measured back in 1960 (Grosjean, 2003). Vertical profiles measured from aircraft over the United States and off the Pacific coasts typically show PAN concentrations above the boundary layer of only a few hundred ppt, although there are significant enhancements associated with long-range transport of pollution plumes from Asia (Kotchenruther et al., 2001; Roberts et al., 2004).

Observed ratios of PAN to NO_2 as a function of NO_x at a site at Silwood Park, Ascot, Berkshire, UK are shown in Figure AX3.2-11 United Kingdom Air Quality Expert Group (U.K. AQEG, 2004). As can be seen there is a very strong inverse relation between the ratio and the NO_x concentration, indicating photochemical oxidation of NO_x has occurred in aged air masses and that PAN can make a significant contribution to measurements of NO_2 especially at low levels of NO_2 (cf. ISA, Section 2-3). It should be noted that these ratios will likely differ from those found in the United States because of differences in the composition of precursor emissions, the higher solar zenith angles found in the UK compared to the United States, and different climactic conditions.

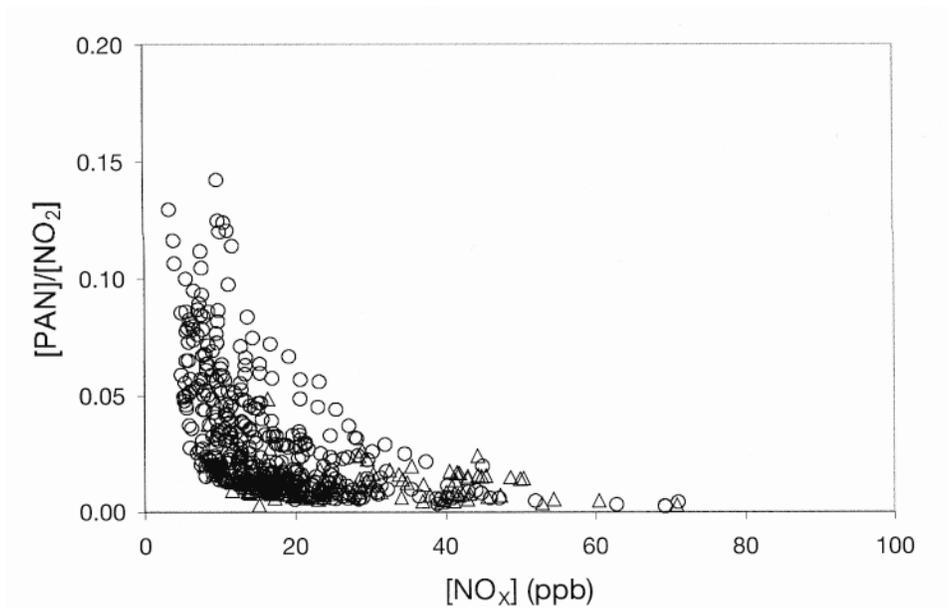

Nevertheless, these results indicate the potential importance of interference from NO_y compounds in measurements of NO_2 .

AX3.2.3.2. HONO

The ratio of HONO to NO₂ as a function of NO_x measured at a curbside site in a street canyon in London, UK is shown in Figure AX3.2-12 (U.K. AQEG, 2004). The ratio is highly variable, ranging from about 0.01 to 0.1, with a mean ~0.05. As NO₂ constitutes several percent of motor vehicle emissions of NO_x, the above implies that emissions of HONO represent a few tenths of a percent of mobile NO_x emissions. A similar range of ratios have been observed at other urban sites in the United Kingdom (Lammel and Cape, 1996). The ratios of HONO to NO₂ shown in Figure AX3.2-12 indicate that HONO can make a measurable contribution to measurements of NO₂ (cf. ISA, Section 2-3). However, similar arguments about extrapolating the use of UK data to the United States can be made for HONO as for PAN.

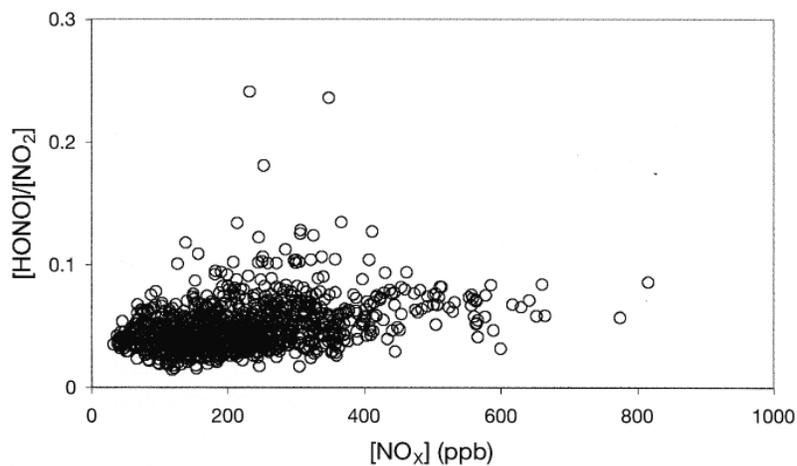

AX3.2.3.3. HNO₃ and NO₃

Elevated O₃ is generally accompanied by elevated HNO₃, although the correlation is not as strong as between O₃ and organic nitrates. O₃ is often associated with HNO₃ because they have the same precursor NO_x. However, HNO₃ can be produced in significant quantities in winter, even when O₃ is low. The ratio between O₃ and HNO₃ also shows great variation in air pollution events, with NO_x-saturated environments having much lower ratios of O₃ to HNO₃ (Ryerson et al., 2001). Aerosol nitrate is formed primarily by the combination of nitrate (supplied by HNO₃) with ammonia, and may be limited by the availability of either nitrate or ammonia. Nitrate is expected to correlate loosely with O₃ (see above), whereas ammonia is not expected to correlate with O₃. Concentrations of particulate nitrate measured as part of the Environmental Protection Agency's speciation network at several locations are shown in Figure AX3.2-13. Concentrations shown are annual averages for 2003. Also shown are the estimated contributions from regional and local sources. A concentration of 1 μg/m³ corresponds to ~0.40 ppb equivalent gas phase concentration for NO₃⁻.

Source: UK AQEG (2004).

Figure AX3.2-11. Ratios of PAN to NO₂ observed at Silwood Park, Ascot, Berkshire, U.K. from July 24 to August 12 1999. Each data point represents a measurement averaged over 30 minutes.

Source: UK AQEG (2004).

Figure AX3.2-12. Ratios of HONO to NO₂ observed in a street canyon (Marylebone Road) in London, U.K. from 11 a.m. to midnight during October 1999. Data points reflect 15-min avg concentrations of HONO and NO₂.

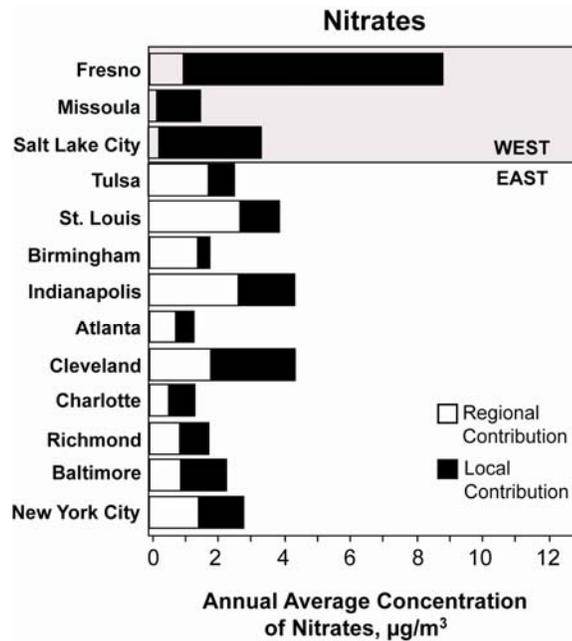

Thus, annual average particulate nitrate can account for several ppb of NO_Y, with the higher values in the West. There is a strong seasonal variation, which is especially pronounced in western areas where

there is extensive wood burning in the winter resulting in a larger fractional contribution of local sources. Areas in the East where there are topographic barriers might be expected to show higher fractional contributions from local sources than other eastern areas that are influenced by regionally dispersed sources.

However, depending on the acidity of the particles, which in turn depends strongly on their sulfate and ammonium contents, higher nitrate concentrations could be found in coarse mode particles $PM_{10-2.5}$ than in $PM_{2.5}$ samples. The average nitrate content of $PM_{2.5}$ and PM_{10} is typically about a percent in the eastern United States; and 15.7% and 4.5% in the western United States (U.S. Environmental Protection Agency, 1996). These values suggest that most of the nitrate was in the $PM_{2.5}$ size fraction in the studies conducted in the western United States, but nitrate in the studies in the eastern United States was mainly in the $PM_{10-2.5}$ size fraction.

AX3.2.3.4. Nitro-PAHs

Nitro-PAHs are widespread and found even in high altitude, relatively unpolluted environments (Schauer et al., 2004) but there are differences in composition and concentration profiles both within and between sites (rural vs. urban) as well as between and within urban areas (Albinet et al., 2006; Söderström et al., 2005; Naumova et al., 2002, 2003), with some differences in relative abundances of nitro- and oxo-PAHs also reported. Source attribution has remained largely qualitative with respect to concentrations or mutagenicity (Eide et al., 2002). The spatial and temporal concentration pattern for the NPAHs may differ from that of the parent compounds (PAHs) because concentrations of the latter are dominated by direct emission from local combustion sources. These emissions results in higher concentrations during atmospheric conditions more typical of wintertime when mixing heights tend to be low. The concentrations of secondary Nitro-PAHs are elevated under conditions that favor hydroxyl and nitrate radical formation, i.e., during conditions more typical of summertime, and are enhanced downwind of areas of high emission density of parent PAHs and show diurnal variation (Fraser et al., 1998; Reisen and Arey, 2005; Kameda et al., 2004). Nitro-naphthalene concentrations in Los Angeles, CA varied between about 0.15 to almost 0.30 ng/m^3 compared to 760 to 1500 ng/m^3 for naphthalene. Corresponding values for Riverside, CA were 0.012 to more than 0.30 ng/m^3 for nitro-naphthalene and 100 to 500 ng/m^3 for naphthalene. Nitro-pyrene concentrations in LA varied between approximately 0.020 to 0.060 ng/m^3 compared to 3.3 to 6.9 ng/m^3 pyrene, whereas corresponding values for Riverside were 0.012 to 0.025 ng/m^3 and 0.9 to 2.7 ng/m^3 .

Source: U.S. Environmental Protection Agency (2004).

Figure AX3.2-13. Concentrations of particulate nitrate measures as part of the EPA's speciation network. 1 µg/m³ ~0.45 ppb equivalent gas phase concentration for NO₃⁻. (Note: Regional concentrations are derived from the rural IMPROVE monitoring network, <http://vista.cira.colostate.edu/improve>.)

AX3.3. Measuring Personal and Indoor NO₂ Concentrations

AX3.3.1. Issues in Measuring Personal/Indoor NO₂

Nitrogen dioxide has been sampled in ambient and indoor air using active pumped systems both for continuous monitoring and collection onto adsorbents, and by diffusive samplers of various designs, including badges and tubes. Nitrogen dioxide concentrations in personal air have been typically measured using diffusive samplers because they are: (1) small in size and light-weight, (2) unobtrusive and thus more readily used by study participants, (3) comparatively easier to use and handle in field studies because they do not require power (e.g., battery or extra electrical sources), (4) cost-effective, and (5) usable not only for residential indoor and outdoor air sampling but also personal monitoring. However, diffusive samplers usually have lower equivalent sampling rates than active methods and so require relatively long sampling times (24-h or longer). Consequently, diffusive samplers including those used for NO₂ monitoring provide integrated but not short-term concentration measurements.

Both active and passive sampling methods can collect other gas-phase nitrogen oxide species. However, semivolatile nitrogen oxide compounds require separation of the gas- and particle-bound phases. This selective separation of gases from gas-particle matrices is commonly done by means of diffusion denuders (Vogel, 2005), an approach also useful for measuring other gas phase airborne contaminants such as SO₂ (Rosman et al., 2001). Application of denuder sampling to personal exposure or indoor air monitoring has been relatively limited.

Active air sampling with a pump can collect larger volumes of air and thus detect the lower concentrations found in community environments within relatively short time periods. Automated active

sampling methods have been the preferred method used to monitor NO₂ continuously at ambient sites for environmental regulation compliance purposes. However, practical considerations impede the use of these continuous monitors in residential air and exposure monitoring studies. Small, low flow active samplers using battery-operated pumps have been used instead, however, there are only a few such studies.

The first passive sampling devices for NO₂ were intended for occupational exposure monitoring, but were later adapted for environmental monitoring purposes. Since this sampler, the Palmes tubes (Palmes et al., 1976), was first developed, other tube, badge-type (Yanagisawa and Nishimura, 1982) and radial (Cocheo et al., 1996) diffusive samplers have been employed as monitors in exposure studies worldwide. The theories behind and applications of Palmes tubes and Yanagisawa badges have been described in the last AQCD for Oxides of Nitrogen (U.S. Environmental Protection Agency, 1993). There are currently several commercially available samplers (e.g., Ogawa, 1998; Radiello, 2006) which are modifications of the original Palmes tube design. Most modifications are directed at reducing effects related to meteorological conditions (e.g., insufficient or too high a wind speed, humidity, temperature), increasing the sampling uptake rate, and improving analytical sensitivity.

AX3.3.1.1. Active (Pumped) Sampling

Nitrogen dioxide measurement by active pumping systems as part of continuous monitors has been widely employed for ambient air monitoring as these instruments require relatively little maintenance; however they have been used less frequently for indoor sampling. Devices needing a pump to draw air can measure average concentrations of pollutants over short time periods, but are not generally suitable for measuring personal exposures because they are heavy and large. Some exposure studies employed this approach for active sampling with stationary chemiluminescent analyzers or portable monitors to measure nitrogen dioxide levels in residential indoor air (Mourgeon et al., 1997; Levesque et al., 2000; Chau et al., 2002). Recently, Staimer and his colleagues (2005) evaluated a miniaturized active sampler, suitable for personal exposure monitoring, to estimate the daily exposure of pediatric asthmatics to nitrogen dioxide, and reported that this small active sampling system is useful for this purpose in exposure studies where daily measurements are desired.

AX3.3.1.2. Passive (Diffusive) Sampling

Passive samplers are based on the well known diffusion principle described by Fick's law (Krupa and Legge, 2000). A convenient formulation of this law that can be easily related to sampler design considerations is:

$$J = D(A/L)(C_{air} - C_{sor}) \quad (\text{AX3.3-1})$$

where:

J = flux (mg/s)

D = diffusion coefficient in air (cm²/s)

A = diffusion cross-sectional area of the sampler (cm²)

L = diffusion path length from the inlet to sorbent (cm),

C_{air} = concentration of analyte in air (mg/cm³)

C_{sor} = concentration of analyte at the sorbent (mg/cm³)

The term $D(A/L)$ can be related to the uptake or sampling rate (cm^3/s) which is conceptually analogous to the sampling rate in an active monitor. Once the amount of analyte in the passive sampler sorbent is determined, the concentration in air (C_{air}) can be calculated as:

$$\text{Concentration}(\text{mg}/\text{cm}^3) = M(\text{mg})/D(A/L)(\text{cm}^3/\text{s})/t(\text{sec}) \quad (\text{AX3.3-2})$$

where:

M = mass of analyte collected in the sorbent

t = sampling time

Fick's law strictly applies only under ideal, steady state conditions assuming that the sorbent is a perfect sink. However, there can be deviations between the theoretical sampling rate for a given analyte and the actual rate depending on sampling conditions. It is also clear that sampling rate can be optimized by modifying the geometry of the diffusive sampler, either by reducing L , increasing A or a suitable combination. However, the impact of deviations from ideality on actual sampling rate due to geometry also poses a limit to the extent of possible modifications. Thus, passive samplers, either diffusive or permeation, are prepared as tubes or badges. These two main designs are the basis for all further modifications which, as indicated above, have been made in order to improve efficiency, reduce sensitivity to wind turbulence of the samplers, and to simplify analyte desorption. Tube-type samplers are characterized by a long, axial diffusion length, and a low cross-sectional area; this results in relatively low sampling rates (Namiešnik et al., 2005). Badge-type samplers have a shorter diffusion path length and a greater cross-sectional area which results in uptake rates that are typically higher than diffusion tubes (Namiešnik et al., 2005) but the sampling rate may be more variable because it is more affected by turbulence. Physical characteristics of these two fundamental passive sampler types, tube-type and badge-type, are summarized and provided in Table AX3.3-1. Performance characteristics are presented in Table AX3.3-2.

The sorbent can be either physically sorptive or chemisorptive; passive samplers for NO_2 are chemisorptive, that is, a reagent coated on a support (e.g., metal mesh, filter) reacts with the NO_2 . The sorbent is extracted and analyzed for one or more reactive derivatives; the mass of NO_2 collected is derived from the concentration of the derivative(s) based on the stoichiometry of the reaction. Thus, an additional approach to reducing detection limits associated with passive samplers is to modify the chemisorptive reaction and the extraction and analysis methods to increase analytical sensitivity. However, although chemisorption is less prone to the back diffusion phenomenon of sorptive-only methods, analyte losses could occur due to interferences from other pollutants that also react with the sorbent or the derivatives. The most commonly used NO_2 passive samplers rely on the classical reaction with triethanolamine (TEA). TEA requires hydration for quantitative NO_2 sampling (i.e., 1:1 conversion to nitrite) and the reaction products have been subject to a number of investigations and several have been reported, including TEA-nitrate and nitrite, triethanolammonium nitrate, nitrosodiethanolamine, and triethanolamine N-oxide (Glasius et al., 1999). Known interferences include HONO, PAN, and nitric acid (Gair et al., 1991.).

The tube-type passive samplers (Palmes tubes) require week-long sampling periods and have been extensively used for residential indoor/outdoor measurements, mostly for exploring the relationship between indoor and outdoor levels (Cyrus et al., 2000; Raw et al., 2004; Simoni et al., 2004; Janssen et al., 2001). Passive diffusion tubes have also been widely used for measurements of NO_2 in ambient air (Gonzales et al., 2005; Gauderman et al., 2005; Da Silva et al., 2006; Lewné et al., 2004; Stevenson et al., 2001; Glasius et al., 1999). Personal exposure studies have also been conducted using the Palmes tubes (Mukala et al., 1996; Kousa et al., 2001). Some of these studies evaluated passive sampler performance by collocating them with chemiluminescence analyzers during at least some portion of the field studies (Gair et al., 1991; Gair and Penkett, 1995; Plaisance et al., 2004; Kirby et al., 2001). The majority of these studies indicate that these samplers have very good precision (generally within 5%) but tend to

overestimate NO₂ by 10 to 30%. However, there has not been a methodical evaluation of variables contributing to variance for the range of samplers available when used in field conditions. Thus, it is not clear if the bias is due to deviations from ideal sampling conditions that can affect actual sampling rates, contributions from co-reacting contaminants or, most probably, a combination of these variables.

A badge-type sampler was introduced by Yanagisawa and Nishimura (1982) to overcome the long sampling time required by Palmes tubes. Since then, these sensitive NO₂ short path length samplers (Toyo Roshi Ltd) have been optimized and evaluated for indoor air and for personal monitoring (Lee et al., 1993a,b). They have been used extensively for personal exposure studies (Ramirez-Aguilar et al., 2002; Yanagisawa et al., 1986; Berglund et al., 1994, Lee et al., 2004) and indoor air measurements (Kodama et al., 2002; Bae et al., 2004; Algar et al., 2004; Shima and Adachi, 2000; Smedje, et al., 1997) and to a more limited amount for ambient monitoring (Tashiro and Taniyama, 2002; Levy et al., 2006; Norris and Larson, 1999). Due to the greater uptake rate resulting from the larger cross sectional area of the badges and shorter diffusion length compared to the tube-type samplers, sampling times can be decreased from one-week to one-day for typical environmental air concentrations. This makes diffusive filter-badges more suitable for shorter-term sampling while long-term ambient monitoring can still be conducted using the Palmes-tubes.

AX3.3.1.3. Tube Type Samplers

Gradko Sampler (<http://www.gradko.co.uk>)

The Gradko sampler is based on the Palmes tube design (Gerboles et al., 2006a). It collects O₃ or NO₂ by molecular diffusion along an inert tube by chemisorption. A stable complex is formed with triethanolamine coated on a stainless steel screen in the tube. The complex is spectroscopically analyzed by adding an azo dye (Chao and Law, 2000). The sampler has a detection limit of 0.5 ppb for NO/NO₂ and the precision of ± 6% above 5 ppb levels when used for two weeks (Table AX3.3-2). This sampler has been used to measure personal exposures, concentrations of residential air indoors such as in the kitchen and bedroom, and concentrations of outdoor air (Chao and Law, 2000; Gallelli et al., 2002; Lai et al., 2004). It has been used to measure ambient NO₂ levels in Southern California as a marker of traffic-related pollution in San Diego County (Ross et al., 2006).

Passam Sampler (<http://www.passam.ch>)

This sampler is also based on the design of the Palmes tube (Palmes et al., 1976). It collects NO₂ by molecular diffusion along an inert polypropylene tube to an absorbent, triethanolamine. The collected NO₂ is determined spectrophotometrically by the well-established Saltzman method. When used outdoors the samplers are placed in a special shelter to protect them from rain and minimize wind turbulence effects. The Passam sampler is sold in two different models, one for long-term and one for short-term sampling.

Analyst™ Sampler (<http://www.monitoreurope.com>)

The Analyst™ sampler is also a modification of the open-Palmes-tube design and was developed by the Italian National Research Council (CNR – Istituto Inquinamento Atmosferico) in 2000 (Bertoni et al., 2001). The Analyst™ consists of a glass vessel, which contains a reactant supported on a stainless steel grid. It is suitable for long-term monitoring (typically one month) of oxides of nitrogen, sulfur dioxide, and volatile organic compounds in ambient air. The target compound is analyzed by gas chromatography with minimum detection limit of 0.1 mg/m³ (~52 ppb) for a twelve-week sample duration, and has relatively high precision. The Analyst™ method development (De Santis et al., 1997, 2002) and actual field application (De Santis et al., 2004) have been described. The primary use for Analyst™ is as a reliable tool for long-term determination of concentration in indoor as well as outdoor environments (Bertoni et al., 2001) and as a screening tool for ambient monitoring to identify pollution “hot spots” (De Santis et al., 2004).

AX3.3.1.4. Badge-Types Samplers

Ogawa Passive Sampler (<http://www.ogawausa.com>)

This sampler is a double face badge that can monitor NO, NO_x, and NO₂. The design can be used also for the determination of SO₂, O₃, and NH₃ levels in air. The manufacturer-reported detection limits for nitrogen oxides are 2.3 ppb and 0.32 ppb for 24-h and 168-h sampling, respectively. Reported actual sampling rates for NO₂ are two to three times higher than the manufacturer's values. The normal operation ranges are 0 to 25 ppm for 24-h exposure and 0 to 3.6 ppm for 168-h exposure. The manufacturer recommends a sampling height of 2.5 meters and storage time of up to 1 year when kept frozen. Ogawa passive samplers have been extensively used for human exposure studies to measure personal air concentrations and (or) indoor/outdoor levels for residents in a number of locations, including adults of Richmond, Virginia (Zipprich et al., 2002), children of Santiago, Chile (Rojas-Bracho et al., 2002), office workers of Paris, France (Mosqueron et al., 2002), and cardiac compromised individuals of Toronto, Canada (Kim et al., 2006). The samplers have been used also in air monitoring networks to assess traffic-related pollutant exposure (Singer et al., 2004), as well as to evaluate spatial variability of nitrogen dioxide ambient concentrations in Montreal, Canada (Gilbert et al., 2005).

IVL Sampler (http://www.ivl.se/en/business/monitoring/diffusive_samplers.asp)

The IVL method development has been described in detail by Ferm and Svanberg (1998). It was developed by Swedish Environmental Research Institute in the mid of 1980s (Sjödín et al., 1996), is designed to minimize turbulent wind effects outdoors as well as “starvation effects” indoors (i.e., very low face velocities), interferences from within sampling tube chemistry, temperature and humidity effects, and artifacts and losses during post-sampling storage. Manufacturer-reported detection limits for this sampler with sampling times of ~1 month are 0.1 µg/m³ (0.05 ppb) for NO₂, and 0.5 µg/m³ (0.42 ppb) for NO, respectively. Due to its long sampling time, this sampler has been extensively used for NO₂ background monitoring in ambient air in rural or urban areas (Fagundez et al., 2001; Sjödín et al., 1996; Pleijel et al., 2004).

Willems Badge Sampler

The Willems badge, a short-term diffusion sampler, was developed at the University of Wageningen, Netherlands, originally for airborne ammonia measurements and later for measuring NO₂ (Hagenbjörk-Gustafsson et al., 1996). It consists of a cylinder of polystyrene with a Whatman GF-A glass fiber filter impregnated with triethanolamine at its based held in place by a 6 mm distance ring. A Teflon filter is placed on the 6 mm polystyrene ring, which is secured with a polystyrene ring of 3 mm (Hagenbjörk-Gustafsson et al., 1996). The badge is closed by a polyethylene cap to limit influences by air turbulence. The diffusion length in the badge is 6 mm. This sampler was evaluated for ambient air measurements in laboratory and field tests (Hagenbjörk-Gustafsson et al., 1999). It has a manufacturer's reported detection limit of 2 µg/m³ (~1 ppb) for 48-h sampling duration. When used for personal sampling in an occupational setting with a minimum wind velocity of 0.3 m/s, detection limits of 18 (~9.4 ppb) and 2 µg/m³ (~1 ppb) for 1-h and 8-h sampling, respectively, have been reported (Hagenbjörk-Gustafsson et al., 2002, Glas et al., 2004).

AX3.3.1.5. Radial Sampler Types

Radiello® -the radial diffusive sampler (<http://www.radiello.com>)

Radiello® samplers use radial diffusion over a microporous cylinder into an absorbing inner cylinder, instead of axial diffusion, which increases the uptake rate by a factor of about 100 (Hertel et al., 2001). Nitrogen dioxide is chemiadsorbed onto triethanolamine as nitrite, which is quantified by visible spectrometry. Sample collection of up to 15 days is feasible but relative humidity higher than 70% can cause interferences when used for extended periods of more than 7 days. The manufacturer-reported typical sampling rate for nitrogen dioxide sampling is 75 ± 3.72 ml/min at temperatures between -10 and 40 °C. The rate can vary with humidity in the range of 15 to 90% and wind speed between 0.1 and 10 m/s

(Radiello® Manual, 2006). A Danish study (Sørensen et al., 2005) recruited 30 subjects during each of four seasons in Copenhagen, and measured the subjects' personal exposures, home indoor/front door air concentrations during 2-day periods with this sampler.

EMD (Ecole des Mines de Douai) Sampler

A new high-uptake rate diffusive sampler has been recently developed by the Ecole des Mines de Douai (EMD) laboratory (Piechocki-Minguy et al., 2003) and evaluated in the laboratory and field for measurement of NO₂ levels in ambient air. It is composed of a porous cartridge impregnated with triethanolamine and fitted in a cylindrical protective box equipped with caps at its extremities (Piechocki-Minguy et al., 2006). The large sampling area (cartridge surface) and the two circular openings provide a high uptake rate (exceeding 50 cm³/min). The sampling rate was reported to be on average 0.89 cm³/s for indoor sampling and 1.00 cm³/s for outdoor sampling. Detection limits were determined to be 11 µg/m³ (~5.8 ppb) for 1-h measurement. The sampling rate was not significantly influenced by wind at speeds higher than 0.3 m/s (Piechocki-Minguy et al., 2003). This sampler has been used in France to assess personal exposures in a series of microenvironments (home, other indoor places, transport and outdoor) for two 24-h time periods (weekday and weekend) (Piechocki-Minguy et al., 2006).

AX3.4. NO_x in Indoor Air

AX3.4.1. Indoor Sources and Concentrations of NO_x

Penetration of outdoor NO₂ and combustion in various forms are the major sources of NO₂ to indoor environments. These environments include homes, schools, restaurants, theaters etc. As might be expected, indoor concentrations of NO₂ in the absence of combustion sources are determined by the infiltration of outdoor NO₂ (Spengler et al., 1994; Weschler et al., 1994; Levy et al., 1998a), with a much smaller contribution from chemical reactions in indoor air. Indoor sources of nitrogen oxides have been characterized in several reviews, namely the last AQCD for Oxides of Nitrogen (U.S. Environmental Protection Agency, 1993); the Review of the Health Risks Associated with Nitrogen Dioxide and Sulfur Dioxide in Indoor Air for Health Canada (Brauer et al., 2002); and the Staff Recommendations for revision of the NO₂ Standard in California (CARB, 2007). Mechanisms by which nitrogen oxides are produced in the combustion zones of indoor sources were reviewed in the last AQCD for Oxides of Nitrogen (U.S. Environmental Protection Agency, 1993) and will not be repeated here. Sources of ambient NO₂ are reviewed in Chapter 2 of this document. It should also be noted that indoor sources can affect ambient NO₂ levels, particularly in areas in which atmospheric mixing is limited.

Ideally, exposure to NO₂ should be cumulated over all indoor environments in which an individual spends time. These indoor environments may include homes, schools, offices, restaurants, theaters, ice skating rinks, stores, etc. However, in a study by Leaderer et al. that used two-week integrated measures, concentrations of NO₂ inside the home accounted for 80% of the variance in total personal exposure, indicating that home concentrations are a reasonable proxy for personal exposure (Leaderer et al., 1986).

AX3.4.1.1. Gas Cooking Appliances

A large number of studies, as described in the reviews cited above, have all noted the importance of gas cooking appliances as sources of NO₂ emissions. Depending on geographical location, season, other sources, length of monitoring period, and household characteristics, homes with gas cooking appliances have approximately 50% to over 400% higher NO₂ concentrations than homes with electric cooking appliances (Gilbert et al., 2006; Lee et al., 2000, 2002; García-Algar et al., 2004; Raw et al., 2004; Leaderer et al., 1986; García-Algar, 2003). Gas cooking appliances remain significantly associated with

indoor NO₂ concentrations after adjusting for several potential confounders including season, type of community, socioeconomic status, use of extractor fans, household smoking, and type of heating (García-Algar et al., 2004; Garrett et al., 1999).

Gas appliances with pilot lights emit more NO₂ than gas appliances with electronic ignition. Spengler et al. (1994) found that NO₂ concentrations in bedrooms of homes with a gas range without a pilot light averaged 4 ppb higher than in homes with an electric range, but were 15 ppb higher in homes with gas ranges with pilot lights. Lee et al. (1998) found somewhat larger differences in NO₂ concentrations in homes in the Boston area, with minor seasonal variation. Homes with gas stoves without pilot lights averaged between 11 ppb (summer) and 18 ppb (fall) higher than homes with electric stoves, while those with pilot lights averaged between 19 ppb (summer) and 27 ppb (fall) higher than electric stove homes.

Use of extractor fans reduces NO₂ concentrations in homes with gas cooking appliances (Gallelli et al., 2002; García-Algar et al., 2003), although absolute NO₂ levels tend to remain higher than in homes with electric stoves. In a multivariate analysis, García-Algar et al. (2004) found that having a gas cooker remained significantly increased NO₂ concentrations even after adjusting for extractor fan use. Raw et al. (2004) found only a small effect of extraction fan use on NO₂ levels in the bedroom in gas cooker homes. Among homes with gas cooking, geometric mean bedroom NO₂ levels were 1.7 ppb lower in homes with an extractor fan than in homes without one. As expected, among homes with no fossil fuel cooking, there were no differences in mean bedroom levels of NO₂ in homes with and without extractor fans.

AX3.4.1.2. Other Combustion Sources

Secondary heating appliances are additional sources of NO₂ in indoor environments, particularly if they are unvented or inadequately vented. As heating costs increase, the use of these secondary heating appliances tends to increase. From 1988 to 1994, an estimated 13.7 million homes used unvented heating appliances, with disproportionately higher usage rates among southern, rural, low-income, and African-American homes (Slack and Heumann, 1997). Of the 83.1 million households using gas stoves or ovens for cooking, 7.7 million (9.3%) also used the stove for heating (Slack and Heumann, 1997).

Gas heaters, particularly when unvented or inadequately vented, produce high levels of NO₂. Kodama et al. (2002) examined the associations between secondary heating sources and NO₂ concentrations measured over a 48-h exposure period in the living rooms of homes in Tokyo, Japan. They found much higher NO₂ concentrations during February 1998 and January 1999 in homes with kerosene heaters in both southern (152.6 ppb and 139.7 ppb for 1998 and 1999, respectively) and northern (102.4 and 93.1 ppb for 1998 and 1999, respectively) areas of Tokyo compared to homes with electric heaters (30.8 and 31.1 for the southern and 37.2 and 31.6 for northern areas, 1998 and 1999, respectively).

In a study by Garrett et al. (1999) of 78 homes in Latrobe Valley, Australia, the two highest indoor NO₂ levels recorded in the study were 129 ppb for the only home with an unvented gas heater and 69 ppb for a home with a vented gas heater. Levels of NO₂ in the kitchens and living rooms of homes with a vented gas heater (mean = 6.9 ppb in living room, 7.3 ppb in kitchen, n = 15) were comparable to homes with gas stoves (mean = 6.7 ppb in living room, 8.0 ppb in kitchen, n = 15) (Table AX3.4-1). These concentrations include results from all seasons combined, so the levels are somewhat lower than those found by Triche et al. (2005) for winter monitoring periods only.

Triche et al. (2005) also found high levels of NO₂ in homes with gas space heaters, although information on whether the appliance was vented or unvented was not available. Data from this study were analyzed in more detail and are shown in Table AX3.4-2. The median NO₂ concentration in the 6 homes with gas space heater use during monitoring periods with no gas stove use was 15.3 ppb; a similar incremental increase in total NO₂ levels was noted for homes with gas space heater use during periods when gas stoves were also used (Median = 36.6 ppb) compared to homes where gas stoves were used but no secondary heating sources were present (Median = 22.7 ppb) (Table AX3.4-2).

Shima and Adachi (1998) examined associations between household characteristics, outdoor NO₂, and indoor NO₂ in 950 homes during the heating season (640 with unvented and 310 vented heaters) and 905 homes during the non-heating season in urban, suburban, and rural areas of Japan. While no information is provided on gas stove use, the authors note that nearly all homes in Japan have gas stoves, though relatively few have pilot lights. During the heating season, geometric mean NO₂ levels in homes with unvented heaters (66.4 ppb) are about three times higher than in homes with vented heaters (20.6 ppb). In the non-heating season, the mean levels were lower at only 13.8 ppb, suggesting a contribution from vented heaters as well.

In multivariate analyses, Gilbert et al. (2006) found that gas and mixed/other heating systems were significantly associated with NO₂ levels, adjusting for presence of gas stoves and air exchange rates in 96 homes in Quebec City, Canada during the winter/early spring period. Many homes with gas space heaters also have gas stoves, and the contribution from multiple sources is much higher than from any single source alone (Garrett et al., 1999). In the Garrett et al. (1999) study, homes were classified into five categories: no indoor source (n = 15), gas stove only (n = 15), gas heater only (n = 14), smoker in the household only (n = 7), and multiple sources (n = 29). Homes with multiple sources had much higher NO₂ concentrations homes with either a gas stove only or gas heater only Table 3.4-1.

Kerosene heaters are also important contributors to indoor NO₂ levels. Leaderer et al. (1986) enrolled a cohort of kerosene heater users identified from local kerosene dealers and a cohort of controls systematically chosen from the same neighborhoods with each matched pair treated as a sampling unit (i.e., sampled at the same randomly assigned time period). A total of 302 homes were monitored for at least one two-week period. While outdoor concentrations never exceeded 100 µg/m³ (53 ppb), approximately 5% of homes with either no gas but 1 kerosene heater or gas but no kerosene heater had levels exceeding 53 ppb. Between 17%-33% of homes with both gas and kerosene heater(s) exceeded this limit, while nearly one quarter of homes with no gas, but two or more kerosene heaters had these levels.

Data from Triche et al. (2005) (Table AX3.4-2) also indicated increased levels of NO₂ for kerosene heater homes during monitoring periods with no gas stove use (Median = 18.9 ppb) compared to homes with no sources (Median = 6.3 ppb), which is similar to levels found in homes using gas space heaters (Median = 15.3 ppb). However, these NO₂ concentrations are of the same magnitude as those in homes with gas stove use (Median = 17.2 ppb).

Data are available for unvented gas hot water heaters from a number of studies conducted in the Netherlands. Results summarized by Brauer et al. (2002) indicate that concentrations of NO₂ in homes with unvented gas hot water heaters were 10 to 21 ppb higher than in homes with vented heaters, which in turn, had NO₂ concentrations 7.5 to 38 ppb higher than homes without gas hot water heaters.

The contribution from combustion of biomass fuels has not been studied as extensively as that from gas. A main conclusion from the previous AQCD was that properly vented wood stoves and fireplaces would make only minor contributions to indoor NO₂ levels. Several studies conclude that use of wood burning appliances does not increase indoor NO₂ concentrations. Levesque et al. (2001) examined the effects of wood-burning appliances on indoor NO₂ concentrations in 49 homes in Quebec City, Canada. The homes, which had no other combustion source, were sampled for 24 h while the wood-burning appliance was being used. No significant differences in mean NO₂ levels were found in homes with (6.6 + 3.6 ppb) and without (8.8 + 1.9 ppb) a wood-burning appliance. Data from Triche et al. (2005) confirm these findings (Table AX3.4-2). Homes with wood burning sources had comparable NO₂ concentrations to homes without other secondary heating sources, with (Median = 5.9 ppb) and without (Median = 16.7 ppb) gas stove use.

Data are available for unvented gas hot water heaters from a number of studies conducted in the Netherlands. Results summarized by Brauer et al. (2002) indicate that concentrations of NO₂ in homes with unvented gas hot water heaters were 10 to 21 ppb higher than in homes with vented heaters, which in turn, had NO₂ concentrations 7.5 to 38 ppb higher than homes without gas hot water heaters.

As can be seen from the tables, shorter-term average concentrations tend to be much higher than longer term averages. However, as Triche et al. (2005) point out, the 90th percentile concentrations can be

substantially greater than the medians, even for two week long samples. This finding illustrates the high variability found among homes.

In 10% of homes with fireplaces studied by Triche et al. (2005), NO₂ concentrations were greater than or equal to 80 ppb, or about twice the level found in homes with no indoor combustion source (see Table AX3.4-2). In a study of students living in Copenhagen, Sørensen et al. (2005) found that personal exposures to NO₂ were significantly associated with time exposed to burning candles in addition to other sources. However, they did not provide data for concentrations in spaces in which candles were burned. Results of studies relating NO₂ concentrations and exposures to environmental tobacco smoke (ETS) have been mixed. Several studies found positive associations between NO₂ levels and ETS (e.g., Linaker et al., 1996); Farrow et al., 1997; Alm et al., 1998; Levy et al., 1998a; Monn et al., 1998; Cyrus et al., 2000; Lee et al., 2000; García-Algar et al., 2004) whereas others have not (e.g., Hackney et al., 1992; Kawamoto et al., 1993). In a study of 57 homes in Brisbane, Australia (Lee et al., 2000), levels of NO₂ were higher in homes with smokers present (14.9 ± 7.7 ppb) than without smokers (9.9 ± 5.0 ppb). However, these concentrations did not account for presence of a gas range (n = 18 of 57 homes had a gas range). Garrett et al. (1999) found that smoking in the home increased levels of NO₂ in the winter, but not in the summer when windows tended to be opened. In a study of students living in Copenhagen, Sørensen et al. (2005) did not find a significant association between ETS and personal exposures to NO₂. However, they found that burning candles was a significant prediction of bedroom levels of NO₂.

AX3.4.1.3. Other Indoor Environments

Indoor ice skating rinks have been cited as environments containing high levels of NO₂ when fuel powered ice resurfacing machines are used especially without ventilation. As part of a three year study, Levy et al. (1998b) measured NO₂ concentrations at 2 locations at the outside of the ice surface in 19 skating rinks in the Boston area over 3 winters. Although different passive samplers were used in the first year (Palmes tubes, 7 day sampling time) and in years 2 and 3 (Yanagisawa badges, 1 day working hours) of the study, consistently high mean NO₂ concentrations were associated with the use of propane fueled resurfacers (248 ppb in the first year and 206 ppb in the following years) and gasoline fueled resurfacers (54 ppb in the first year and 132 ppb in the following years) than with electric resurfacers (30 ppb in the first year and 37 ppb in the following years). During all three years of the study peak NO₂ concentrations were several times higher in the rinks with propane and gasoline fueled resurfacers than the values given above. A number of earlier studies have also indicated NO₂ concentrations of this order and even higher (Paulozzi et al., 1993; Berglund et al., 1994; Lee et al., 1994; Brauer et al., 1997). In these studies peak averages were in the range of a few ppm.

AX3.4.2. Reactions of NO₂ in Indoor Air

Chemistry in indoor settings can be both a source and a sink for NO₂ (Weschler and Shields, 1997). NO₂ is produced by reactions of NO with ozone or peroxy radicals, while NO₂ is removed by gas phase reactions with ozone and assorted free radicals and by surface promoted hydrolysis and reduction reactions. The concentration of indoor NO₂ also affects the decomposition of peroxyacyl nitrates. Each of these processes is discussed in the following paragraphs. They are important not only because they influence the indoor NO₂ concentrations to which humans are exposed, but also because certain products of indoor chemistry may confound attempts to examine associations between NO₂ and health.

Indoor NO can be oxidized to NO₂ by reaction with ozone or peroxy radicals; the latter are generated by indoor air chemistry involving O₃ and unsaturated hydrocarbons such as terpenes found in air fresheners and other household products (Sarwar et al., 2002a,b; Nazaroff and Weschler, 2004; Carslaw, 2007). The rate coefficient for the reaction

at room temperature (298 K) is 1.9×10^{-14} cm³/molec-sec or 4.67×10^{-4} ppb⁻¹ s⁻¹ (Jet Propulsion Laboratory, 2006). At an indoor O₃ concentration of 10 ppb and an indoor NO concentration that is significantly less than that of O₃, the half-life of NO is 2.5 min. This reaction is sufficiently fast to compete with even relatively fast air exchange rates. Hence, the amount of NO₂ produced from NO tends to be limited by the amount of O₃ available. The indoor concentrations of NO and O₃ are negatively correlated; significant concentrations of NO can only accumulate when small amounts of O₃ are present and vice versa (Weschler et al., 1994).

The rapid reaction between NO and O₃ also means that humans, themselves, can be indirect sources of NO₂ in the rooms they occupy. Exhaled human breath contains NO that is generated endogenously (Gustafsson et al., 1991). For a typical adult male, the average nasal NO output is 325 nL min⁻¹ or 23.9 μg h⁻¹ (Imada et al., 1996). If ozone is present in the indoor air, some or all of these exhaled NO molecules will be oxidized to NO₂. To put this source in perspective, consider the example of an adult male in a 30 m³ room ventilated at 1 air change per hour (h⁻¹) with outdoor air. The steady-state concentration of NO in the room as a consequence of NO in exhaled breath is 0.80 μg/m³ or 0.65 ppb if none of the NO were to be oxidized. However, assuming a meaningful concentration of ozone in the ventilation air (>5 ppb), most of this NO is oxidized to NO₂ before it is exhausted from the room. In this scenario, the single human occupant is indirectly a source for 0.65 ppb of NO₂ in the surrounding air. At higher occupant densities, lower air exchange rates and elevated concentrations of O₃ in the ventilation air, human exhaled breath could contribute as much as 5 ppb to the total concentration of indoor NO₂.

The reaction of NO₂ with ozone produces nitrate radicals (NO₃):

The second order rate-constant for this reaction at room temperature (298 K) is 3.2×10^{-17} cm³/molec-sec or 7.9×10^{-7} ppb⁻¹ s⁻¹ (Jet Propulsion Laboratory, 2006). For indoor concentrations of 20 ppb and 30 ppb for O₃ and NO₂, respectively, the production rate of NO₃ radicals is 1.7 ppb h⁻¹. This reaction is strongly temperature dependent, an important consideration given the variability of indoor temperatures with time of day and season. The nitrate radical is photolytically unstable (Finlayson-Pitts and Pitts, 2000). As a consequence, it rapidly decomposes outdoors during daylight hours. Indoors, absent direct sunlight, nitrate radical concentrations may approach those measured during nighttime hours outdoors. To date there have been no indoor measurements of the concentration of nitrate radicals in indoor settings. Modeling studies by Nazaroff and Cass (1986), Weschler et al. (1992), Sarwar et al. (2002b), and Carslaw (2007) estimate indoor nitrate radical concentrations in the range of 0.01 to 5 ppt, depending on the indoor levels of O₃ and NO₂.

The nitrate radical and NO₂ are in equilibrium with dinitrogen pentoxide (N₂O₅):

Dinitrogen pentoxide reacts with water to form nitric acid. The gas phase reaction with water is too slow (Sverdrup et al., 1987) to compete with air exchange rates in most indoor environments. Due to mass transport limits on the rate at which N₂O₅ is transported to indoor surfaces, reactions of N₂O₅ with

water sorbed to indoor surfaces are much slower than gas phase reactions between nitrate radicals and commonly occurring indoor alkenes.

Once formed, NO₃ radicals can oxidize organic compounds by either adding to an unsaturated carbon bond or abstracting a hydrogen atom (Wayne et al., 1991). In certain indoor settings, the nitrate radical may be a more important indoor oxidant than either ozone or the hydroxyl radical. Table 8 in Nazaroff and Weschler (2004) illustrates this point. Assuming indoor concentrations of 20 ppb, 5 x 10⁻⁶ ppb, and 0.001 ppb for O₃, OH, and NO₃, respectively, the pseudo first-order rate constants for reactions of most terpenoids are larger for reactions with NO₃ than for reactions with either O₃ or OH. For example, for the stated conditions, the half-lives of d-limonene and α-pinene are roughly three times shorter as a consequence of reaction with NO₃ versus reaction with O₃. The products of reactions between NO₃ and various organic compounds include nitric acid, aldehydes, ketones, organic acids and organic nitrates; these have been summarized by Wayne et al. (1991). Nitrate radicals and the products of nitrate radical chemistry may be meaningful confounders in NO₂ exposure studies.

Reactions between NO₂ and various free radicals can be an indoor source of organo-nitrates, analogous to the chain-terminating reactions observed in photochemical smog (Weschler and Shields, 1997). Additionally, based on laboratory measurements and measurements in outdoor air (Finlayson-Pitts and Pitts, 2000), one would anticipate that NO₂, in the presence of trace amounts of HNO₃, can react with PAHs sorbed on indoor surfaces to produce mono- and dinitro-PAHs.

As noted in the ISA, Section 2.2, HONO occurs in the atmosphere mainly via multiphase processes involving NO₂. HONO is observed to form on surfaces containing partially oxidized aromatic structures (Stemmler et al., 2006) and on soot (Ammann et al., 1998). Indoors, surface-to-volume ratios are much larger than outdoors, and the surface mediated hydrolysis of NO₂ is a major indoor source of HONO (Brauer et al., 1990; Febo and Perrino, 1991; Spicer et al., 1993; Brauer et al., 1993; Spengler et al., 1993; Wainman et al., 2001; Lee et al., 2002). Spicer et al. (1993) made measurements in a test house that demonstrated HONO formation as a consequence of NO₂ surface reactions and postulated the following mechanism to explain their observations.

In a series of chamber studies, Brauer et al. (1993) reported HONO formation as a consequence of NO₂ surface reactions and further reported that HONO production increased with increasing relative humidity. Wainman et al. (2001) confirmed Brauer's findings regarding the influence of relative humidity. They also found that NO₂ removal and concomitant HONO production was greater on synthetic carpet surfaces compared to Teflon surfaces, and that the affinity of a surface for water influences HONO's desorption from that surface. Lee et al. (2002) measured HONO and NO₂ concentrations in 119 Southern California homes. Average indoor HONO levels were about 6 times larger than outdoors (4.6 ppb versus 0.8 ppb). Indoor HONO concentrations averaged 17% of indoor NO₂ concentrations, and the two were strongly correlated. Indoor HONO levels were higher in homes with humidifiers compared to homes without humidifiers (5.9 ppb versus 2.6 ppb). This last observation is consistent with the studies of Brauer et al. (1993) and Wainman et al. (2001) indicating that the production rate of HONO from NO₂/surface reactions is larger at higher relative humidities. Based on detailed laboratory studies, the hydrolysis mechanism, Equations AX3.4-4 and AX3.4-5, have been refined. Finlayson-Pitts et al. (2003) hypothesize that the symmetric form of the NO₂ dimer is sorbed on surfaces, isomerizes to the asymmetric dimer which auto ionizes to NO⁺NO₃⁻; the latter then reacts with water to form HONO and surface adsorbed HNO₃. FTIR-based analyses indicate that the surface adsorbed HNO₃ exists as both undissociated nitric acid-water complexes, (HNO₃)_x(H₂O)_y, and nitrate ion-water complexes,

$(NO_3^-)_X(H_2O)_Y$ (Dubowski et al., 2004, Ramazan et al., 2006). Such adsorbed species may serve as oxidizing agents for organic compounds sorbed to these same surfaces (Ramazan et al., 2006).

HONO and much smaller amounts of HNO_3 are also emitted directly by combustion by gas appliances and can infiltrate from outdoors. Spicer et al. (1993) compared the measured increase in HONO in a test house resulting from direct emissions of HONO from a gas range and from production by surface reactions of NO_2 . They found that emissions from the gas range could account for about 84% of the measured increase in HONO and surface reactions for 11% in an experiment that lasted several hours. An equilibrium between adsorption of HONO from the gas range (or other indoor combustion sources) and HONO produced by surface reactions (see Equation AX3.4-5) also determines the relative importance of these processes in producing HONO in indoor air. In a study of Southern CA homes (Lee et al., 2002), indoor levels of NO_2 and HONO were positively associated with the presence of gas ranges.

It is known that the photolysis of HONO (g) in the atmosphere (outdoors) is a major source of the hydroxyl radical (OH). Given high indoor HONO concentrations and the presence of lighting (sun light penetrating windows, incandescent lights, fluorescent lights), the photolysis of indoor HONO may be a meaningful source of indoor hydroxyl radical, under favorable reaction conditions. Given the large suite of man-made chemicals present indoors at elevated concentrations, indoor free radicals (e.g., OH and NO_3) can initiate and drive a complex series of indoor chemical reactions.

NO_2 can also be reduced on certain surfaces, forming NO. Spicer et al. (1989) found that as much as 15% of the NO_2 removed on the surfaces of masonite, ceiling tile, plywood, plasterboard, bricks, polyester carpet, wool carpet, acrylic carpet and oak paneling was re-emitted as NO. Weschler and Shields (1996) found that the amount of NO_2 removed by charcoal building filters were almost equally matched by the amount of NO subsequently emitted by these same filters.

Spicer et al. (1993) determined the 1st order rate constants for removal of several NO_Y components by reaction with indoor surfaces. They found lifetimes (e-folding times) of about half an hour for HNO_3 , an hour for NO_2 , and hours for NO and HONO. Thus the latter two components, if generated indoors are more likely to be lost to the indoor environment through exchange with outside air than by removal on indoor surfaces. However, HONO is in equilibrium with the nitrite ion (NO_2^-) in aqueous surface films

Ozone oxidation of nitrite ions in such films is a potential sink for indoor HONO (Lee et al., 2002). Jakobi and Fabian (1997) measured indoor and outdoor concentrations of ozone and peroxyacetyl nitrate (PAN) in several offices, private residences, a classroom, a gymnasium and a car. They found that indoor levels of PAN were 70% to 90% outdoor levels, and that PAN's indoor half-life ranged from 0.5 to 1 h. The primary indoor removal process is thermal decomposition.

As is indicated by Equation AX3.4-7, PAN is in equilibrium with the peroxyacetyl radical and NO_2 . Hence, the indoor concentration of NO_2 affects the thermal decomposition of PAN and, analogously, other peroxyacetyl nitrates. Peroxylalkyl radicals rapidly oxidize NO to NO_2 , so the indoor concentration of NO also influences the thermal decomposition of PAN type species (Finlayson-Pitts and Pitts, 2000).

Reactions between hydroxyl radicals and aldehydes in the presence of NO_2 can lead to the formation of peroxyacetyl nitrates. Weschler and Shields (1997) have speculated that such chemistry may sometimes occur indoors. For example, the requisite conditions for the formation of the highly irritating compound peroxybenzoyl nitrate may occur when ozone, certain terpenes, styrene and NO_2 are present simultaneously at low air exchange rates. This relatively common indoor mixture of pollutants produces hydroxyl radicals and benzaldehyde, which can subsequently react as noted above. In her detailed model

of indoor chemistry, Carslaw (2007) explores the indoor formation of PAN-type species (see Figure 2 in the cited reference).

Recent work indicates that indoor NO₂ also can affect the formation of secondary organic aerosols (SOA) resulting from the reaction of O₃ with terpenes such as d-limonene and α-pinene (Nøjgaard et al., 2006). At concentrations of 50 ppb for O₃ and the terpenes, NO₂ decreased the formation of SOA compared to the levels formed in the absence of NO₂. The effect was more pronounced for SOA derived from α-pinene than d-limonene, and at lower NO₂ concentrations, appears to be explained by the O₃ loss resulting from its reaction with NO₂. The resultant nitrate radicals apparently are not as efficient at producing SOA as the lost O₃.

Nitro-PAHs have been found in indoor environments (Mumford et al., 1991; Wilson et al., 1991). The major indoor sources of nitro-PAHs include cooking, wood burning, and the use of kerosene heater (World Health Organization (WHO), 2003). It is also likely that nitro-PAHs outdoors can infiltrate indoors. One of the potential sources of nitro-PAHs indoors, which has not been characterized, is reactions via indoor chemistry. The reactions of PAHs with OH and NO₃ may occur in indoor environments. Although no direct measurements of OH or NO₃ in indoor environments, OH and NO₃ can be formed via indoor chemistry and may present at significant levels indoors (Nazaroff and Cass 1986, Sarwar et al., 2002a; Carslaw, 2007). Concentrations of ~10⁻⁶ ppb for OH and 0.01-5 ppt of NO₃ have been predicted through indoor chemical reactions (Nazaroff and Cass 1986, Sarwar et al., 2002a, Carslaw, 2007), depending on the indoor levels of O₃, alkenes, and NO₂. Observation of secondary organic aerosols (SOA) formation in a simulated indoor environment also suggested that ~10⁻⁵ ppb steady-state OH radicals were generated from the reactions of O₃ with terpenes (Fan et al., 2003). PAHs are common indoor air pollutants (Chuang et al., 1991; Naumova et al., 2002), and the concentrations of some PAHs indoors are often higher than outdoors (Naumova et al., 2002). Therefore, the reactions of OH and NO₃ with PAHs may occur at rates comparable to air exchange rates to form nitro-PAHs indoors. In addition, the reactions of NO₃ with PAHs may be more significant indoors than outdoors because indoor NO₃ is more stable due to the low uv in indoor environments. Given the high surface areas available indoors, the formation of nitro-PAHs via surface reactions of PAHs with nitrating species may be more important compared to heterogeneous reactions outdoors.

In summary, indoor chemistry can meaningfully alter the indoor concentration of NO₂. Indoor exposure to NO₂ may be accompanied by indoor exposures to nitrate radicals, organic nitrates, and nitro-PAHs.

AX3.5. Personal Exposure

AX3.5.1. Personal Exposure in the Residential Indoor Environment

People spend most of their daily time in a residential indoor environment (Klepeis et al., 2001). NO₂ found in an indoor environment originates both indoor and outdoors; and therefore, people in an indoor environment are exposed to both indoor and outdoor generated NO₂. In a residential indoor environment, personal exposure concentration equals the residential indoor concentration (if there is no personal cloud) which can be broken down into two parts: indoor generation and ambient contribution.

The relationship between personal NO₂ exposure and ambient NO₂ can be modified by the indoor environment in the following ways: (1) during the infiltration processes, ambient NO₂ can be lost through penetration and decay (chemical and physical processes) in the indoor environment, and therefore, the concentration of indoor NO₂ of ambient origin is not the ambient NO₂ concentration but the product of the ambient NO₂ concentration and the infiltration factor (F_{inf} , or α if people spend 100% of their time indoors); (2) in an indoor environment, people are exposed to not only ambient generated NO₂ but also indoor generated NO₂, and therefore, the relative contribution of ambient and nonambient NO₂ to

personal exposure depends not only on the ambient NO₂ concentration but also on the infiltration factor (attenuation factor) and the indoor source contribution; (3) the strength of the association between personal exposure to NO₂ of ambient origin and ambient NO₂ concentration is determined by the temporal and spatial variation in the infiltration factor; and (4) the strength of the association between personal total exposure and ambient NO₂ is determined by the variation in the indoor source contribution and the variation in the infiltration factor. Below, factors affecting infiltration factor and the indoor source contribution will be evaluated, and the key issues, such as those mentioned above, related to ambient contribution to personal NO₂ exposure will be addressed.

Due to the lack of specific P , k , and a for study homes or a study population, instead of using P , k , and a , alternative approaches to obtain the infiltration factor are the ratio of indoor/outdoor NO₂ and the regression based RCS model. The basic rationale of the RCS model has been introduced in the previous section. Without indoor sources, the ratio between indoor NO₂ and outdoor NO₂ should be always less than or equal to 1. If the indoor to outdoor ratio is larger than 1 (after adjusting for measurement error), we can surely say that indoor sources exist. However, if an indoor/outdoor ratio is less than one, we cannot exclude the effect of indoor sources; otherwise, the infiltration factor would be overestimated. In order to use an indoor/outdoor ratio as the infiltration factor, study designs and questionnaires must be carefully read, and only the ratio for homes without identified indoor sources can be used as an indicator of infiltration factor. The population averaged infiltration factor is the slope of the regression line of indoor concentration vs. outdoor concentration. The reliability of the regression slope is dependent upon the sample size and how to deal with the outlier effects. Indoor/outdoor ratios and the regression slopes are summarized in Table AX3.5-1a. Most of the infiltration factors range from 0.4 to 0.7. Similarly, α ranges from 0.3 to 0.61 (Table AX3.5-1b). Theoretically, infiltration factor is a function of air exchange rate, which has been indicated by season in some studies. However, most studies do not report the infiltration factor by season, and therefore, a seasonal trend of infiltration factor could not be observed in Table AX3.5-1a.

As mentioned before, personal NO₂ exposure is not only affected by air infiltrating from outdoors but also by indoor sources. The NO₂ residential indoor sources reported are gas cooking, gas heating, kerosene heating, smoking and burning candles (Schwab et al., 1994; Spengler et al., 1994; Nakai et al., 1995; Lee et al., 1996; Linaker et al., 1996; Cotterill and Kingham, 1997; Farrow et al., 1997; Kawamoto et al., 1997; Lee, 1997; Raaschou-Nielsen et al., 1997; Alm et al., 1998; Levy et al., 1998a; Monn et al., 1998; Garrett et al., 1999; Chao, 2001; Dennekamp et al., 2001; Dutton et al., 2001; Emenius et al., 2003; Kodama et al., 2002; Lee et al., 2002; Mosqueron et al., 2002; Garcia-Algar et al., 2003; Garcia-Algar et al., 2004; Lai et al., 2004; Lee et al., 2004; Yang et al., 2004; Zota et al., 2005; Sørensen et al., 2005; Lai et al., 2006). Spengler et al. (1994) reported that personal exposures in homes with gas range with pilot light were 15 ppb higher than those in homes with electric range, and it was 5 ppb higher in homes with gas range without pilot light than homes with electric ranges. Schwab et al. (1994) reported that homes with gas stove with pilot light had higher indoor NO₂ concentrations (peak concentrations ranging from 30 to 35 ppb), followed by homes with gas stove without a pilot light (peak concentrations ranging from 15 to 20 ppb) and then homes with electric stoves (peak concentrations ranging from 5 to 10 ppb). In an international study, Levy et al., (1998a) reported that the use of a gas stove in the home was the dominant activity influencing NO₂ concentrations with a 67% increase in mean personal NO₂ exposure and an increase in indoor-outdoor ratios from 0.7 to 1.2. Smoking was found to be another significant factor elevating personal and indoor NO₂ exposure. Monn et al. (1998) reported that during 1-week integrated measurement, smoking contributed 1 ppb more NO₂ exposure. Alm et al. (1998) reported that one-week integrated personal NO₂ exposure for smokers and nonsmokers were 12.9 ppb and 10.7 ppb, respectively. Zota et al. (2005) observed that smoking was not a significant indoor source. However, the authors pointed out that the effect of smoking might have been overwhelmed by the presence of the gas stove. Sørensen et al. (2005) found that burning candles were significantly associated with the elevation of indoor NO₂ ($p = 0.02$). NO₂ concentration in an indoor environment affected by the indoor sources is not homogeneously distributed: NO₂ concentration is usually the highest in the kitchen, lowest in the bedroom and the concentration in a living room is in between as shown in Table AX3.5-2. The

concentration differences between a bedroom and a kitchen ranged from 1 ppb to 28 ppb, and largest difference occurred in homes with gas stoves.

The concentration differences in indoor microenvironments reflect the differences in personal exposure in those microenvironments, which is related to personal activities and behaviors. People who spend more time in a kitchen are expected to have higher NO₂ exposures. Also, in most exposure studies, integrated indoor and personal exposures were measured from 2 days to 2 weeks with passive samplers. Therefore, the peak exposure concentration could be even higher.

Indoor source contributions to indoor and personal exposure are determined by indoor source strength (S), house volume (V), air exchange rate (a) and the NO₂ decay rate (k) in an indoor environment, through the equation $C_{\text{nona}} = S/[V(a + k)]$. Indoor source strength has been summarized in a previous section (Indoor sources and concentrations of nitrogen oxides). With a mass balance approach, Yang et al. (2004) reported that the source strength for electric range was 3.5 ppb/h, 11.5 ppb/h for gas range in Brisbane, and 23.4 ppb/h for gas range in Seoul. The age of house and the house type are associated with ventilation, indoor sources, and house volume. As mentioned before, Lee et al. (1996) reported that the building type was significantly associated with volume of dwelling unit, and air exchange rate. Garrett et al. (1999) reported that older houses were associated with higher nitrogen dioxide levels, possibly as a result of older and less efficient appliances in older homes or due to smaller rooms.

In theory, personal exposure of ambient origin should be at least as much as the indoor NO₂ of ambient origin in that people spend time in either an indoor or an outdoor environment. However, it was shown in the previous part (Table AX3.5-3a and Table AX3.5-3b) that the ambient contribution to population exposure ranged from 20% to 50% based on four studies (Rojas-Bracho et al., 2002; Monn et al., 1998; Levy et al., 1998a; Spengler et al., 1994); and results here show that the ambient contribution to indoor NO₂ is around 70% with a wide range from 40 to 90% based on another four studies (Mosqueron et al., 2002; Yang et al., 2004; Kulkarni et al., 2002; Monn et al., 1998). It is not clear at present why the indoor NO₂ of ambient origin is larger than the personal NO₂ exposure of ambient origin.

The strength of the indoor, outdoor and personal NO₂ associations (r_p : Pearson correlation coefficient; r_s : Spearman correlation coefficient; and R^2 : coefficient of determination) are summarized in Table AX3.5-4. The strength of the associations are determined by the variation in F_{inf} (P , k , and a) and indoor source contributions from home to home and from day to day. In general, the correlation between indoor and outdoor NO₂ ranges from poor to good (r_p : 0.06 to 0.86). When we break down the correlation coefficient by season and indoor sources, it is obvious that the association between indoor and outdoor NO₂ is stronger during spring and summer but weaker during wintertime, and the association is stronger for homes without indoor sources but weaker for homes with strong indoor sources. Mukala et al. (2000) reported an r_p of 0.86 for the indoor and outdoor NO₂ association during the spring and it reduced to 0.54 during the winter. Spengler et al. (1994) reported that the associations were 0.66 and 0.75 (r_p) for homes with and without air conditioning system, respectively. Emenius et al. (2003) reported that the association between indoor and outdoor NO₂ was 0.69 (r_p) for homes without smoker and without gas stove using, but the association was not significant for homes with gas stove or smokers. Yang et al. (2004) reported that the indoor and outdoor NO₂ association was 0.70 (R^2) for homes with electric ranges, and was 0.57 (R^2) for homes with gas ranges. In other words, personal exposure to ambient NO₂ in a residential indoor environment will be modified the least when the air exchange rate is high and the indoor source contribution is not significant. Considering the large spatial variation in ambient NO₂ concentrations and the relative sparseness of ambient NO₂ monitors, the associations between indoor and outdoor concentrations are usually stronger than the associations between indoor and ambient concentrations. As shown in Table AX3.5-4, a stronger personal vs. residential indoor relationship than the personal vs. outdoor relationship has been reported by most studies (Lai et al., 2004; Monn et al., 1998, Levy et al., 1998a; Spengler et al., 1994; Kousa et al., 2001; Linaker et al., 1996), which is a reminder that personal exposure to ambient NO₂ mostly happens in the residential indoor environment. It should be pointed out that the association between indoor, outdoor and personal NO₂ and the relative contributions of indoor and outdoor NO₂ to indoor and personal exposures were calculated based on time integrated indoor, outdoor and personal NO₂ measurement with passive samplers and an average measurement time of a

couple of days to two weeks. In most studies, an equilibrium condition was assumed and the effects of dynamics on the indoor, outdoor, and personal association were not evaluated, which could result in missing the peak exposure and obscuring the real short-term outdoor contribution to indoor and personal exposure. For example, the NO₂ concentrations at locations close to busy streets in urban environments may vary drastically with time. If the measurement is carried out during a non-steady-state period, the indoor/outdoor concentration ratio may indicate either a too low relative importance of indoor sources (if the outdoor concentration is in an increasing phase) or a too high relative importance of indoor resources (if the outdoor concentration is in a decreasing phase). The lower the air exchange rate, the greater the error due to the effects of transients (Ekberg, 1996).

AX3.5.1.1. School and Office

Workplaces (schools and offices) are the places where people spend most of their time after homes in an urban area. The location, indoor sources as well as the ventilation pattern of schools and offices could be different from people's homes. Therefore, personal exposure patterns in schools and offices could be different from exposure patterns at home. However, NO₂ concentrations in schools and offices have only been measured in only a few exposure studies.

Most studies reported the personal exposure levels were lower than or equal to office NO₂ levels. Lai et al. (2004) reported that a cohort in Oxford spent 17.5% of their daily time in offices, and mean personal total NO₂ exposure was 15 ppb and 16.8 ppb for mean office concentrations. Mosqueron et al. (2002) reported Paris office worker exposure levels and no significant difference was found between personal total exposure (22.8 ppb) and NO₂ concentrations in office (23.5 ppb). Personal exposures in schools were studied in Helsinki, Southampton and Southern California. Alm et al. (1998) and Mukala et al. (2000) reported the personal exposure levels in Helsinki for pre-school children. They reported that median personal exposures were lower than the median NO₂ concentrations measured inside the day care center (13.1 ppb for personal exposure versus 18.8 ppb for inside day-care center for downtown winter; 14.7 ppb versus 24.1 ppb for downtown spring; 8.9 ppb versus 15.2 ppb for suburban winter; and 8.9 ppb versus 13.1 ppb for suburban spring). Linaker et al. (1996) found that the geometric mean of school children exposures (18.8 ppb) was higher than geometric means of the NO₂ concentrations in classrooms (8.4 to 14.1 ppb) in a study of children's exposures to NO₂ in Southampton, UK. A similar exposure pattern was found by Linn et al. (1996) during the Southern California school children exposure study. During the study, personal exposure (22 ppb) was higher than the NO₂ concentration inside school (16 ppb). NO₂ concentration in school/office is determined by ambient NO₂ level, local traffic sources, floor height and building ventilation pattern. Partti-Pellinen et al. (2000) studied the effect of ventilation and air filtration systems on indoor air quality in a children's day-care center in Finland. Without filtration, NO_x and PM generated by nearby motor traffic penetrated readily indoors. With chemical filtration, 50 to 70% of nitrogen oxides could be removed. The authors suggested that the possible adverse health effects of nitrogen oxides and particles indoors could be countered by efficient filtration. Mosqueron et al. (2002) reported 24% of variations in in-office NO₂ concentrations could be explained by outdoor NO₂ levels (18%), and floor height (6%) and an inverse relation was observed between in-office concentration and floor height. Alm et al. (1998) attributed the high NO₂ concentration in the day-care center to its close to major roads. Obviously, the relative scale of personal exposure and school concentration also depends on personal activities outside schools and workplaces.

Significant associations between personal exposure and workplace concentrations were reported by most studies. Mosqueron et al. (2002) reported office NO₂ was a significant predictor of personal exposure and 15% of the personal exposure was explained by time weighted office NO₂ concentrations. Alm et al. (1998) reported population NO₂ exposures were highly correlated with the NO₂ levels inside the day-care centers ($R^2 = 0.88$). However, Lai et al. (2004) reported a nonsignificant Pearson correlation coefficient (0.15) between personal exposure and workplace indoor concentration and the authors suggested that the strong residential indoor sources and long time indoors obscured the personal versus

office relationship. Personal total exposure is a function of NO₂ concentrations in different indoor and outdoor microenvironments and how long a person stays in that microenvironment. The large variation of NO₂ exposure in some microenvironments could obscure the association between personal exposure and NO₂ concentrations in other microenvironments.

AX3.5.1.2. Exposure Reconstruction

Personal exposure has been evaluated in each major microenvironment, where either the NO₂ concentration is high or people spend most of their daily time. Personal exposure could be reasonably reconstructed if we know the NO₂ concentration in each microenvironment and the duration of personal exposure in each microenvironment. Levy et al., (1998a) reconstructed personal exposures measured in an international study with a time-weighted average exposure model. The personal exposure was reconstructed based on the measured NO₂ concentrations in residential indoor, residential outdoor, and workplace microenvironments, and the time people spent in those environments. The mean measured personal NO₂ exposure was 28.8 ppb and a mean of estimated NO₂ exposure was 27.2 ppb. The Spearman correlation coefficient between personal measured exposure and reconstructed exposure was 0.81. The same approach was applied by Kousa et al. (2001) to reconstruct the personal exposures in the EXPOLIS study. A correlation coefficient of 0.86 was observed for the association between measured NO₂ exposure and reconstructed NO₂ exposure (data were log-transformed), and the slope and the intercept were 0.90 and 0.22 respectively for the reconstructed exposure vs. measured exposure. In the two studies mentioned above, NO₂ exposure during commuting was not measured. Probably that is part of the reason why reconstructed NO₂ exposure was lower than the measured NO₂ exposure.

AX3.5.2. Factors Affecting Exposure

Physically, personal exposure levels are determined by the time people spend in each microenvironment and the NO₂ concentrations in each microenvironment, which is determined by source emission strength, air exchange rate, penetration coefficient, the NO₂ decay rate and the volume of the microenvironment. Any factors that can influence the above physical parameters can modify the level of personal exposure. The indoor, outdoor and personal NO₂ levels on each stratum of those factors will be summarized.

Those factors can be classified in to the following categories: (1) factors associated with environmental conditions, such as weather and season; (2) factors associated with dwelling conditions, such as the location of the house and ventilation system; (3) factors associated with indoor sources, such as the type of range and the fuel type; (4) factors associated with personal activities, such as the time spent on cooking or commuting; (5) socioeconomic status, such as the level of education and the income level; and (6) demographic factors, such as age and gender.

Most studies addressed the influences of dwelling condition and indoor sources on indoor and personal exposures. A few studies explored the impacts of environmental factors and personal activities on personal exposures. Indoor and personal exposures have rarely been stratified by socioeconomic and demographic factors. Indoor, outdoor, and personal exposure levels are presented in Table AX3.5-5, stratified by environmental factors, dwelling conditions, indoor sources, and personal activities factors. The effects of socioeconomic and demographic factors on the indoor, outdoor, and personal levels are summarized in Table AX3.5-6.

Season is an environmental factor affecting both indoor and outdoor levels, and thus personal NO₂ levels. During the wintertime, the mixing height is usually lower than during the summer, and therefore concentrations of many primary pollutants are higher than in the summer. Wintertime is also a heating season, which usually leads to higher indoor source emissions and lower air exchange rates. Therefore, a higher indoor NO₂ concentration can be expected during the winter. For most cases, the differences of indoor or personal NO₂ exposure between the heating and non-heating season are within several ppb, but

sometimes the difference could be close to 20 ppb (Zota et al., 2005). Other environmental factors include day of the week (weekday versus weekend), and the wind direction.

The dwelling conditions are also associated with indoor, outdoor, and personal NO₂ levels. A house located in an urban center or close to a major road is expected to have higher outdoor and indoor NO₂ levels, and the differences in NO₂ exposures are often within 20 ppb based on passive sampler monitoring. The age of the house, house type, and window type can affect the ventilation of dwelling units, and sometimes the type of heating and cooking appliances in a house. Range and fuel type are the indoor source factors discussed the most in the literature. It is common to see differences larger than 10 ppb in indoor and personal NO₂ exposures between a gas range home (especially gas range with pilot light) and an electric range home. Sometimes the differences could be as high as 40 ppb. For peak short-term exposures, the difference could reach 100 ppb.

The level of personal exposure is dependent upon the time a person spends in each microenvironment. Kawamoto et al. (1997), Levy et al. (1998a), and Chao and Law (2000) clearly showed that personal NO₂ exposure increases with time spent cooking or commuting.

There are inconsistencies in the literature. For example, smoking is found to be a significant factor in some studies but not in others, and the same can be said for proximity to a major road. For another example, a higher indoor NO₂ level could be found in a rural home rather than in an urban home, although most studies found the opposite. Part of the reason is that exposure indicators function together, as a multidimensional parameter space, on indoor and personal exposures. They are not independent of each other. Unfortunately, studies have rarely been conducted to understand the associations between these exposure indicators and to use the study findings to explain indoor and personal NO₂ exposures.

More effort put on exposure indicator studies should help in finding better surrogate measurements for personal exposures. Although misclassifying exposures in epidemiological studies is almost inevitable, and it is unlikely that the personal exposures of all subjects will be measured, a better knowledge of the effects of exposure indicators on personal exposure will help reduce exposure errors in exposure and epidemiological studies and help interpret those study results.

AX3.5.3. Associations between HONO and NO₂

Spicer et al. (1993) and Wainman et al. (2000) suggested the presence of a strong indoor source of HONO from heterogeneous reactions involving NO₂ and water films on indoor surfaces. Hence, combustion appliances are sources for exposures to both NO₂ exposure and HONO. Epidemiological studies of NO₂ health effects should consequently consider the potential confounding effects of NO₂ and vice versa.

Jarvis et al. (2005) reported the indoor nitrous acid and lung function in adults as part of European Community Respiratory Health Survey (ECRHS). Indoor HONO and indoor and outdoor NO₂ were measured. Indoor NO₂ were correlated with HONO ($r_p = 0.77$) but no significant association of indoor NO₂ with symptoms or lung function was observed.

Lee et al. (2002) studied the nitrous acid, nitrogen dioxide, and ozone concentrations in residential environments. The authors found that indoor NO₂ was significantly correlated with HONO ($r_p = 0.511$).

As shown above, very few studies showed the relationship between personal NO₂ exposure and other pollutant exposures. In general, personal NO₂ was moderately correlated with PM_{2.5} and CO. Due to the lack of personal HONO exposure data, indoor HONO was used as an indicator for personal exposure, and current studies showed that indoor HONO was correlated with indoor NO₂ with high correlation coefficients, which suggested that the collection of HONO exposure data would help interpret adverse health outcome in the NO₂ health risk assessment.

AX3.6. Modeling Human Exposures to NO₂

AX3.6.1. Exposure Models

Predictive (or prognostic) exposure modeling studies¹, specifically focusing on NO₂, could not be identified in the literature, though, often, statistical (diagnostic) analyses have been reported using data obtained in various field exposure studies. However, existing prognostic modeling systems for the assessment of inhalation exposures can in principle be directly applied to, or adapted for, NO₂ studies; specifically, such systems include APEX, SHEDS, and MENTOR-1A, to be discussed in the following sections. Nevertheless, it should be mentioned that such applications will be constrained by data limitations, such as the degree of ambient concentration characterization (e.g., concentrations at the local level) and quantitative information on indoor sources and sinks.

Predictive models of human exposure to ambient air pollutants such as NO₂ can be classified and differentiated based upon a variety of attributes. For example, exposure models can be classified as:

- models of potential (typically maximum) outdoor exposure versus models of actual exposures (the latter including locally modified microenvironmental exposures, both outdoor and indoor),
- Population Based Exposure Models (PBEM) versus Individual Based Exposure Models (IBEM),
- deterministic versus probabilistic (or statistical) exposure models,
- observation-driven versus mechanistic air quality models.

Some points should be made regarding terminology and essential concepts in exposure modeling, before proceeding to the overview of specific developments reported in the current research literature:

First, it must be understood that there is significant variation in the definitions of many of the terms used in the exposure modeling literature; indeed, the science of exposure modeling is a rapidly evolving field and the development of a standard and commonly accepted terminology is an ongoing process (see, e.g., WHO, 2004).

Second, it should also be mentioned that, very often, procedures that are called exposure modeling, exposure estimation, etc. in the scientific literature, may in fact refer to only a sub-set of the complete set of steps or components required for a comprehensive exposure assessment. For example, certain self-identified exposure modeling studies focus solely on refining the sub-regional or local spatio-temporal dynamics of pollutant concentrations (starting from raw data representing monitor observations or regional grid-based model estimates). Though not exposure studies per se, such efforts have value and are included in the discussion of the next sub-section, as they provide potentially useful tools that can be used in a complete exposure assessment. On the other hand, formulations that are self-identified as exposure models but actually focus only on ambient air quality predictions, such as chemistry-transport models, are not included in the discussion that follows.

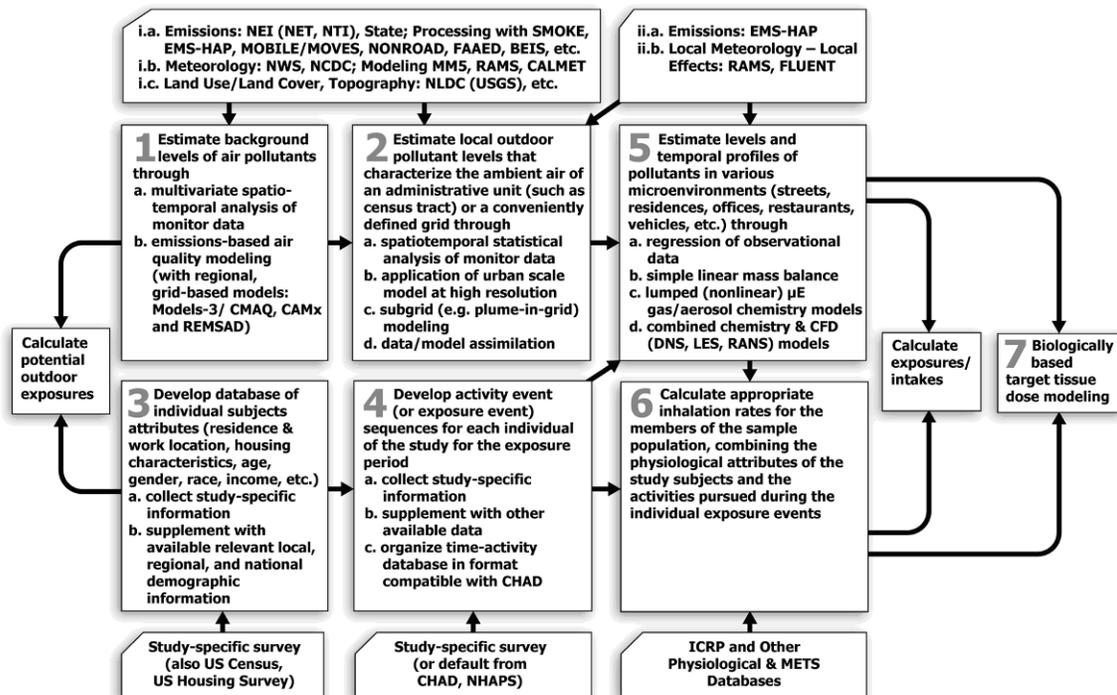

Third, the process of modeling human exposures to photochemical pollutants (traditionally focused on ozone) is very often identified explicitly with population-based modeling, while models describing the specific mechanisms affecting the exposure of an actual individual (at specific locations) to an air contaminant (or to a group of co-occurring gas and/or aerosol phase pollutants) are usually associated with studies focusing specifically on indoor air chemistry modeling.

Finally, fourth, the concept of microenvironments, introduced in earlier sections of this document, should be clarified further, as it is critical in developing procedures for exposure modeling. In the past, microenvironments have typically been defined as individual or aggregate locations (and sometimes even as activities taking place within a location) where a homogeneous concentration of the pollutant is

¹ i.e. Assessments that start from emissions and demographic information and explicitly consider the physical and chemical processes of environmental and microenvironmental transport and fate, in conjunction with human activities, to estimate inhalation intake and uptake.

encountered. Thus a microenvironment has often been identified with an ideal (i.e. perfectly mixed) compartment of classical compartmental modeling. More recent and general definitions view the microenvironment as a control volume, either indoors or outdoors, that can be fully characterized by a set of either mechanistic or phenomenological governing equations, when appropriate parameters are available, given necessary initial and boundary conditions. The boundary conditions typically would reflect interactions with ambient air and with other microenvironments. The parameterizations of the governing equations generally include the information on attributes of sources and sinks within each microenvironment. This type of general definition allows for the concentration within a microenvironment to be non-homogeneous (non-uniform), provided its spatial profile and mixing properties can be fully predicted or characterized. By adopting this definition, the number of microenvironments used in a study is kept manageable, but variability in concentrations in each of the microenvironments can still be taken into account. Microenvironments typically used to determine exposure include indoor residential microenvironments, other indoor locations (typically occupational microenvironments), outdoors near roadways, other outdoor locations, and in-vehicles. Outdoor locations near roadways are segregated from other outdoor locations (and can be further classified into street canyons, vicinities of intersections, etc.) because emissions from automobiles alter local concentrations significantly compared to background outdoor levels. Indoor residential microenvironments (kitchen, bedroom, living room, etc. or aggregate home microenvironment) are typically separated from other indoor locations because of the time spent there and potential differences between the residential environment and the work/public environment.

Once the actual individual and relevant activities and locations (for Individual Based Modeling), or the sample population and associated spatial (geographical) domain (for Population Based Modeling) have been defined along with the temporal framework of the analysis (time period and resolution), the comprehensive modeling of individual/population exposure to NO₂ (and related pollutants) will in general require seven steps (or components, as some of them do not have to be performed in sequence) that are listed below. This list represents a composite based on approaches and frameworks described in the literature over the last twenty-five years (Ott, 1982; Ott, 1985; Liou, 1990; U.S. Environmental Protection Agency, 1992; Georgopoulos and Liou, 1994; U.S. Environmental Protection Agency, 1997; Buck et al., 2003; Price et al., 2003; Georgopoulos et al., 2005; WHO, 2005; U.S. Environmental Protection Agency, 2006a; Georgopoulos and Liou, 2006) as well on the structure of various inhalation exposure models (NEM/pNEM, HAPEM, SHEDS, REHEX, EDMAS, MENTOR, ORAMUS, APEX, AIRPEX, AIRQUIS, etc., to be discussed in the following section) that have been used in the past or in current studies to specifically assess inhalation exposures. Figure AX3.6-1, adapted from Georgopoulos et al. (2005), schematically depicts the sequence of steps involved that are summarized here (and further discussed in the following sub-sections).

Source: Figure adapted with modifications from Georgopoulos et al. (2005).

Figure AX3.6-1. Schematic description of a general framework identifying the processes (steps or components) involved in assessing inhalation exposures and doses for individuals and populations. In general terms, existing comprehensive exposure modeling systems such as SHEDS, APEX, and MENTOR-1A follow this framework.

6. Estimation of the background or ambient levels of both NO_2 and related photochemical pollutants. This is done through either (or a combination of):

- a. multivariate spatio-temporal analysis of fixed monitor data, or
- b. emissions-based, photochemical, air quality modeling (typically with a regional, grid-based model such as Models-3/CMAQ or CAMx) applied in a coarse resolution mode.

7. Estimation of local outdoor pollutant levels of both NO_2 and related photochemical pollutants. These levels could typically characterize the ambient air of either an administrative unit (such as a census tract, a municipality, a county, etc.) or a conveniently defined grid cell of an urban scale air quality model. Again, this may involve either (or a combination of):

- a. spatio-temporal statistical analysis of monitor data, or
- b. application of an urban multi-scale, grid based model (such as CMAQ or CAMx) at its highest resolution (typically around 2-4 km), or
- c. correction of the estimates of the regional model using some scheme that adjusts for observations and/or for subgrid chemistry and mixing processes.

8. Characterization of relevant attributes of the individuals or populations under study (residence and work locations, occupation, housing data, income, education, age, gender, race, weight, and other physiological characteristics). For Population Based Exposure Modeling (PBEM) one can either:

- a. select a fixed-size sample population of virtual individuals in a way that statistically reproduces essential demographics (age, gender, race, occupation, income, education) of the administrative population unit used in the assessment (e.g., a sample of 500 people is typically used to represent the demographics of a given census tract, whereas a sample of about 10,000 may be needed to represent the demographics of a county), or
- b. divide the population-of interest into a set of cohorts representing selected subpopulations where the cohort is defined by characteristics known to influence exposure.

9. Development of activity event (or exposure event) sequences for each member of the sample population (actual or virtual) or for each cohort for the exposure period. This could utilize:

- a. study-specific information, if available
- b. existing databases based on composites of questionnaire information from past studies
- c. time-activity databases, typically in a format compatible with U.S. Environmental Protection Agency's Consolidated Human Activity Database (CHAD - McCurdy et al., 2000)

10. Estimation of levels and temporal profiles of both NO₂ and related photochemical pollutants in various outdoor and indoor microenvironments such as street canyons, roadway intersections, parks, residences, offices, restaurants, vehicles, etc. This is done through either:

- a. linear regression of available observational data sets,
- b. simple mass balance models (with linear transformation and sinks) over the volume (or a portion of the volume) of the microenvironment,
- c. lumped (nonlinear) gas or gas/aerosol chemistry models, or
- d. detailed combined chemistry and Computational Fluid Dynamics modeling.

11. Calculation of appropriate inhalation rates for the members of the sample population, combining the physiological attributes of the (actual or virtual) study subjects and the activities pursued during the individual exposure events.

12. Calculation of target tissue dose through biologically based modeling estimation (specifically, respiratory dosimetry modeling in the case of NO₂ and related reactive photochemical pollutants) if sufficient information is available.

Implementation of the above framework for comprehensive exposure modeling has benefited significantly from recent advances and expanded availability of computational technologies such as Relational Database Management Systems (RDBMS) and Geographic Information Systems (GIS) (Purushothaman and Georgopoulos, 1997, 1999a,b; Georgopoulos et al., 2005).

In fact, only relatively recently comprehensive, predictive, inhalation exposure modeling studies for ozone, PM, and various air toxics, have attempted to address/incorporate all the components of the general framework described here. In practice, the majority of past exposure modeling studies have either incorporated only subsets of these components or treated some of them in a simplified manner, often focusing on the importance of specific factors affecting exposure. Of course, depending on the objective

of a particular modeling study, implementation of only a limited number of steps may be necessary. For example, in a regulatory setting, when comparing the relative effectiveness of emission control strategies, the focus can be on expected changes in ambient levels (corresponding to those observed at NAAQS monitors) in relation to the density of nearby populations. The outdoor levels of pollutants, in conjunction with basic demographic information, can thus be used to calculate upper bounds of population exposures associated with ambient air (as opposed to total exposures that would include contributions from indoor sources) useful in comparing alternative control strategies. Though the metrics derived would not be quantitative indicators of actual human exposures, they can serve as surrogates of population exposures associated with outdoor air, and thus aid in regulatory decision making concerning pollutant standards and in studying the efficacy of emission control strategies. This approach has been used in studies performing comparative evaluations of regional and local emissions reduction strategies in the eastern United States (e.g., Purushothaman and Georgopoulos, 1997; Georgopoulos et al., 1997a; Foley et al., 2003).

AX3.6.1.1. Population Exposure Models

Existing comprehensive inhalation exposure models consider the trajectories of individual human subjects (actual or virtual), or of appropriately defined cohorts, in space and time as sequences of exposure events. In these sequences each event is defined by time, a geographic location, a microenvironment, and the activity of the subject. U.S. Environmental Protection Agency offices (OAQPS and NERL) have supported the most comprehensive efforts in developing models implementing this general concept (see, e.g., Johnson, 2002), and these efforts have resulted in the NEM/pNEM (National Exposure Model and Probabilistic National Exposure Model - Whitfield et al., 1997), HAPEM (Hazardous Air Pollutant Exposure Model - Rosenbaum, 2005), SHEDS (Simulation of Human Exposure and Dose System - Burke et al., 2001), APEX (Air Pollutants Exposure model – U.S. Environmental Protection Agency, 2006b,c), and MENTOR (Modeling Environment for Total Risk studies - Georgopoulos et al., 2005; Georgopoulos and Liroy, 2006) families of models. European efforts have produced some formulations with similar general attributes as the above U.S. models but, generally, involving simplifications in some of their components. Examples of European models addressing exposures to photochemical oxidants (specifically ozone) include the AirPEX (Air Pollution Exposure) model (Freijer et al., 1998), which basically replicates the pNEM approach and has been applied to the Netherlands, and the AirQUIS (Air Quality Information System) model (Clench-Aas et al., 1999).

The NEM/pNEM, SHEDS, APEX, and MENTOR-1A (MENTOR for One-Atmosphere studies) families of models provide exposure estimates defined by concentration and breathing rate for each individual exposure event, and then average these estimates over periods typically ranging from one hour to one year. These models allow simulation of certain aspects of the variability and uncertainty in the principal factors affecting exposure. An alternative approach is taken by the HAPEM family of models that typically provide annual average exposure estimates based on the quantity of time spent per year in each combination of geographic locations and microenvironments. The NEM, SHEDS, APEX, and MENTOR-type models are therefore expected to be more appropriate for pollutants with complex chemistry such as NO₂, and could provide useful information for enhancing related health assessments. More specifically, regarding the consideration of population demographics and activity patterns:

1. pNEM divides the population of interest into representative cohorts based on the combinations of demographic characteristics (age, gender, and employment), home/work district, residential cooking fuel and replicate number, and then assigns activity diary record from CHAD (Consolidated Human Activities Database) to each cohort according to demographic characteristic, season, day-type (weekday/weekend) and temperature.
2. HAPEM6 divides the population of interest into demographic groups based on age, gender and race, and then for each demographic group/day-type (weekday/weekend) combination,

select multiple activity patterns randomly (with replacement) from CHAD and combine them to find the averaged annual time allocations for group members in each census tract for different day types.

3. SHEDS, APEX, and MENTOR-1A generate population demographic files, which contain a user-defined number of person records for each census tract of the population based on proportions of characteristic variables (age, gender, employment, and housing) obtained from the population of interest, and then assign a matching activity diary record from CHAD to each individual record of the population based on the characteristic variables. It should be mentioned that, in the formulations of these models, workers may commute from one census tract to another census tract for work. So, with the specification of commuting patterns, the variation of exposure concentrations due to commuting between different census tracts can be captured.

The essential attributes of the pNEM, HAPEM, APEX, SHEDS, and MENTOR-1A models are summarized in Table AX3.6-1.

The conceptual approach originated by the SHEDS models was modified and expanded for use in the development of MENTOR-1A (Modeling Environment for Total Risk – One Atmosphere). Flexibility was incorporated into this modeling system, such as the option of including detailed indoor chemistry of the O₃-NO_x system and other relevant microenvironmental processes, and providing interactive linking with CHAD for consistent definition of population characteristics and activity events (Georgopoulos et al., 2005).

NEM/pNEM implementations have been extensively applied to ozone studies in the 1980s and 1990s. The historical evolution of the pNEM family of models of OAQPS started with the introduction of the first NEM model in the 1980's (Biller et al., 1981). The first such implementations of pNEM/O₃ in the 1980's used a regression-based relationship to estimate indoor ozone concentrations from outdoor concentrations. The second generation of pNEM/O₃ was developed in 1992 and included a simple mass balance model to estimate indoor ozone concentrations. A report by Johnson et al. (2000) describes this version of pNEM/O₃ and summarizes the results of an initial application of the model to 10 cities. Subsequent enhancements to pNEM/O₃ and its input databases included revisions to the methods used to estimate equivalent ventilation rates, to determine commuting patterns, and to adjust ambient ozone levels to simulate attainment of proposed NAAQS. During the mid-1990's, Environmental Protection Agency applied updated versions of pNEM/O₃ to three different population groups in selected cities: (1) the general population of urban residents, (2) outdoor workers, and (3) children who tend to spend more time outdoors than the average child. This version of pNEM/O₃ used a revised probabilistic mass balance model to determine ozone concentrations over one-h periods in indoor and in-vehicle microenvironments (Johnson, 2001).

In recent years, pNEM has been replaced by (or “evolved to”) the Air Pollution Exposure Model (APEX). APEX differs from earlier pNEM models in that the probabilistic features of the model are incorporated into a Monte Carlo framework (Langstaff, 2007; U.S. Environmental Protection Agency, 2006b,c). Like SHEDS and MENTOR-1A, instead of dividing the population-of-interest into a set of cohorts, APEX generates individuals as if they were being randomly sampled from the population. APEX provides each generated individual with a demographic profile that specifies values for all parameters required by the model. The values are selected from distributions and databases that are specific to the age, gender, and other specifications stated in the demographic profile. Environmental Protection Agency has applied APEX to the study of exposures to ozone and other criteria pollutants; APEX can be modified and used for the estimation of NO₂ exposures, if required.

Reconfiguration of APEX for use with NO₂ or other pollutants would require significant literature review, data analysis, and modeling efforts. Necessary steps include determining spatial scope and resolution of the model; generating input files for activity data, air quality and temperature data; and developing definitions for microenvironments and pollutant-microenvironment modeling parameters (penetration and proximity factors, indoor source emissions rates, decay rates, etc.) (ICF Consulting

2005). To take full advantage of the probabilistic capabilities of APEX, distributions of model input parameters should be used wherever possible.

AX3.6.1.2. Ambient Concentrations of NO₂ and Related Air Pollutants

As mentioned earlier, background and regional outdoor concentrations of pollutants, over a study domain, may be estimated either through emissions-based mechanistic modeling, through ambient-data-based modeling, or through a combination of both. Emissions-based models calculate the spatio-temporal fields of the pollutant concentrations using precursor emissions and meteorological conditions as inputs. The ambient-data-based models typically calculate spatial or spatio-temporal distributions of the pollutant through the use of interpolation schemes, based on either deterministic or stochastic models for allocating monitor station observations to the nodes of a virtual regular grid covering the region of interest. The geostatistical technique of kriging provides various standard procedures for generating an interpolated spatial distribution for a given time, from data at a set of discrete points. Kriging approaches were evaluated by Georgopoulos et al. (Georgopoulos et al., 1997b) in relation to the calculation of local ambient ozone concentrations for exposure assessment purposes, using either monitor observations or regional/urban photochemical model outputs. It was found that kriging is severely limited by the nonstationary character of the concentration patterns of reactive pollutants; so the advantages this method has in other fields of geophysics do not apply here. The above study showed that the appropriate semivariograms had to be hour-specific, complicating the automated reapplication of any purely spatial interpolation over an extended time period.

Spatio-temporal distributions of pollutant concentrations, such as ozone, PM, and various air toxics have alternatively been obtained using methods of the Spatio-Temporal Random Field (STRF) theory (Christakos and Vyas, 1998a,b). The STRF approach interpolates monitor data in both space and time simultaneously. This method can thus analyze information on temporal trends, which cannot be incorporated directly in purely spatial interpolation methods such as standard kriging. Furthermore, the STRF method can optimize the use of data that are not uniformly sampled in either space or time. STRF was further extended within the Bayesian Maximum Entropy (BME) framework and applied to ozone interpolation studies (Christakos and Hristopoulos, 1998; Christakos and Kolovos, 1999; Christakos, 2000). It should be noted that these studies formulate an over-arching scheme for linking air quality with population dose and health effects; however they are limited by the fact that they do not include any microenvironmental effects. MENTOR has incorporated STRF/BME methods as one of the steps for performing a comprehensive analysis of exposure to ozone and PM (Georgopoulos et al., 2005).

Subgrid spatial variability is a major issue with respect to characterizing local concentrations of NO₂. Indeed, the fast rates of the reactions involving the O₃-NO_x system result in significant concentration gradients in the vicinity of sources of NO_x. These gradients are not resolved directly by currently operational grid photochemical air quality simulation models (PAQSMs) such as CMAQ and CAMx. However, both these models include a plume-in-grid. (PinG) option (AER, 2004; Emery and Yarwood, 2005; Gillani and Godowitch, 1999; U.S. Environmental Protection Agency, 2006d) that can be used for large point NO_x sources (such as smokestacks). Nevertheless, PinG formulations typically will resolve gradients in upper atmospheric layers and thus are not necessarily relevant to human exposure calculations, which are affected by gradients caused by a multiplicity of smaller ground level or near ground level combustion sources such as motor vehicles.

Currently PAQSMs are typically applied with horizontal resolutions of 36 km, 12 km, and 4 km and a surface layer thickness that is typically of the order of 30 m. Though computationally it is possible to increase the resolution of these simulations, there are critical limits that reflect assumptions inherent in the governing equations for both (a) the fluid mechanical processes embodied in the meteorological models (e.g., typically MM5 and RAMS) that provide the inputs for the PAQSMs, and (b) the dispersion processes which become more complex at fine scales (see, e.g., Georgopoulos and Seinfeld, 1989) and

thus cannot be described by simple formulations (such as constant dispersion coefficients) when the horizontal resolutions is 2 km or finer.

Application of PAQSMs to urban domains is further complicated by urban topography, the urban heat island, etc. It is beyond the scope, however, of the present discussion, to overview the various issues relevant to urban fluid dynamics and related transport/fate processes of contaminants. However, the issue of modeling subgrid atmospheric dispersion phenomena within complex urban areas in a consistent manner is a very active research area. Reviews of relevant issues and of available approaches for modeling urban fluid mechanics and dispersion can be found in, e.g., Fernando et al. (2001) and Britter and Hanna (2003).

The issue of subgrid variability (SGV) from the perspective of interpreting and evaluating the outcomes of grid-based, multiscale, PAQSMs is discussed in Ching et al. (2006), who suggest a framework that can provide for qualitative judgments on model performance based on comparing observations to the grid predictions and its SGV distribution. From the perspective of Population Exposure Modeling, the most feasible/practical approach for treating subgrid variability of local concentrations is probably through (1) the identification and proper characterization of an adequate number of outdoor microenvironments (potentially related to different types of land use within the urban area as well as to proximity to different types of roadways) and (2) then, concentrations in these microenvironments will have to be adjusted from the corresponding local background ambient concentrations through either regression of empirical data or various types of local atmospheric dispersion/transformation models. This is discussed further in the next subsection.

AX3.6.1.3. Characterization of Microenvironmental Concentrations

Concentrations in microenvironments that can represent either outdoor or indoor settings when individuals come in contact with the contaminant of concern (e.g., NO₂) can be characterized. This process can involve modeling of various local sources and sinks, and interrelationships between ambient and microenvironmental concentration levels. Three general approaches have been used in the past to model microenvironmental concentrations:

- Empirical (typically linear regression) fitting of data from studies relating ambient/local and microenvironmental concentration levels to develop analytical relationships.
- Parameterized mass balance modeling over, or within, the volume of the microenvironment. This type of modeling has ranged from very simple formulations, i.e. from models assuming ideal (homogeneous) mixing within the microenvironment (or specified portions of it) and only linear physicochemical transformations (including sources and sinks), to models incorporating analytical solutions of idealized dispersion formulations (such as Gaussian plumes), to models that take into account aspects of complex multiphase chemical and physical interactions and nonidealities in mixing.
- Detailed Computational Fluid Dynamics (CFD) modeling of the outdoor or indoor microenvironment, employing either a Direct Numerical Simulation (DNS) approach, a Reynolds Averaged Numerical Simulation (RANS) approach, or a Large Eddy Simulation (LES) approach, the latter typically for outdoor situations (see, e.g., Milner et al., 2005; Chang and Meroney, 2003; Chang, 2006).

Parameterized mass balance modeling is the approach currently preferred for exposure modeling for populations. As discussed earlier, the simplest microenvironmental setting corresponds to a homogeneously mixed compartment, in contact with possibly both outdoor/local environments as well as other microenvironments. The air quality of this idealized microenvironment is affected mainly by the following processes:

- a. Transport processes: These can include advection/convection and dispersion that are affected by local processes and obstacles such as vehicle induced turbulence, street canyons, building structures, etc.
- b. Sources and sinks: These can include local outdoor emissions, indoor emissions, surface deposition, etc.
- c. Transformation processes: These can include local outdoor as well as indoor gas and aerosol phase chemistry, such as formation of secondary organic and inorganic aerosols.

Examples of the above are discussed next, specifically for outdoor and for indoor microenvironments.

AX3.6.1.4. Characterization of Outdoor Microenvironments Concentrations

Empirical regression analyses have been used in some studies to relate specific outdoor locations - that can be interpreted as generalized types of exposure microenvironments - to spatial variability of NO₂ concentrations. For example, Gilbert et al. (2005) in May 2003 measured NO₂ for 14 consecutive days at 67 sites across Montreal, Canada. Concentrations ranged from 4.9 to 21.2 ppb (median 11.8 ppb), and they used linear regression analysis to assess the association between logarithmic values of NO₂ concentrations and land-use variables via a geographic information system. In univariate analyses, NO₂ was negatively associated with the area of open space and positively associated with traffic count on nearest highway, the length of highways within any radius from 100 to 750 m, the length of major roads within 750 m, and population density within 2000 m. Industrial land-use and the length of minor roads showed no association with NO₂. In multiple regression analyses, distance from the nearest highway, traffic count on the nearest highway, length of highways and major roads within 100 m, and population density showed significant associations with NO₂. The authors of that study point out the value of using land-use regression modeling to assign exposures in large-scale epidemiologic studies. Similar analyses have been performed in a predictive setting by Sahuvaroglu et al. (2006) for Hamilton, Ontario, Canada.

The category of parameterized mass balance models for outdoor microenvironments includes various local roadway, intersection, and street canyon models. For example, Fraigneau et al. (1995) developed a simple model to account for fast nitrogen oxide – ozone reaction/dispersion in the vicinity of a motorway. Venegas and Mazzeo (2004) applied a combination of simple point and area source analytical plume models to characterize NO₂ concentration patterns in Buenos Aires, Argentina, which they used for a simplified (potential) population exposure study. ROADWAY-2 (Rao, 2002), is another near-highway pollutant dispersion model that incorporates vehicle wake parameterizations derived from canopy flow theory and wind tunnel measurements. The atmospheric velocity and turbulence fields are adjusted to account for velocity-deficit and turbulence production in vehicle wakes and a turbulent kinetic energy closure model of the atmospheric boundary layer is used to derive the mean velocity, temperature, and turbulence profiles from input meteorological data.

In parameterized street canyon models, typically, concentrations of exhaust gases are calculated using a combination of a plume model for the direct contribution and a box model for the recirculating part of the pollutants in the street. Parameterization of flow and dispersion conditions in these models is usually deduced from analysis of experimental data and model tests that considered different street configurations and various meteorological conditions. An example of a current model that belongs in the parameterized mass balance category is the Danish Operational Street Pollution Model (OSPM) (Berkowicz, 2002), which updates earlier formulations of street canyon models such as STREET of Johnson et al. (1973) and CPBM (Canyon Plume-Box Model) of Yamartino and Weigand (1986). A variation of this simple approach is the model of Proyou et al. (1998), which uses a three-layer photochemical box model to represent a street canyon.

A variety of CFD based street canyon models have been developed in recent years (see, e.g., the series of International Conferences on Harmonization - <http://www.harmonization.org>), employing various

alternatives for closure of the turbulent transport equations. A review and intercomparison of five of these models (CHENSI, CHENSI-2, MIMO, MISKAM, TASCflow) vis-a-vis field data from a street canyon in Hannover, Germany can be found in the articles by Sahm et al. (2002) and by Ketzel et al. (2002).

These complex localized models could be useful for improving population exposure model estimates by calculating pollutant concentrations at the microenvironmental level. Lack of input parameter data and parameter variation across the modeling domain (spatial and temporal) contributes to uncertainty in microenvironmental concentrations calculated by exposure models. In such cases, parameterized mass balance models could provide outdoor concentration values for estimating exposure. If infiltration factors are known, these concentrations could also be used to estimate indoor exposures.

AX3.6.1.5. Characterization of Indoor Microenvironments

Numerous indoor air quality modeling studies have been reported in the literature; however, depending on the modeling scenario, only few of them address (and typically only a limited subset of) physical and chemical processes that affect photochemical oxidants indoors (Nazaroff and Cass, 1986; Hayes, 1989, 1991; Freijer and Bloemen, 2000).

It is beyond the scope of the present discussion to review in detail the current status of indoor air modeling. Existing indoor air concentration models indeed are available as a wide range of (a) empirical regression relationships, (b) parameterized mass balance models (that can be either single-zone—that is, single well-mixed room—or multi-zone models), and (c) CFD formulations. Recent overviews of this area can be found in Milner et al. (2005), who focus, in particular, on the issue of entrainment from outdoor sources, and in Teshome and Haghghat, (2004), who focus on different formulations of zonal models and on how they compare with more complex CFD models.

Few indoor air models have considered detailed nonlinear chemistry, which, however, can have a significant effect on the indoor air quality, especially in the presence of strong indoor sources (e.g., gas stores and kerosene heaters, in the case of NO₂). Indeed, the need for more comprehensive models that can take into account the complex, multiphase processes that affect indoor concentrations of interacting gas phase pollutants and particulate matter has been recognized and a number of formulations have appeared in recent years. For example, the Exposure and Dose Modeling and Analysis System (EDMAS) (Georgopoulos et al., 1997c) included an indoor model with detailed gas-phase atmospheric chemistry to estimate indoor concentrations resulting from penetration and reaction of ambient pollutants. This indoor model was dynamically coupled with (a) the outdoor photochemical air quality models UAM-IV and UAM-V, which provided the gas-phase composition of influent air; and (b) with a physiologically based uptake and dosimetry model. Subsequent work (Isukapalli et al., 1999) expanded the approach of the EDMAS model to incorporate alternative representations of gas-phase chemistry as well as multiphase photochemistry and gas/aerosol interactions. The microenvironmental model corresponding to this more general formulation is mathematically represented by the following equation, when an assumption of uniform mixing is used for each component (e.g., individual room) of the indoor environment. Sarwar et al. (2001) presented a more comprehensive modeling study of the gas phase aspects of ozone indoor chemistry focusing on the impact of different factors (such as outdoor ozone, indoor emissions, ventilation rates, etc.) on the levels of indoor hydroxyl radicals (OH), which in turn are expected to control the rate of formation of secondary toxicants indoors.

$$V_i \frac{dC_i^{(m)}}{dt} = \sum_{j=1}^N Q_{ji} C_j^{(m)} - \sum_{j=1}^N Q_{ij} C_i^{(m)} + S_i^{(m)} + \sum_{j=1}^N K_{ji}^{(m)} a_{ji} (C_j^{*(m)} - C_i^{(m)}) + R_i^{(m)} \quad (\text{AX3.6-1})$$

where,

V_i = volume of compartment (m³)

C_i = concentration of species in compartment (mol/m³)

K_{ij} = mass transfer coefficient from compartment (m/h)

a_{ij} = interfacial air exchange area between compartments (m^2)

C_{ij} = concentration in compartment i in equilibrium with concentration in j (mol/m^3)

Q_{ij} = volumetric flow rate from compartment i to j (m^3/h)

R_i = rate of formation of species in compartment i ($gmol/h$)

and,

$$S_i \begin{cases} S_{i,emis} - S_{i,depos} - S_{i,condens} & ; \text{for gases} \\ S_{i,emis} - S_{i,depos} + S_{i,resusp} + S_{i,condens} + S_{i,nucl} + S_{i,coag} & ; \text{for PM} \end{cases} \quad (\text{AX3.6 -2})$$

More recent work (Sørensen and Weschler, 2002) has coupled CFD calculations with gas-phase atmospheric chemistry mechanisms to account for the impact of nonideal flow mixing (and associated concentration gradients) within a room on the indoor spatial distribution of ozone and other secondary pollutants. This work has identified potential limitations associated with the assumption of uniform mixing in indoor microenvironments when calculating personal exposures.

A recent indoor air model that specifically focuses on NO_2 (along with CO, PM_{10} , and $PM_{2.5}$) is INDAIR (Dimitroulopoulou et al., 2006). The INDAIR model considers three interconnected residential microenvironments: kitchen, lounge, and bedroom. Removal processes are lumped together and quantified via an apparent deposition velocity. Specifically, a loss rate of $0.99 \pm 0.19/h$ (Yamanaka, 1984), is used in this model corresponding to a mean deposition velocity of $1.2 \times 10^{-4} m/s$. The sources of NO_2 considered in INDAIR are from gas stove cooking and from cigarette smoking, but only the former contributes significantly to indoor NO_2 levels, based on available model parameterizations.

Estimation of NO_2 emission rates from gas cooking utilized the following empirical information: (a) NO_x emission rate equal to $0.125 g kWh^{-1}$ (Wooders, 1994); (b) an assumption that NO_2 represents 25% of the total NO_x emissions and (c) gas consumption per household in cooking equal to 5–7 kWh/day, assuming 1 h cooking per day. By multiplying the estimates in (a), (b), and (c) together, NO_2 gas cooking emission rates were calculated to be in the range 0.16 to 0.22 g/h, with a uniform distribution.

In a range of simulations performed with INDAIR for houses in the UK, it was found that the predicted maximum 1-h mean concentrations in the kitchen were increased, compared to no-source simulations, by a factor of 10 for NO_2 (30 for PM_{10} and 15 for $PM_{2.5}$) and were higher in winter than in summer. Cooking activity in the kitchen resulted in significantly elevated 24-h mean concentrations of NO_2 , PM_{10} , and $PM_{2.5}$ in the lounge, as well as the kitchen, while there was a relatively small effect in the bedroom, which was not connected directly to the kitchen in the model structure (i.e., the direct internal air exchange rate was zero).

A very wide range of predictions was derived from the INDAIR simulations. The 95th percentile concentrations were typically 50% higher than mean concentrations during periods of average concentration, and up to 100% higher than mean concentrations during concentration peaks, which were associated with cooking emissions. There was approximately a factor of 2 variation in concentrations, and all modeled concentrations were below those outdoors. The effect of cooking was to shift the distribution to the right, but the degree of variation was not greatly increased. This may reflect the fact that for the fixed emission scenarios that were used, the additional variation in emission rates was small compared to that of other factors such as deposition rate and air exchange rate. In this scenario, modeled concentrations in the lounge all remained below those outdoors, but a proportion of kitchens (16%) had modeled values above the outdoor concentration. For the gas-cooking scenario, indoor/outdoor ratios for NO_2 ranged from 0.5 to 0.8 for the bedroom, 0.7 to 1.6 for the lounge and 0.9 to 3.6 for the kitchen. According to Dimitroulopoulou et al. (2006), these results were broadly consistent with indoor/outdoor

ratios reported for the UK. Modeled peak concentrations associated with gas cooking, of about 300 ppb in the kitchen and 100 ppb in the lounge, were also consistent with results from UK studies.

AX3.6.1.6. Characterization of Activity Events

An important development in inhalation exposure modeling has been the consolidation of existing information on activity event sequences in the Consolidated Human Activity Database (CHAD) (McCurdy, 2000; McCurdy et al., 2000). Indeed, most recent exposure models are designed (or have been re-designed) to obtain such information from CHAD which incorporates 24-h time/activity data developed from numerous surveys. The surveys include probability-based recall studies conducted by Environmental Protection Agency and the California Air Resources Board, as well as real-time diary studies conducted in individual U.S. metropolitan areas using both probability-based and volunteer subject panels. All ages of both genders are represented in CHAD. The data for each subject consist of one or more days of sequential activities, in which each activity is defined by start time, duration, activity type (140 categories), and microenvironment classification (110 categories). Activities vary from one min to one h in duration, with longer activities being subdivided into clock-hour durations to facilitate exposure modeling. A distribution of values for the ratio of oxygen uptake rate to body mass (referred to as metabolic equivalents or METs) is provided for each activity type listed in CHAD. The forms and parameters of these distributions were determined through an extensive review of the exercise and nutrition literature. The primary source of distributional data was Ainsworth et al. (1993), a compendium developed specifically to facilitate the coding of physical activities and to promote comparability across studies.

AX3.6.1.7. Characterization of Inhalation Intake and Uptake

Use of the information in CHAD provides a rational way for incorporating realistic intakes into exposure models by linking inhalation rates to activity information. As mentioned earlier, each cohort of the pNEM-type models, or each (virtual or actual) individual of the SHEDS, MENTOR, APEX, and HAPEM4 models, is assigned an exposure event sequence derived from activity diary data. Each exposure event is typically defined by a start time, a duration, assignments to a geographic location and microenvironment, and an indication of activity level. The most recent versions of the above models have defined activity levels using the activity classification coding scheme incorporated into CHAD. A probabilistic module within these models converts the activity classification code of each exposure event to an energy expenditure rate, which in turn is converted into an estimate of oxygen uptake rate. The oxygen uptake rate is then converted into an estimate of total ventilation rate (V_E), expressed in liters/min. Johnson (2001) reviewed briefly the physiological principles incorporated into the algorithms used in pNEM to convert each activity classification code to an oxygen uptake rate and describes the additional steps required to convert oxygen uptake to V_E .

McCurdy (1997a,b, 2000) has recommended that the ventilation rate should be estimated as a function of energy expenditure rate. The energy expended by an individual during a particular activity can be expressed as $EE = (MET)(RMR)$ in which EE is the average energy expenditure rate (kcal/min) during the activity and RMR is the resting metabolic rate of the individual expressed in terms of number of energy units expended per unit of time (kcal/min). MET (the metabolic equivalent of tasks) is a ratio specific to the activity and is dimensionless. If RMR is specified for an individual, then the above equation requires only an activity-specific estimate of MET to produce an estimate of the energy expenditure rate for a given activity. McCurdy et al. (2000) developed distributions of MET for the activity classifications appearing in the CHAD database.

Finally, in order to relate intake to dose delivered to the lungs, it is important to take into account the processes affecting uptake following inhalation intake of NO_2 , in a biologically based dosimetry

modeling framework. As a reactive gas, NO₂ participates in transformation reactions in the lung epithelial lining fluid, and products of these reactions are thought to be responsible for toxic effects (Postlethwait et al., 1991), although kinetic modeling of these reactions has not been performed. Dosimetry models indicate that deposition varies spatially within the lung and that this spatial variation is dependent on ventilation rate (Miller et al., 1982; Overton and Graham, 1995). Controlled exposure studies found that fractional uptake of NO₂ increases with exercises and ventilation rate (e.g., Bauer et al., 1986), making activities with high MET values important for quantifying total NO₂ exposure. Further discussion of NO₂ dosimetry modeling is provided in Section 4.2.

AX3.6.1.8. Issues to be Addressed in Future Exposure Modeling Efforts

An issue that should be mentioned in closing is that of evaluating comprehensive prognostic exposure modeling studies, for either individuals or populations, with field data. Although databases that would be adequate for performing a comprehensive evaluation are not expected to be available any time soon, there have been a number of studies, reviewed in earlier sections of this Chapter, that can be used to start building the necessary information base. Some of these studies report field observations of personal, indoor, and outdoor ozone levels and have also developed simple semi-empirical personal exposure models that were parameterized using the observational data and regression techniques.

In conclusion, though existing inhalation exposure modeling systems have evolved considerably in recent years, limitations of available modeling methods and data, in relation to potential NO₂ studies that include the following, should be taken into account and be addressed by future research efforts:

- Ambient photochemical modeling systems are not optimized for estimating NO₂ at a local scale.
- Subgrid scale modeling (LES, RANS, DNS) is needed to properly characterize effects of nonhomogeneous mixing (i.e., of spatial subgrid variability) on fast nonlinear chemical transformations; the outcomes of this characterization then should be incorporated in simpler models, appropriate for use in conjunction with exposure modeling systems.
- Microenvironmental modeling efforts need to balance mechanistic detail and usability by developing:
 - — A simplified but adequate indoor chemistry mechanism for NO₂ and related oxidants,
 - — Databases of realistic distributions of indoor NO₂ source magnitudes and activities,
 - — Flexible, multi-zonal models of indoor residential and occupational microenvironments.

Existing prognostic modeling systems for inhalation exposure can in principle be directly applied to, or adapted for, NO₂ studies; APEX, SHEDS, and MENTOR-1A are candidates. However, such applications would be constrained by data limitations such as ambient characterization at the local scale and by lack of quantitative information for indoor sources and sinks.

(1998)	Location: Geneva, Basle, Lugano, Aarau, Wald, Payerne, Montana, and Davos (SAPALDIA study, Switzerland) Subjects: 140 subjects Time period: Dec 1993 to Dec 1994 Method: each home was monitored for 3 periods of 1 mo; in the 1st wk of each period, personal, indoor and outdoor levels were measured; for the next 3 wks, only outdoor levels were measured (1-wk averaged measurement).	Overall study seasons	Residential indoor vs. residential outdoor	All homes	0.47 (n = 1544)	R ² was 0.37.
				Homes without smokers and gas-cooking	0.40 (n = 968)	R ² was 0.33.
Spengler et al. (1994)	Location: Los Angeles Basin, CA Subjects: probability-based sample, 70 subjects Time period: May 1987 to May 1988 Method: 48-h averaged, in the micro-environmental component, each participant was monitored during each of 8 sampling cycles throughout the yr.	Overall study seasons	Residential indoor vs. residential outdoor	Gas range with pilot light	0.49 (n = 314)	R ² was 0.44.
				Gas range without pilot light	0.4 (n = 148)	R ² was 0.39.
				Electric stove	0.4 (n = 170)	R ² was 0.41.

Table 3.5-1b. Summary of regression models of personal exposure to ambient/outdoor NO₂

STUDY	LOCATION	SEASON	MODEL TYPE	SLOPE (SE)	INTERCEPT / ppb	R ²
Rojas-Bracho et al. (2002)	Location: Santiago, Chile Subjects: 20 children Time period: winters of 1998 and 1999 Method: five, 24-h avg samples on consecutive days for each child.	Winter	Personal vs. outdoor (n = 87)	0.33 (0.05)	7.2	0.27
Alm et al. (1998)	Location: Helsinki, Finland Subjects: 246 children aged 3-6 yrs Time period: winter and spring of 1991 Method: 1-wk averaged sample for each person, 6 consecutive wks in the winter and 7 consecutive wks in the spring.	Winter + Spring	Population vs. outdoor (n = 23)	0.4	4.7	0.86
Monn et al. (1998)	Location: Geneva, Basle, Lugano, Aarau, Wald, Payerne, Montana, and Davos (SAPALDIA study, Switzerland) Subjects: 140 subjects Time period: Dec 1993 to Dec 1994 Method: each home was monitored for 3 periods of 1 mo; in the 1st wk of each period, personal, indoor and outdoor levels were measured, and in the next 3 consecutive wks, only outdoor levels were measured (1-wk averaged measurement).	All	Personal (all subjects) vs. outdoor (n = 1,494)	0.45	7.2	0.33
			Personal (no smokers and gas cooking) vs. outdoor (n = 943)	0.38	7.2	0.27
Levy et al. (1998b)	Location: 18 cities across 15 countries Subjects: 568 adults Time period: Feb or Mar 1996 Method: One, 48-h avg measurement for each person, all people were measured on the same day.	Winter	Personal vs. outdoor (n = 546)	0.49	14.5	—
Spengler et al. (1994)	Location: Los Angeles Basin Subjects: probability-based sample, 70 subjects Time period: May 1987 to May 1988 Method: in the microenvironmental component of the study, each participant was monitored for 48 h during each of 8 sampling cycles throughout the yr.	All	Personal vs. outdoor	0.56	15.8	0.51
Sørensen et al. (2005)	Location: Copenhagen, Denmark Subjects: 30 subjects (20-33 yrs old) in each measurement campaign Time period: fall 1999, and winter, spring and summer of 2000 Method: four measurement campaigns in 1 yr; each campaign lasted 5 wks with 6 subjects each wk; one 48-h avg NOR2R measurement for each subject.	All	Personal vs. outdoor (n = 73)	0.60 (0.07)	—	—
		(>8 °C)	Personal vs. outdoor (n = 35)	0.68 (0.09)	—	—
		(<8 °C)	Personal vs. outdoor (n = 38)	0.32 (0.13)	—	—
Piechocki-	Location: Pooled, Lille (northern France)	All	Personal vs.	0.13	6.0	0.09

STUDY	LOCATION	SEASON	MODEL TYPE	SLOPE (SE)	INTERCEPT / ppb	R ²
Minguy et al. (2006)	Subjects: 13 participants in the first campaign, and 31 participants in the second campaign Time period: winter 2001 (first campaign), and summer 2002 (second campaign) Method: two 24-h sampling periods (one during the workdays and the other during the weekends) for each subject in each campaign; during each sampling period, each subject received four samplers to measure personal exposure in four different microenvironments (home, other indoor environment, transport, and outdoors).	Summer (homes with no major indoor NOR2R sources)	central (Assuming people stayed indoors all the time)	0.86	19.7	0.61
Sørensen et al. (2005)	Location: Copenhagen Subjects: 30 subjects (20-33 yrs old) in each measurement campaign Time period: fall 1999, and winter, spring and summer of 2000 Method: four measurement campaigns in 1 yr; each campaign lasted 5 wks with 6 subjects each wk; one 48-h avg NOR2R measurement for each subject.	All	Personal vs. central (n = 66)	0.56 (0.09)	—	—
Alm et al. (1998)	Location: Helsinki, Finland Subjects: 246 children aged 3-6 yrs Time period: winter and spring of 1991 Method: 1-wk averaged sample for each person, 6 consecutive wks in the winter and 7 consecutive wks in the spring.	Winter + Spring	Population vs. central (n = 24)	0.3	5.0	0.37
Sarnat et al. (2001)	Location: Baltimore, MD Subjects: 56 seniors, Schoolchildren, and people with COPD Time period: summer of 1998 and winter of 1999 Method: 14 of 56 subjects participated in both sampling seasons; all subjects were monitored for 12 consecutive days (24-h avg sample) in each of the one or two seasons, with the exception of children who were measured for 8 consecutive days during the summer.	Summer	Personal vs. central (n = 225 for 24 subjects)	0.04*	9.5	—
		Winter	Personal vs. central (n = 487 for 45 subjects)	10.05*	18.2	—
Sarnat et al. (2005)	Location: Boston, MA Subjects: 43 seniors and schoolchildren Time period: summer of 1999 and winter of 2000 Method: Similar study design as Sarnat et al., 2001.	Summer	Personal vs. central (n = 341)	0.19	—	—
		Winter	Personal vs. central (n = 298)	10.03*	—	—
Sarnat et al. (2006)	Location: Steubenville Subjects: 15 senior subjects Time period: summer and fall of 2000 Method: two consecutive 24-h samples were collected for each subject for each wk, 23 wks total.	Summer	Personal vs. central (n = 122)	0.25 (0.06)	—	0.14

Table AX3.5-2. NO₂ concentrations (ppb) in different rooms.

STUDY	CONDITIONS	OUTDOOR	KITCHEN	LIVING ROOM	BEDROOM	COMMENTS
Topp et al. (2004)	First visit	12.4	—	7.8	7.2	Indoor and outdoor NO ₂ concentrations for 777 residential homes in five study areas were measured: Erfurt, Hamburg, Zerbst, Bitterfeld and Hettstedt during two visits (from June 1995 to May 1997, and from April 1996 to Sept 1998). In the study, one-week averaged NO ₂ were measured by Palmes tube.
	Second visit	12.5	—	8.0	7.6	
Garrett et al. (1999)	No identified indoor sources	4.7	3.8	3.8	3.0	Garrett (1999) investigated the levels and sources of NO ₂ in Australian homes. During the study, four-day averaged NO ₂ was monitored using Yanagisawa passive samplers in 80 homes in the Latrobe Valley, Victoria in March-April 1994, and Jan-Feb 1995.
	Gas stove homes	4.7	8.0	6.7	6.3	
	Gas heater homes	4.7	7.3	6.9	5.0	
	Smoking homes	4.7	6.6	6.0	5.7	
	Homes with multiple sources	4.7	10.7	14.5	11.2	
Cotterill and Kingham (1997)	Gas Stove homes	20.9	35.6	17.3	11.5	Three consecutive two-week averaged outdoor, kitchen, living room, and bedroom NO ₂ were measured using Palmes tubes in 40 houses in Huddersfield, UK in late 1994. Half the houses were located close to a busy main road and half on residential roads set back and parallel to the main road. The sample was split so that half had gas cookers and half had electric cookers. These subsets were split again so that half had double glazing and half had single glazed windows.
	Electric cooker homes	20.9	9.9	8.9	7.3	
	Gas cooker home with single glazing window	20.9	31.4	16.8	11.0	
	Gas cooker home with double glazing window	20.9	39.8	18.3	12.0	
Zota et al. (2005)	Overall	19	43	36	—	The indoor and outdoor NO ₂ concentrations for low-income, urban neighborhoods were measured, where asthma prevalence is high. NO ₂ was measured in 77 homes within three Boston public housing developments, using Palmes tubes (two-wk integrated sample) placed in the kitchen, living room, and outdoors. Air exchange rate for each home was also measured.
	Heating season	21	50	43	—	
	Non-heating season	17	33	26	—	
Gallelli et al. (2002)	Overall study	—	24.6	—	13.0	During the study, one-wk integrated indoor (kitchen and bedroom) and personal NO ₂ were measured in Genoa, Italy, for 89 subjects with Palmes samplers. Study volunteers included students, workers, and housewives living in three areas of Genoa differing by street traffic and industrial plant location.
	With vent	—	18.1	—	—	
	Without vent	—	30.9	—	—	
Linaker et al. (1996)	Overall study	—	27.2	20.9	—	During the study, one-wk integrated personal, indoor (kitchen, living room), classroom, and playground NO ₂ were measured using Palmes tubes for school children in Southampton.
Kodama et al. (2002)	Feb 1998	40, 31.3	81.8	73.5	55.2	The first number in outdoor column was the ambient concentration in the South Area; and the second number is the ambient concentration in the North Area. During the study, personal, indoor (kitchen, living room, bedroom and study room), and outdoor NO ₂ were measured for 150 junior high school students with Yanagisawa badges in Tokyo. The investigation was conducted five times seasonally, 3 days each, from February 1998 to January 1999.
	June 1998	38, 28	33.2	28.8	24	
	July 1998	29, 26.7	24.8	21.9	17.4	
	Oct 1998	40, 35	23.5	24.7	18.2	
	Jan 1999	49, 50	70.9	65.8	50.7	
Chao and Law (2000)	Overall study	37.6	31.9	28.2	26.4	Personal and indoor exposures were monitored with passive sampler in Hong Kong for 60 subjects. Twelve of the subjects were selected to conduct more detailed study to examine the behavioral and microenvironmental effects on personal exposure to NO ₂ .

Table AX3.5-3a. Average ambient and nonambient contributions to population exposure

STUDY	MODEL TYPE	SLOPE (SE)	INTERCEPT / ppb	MEAN OF PERSONAL TOTAL EXPOSURE / ppb	MEAN AMBIENT CONTRIBUTION / ppb	PERCENT AMBIENT CONTRIBUTION %	PERCENT NONAMBIENT CONTRIBUTION %
Rojas-Bracho et al. (2002)	Personal vs. outdoor	0.33 (0.05)	7.2	36.4	7.2	19.8	80.2
Alm et al. (1998)	Personal vs. central	0.3	5.0	—	5.0	—	—
	Personal vs. outdoor	0.4	4.7	—	4.7	—	—
Monn et al. (1998)	Personal (all subjects) vs. outdoor	0.45	7.2	14.1	7.2	51.1	48.9
	Personal (no smokers and gas cooking) vs. outdoor	0.38	7.2	—	7.2	—	—
Levy et al. (1998a)	Personal vs. outdoor	0.49	14.5	28.8	14.5	50.3	49.7
Spengler et al. (1994)	Personal vs. outdoor	0.56	15.8	37.6	15.8	42.0	58.0

Table AX3.5-4. The association between indoor, outdoor, and personal NO₂:

STUDY	SUMMARY	CONDITION	INDOOR VS. OUTDOOR	PERSONAL VS. INDOOR	PERSONAL VS. OUTDOOR	COMMENTS
Mosqueron et al. (2002)	Simultaneous personal, indoor, and in-office 48-h averaged NO ₂ concentrations were measured with Ogawa badges for 62 people, and ambient concentrations were provided by local air monitoring network.	Overall study	0.07 (partial R ²)	—	—	Gas cooking interpreted another 7% of indoor NO ₂ variation
Emenius et al. (2003)	Palms tubes were used to measure indoor (in the main living room) and outdoor (outside the window of this room) NO ₂ concentrations during a four-wk period (mean 28 days, range 26-31) in the first winter season following recruitment in the case-control study.	Without smoker and gas stove was not used	0.69 (r _p)	—	—	p < 0.001
		With gas stove and with smoker	0.13 (r _p)	—	—	p = 0.43
		With gas stove but without smoker	0.06 (r _p)	—	—	p = 0.75
Lee et al. (1999)	Indoor and outdoor air quality of 14 public places with mechanical ventilation systems in Hong Kong were measured from Oct 1996 to March 1997. Traffic peak h NO, NO ₂ was sampled using Teflon bags and then shipped back to the laboratory for further analysis.	Overall study	0.59 (R ²)	—	—	0.92 for NO and 0.92 for NO _x .

STUDY	SUMMARY	CONDITION	INDOOR VS. OUTDOOR	PERSONAL VS. INDOOR	PERSONAL VS. OUTDOOR	COMMENTS
García-Algar et al. (2003)	Yanagisawa passive filter badges were used to measure indoor NO ₂ concentrations for 7~15 days for 340 homes in Barcelona, Spain during 1996~1999. Outdoor NO ₂ concentrations were obtained from the fixed monitoring stations by the method of CL.	Overall study	0.15 (r _p)	—	—	p = 0.007
Lai et al. (2006)	The study was conducted between 1996 and 2000 in six EU cities: Athens, Basel, Helsinki, Milan, Oxford, and Prague. 48-h averaged indoor and outdoor NO ₂ were collected each home using diffusion tubes for 302 homes.	Overall study	0.13 (partial R ²)	—	—	The overall R ² for the multiple linear regression was 0.67
Lee et al. (2002)	Six-day integrated indoor and outdoor concentrations of NO ₂ were measured in two communities in Southern California using Yanagisawa badges for 119 homes in April and May 1996.	Overall study	0.60 (r _p)	—	—	—
Mukala et al. (2000)	The one-week averaged indoor (day-care center), outdoor (outside day care center) and personal NO ₂ for 162 children aged 3-6 years old nitrogen dioxide exposure were measured by Palmes tube in Helsinki, in 1991.	Spring	0.86 (r _p)	—	—	—
		Winter	0.54 (r _p)	—	—	—
		Spring (ambient vs. indoor)	0.45 (r _p)	—	—	—
		Winter (ambient vs. indoor)	0.36 (r _p)	—	—	—
Garrett et al. (1999)	Four-day averaged NO ₂ was monitored using Yanagisawa passive samplers in 80 homes in the Latrobe Valley, Victoria, Australia in March-April 1994, and Jan-Feb 1995.	Overall study	0.28 (R ²)	—	—	Log10 transformed data
Cotterill and Kingham (1997)	Three consecutive two-week averaged outdoor, kitchen, living room, and bedroom NO ₂ were measured using Palmes tubes in 40 houses in Huddersfield, UK in late 1994. Half the houses were located close to a busy main road and half on residential roads set back and parallel to the main road. The sample was split so that half had gas cookers and half had electric cookers. These subsets were split again so that half had double glazing and half had single glazed windows.	Overall study	0.59 (r _p)	—	—	—
Yang et al. (2004)	Daily indoor and outdoor NO ₂ concentrations were measured for 30 consecutive days in 28 house in Brisbane (between April and May in 1999), and for 21 consecutive days in 37 houses in Seoul (between June and Aug in 2000) using Yanagisawa badges.	Brisbane, electric range house	0.70 (R ²)	—	—	—
		Brisbane, gas range house	0.57 (R ²)	—	—	—
		Seoul, gas range house	0.52 (R ²)	—	—	—
Lai et al. (2004)	During the study, 48-averaged personal, residential indoor, residential outdoor, and workplace indoor pollutants were measured for 50 adults between 1998 and 2000 in Oxford, once per person. NO ₂ were measured using passive sampling badges.	Overall study	0.29 (r _p) (not significant)	0.47 (r _p) (p < 0.01)	-0.41 (r _p) (p < 0.05)	Data were log-transformed
Monn et al. (1998)	During the study, one-wk integrated indoor, outdoor and personal samples were collected for a subpopulation (n = 140) of SAPALDIA study using Palmes tube between Dec 1993 and Dec 1994 at eight study centers in Switzerland.	Overall study	0.37 (R ²)	0.51 (R ²)	0.33 (R ²)	—
		Homes without smoker and without gas-cooking	0.34 (R ²)	0.47 (R ²)	0.27 (R ²)	—

STUDY	SUMMARY	CONDITION	INDOOR VS. OUTDOOR	PERSONAL VS. INDOOR	PERSONAL VS. OUTDOOR	COMMENTS
Levy et al., (1998a)	48-h averaged indoor, outdoor and personal NO ₂ were measured in 18 cities in 15 countries around the world with passive filter badges in Feb or March, 1996.	Overall study	—	0.75 (r _s)	0.57 (r _s)	—
Spengler et al. (1994)	Probability based population, Los Angeles Basin, 48-h averaged indoor, outdoor and personal NO ₂ were measured (microenvironmental component of the study), from May 1987 to May 1988	Overall study	0.4 (R ²)	0.6 (R ²)	0.51 (R ²)	—
		Electric range	0.41 (R ²)	—	0.52 (R ²)	—
		Gas range without pilot light	0.39 (R ²)	—	—	—

Annex 4. Toxicological Effects of NO_x

AX4.1. Pulmonary Effects of NO_x

AX4.1.1. Effects of NO₂ on Oxidant and Antioxidant Metabolism

NO₂ is an oxidant; lipid peroxidation is believed to be a major molecular event responsible for its toxicity. As a result, there has been considerable attention paid to the effect of NO₂ on the antioxidant defense system in the epithelial lining fluid and in pulmonary cells. Repeated exposure to NO₂ at concentrations ranging from 0.04 to 33 ppm has been shown to alter low molecular weight antioxidants such as glutathione, vitamin E, and vitamin C, as well as some enzymes involved in cell oxidant homeostasis.

A number of studies have investigated the hypothesis, originally proposed by Menzel (1970), that antioxidants might protect the lung from NO₂ damage by inhibiting lipid peroxidation (see Table AX4.1). Changes in the activity of enzymes in the lungs of NO₂-exposed animals that regulate levels of glutathione (GSH) have been reported in response to relatively low exposure concentrations. Sagai et al. (1984) studied the effects of prolonged (9 and 18 months) exposure to 0.04, 0.4, and 4.0 ppm NO₂ on rats. After exposure duration, non-protein sulfhydryl levels were increased at 0.4 ppm or greater, and exposure to 4.0 ppm decreased the activity of GSH peroxidase but increased glucose-6-phosphate dehydrogenase activity. Glutathione peroxidase activity was also decreased in rats exposed to 0.4 ppm NO₂ for 18 months. Three GSH S-transferases were also studied, two of which (aryl S-transferase and aralkyl S-transferase) exhibited decreased activities after 18 months of exposure to 0.4 ppm or greater NO₂. No effects were observed on the activities of 6-phosphogluconate dehydrogenase, superoxide dismutase, or disulfide reductase. Effects followed a concentration- and exposure-duration response function. The decreases in glutathione-related enzyme activities were inversely related to the apparent formation of lipid peroxides (see lipid peroxidation subsection). Shorter exposures (4 months) to NO₂ between 0.4 and 4.0 ppm also caused concentration- and duration-dependent effects on antioxidant enzyme activities (Ichinose and Sagai, 1982). For example, glucose-6-phosphate dehydrogenase increased, reaching a peak at 1 month, and then decreased towards the control value. Shorter (2-week) exposure to 0.4 ppm NO₂ caused no such effects in rats or guinea pigs (Ichinose and Sagai, 1989).

The activities of GSH reductase and glucose-6-phosphate dehydrogenase were significantly increased during exposure to 6.2 ppm NO₂ for 4 days; GSH peroxidase activity was not affected (Chow et al., 1974). The possible role of edema and cellular inflammation in these findings was not examined. Since NO₂ had no significant effect on lung GSH peroxidase activity in this study, but did significantly increase the activities of GSH reductase and glucose-6-phosphate dehydrogenase, the authors concluded that NO₂ attacks mainly GSH and NADPH.

Newer studies also identified effects on GSH. Changes in GSH status in the blood and lung (bronchoalveolar lavage (BAL) fluid) occurred in rats exposed to 5 ppm and 10 ppm NO₂ continuously for 24 h, but not for 7 days (Pagani et al., 1994). Total glutathione – total of reduced (GSH) and oxidized (GSSG) form – was significantly increased in blood but not in BAL fluid; however, GSSG was elevated in BAL fluid only. A decreased GSH/GSSG ratio was observed in the blood and BAL fluid, but not in lung type II cells, of rats continuously exposed to 10 ppm NO₂ for 3 or 20 days (Hochscheid et al., 2005). Interestingly, lipid peroxidation was decreased in type II cells at 3 days, but was similar to controls at 20 days. Gene expression, as measured by mRNA levels of the enzymes involved in the biosynthesis of glutathione – gamma-glutamylcysteine synthetase (γ GCS) and glutathione synthetase (GS), decreased at both time points, but gamma-glutamyltranspeptidase (γ GT) mRNA expression increased. No GSH

peroxidase activity (important for hydroperoxide reduction of complex lipids) was detected at 3 days, and was barely detected at 20 days.

Malnutrition of animals can drastically affect their response to toxicants, including NO₂. Experimental interest in this area has mainly focused on dietary lipids, vitamin E and other lipid-soluble antioxidants, and vitamin C and other water-soluble antioxidants. Ayaz and Csallany (1978) exposed vitamin E-deficient and vitamin E-supplemented (30 or 300 mg/kg of diet) weanling mice continuously for 17 months to 0.5 or 1.0 ppm NO₂ and assayed blood, lung, and liver tissues for GSH peroxidase activity. Exposure to 1.0 ppm NO₂ alone or combined with vitamin E deficiency decreased the enzyme activity in the blood and lungs. Neither vitamin E deficiency nor NO₂ exposure affected liver GSH peroxidase activity. However, in vitamin E-supplemented mice, GSH peroxidase activity increased at 0.5 ppm and 1.0 ppm NO₂.

AX4.1.2. Lipid Metabolism and Content of the Lung

Lipid peroxidation is an important mechanism of cell damage arising from changes in cell membrane structure and function. The ability of NO₂ exposure to induce lipid peroxidation in the respiratory tract has been demonstrated; as measured by increased ethane exhalation in the breath, as thiobarbituric acid (TBA) reactive substances in tissues, and as the content of conjugated dienes in tissue homogenates.

A number of studies investigated the effects of NO₂ exposure on lipid metabolism and lipid content of the lung. Lipid peroxidation induced by NO₂ exposure has been detected at exposure concentrations as low as 0.04 ppm. Increased ethane exhalation was observed in rats exposed to 0.04 or 0.12 ppm after 9 and 18 months of exposure (Sagai et al., 1984). Exposure to 0.4 ppm NO₂ for 9 months or longer and to 4.0 ppm for 6 months resulted in increased TBA reactants (Ichinose et al., 1983). NO₂ exposure for shorter durations also increased lipid peroxidation in rats. For example, NO₂ exposure of 1.2 ppm or greater for 1 week (Ichinose and Sagai, 1982; Ichinose et al., 1983) increased ethane exhalation in rats, while exposure of pregnant rats to 0.53 or 5.3 ppm NO₂ for 5 h/day for 21 days resulted in increased lung lipid peroxidation products (Balabaeva and Tabakova, 1985). These results indicate at least some degree of duration-dependence in the formation of lipid peroxidation, with lower effect thresholds identified with longer durations of exposure.

Lipid peroxidation results in altered phospholipid composition, which in turn may adversely affect membrane fluidity and thus, membrane function. Significant depression of lipid content and total content of saturated fatty acids such as phosphatidyl-ethanolamine, lecithin (phosphatidylcholine), phosphatidylinositol, and phosphatidylserine were measured in rats exposed to 2.9 ppm NO₂ for 24 h/day, 5 days/week for 9 months (Arner and Rhoades, 1973). Exposure of rabbits to 1.0 ppm NO₂ for 2 weeks also caused depression of lecithin synthesis after one week of exposure (Seto et al., 1975), while exposure of rats to 5.5 ppm NO₂ for 3 h/day for 7 or 14 days elicited only few changes in lipid metabolism (Yokoyama et al., 1980). In beagle dogs, the amount of unsaturated fatty acids in the phospholipids from the lungs was increased after exposure to concentrations ranging from 5 to 16 ppm, but not to 3 ppm (Dowell et al., 1971). Exposure of either mice or guinea pigs to 0.4 ppm for a week resulted in a decreased concentration of phosphatidylethanolamine and a relative increase in the phosphatidylcholine concentration (Sagai et al., 1987). Concentration- and exposure duration-dependent increases were reported in phospholipid components in BAL fluid, when rats were exposed to 10 ppm NO₂ continuously for 1 day or 3 days (Müller et al., 1994).

Functional studies conducted on surfactant phospholipid extracts indicated that NO₂ exposures of 5 ppm or greater, directly impaired surface tension, although the structure of the surfactant protein A (SP-A) was not altered by NO₂ exposure. Changes in the phospholipid composition of membranes may result in disruption of the cell membrane barrier. Müller et al. (2003) found that uptake of liposomes by type II lung cells occurred more easily from animals exposed to 10 ppm NO₂ for 3 to 28 days, possibly as a result of increased demand of phosphatidylcholine during lung injury.

Lipid peroxidation can also activate phospholipases. Activation of phospholipase A1 in cultured endothelial cells occurred at 5 ppm after 40 h of exposure and was speculated to depend on a specific NO₂-induced increase in phosphatidyl serine in the plasma membranes (Sekharam et al., 1991).

One function of phospholipases is the release of arachidonic acid (AA), which serves as a mediator of inflammatory response. NO₂ exposure affects the release and metabolism of arachidonic acid both in vivo and in vitro. The products of arachidonic acid metabolism, such as prostaglandins, prostacyclin, thromboxanes, and leukotrienes play an important role (such as recruitment of neutrophils to sites of local irritation) in modulating inflammatory response. Schlesinger et al. (1990) reported elevated concentrations of thromboxane B2 (TxB₂) following NO₂ exposures of 1.0 ppm for 2 h, depressed concentrations at 3.0 ppm, and significant depression 24-h postexposure at 10 ppm NO₂. The same investigators also reported depressed level of 6-keto-prostaglandin F1 α at 1.0 ppm NO₂, but exposure to NO₂ did not affect prostaglandins E2 and F2 and leukotriene B4 (LTB₄) levels.

Changes in activation of arachidonate metabolism were also reported in rat alveolar macrophages (AMs) when these animals were exposed to 0.5 ppm NO₂ for 0.5, 1, 5, and 10 days (Robison et al., 1993). Unstimulated AM synthesis of LTB₄ was depressed after 0.5 days and again after 5 days of exposure to NO₂. Alveolar macrophage production of TxB₂, LTB₄, and 5-hydroxyeicosatetraenoic acid (5-HETE) in response to stimulation with the calcium ionophore, A23187, was depressed after 0.5 days of exposure and recovered to air-control values with longer exposure periods. 5-HETE levels were increased after 10 days of exposure. However, AM production of LTB₄ in response to zymosan-activated rat serum was depressed only after 5 days of exposure.

The effects of NO₂ on structural proteins of the lungs have been of concern because elastic recoil is lost after exposure. Collagen synthesis rates were increased in rats exposed to NO₂ concentrations as low as 5.0 ppm NO₂. It has been assumed that increased collagen synthesis reflect increases in total lung collagen which, if sufficient, could result in pulmonary fibrosis after longer periods of exposure. Such correlation has yet to be confirmed by in vivo studies involving NO₂ exposure.

Alterations in xenobiotic metabolism pathways following NO₂ exposure are also summarized in Table AX4.2, in addition to changes in phase I enzymes (such as cytochrome P450s) and phase II enzymes (GST as described earlier). While these changes are not necessarily toxic manifestations of NO₂ per se, such changes may impact the metabolism and toxicity of other chemicals. Glycolytic pathways may also be affected. For example, glycolytic metabolism was increased by NO₂ exposure, possibly due to a concurrent increase in type II cells (Mochitate et al., 1985).

AX4.1.3. Lung Host Defense, Lung Permeability and Inflammation, Immune Responses, and Infectious Agents

Impaired lung host-defenses, increased risk of susceptibility to both viral and bacterial agents, as well as increased lung permeability and inflammation, provide some important evidence for mechanisms of action potentially underlying the health effects observed in epidemiology studies. These effects are discussed in Chapter 3 but study details are provided in Tables AX 4.3, 4.4, 4.5, and 4.6.

AX4.1.4. Emphysema Following NO₂ Exposure

Emphysema as a result of chronic exposure to NO₂ has been reported in animal studies. The definition of emphysema has changed over time; thus, it is important to compare the findings of studies using the current definition of emphysema. U.S. Environmental Protection Agency (1993) evaluated animal studies reporting emphysema caused by or in response to chronic exposure to NO₂ based upon the most recent definition of emphysema from the report of the National Heart, Lung and Blood Institute (NHLBI), Division of Lung Diseases Workshop (Snider et al., 1985), and U.S. Environmental Protection Agency (1993). Because the focus of this document is an extrapolation from NO₂ exposure to potential

hazard for humans, only those studies reporting emphysema of the type seen in human lungs were included AQCD (1993).

Humanlike emphysema linked to > 5 ppm NO₂ exposure was reported by Haydon et al. (1967) in rabbits and rats (Freeman et al., 1972; Barth et al., 1995). See Annex Table AX4.7 for more recent studies linking NO₂ exposure and lung structure changes.

AX4.1.5. Lung Function

Lung function is discussed extensively in Section 3.1.5 of the ISA. The limited animal toxicology data is presented in Table AX4.8.

AX4.1.6. Nitrates (NO₃⁻)

Busch et al. (1986) exposed rats and guinea pigs with either normal lungs or elastase-induced emphysema to ammonium nitrate aerosols at 1 mg/m³ for 6 h/day, 5 days/week for 4 weeks. Using light and electron microscopy, the investigators concluded that there were no significant effects of exposure on lung structure.

AX4.2. Dosimetry of Inhaled NO_x

This section provides an overview of NO₂ dosimetry and updates information provided in the 1993 AQCD for NO_x. Dosimetry of NO₂ refers to the measurement or estimation of the amount of NO₂ or its reaction products reaching and persisting at specific sites in the respiratory tract following an exposure. NO₂, classified as a reactive gas, interacts with surfactants, antioxidants, and other compounds in the epithelial lining fluid (ELF). The compounds thought responsible for adverse pulmonary effects of inhaled NO₂ are the reaction products themselves or the metabolites of these products in the ELF. At the time of the 1993 NO_x AQCD, it was thought that inhaled NO₂ probably reacted with the water molecules in the ELF to form nitrous acid (HNO₂) and nitric acid (HNO₃). However, some limited data suggested that the absorption of NO₂ was linked to reactive substrates in the ELF and subsequent nitrite production. Since then, the reactive absorption of NO₂ has been examined in a number of studies (see Section 4.2.2). These studies have characterized the absorption kinetics and reactive substrates for NO₂ delivered to various sites in the respiratory tract. Researchers have attempted to obtain a greater understanding of how these complex interactions affect NO₂ absorption and NO₂-induced injury.

With respect to quantifying absolute NO₂ absorption, the following were reported in the 1993 NO_x AQCD. The principles of O₃ uptake were generally assumed applicable for NO₂ modeling studies. The results indicated that NO₂ is absorbed throughout the lower respiratory tract, but the major delivery site is the centriacinar region, i.e., the junction between the conducting and respiratory airways in humans and animals. Experimental studies have found that the total respiratory tract uptake in humans ranges from 72 to 92% depending on the study and the breathing conditions. The percent total uptake increases with increasing exercise level. In laboratory animals, upper respiratory tract uptakes ranged from as low as 25% to as high as 94% depending on the study, species, air flow rate, and mode of breathing (nasal or oral). Upper respiratory tract uptake of NO₂ was found to decrease with increasing ventilation. Uptake during nasal breathing was determined to be significantly greater than during oral breathing.

AX4.2.1. Mechanisms of NO₂ Absorption

The ELF is the initial barrier against NO₂ delivery to the underlying epithelial cells. Postlethwait and Bidani (1990) suggested that acute NO₂ uptake in the lower respiratory tract was rate limited by chemical reactions of NO₂ with ELF constituents rather than by gas solubility in the ELF. Subsequently, Postlethwait et al. (1991) reported that inhaled NO₂ (10 ppm) did not penetrate the ELF to reach underlying sites and suggested that cytotoxicity may be due to NO₂ reactants formed in the ELF. Since then, the reactive absorption of NO₂ has been examined in a number of studies that have sought to identify reactive substrates for NO₂ and quantify the absorption kinetics of NO₂ in the respiratory tract.

Postlethwait and Bidani (1994) concluded that the reaction between NO₂ and water does not significantly contribute to the absorption of inhaled NO₂. Uptake is a first-order process for NO₂ concentrations less than 10 ppm, is aqueous substrate-dependent, and is saturable. The absorption of inhaled NO₂ is thought to be coupled with free radical-mediated hydrogen abstraction to form HNO₂ and an organic radical (Postlethwait and Bidani, 1989, 1994). At physiologic pH, the HNO₂ subsequently dissociates to H⁺ and nitrite (NO₂⁻). The concentration of the resulting nitrite is thought insufficient to be toxic, so effects are thought to be due to the organic radical and/or the proton load. Nitrite may enter the underlying epithelial cells and blood. In the presence of red blood cells, nitrite is oxidized to nitrate (NO₃⁻) (Postlethwait and Mustafa, 1981). Beyond cell susceptibility and the concentration of NO₂ in the lumen, site-specific injury was proposed to depend on rate of 'toxic' reaction product formation and the quenching of these products within the ELF. Related to the balance between reaction product formation and removal, it was further suggested that cellular responses may be nonlinear with greater responses being possible at low levels of NO₂ uptake versus higher levels of uptake. Since the ELF may vary throughout the respiratory tract, the uptake of inhaled NO₂ and reaction with constituents of the pulmonary ELF may be related to the heterogeneous distribution of epithelial injury observed from NO₂ exposure.

Postlethwait et al. (1995) sought to determine the absorption substrates for NO₂ in the ELF lavaged from male Sprague-Dawley rats. Since the bronchoalveolar lavage fluid (BALF) collected from the rats may be diluted up to 100-fold relative to the native ELF, the effect of concentrating the BAL fluid on NO₂ absorption was investigated. A linear association was found between the first-order rate constant for NO₂ absorption and the concentration of the BALF. This suggested that concentration of the reactive substrates in the ELF determines the rate of NO₂ absorption. The absorption due to specific ELF constituents was also examined in chemically pure solutions. Albumin, cysteine, reduced GSH, ascorbic acid, and uric acid were hydrophilic moieties found to be active substrates for NO₂ absorption. Unsaturated fatty acids (such as oleic, linoleic, and linolenic) were also identified as active absorption substrates and thought to account for up to 20% of NO₂ absorption. Vitamins A and E exhibited the greatest reactivity of the substrates that were examined. However, the low concentrations of uric acid and vitamins A and E were thought to preclude them from being appreciable substrates *in vivo*. The authors concluded that ascorbate and GSH were the primary NO₂ absorption substrates in rat ELF. Postlethwait et al. (1995) also found that the pulmonary surfactant, dipalmitoyl phosphatidylcholine, was not an effective substrate for NO₂ absorption. Later, Connor et al. (2001) suggested that dipalmitoyl phosphatidylcholine may actually inhibit NO₂ absorption.

In Vitro

In a subsequent study, Velsor and Postlethwait (1997) investigated the mechanisms of acute epithelial injury from NO₂ exposure. The impetus for this work was to evaluate the supposition that NO₂ reaction products rather than NO₂ itself caused epithelial injury. Red blood cell membranes were immobilized to the bottom of Petri dishes, covered with a variety of well characterized aqueous layers, and exposed to gaseous NO₂ (10 ppm for 20 min). The study focused on the potential roles of GSH and ascorbic acid reaction products in mediating cellular injury. Based on negligible membrane oxidation when covered with only an aqueous phosphate buffer, the diffusive/reactive resistance of a thin aqueous

layer clearly prevented direct interaction between NO₂ and the underlying membrane. The presence of unsaturated fatty acids was not observed to affect NO₂ absorption, but a sufficiently thin liquid layer was required for membrane oxidation to occur. Interestingly, membrane oxidation was not a simple monotonic function of GSH and ascorbic acid levels. The maximal levels of membrane oxidation were observed at low antioxidant levels versus null or high antioxidant levels. Glutathione and ascorbic acid related membrane oxidation were superoxide and hydrogen peroxide dependent, respectively. The authors suggested that at the higher antioxidant concentrations, there was increased absorption of NO₂, but little secondary oxidation of the membrane because the reactive species (e.g., superoxide and hydrogen peroxide) generated during absorption were quenched. At the low antioxidant concentrations, there was a lower rate of NO₂ absorption, but oxidants were not quenched and so were available to interact with the cell membrane.

Humans (In Vivo)

Kelly et al. (1996a) examined the effect of a 4-h NO₂ (2 ppm) exposure on antioxidant levels in bronchial lavage fluid (BLF) and BALF of 44 healthy nonsmoking adults (19-45 year, median 24 years). Subjects were randomly assigned to three groups and lavaged at either 1.5-h (n = 15), 6-h (n = 15), or 24-h (n = 14) after the NO₂ exposure. The baseline concentrations of uric acid and ascorbic acid were strongly correlated between the BLF and BALF within individuals (r = 0.88, p < 0.001; r = 0.78, p = 0.001; respectively), whereas the concentrations of GSH in the BLF and BALF were not correlated. Uric acid levels in both lavage fractions were significantly reduced at 1.5-h (p < 0.04), significantly increased at 6-h (p < 0.05), and back to baseline at 24-h postexposure. A statistically significant loss of ascorbic acid was also found in both lavage fractions at 1.5-h (p < 0.05). At 6 and 24-h postexposure, the ascorbic acid levels had returned to baseline. In contrast, GSH levels were significantly increased at both 1.5-h (p < 0.01) and 6-h (p < 0.03) in BLF. At 24 h postexposure, the GSH levels in BLF returned to baseline. Although GSH in BLF increased at 1.5 and 6 h postexposure, oxidized GSH levels remained similar to baseline in both BLF and BALF. No changes in BALF levels of GSH were observed at any time point.

Humans (Ex Vivo)

The depletion of uric acid and ascorbic acid, but not GSH has also been observed with ex vivo exposure of human BALF to NO₂. Kelly et al. (1996b) collected BALF from male lung cancer patients (n = 16) and exposed the BALF ex vivo at 37°C to NO₂ (0.05 to 2.0 ppm; 4 h) or O₃ (0.05 to 1.0 ppm; 4 h). Kelly and Tetley (1997) also collected BALF from lung cancer patients (n = 12, 54 ± 16 years) and exposed the BALF ex vivo to NO₂ (0.05 to 1.0 ppm; 4 h). Both studies found that NO₂ depletes uric acid and ascorbic acid, but not GSH from BALF. Kelly et al. (1996b) noted a differential consumption of the antioxidants with uric acid loss being greater than that of ascorbic acid which was lost at a much greater rate than GSH. Kelly and Tetley (1997) found that the rates of uric acid and ascorbic acid consumption were correlated with their initial concentrations in the BAL fluid, such that higher initial antioxidant concentrations were associated with a greater rate of antioxidant depletion. Illustrating the complex interaction of antioxidants, these studies also suggest that GSH oxidized by NO₂ may be again reduced by uric acid and/or ascorbic acid.

AX4.2.2. Regional and Total Respiratory Absorption of NO₂

There has been very limited work related to the quantification of NO₂ uptake since the 1993 NO_x AQCD. As a result, there is an abbreviated discussion here of some papers that were previously reviewed.

AX4.2.2.1. Dosimetry Models

There is a paucity of theoretical studies investigating NO₂ dosimetry. Like O₃, NO₂ is highly reactive in ELF and is not very soluble. An O₃ model has been utilized to predict the uptake of NO₂ in the lower respiratory tract of humans, rats, guinea pigs, and rabbits (Miller et al., 1982; Overton, 1984). In this model, there was a strong distinction between uptake and dose. Uptake referred to the amount of NO₂ being removed from gas phase per lung surface area (μg/cm²), whereas, dose referred to the amount of NO₂ per lung surface area (μg/cm²) that diffused through the ELF and reached the underlying tissues. These investigators assessed NO₂ uptake and dose on a breath by breath basis. Miller et al. (1988) provided uptake and dose rates (μg/cm²-min) for O₃ in the same species.

Miller et al. (1982) and subsequently Overton (1984) did not attempt to predict the amount of reactants in the ELF or the transport of reactants to the tissues. Rather, they focused mainly on the sensitivity of NO₂ tissue dose on NO₂ reaction rates in the ELF and the Henry's law constant. Reaction rates of NO₂ in the ELF were varied from zero, 50%, and 100% of the reaction rate for O₃ in ELF. The Henry's law constant was varied from half to double the Henry's law constant for NO₂ in water at 37 °C. Effects of species, lung morphology, and tidal volume (V_T) were also examined. In general, the model predicted that NO₂ is taken up throughout the lower respiratory tract. In humans, NO₂ uptake was fairly constant from the trachea to the terminal bronchioles, beyond which uptake decreased with distal progression. This pattern of NO₂ uptake predicted for humans is very similar to the pattern of O₃ uptake per unit time predicted for humans, rats, rabbits, and guinea pigs by Miller et al. (1988). Thus, it is reasonable to expect that the pattern NO₂ uptake per unit time will also be similar between these species. The NO₂ tissue dose was highly dependent on the Henry's law constant and reaction rate in the ELF. In the conducting airways, the NO₂ tissue dose decreased as the Henry's law constant increased (i.e., decreased gas solubility), whereas the NO₂ tissue dose in the alveolar region increased. The site of maximal NO₂ tissue dose was fairly similar between species, ranging from the first generation of respiratory bronchioles in humans to the alveolar ducts in rats. In guinea pigs and rabbits, the maximal NO₂ tissue dose was predicted to occur in the last generation of respiratory bronchioles. Based on Miller et al. (1988), the dose rate of NO₂ is also expected to be similar between species. The simulations also showed that exercise increases the NO₂ tissue dose in the pulmonary region relative to rest. Miller et al. (1982) also reported that increasing the NO₂ reaction rate decreased NO₂ tissue dose in the conducting airways, but had no effect on the dose delivered to the pulmonary region.

Simultaneously occurring diffusion and chemical reactions in the ELF have been suggested as the limiting factors in O₃ (Santiago et al., 2001) and NO₂ uptake (Postlethwait and Bidani, 1990). Hence, Miller et al. (1982) should have found an increase in the uptake of NO₂ in the conducting airways with increasing the rate of chemical reactions in the ELF. This increase in NO₂ uptake in the conducting airways would then lead to a reduction in the amount of NO₂ reaching and taken up in the pulmonary region. The Miller et al. (1982) model considered reactions of NO₂ with constituents in the ELF as protective in that these reactions reduced the flux of NO₂ to the tissues. Others have postulated that NO₂ reactants formed in the ELF, rather than NO₂ itself, could actually cause adverse responses (Overton, 1984; Postlethwait and Bidani, 1994; Velsor and Postlethwait, 1997).

Overton and Graham (1995) examined NO₂ uptake in an asymmetric anatomic model of the rat lung. The multiple path model of Overton and Graham (1995) allowed for variable path lengths from the trachea to the terminal bronchioles, whereas Miller et al. (1982) used a single or typical path model of the conducting airways. The terms "dose" and "uptake" were used synonymously to describe the amount of NO₂ gas lost from the gas phase in a particular lung region or generation by Overton and Graham (1995). Reactions of NO₂ in the ELF were not explicitly considered. Their simulations were conducted for rats breathing at 2 mL V_T at a frequency of 150 breaths per minute. The mass transfer coefficients of 0.173, 0.026, and 0.137 cm/sec were assumed for the upper respiratory tract, the tracheobronchial airways, and the pulmonary region, respectively. Uptake was predicted to decrease with distal progression into the lung. In general, the modeled NO₂ dose varied among anatomically equivalent ventilatory units as a

function of path length from the trachea with shorter paths showing greater dose. A sudden increase in NO₂ uptake was predicted in the proximal alveolar region (PAR) which was due to the increase in the assumed mass transfer coefficient relative to the adjacent terminal bronchiole. Overton et al. (1996) showed that increasing the mass transfer coefficient of the tracheobronchial airways decreased the dose to the PAR and vice versa. Additionally, the PAR dose would also be reduced by the more realistic modeling of tracheobronchial airways expansion during inspiration versus the static condition employed by Overton and Graham (1995).

More recently, two studies examined the influence of age on reactive gas dosimetry in humans (Ginsberg et al., 2005; Sarangapani et al., 2003). Both studies specifically considered the dosimetry O₃ during light activity (on average) in their analysis. It is assumed here that their general findings should also be applicable to NO₂. Sarangapani et al. (2003) used a physiologically based pharmacokinetic model and found that regional uptake of O₃ is relatively insensitive to age (range: infants to elderly). Ozone uptake per unit surface area was 2- to 8-fold higher in infants compared to adults. However, this finding (i.e., uptake per unit surface area) is a less informative expression of dose than the rate of uptake per unit surface area. The rate of uptake, obtained by multiplying by the ventilation rate, adjusts for the greater rate of gas intake by adults relative to children. Ginsberg et al. (2005) utilized the U.S. EPA (1994) reference concentration methodology and found no effect of age (infants vs. adults) on the uptake rate of O₃ per unit surface area.

In summary, these modeling studies predict that the net NO₂ dose (NO₂ flux to air-liquid interface) is relatively constant from the trachea to the terminal bronchioles and then rapidly decreases in the pulmonary region. The pattern of net NO₂ dose rate or uptake rate is expected to be similar between species and unaffected by age in humans. The predicted tissue dose and dose rate of NO₂ (NO₂ flux to liquid-tissue interface) is low in the trachea, increases to a maximum in the terminal bronchioles and the first generation of the pulmonary region, and then decreases rapidly with distal progression. The site of maximal NO₂ tissue dose is predicted to be fairly similar between species, ranging from the first generation of respiratory bronchioles in humans to the alveolar ducts in rats. The production of toxic NO₂-reactants in the ELF and the movement of the reactants to the tissues have not been modeled.

AX4.3. Experimental Studies of NO₂ Uptake

AX4.3.1. Upper Respiratory Tract Absorption

The nasal uptake of NO₂ has been experimentally measured in dogs, rabbits, and rats under conditions of unidirectional flow. Yokoyama (1968) reported $42.1 \pm 14.9\%$ (Mean \pm SD) uptake of NO₂ in the isolated nasal passages of two dogs (3.5 L/min) and three rabbits (0.75 L/min) exposed to 4 and 41 ppm NO₂. Uptake did not appear to depend on the exposure concentration and was relatively constant over a 10 to 15 min period. Cavanagh and Morris (1987) measured uptakes of 28% and 25% uptake of NO₂ (40.4 ppm) in the noses of four naive and four previously exposed rats (0.10 L/min), respectively. Uptake was not affected by a 4-h prior exposure (naive versus previously exposed rats) to 40.4 ppm NO₂ and was constant over the 24-min period during which uptake was determined.

Kleinman and Mautz (1991) measured the penetration of NO₂ through the upper airways during inhalation in six tracheotomized dogs exposed to 1.0 or 5.0 ppm NO₂. Uptake in the nasal passages was significantly greater at 1.0 ppm than at 5.0 ppm, although the magnitude of this difference was not reported. The mean uptake of NO₂ (1.0 ppm) in the nasal passages decreased from 55% to 40% as the ventilation rate increased from about 2 to 8 L/min. During oral breathing, uptake was not dependent on concentration. The mean oral uptake of NO₂ (1.0 and 5.0 ppm) decreased from 65% to 30% as the ventilation rate increased from 2 to 8 L/min.

AX4.3.2. Lower Respiratory Tract Absorption

Postlethwait and Mustafa (1989) investigated the effect of exposure concentration and breathing frequency on the uptake of NO₂ in isolated perfused rat lungs. To evaluate the effect of exposure concentration, the lungs were exposed to NO₂ (4 to 20 ppm) while ventilated at 50 breaths/min with a V_T of 2.0 mL. To examine the effect of breathing frequency, the lungs were exposed to NO₂ (5 ppm) while ventilated at 30-90 breaths/min with a V_T of 1.5 mL. All exposures were for 90 min. The uptake of NO₂ ranged from 59 to 72% with an average of 65% and was not affected by exposure concentration or breathing frequency. A combined regression showed a linear relationship between NO₂ uptake and total inspired dose (25 to 330 µg NO₂). Illustrating variability in NO₂ uptake measurements, Postlethwait and Mustafa (1989) observed 59% NO₂ uptake in lungs ventilated at 30 breaths/min with a V_T of 1.5 mL, whereas, Postlethwait and Mustafa (1981) measured 35% NO₂ uptake for the same breathing condition. In another study, 73% uptake of NO₂ was reported for rat lungs ventilated 50 breaths/min with a V_T of 2.3 mL (Postlethwait et al., 1992). It should be noted that typical breathing frequencies are around 80, 100, and 160 breaths/min for rats during sleep, rest, and light exercise, respectively (Winter-Sorkina and Cassee, 2002). Hence, the breathing frequencies at which NO₂ uptake has been measured are lower than for rats breathing normally.

In addition to measuring upper respiratory tract uptakes, Kleinman and Mautz (1991) also measured NO₂ uptake in the dog lung. In general, there was about 90% NO₂ uptake in the lungs which was independent of ventilation rates from 3 to 16 L/min.

AX4.3.3. Total Respiratory Tract Absorption

Bauer et al. (1986) measured the uptake of NO₂ (0.3 ppm) in 15 adult asthmatics exposed for 30 min (20 min at rest, then 10 min exercising on a bicycle ergometer) via a mouthpiece during rest and exercise. There was a statistically significant increase in uptake from 72% during rest to 87% during exercise. The minute ventilation also increased from 8.1 L/min during rest to 30.4 L/min during exercise. Hence, exercise increased the uptake exposure rate of NO₂ by 5-fold in these subjects. In an earlier study of seven healthy adults in which subjects were exposed to a nitric oxide (NO)/NO₂ mixture containing 0.29 to 7.2 ppm NO₂ for brief (but unspecified) periods, Wagner (1970) reported that NO₂ uptake increased from 80% during normal respiration (V_T, 0.4 L) to 90% during maximal respiration (V_T, 2 to 4 L).

Kleinman and Mautz (1991) also measured the total respiratory tract uptake of NO₂ (5 ppm) in female beagle dogs while standing at rest or exercising on a treadmill. The dogs breathed through a small face mask. Total respiratory tract uptake of NO₂ was 78% during rest and increased to 94% during exercise. In large part, this increase in uptake may be due to the increase in V_T from 0.18 L during rest to 0.27 L during exercise. Coupled with an increase in minute ventilation from 3.8 L/min during rest to 10.5 L/min during exercise, the uptake rate of NO₂ was 3-fold greater for the dogs during exercise than rest.

AX4.4. Metabolism, Distribution and Elimination of NO₂

As stated earlier, NO₂ absorption is coupled with nitrous acid (HNO₂) formation, which subsequently dissociates to H⁺ and nitrite (NO₂⁻). Nitrite enters the underlying epithelial cells and subsequently the blood. In the presence of red blood cells and possibly involving oxyhemoglobin, nitrite is oxidized to nitrate (NO₃⁻) (Postlethwait and Mustafa, 1981). Nitrate may subsequently be excreted in the urine. There has been concern that inhaled NO₂ may lead to N-nitrosamine production, many of which are carcinogenic, since NO₂ can produce nitrite and nitrate (in blood). Nitrate can be converted to nitrite by bacterial reduction in saliva, the gastrointestinal tract, and the urinary bladder. Nitrite has been found

to react with secondary amines to form N-nitrosamines. This remains speculative since nitrosamines are not detected in tissues of animals exposed by inhalation to NO₂ unless precursors to nitrosamines and/or inhibitors of nitrosamine metabolism are co-administered. Rubenchik et al. (1995) could not detect N-nitrosodimethylamine (NDMA) in tissues of mice exposed to 4 to 4.5 ppm NO₂ for 1 h. However, NDMA was found in tissues if mice were simultaneously given oral doses of amidopyrine and 4-methylpyrazole, an inhibitor of NDMA metabolism. Nevertheless, the main source of NO₂ in the body is formed endogenously, and food is also a contributing source of nitrite from the conversion of nitrates. Thus, the relative importance of inhaled NO₂ to N-nitrosamine formation has yet to be demonstrated.

Metabolism of inhaled NO₂ may also transform other chemicals that may be present in the body, in some cases into mutagens and carcinogens. Van Stee et al. (1983) reported N-nitrosomorpholine (NMOR), production in mice gavaged with 1 g of morpholine/kg body weight per day and then exposed (5-6 h daily for 5 days) to 16.5 to 20.5 ppm NO₂. N-nitrosomorpholine is a nitrosamine that is a potent animal carcinogen. The single site containing the greatest amount of NMOR was the gastrointestinal tract. Later, Van Stee et al. (1995) exposed mice to approximately 20 ppm ¹⁵NO₂ and to 1 g/kg morpholine simultaneously. N-nitrosomorpholine was found in the body of the exposed mice. Ninety-eight point four percent was labeled with ¹⁵N that was derived from the inhaled ¹⁵NO₂ and 1.6% was derived presumably from endogenous sources.

Inhaled NO₂ may also be involved in the production of mutagenic (and carcinogenic) nitro derivatives of other co-exposed compounds, such as PAHs, via nitration reactions. Miyanishi et al. (1996) co-exposed rats, mice, guinea pigs and hamsters to 20 ppm NO₂ with various PAHs (pyrene, fluoranthene, fluorene, anthracene, or chrysene). Nitro derivatives of these PAHs were excreted in the urine of these animals, which were found to be highly mutagenic in the Ames/*S. typhimurium* assay. Specifically, the nitrated metabolite of pyrene (1-nitro-6/8-hydroxypyrene and 1-nitro-3hydroxypyrene) was detected in the urine. Further studies indicated that these metabolites are nitrated by an ionic reaction in vivo after the hydroxylation of pyrene in the liver.

AX4.5. Extra-Pulmonary Effects of NO₂ and NO

Exposure to NO₂ produces a wide array of health effects beyond the confines of the lung. Thus, NO₂ and/or some of its reactive products penetrate the lung or nasal epithelial and endothelial layers to enter the blood and produce alteration in blood and various other organs. Effects on the systemic immune system were discussed above and the summary of other systemic effects is quite brief because the literature suggests that effects on the respiratory tract and immune response are of greatest concern. A more detailed discussion of extrapulmonary responses can be found in U.S. Environmental Protection Agency (1993).

AX4.5.1. Body Weight, Hepatic, Renal, and Miscellaneous Effects

Conflicting results have been reported on whether NO₂ affects body weight gain in experimental animals as a general indicator of toxicity (U.S. Environmental Protection Agency, 1993). More recent subchronic studies show no significant effects on body weight in rats, guinea pigs, and rabbits exposed up to 4 ppm NO₂ (Tepper et al., 1993; Douglas et al., 1994; Fujimaki and Nohara, 1994).

Effects on the liver, such as changes in serum chemistry and xenobiotic metabolism, have been reported by various investigators to result from exposure to NO₂ (U.S. Environmental Protection Agency 1993). Drozd et al. (1976) found decreased total liver protein and sialic acid, but increased protein-bound hexoses in guinea pigs exposed to 1 ppm NO₂, 8 h/day for 180 days. Liver alanine and aspartate aminotransferase activity was increased in the mitochondrial fraction but decreased in the cytoplasmic

fraction of the liver. Electron micrographs of the liver showed intracellular edema and inflammatory and parenchymal degenerative changes.

No new studies on liver effects were located in the literature since the 1993 NO_x AQCD. Several older studies have shown changes in kidney function and xenobiotic metabolism in animals following NO₂, although no histopathological changes were reported.

Increases in urinary protein and specific gravity of the urine were reported by Sherwin and Layfield (1974) in guinea pigs exposed continuously to 0.5 ppm NO₂ for 14 days. Proteinuria (albumin and alpha-, beta-, and gamma-globulins) was found in another group of animals exposed to 0.4 ppm NO₂ for 4 h/day. However, differences in water consumption or in the histology of the kidney were not found. No new studies were located in the literature since the 1993 NO_x AQCD.

Four studies (Table AX4.9) consider hematologic parameters. Several additional studies report on iron, enzymes and nucleic acid (Table AX4.10).

AX4.5.2. Brain Effects

There are several studies suggesting that NO₂ affects the brain. Decreased activity of protein metabolizing enzymes, increased glycolytic enzymes, changes in neurotransmitter levels (5-HT and noradrenaline), and increased lipid peroxidation, accompanied by lipid profile and antioxidant changes, have been reported (Farahani and Hasan, 1990, 1991, 1992; Sherwin et al., 1986; Drozd et al., 1975). The U.S. Environmental Protection Agency (1993) concluded that “none of these effects have been replicated and all reports lack sufficient methodological rigor; thus, the implications of these findings, albeit important, are not clear and require further investigation”.

A developmental neurotoxicity study by Tabacova et al. (1985) suggest that in utero exposure to NO₂ may result in postnatal neurobehavioral development changes as described in the section on reproductive and developmental toxicology.

AX4.5.3. NO

The genotoxicity of NO has been studied both in vitro and in vivo (Arroyo et al., 1992; Nguyen et al., 1992) (see Tables AX4.11-4.13). Overall, the synthesis of these older studies suggests that NO has some genotoxic potential; however, the effect is slight and to a lesser extent when compared to NO₂.

AX4.5.4. Effects of Mixtures Containing NO₂

Humans are generally exposed to NO₂ in a mixture with other air pollutants. A limitation of animal toxicity studies is the extrapolation of concentration-response data from controlled exposures to NO₂ alone, to air pollutant mixtures that are typically found in the environment. It is difficult to predict the effects of NO₂ in a mixture based on the effects of NO₂ alone. In order to understand how NO₂ is affected by mixtures of other air pollutants, studies are typically conducted with mixtures containing NO₂ and one or two other air pollutants, such as O₃ and/or H₂SO₄. The result of exposure to two or more pollutants may be simply the sum of the responses to individual pollutants (additivity), may be greater than the sum of the individual responses, suggesting some type of interaction or augmentation of the response (synergism) or may be less than additive (antagonism).

Animal toxicity studies have shown an array of interactions, including no interaction, additivity or synergism. Because no clear understanding of NO₂ interactions has yet emerged from this database, only a brief overview is provided here. A more substantive review can be found in U.S. Environmental Protection Agency (1993). There were animal studies, which studied the effects of ambient air mixtures containing NO₂ or gasoline or diesel combustion exhausts containing NO_x. Generally these studies provided useful information on the mixtures, but lacked NO₂-only groups, making it impossible to discern

the influence of NO₂. Therefore, this class of research is not described here, but is reviewed elsewhere (U.S. Environmental Protection Agency, 1993).

AX4.5.5. Simple Mixtures Containing NO₂

Most of the interaction studies involved NO₂ and O₃. After subchronic exposure, lung morphology studies did not show any interaction of NO₂ with O₃ (Freeman et al., 1974) or with SO₂ (Azoulay et al., 1980). Some biochemical responses to NO₂ plus O₃ display no positive interaction or synergism. For example, Mustafa et al. (1984) found synergism for some endpoints (e.g., increased activities of O₂ consumption and antioxidant enzymes), but no interaction for others (e.g., DNA or protein content) in rats exposed for 7 days. Ichinose and Sagai (1989) observed a species dependence in regard to the interaction of O₃ (0.4 ppm) and NO₂ (0.4 ppm) after 2 weeks of exposure. Guinea pigs, but not rats, had a synergistic increase in lung lipid peroxides. Rats, but not guinea pigs, had synergistic increases in antioxidant factors (e.g., non-protein thiols, vitamin C, glucose-6-phosphate dehydrogenase, GSH peroxidase). Duration of exposure can have an impact. Schlesinger et al. (1990) observed a synergistic increase in prostaglandin E₂ and F_{2α} in the lung lavage of rabbits exposed acutely for 2 h to 3.0 ppm NO₂ plus 0.3 ppm O₃; the response appeared to have been driven by O₃. However, with 7 or 14 days of repeated 2-h exposures, only prostaglandin E₂ was decreased and appeared to have been driven by NO₂; there was no synergism (Schlesinger et al., 1991).

Using an infectivity model, Ehrlich et al. (1977) found additivity after acute exposure to mixtures of NO₂ and O₃ and synergism after subchronic exposures. Exposure scenarios involving NO₂ and O₃ have also been performed using a continuous baseline exposure to one concentration or mixture, with superimposed short-term peaks to a higher level (Ehrlich et al., 1979; Gardner, 1980, 1982; Graham et al., 1987). Differences in the pattern and concentrations of the exposure are responsible for the increased susceptibility to pulmonary infection, without indicating clearly the mechanism controlling the interaction.

Some aerosols may potentiate response to NO₂ by producing local changes in the lungs that enhance the toxic action of co-inhaled NO₂. The impacts of NO₂ and H₂SO₄ on lung host defenses have been examined by Schlesinger and Gearhart (1987) and Schlesinger (1987). In the former study, rabbits were exposed for 2 h/day for 14 days to either 0.3 ppm or 1.0 ppm NO₂, or 500 μg/m³ H₂SO₄ alone, or to mixtures of the low and high NO₂ concentrations with H₂SO₄. Exposure to either concentration of NO₂ accelerated alveolar clearance, whereas H₂SO₄ alone retarded clearance. Exposure to either concentration of NO₂ with H₂SO₄ resulted in retardation of clearance in a similar manner to that seen with H₂SO₄ alone. Using a similar exposure design but different endpoints, exposure of rabbits to 1.0 ppm NO₂ increased the numbers of PMNs in lavage fluid at all time points (not seen with either pollutant alone), and increased phagocytic capacity of AMs after two or six exposures (Schlesinger et al., 1987). Exposure to 0.3 ppm NO₂ with acid, however, resulted in depressed phagocytic capacity and mobility. The NO₂/H₂SO₄ mixture was generally either additive or synergistic, depending on the specific cellular endpoint being examined.

Exposure to high levels of NO₂ (#5.0 ppm) with very high concentrations of H₂SO₄ (1 mg/m³) caused a synergistic increase in collagen synthesis rate and protein content of the lavage fluid of rats (Last and Warren, 1987; Last, 1989).

AX4.5.6. Complex Mixtures Containing NO₂

Although many studies have examined the response to NO₂ with only one additional pollutant, the atmosphere in most environments is a complex mixture of more than two materials. A number of studies have attempted to examine the effects of multi-component atmospheres containing NO₂, but as mentioned before, in many cases the exact role of NO₂ in the observed responses is not always clear. One study by Stara et al. (1980) deserves mention because pulmonary function changes appeared to progress after exposure ceased.

In the study by Stara et al. (1980), dogs were exposed for 68 months (16 h/day) to raw or photochemically reactive vehicle exhaust which included mixtures of NO_x: one with a high NO₂ level and a low NO level (0.64 ppm, NO₂; 0.25 ppm, NO), and one with a low NO₂ level and a high NO level (0.14 ppm, NO₂; 1.67 ppm, NO). At the end of exposure, the animals were maintained for about 3 years in normal indoor air. Numerous pulmonary functions, hematological and histological endpoints were examined at various times during and after exposure. The lack of an NO₂-only or NO-only group precludes determination of the nature of the interaction. Nevertheless, the main findings are of interest. Pulmonary function changes appeared to progress after exposure ceased. Dogs in the high NO₂ group had morphological changes considered to be analogous to human centrilobular emphysema. Because these morphological measurements were made after a 2.5- to 3-year holding period in clean air, it cannot be determined with certainty whether these disease processes abated or progressed during this time. This study suggests progression of damage after exposure ends.

Table AX4.1. Oxidant and antioxidant homeostasis.

ppm	EXPOSURE	GENDER	AGE	SPECIES (STRAIN)	EFFECTS	REFERENCES
0.04 0.4 4.0	Continuous, 9 and 18 mos	M	8 wks	Rat (Wistar)	NPSHs increased at ≥0.4 ppm after 9 or 18 mos; GSH peroxidase activity increased after a 9-mo exposure to 4.0 ppm; G-6-P dehydrogenase was increased after a 9- and 18-mo exposure to 4.0 ppm; no effects on 6-P-G dehydrogenase, SOD disulfide reductase; some GSH S-transferase had decreased activities after 18-mo exposure to ≥0.4 ppm.	Sagai et al. (1984) Ichinose et al. (1983)
0.4	2 wks	NR	NR	Rat Guinea Pig	No effect on TBA reactants, antioxidants, or antioxidant enzyme activities.	Ichinose and Sagai (1989)
0.4 1.2 4.0	Continuous, 4 mos	M	13 wks	Rat (Wistar)	Duration dependent pattern for increase in activities of antioxidant enzymes; increase, peaking at wk 4 and then decreasing. Concentration-dependent effects.	Ichinose and Sagai (1982)
0.4- 0.5	Continuous, 1.5 yrs	F	NR	Mouse (NR)	Growth reduced; Vitamin E (30 or 300 mg/kg diet) improved growth.	Csallany (1975)
0.5 1.0	Continuous, 17 mos	F	4 wks	Mouse (C57B1/6J)	At 1 ppm, GSH-peroxidase activity decreased in vitamin E-deficient mice and increased in Vitamin E-supplemented mice.	Ayaz and Csallany (1978)
1.0	4 h/day, 6 days	NR	NR	Rat (Sprague-Dawley)	Vitamin E-supplement reduced lipid peroxidation.	Thomas et al. (1967)
1.0 2.3 6.2	Continuous, 4 days	M	8 wks	Rat (Sprague-Dawley)	Activities of GSH reductase and G-6-P dehydrogenase increased at 6.2 ppm proportional to duration of exposure; plasma lysozyme and GSH peroxidase not affected at 6.2 ppm; no effects at 1.0 or 2.3 ppm.	Chow et al. (1974)
1.2 1.8	Continuous, 3 days	M	12 wks	Rat (Sprague-Dawley)	Increases in G-6-P dehydrogenase, isocitrate dehydrogenase, disulfide reductase, and NADPH cytochrome c reductase activities at 1.8 ppm only.	Lee et al. (1989, 1990)
2.0 10.0	3 days	M/F	5->60 days	Rat (Wistar) Guinea pig (Dunkin Hartley)	Decreased SOD activity in 21-day-old animals.	Azoulay-Dupuis et al. (1983)
2.0 4.0 10.0	14 days 10 days 7 days	M	12-24 wks	Rat (Wistar)	G-6-P dehydrogenase increased at ≥2 ppm; at 2 ppm, 14 days of exposure needed	Mochitate et al. (1985)

ppm	EXPOSURE	GENDER	AGE	SPECIES (STRAIN)	EFFECTS	REFERENCES
3.0	7 days	M/F	1 day to >8 wks	Rat (Sprague-Dawley)	Increased lipid peroxidation (TBA-reactive substances) with vitamin E deficiency.	Sevanian et al. (1982)
9.5	7 h/day, 5 days/wks, 6 mos	M	In utero and 6 mos	Rat (Fischer 344)	Increase in GSH reductase activity in younger rats and SDH peroxidase activity in older rats.	Mauderly et al. (1987)
3.0 7.0 10 15	4 days 4 days 4 days 1-7 days	M	NR	Rat (Sprague-Dawley)	No effects on parameters tested. Increase in lung weight, G-6-P dehydrogenase, GSH reductase, and GSH peroxidase activities. Increased lung weight, G-6-P dehydrogenase; and GSH reductase activities. Increase in lung weight, DNA content, G-6-P dehydrogenase, 6-P-G dehydrogenase, GSH reductase, disulfide reductase, GSH peroxidase, disulfide reductase, succinate oxidase, and cytochrome oxidase activities; no effect on lung protein	Mustafa et al. (1979)
4.0	3 h	M/F	21-33 yrs	Human	Decreased elastase inhibitory capacity and increased lipid peroxidation products in BAL of subjects not administered supplement of vitamin C and E prior to NO ₂ exposure.	Mohsenin (1991)
5.0 10.0	Continuous, 24 h 7 days	M	NR	Rats (CD Cobs)	Changes in the GSH levels in blood and lung occurred in rats exposed for 24 h, but returned to normal after 7 days.	Pagani et al. (1994)
6.0 15 28	4 h/day, 30 days 7 days	F	NR	Mouse (NR)	Increase in GSH reductase and G-6-P dehydrogenase activities. Increase in GSH levels, G-6-P dehydrogenase, and GSH peroxidase activities.	Csallany (1975)
9.5	7 h/day, 5 days/wk, 24 mos	M	18 wks	Rat (Fischer 344)	Increase in GSH reductase activity in BAL.	Mauderly et al., (1990)
10.0	Continuous 3 days, 20 days	NR	NR	Rat (Fischer 344)	Decreased GSH/GSSG ratio in blood and BAL fluid, but not in lung type II cells. Lipid peroxidation was decreased in type II cells at 3 days, but was similar to controls at 20 days. mRNA expression of the enzymes involved in the biosynthesis ((GCS and GS) was decreased at both time points. (GT (redox of GSH) mRNA expression was increased.	Hochscheid et al. (2005)
14.0	NR	NR	NR	Human	Rapid depletion of vitamin C, glutathione and vitamin E	Halliwell et al. (1992)

M = Male
NPSHs = Nonprotein sulfhydryls
G-6-P dehydrogenase = Glucose-6-phosphate dehydrogenase
G6-P-G dehydrogenase = 6-phosphogluconate dehydrogenase
SOD = superoxide dismutase
F = Female
NR = Not Reported
NADP = Nicotinamide-adenine dinucleotide phosphate (reduced form)
TBA = Thiobarbituric acid
BAL = Bronchoalveolar lavage
GR = Glutathione reductase
GS = Glutathione synthetase
GSH = Reduced glutathione
GSSG = Oxidized glutathione
(-GCS - (-Glutamyl-cystein synthetase
(-GT - (-Glutamyltranspeptidase

5.0	Continuous, 1, 3, or 7 days	M	NR	Rat (Sprague-Dawley)	Increased BAL protein at 3 days (day 7 not measured); increased (120% collagen synthesis at 7 days (not measured other days).	Last & Warren (1987)
8.0	Continuous, 14 days	F	NR	Mouse (NR)	Increase in lung protein.	Csallany (1975)
9.5	7 h/day, 5 days/wk, 6 mos	M	In utero and 6 mos	Rat (Fischer 344)	Increase in BAL alkaline phosphatase, acid phosphatase, and LDH in older rats only.	Mauderly et al. (1987)
9.5	7 h/day, 5 days/wk, 24 mos	M	18 wks	Rat (Fischer 344)	Increase in BAL levels of LDH and alkaline phosphatase activities and in collagenous peptides.	Mauderly et al. (1990)
10	24 h or 7 days	M	NR	Rat (CD cobs)	Protein content of BALF increased significantly in rats after only 24 h. BALF elastase activity was not affected. Concentration-dependent increase in α -1 proteinase inhibitor content after 24 h of exposure, but not with longer exposures.	Pagani et al. (1994)
10	Continuous, 14 days	M	8 wks	Rat (Wistar)	Changes in several enzymes in whole lung homogenates.	Sagai et al. (1982)

ppm	EXPOSURE	GENDER	AGE	SPECIES (STRAIN)	EFFECTS	REFERENCES
10 20 30 40	4 h	M	NR	Rat (Long Evans)	Increased activities of various enzymes, sialic acid, and BAL protein; attenuation by high dietary levels of vitamin E.	Guth and Mavis (1985, 1986)
10	24 h/day, 0 (control), 3 days or 20 days	NR	NR	Rat (Fischer 344)	LPO decreased in type II pneumocytes after 3 days compared to controls but remained comparable to controls after 20 days. Authors stated that LPO is a very early reaction during oxidative stress and that the decrease after 3-day exposure suggests an adaptation mechanism. Exposure duration-dependent, statistically significant increase in GPx and GR enzyme activities after 3 and 20 days over control values. Changes in mRNA expression of GSH synthesizing enzymes in type II pneumocytes were also observed.	Hochscheid et al. (2005)
10	24 h/day, for 0, 3, 20, or 28 days	M	NR	Rat (Sprague-Dawley)	Uptake of surfactant-like liposomes by type II pneumocytes in the presence or absence of SP-A was faster and significantly higher in cells from all NO ₂ exposed groups than in control cells. No difference in the uptake kinetics between cells from exposed groups of different duration. Increase in liposome uptake suggests NO ₂ exposure likely disrupted cell membranes to allow liposomes to enter the cells easily. Lipid uptake associated with duration-dependent increase in internalization of label found in PC fraction. Suggests increased demand of PC in lung injury.	Muller et al. (2003)
0.8 5.0 10	Presumably continuous, 1 day or 3 days	M	NR	Rat (Sprague-Dawley)	Phospholipid component in BAL increased in a concentration- and exposure duration-dependent manner, with significance only at 10 ppm, but not at 5 ppm or below, for ≥1 day of exposure. PC content in BAL of exposed animal did not change significantly compared to controls. At 10 ppm, but not at 5 ppm or below, percentage of saturated PC decreased and that of unsaturated PC increased statistically significant, while significant decreases in palmitic acid (16:0) and increases in arachidonic acid (20:4) contained in PC were observed. Sphingomyelin – as a marker for an influx of serum into the alveolar airspace – was also not changed by NO ₂ exposure. Functional studies on surfactant phospholipid extracts indicated increased values for the surface tension at equilibrium, and for the maximal and minimal surface tension of animals exposed to ≥5 ppm, but not to 0.8 ppm. Suggests NO ₂ directly impaired surface tension at ≥5 ppm. Structure of the SP-A not altered by NO ₂ exposure. Authors suggested exposure to NO ₂ impaired surfactant components may be used as markers of altered surfactant metabolism.	Muller et al. (1994)

ppm	EXPOSURE	GENDER	AGE	SPECIES (STRAIN)	EFFECTS	REFERENCES
5 10	24 h or 24 h/day for 7 days	M	NR	Rat (CD Cobs)	Concentration-dependent increase in α -1 PI content. Exposure to 5 and 10 ppm NO ₂ significantly increased α -1 PI content only after 24 h and returned to control values after 7 days at each exposure concentration. Since blood GSH content was also increased together with α -1 PI content at 24 h, authors suggested the increase in these parameters can be considered a prompt protective response resulting in no further increase of α -1 PI.	Pagani et al. (1994)

LPO = Lipid peroxidation
PC = Phosphatidylcholine
SP-A = Surfactant protein-AGPx = Glutathione peroxidase
GPx = Glutathione peroxidase

GR = Glutathione reductase
GSH = Glutathione
 α -1 PI = α -1 proteinase inhibitor

4.0 8.0	Up to 10 days	NR	NR	Rat (Fischer 344)	Increase in number of AMs at both concentrations, reaching a peak on day 3 and 5; no increase in number of PMNs; decrease in AM viability throughout exposure period. Suppression of phagocytic activity after 7 days of exposure to 4 ppm and after 5 days of exposure to 8 ppm; returned to normal value at 10 days. Decrease in superoxide radical production, but at 4 ppm, the effect became significant on days 3, 5, and 10; at 8 ppm, the effect was significant at all time periods tested.	Suzuki et al. (1986)
5.0	7 days	F	NR	Mouse (CD-1)	No effect on phagocytic activity.	Lefkowitz et al. (1986)
5 15	3 h after infection with parainfluenza 3 virus	NR	NR	Rabbit (New Zealand)	AMs lost resistance to challenge with rabbit pox virus after exposure to 15 ppm.	Acton and Myrvik (1972)
5 10 15	3 h	M Fb	NR	Humans (in vitro exposure)	No change in cell viability, release of neutrophil chemotactic factor, or interleukin-1.	Pinkston et al. (1988)
5-60	3 h	NR	NR	Rabbit (New Zealand)	Inhibition of phagocytic activity.	Gardner et al. (1969) Acton and Myrvik (1972)
7.0	24 h	NR	NR	Rabbit	Increased rosette formation in AMs treated with lipase.	Hadley et al. (1977)
9.5	7 h/day; 5 days/wk; 18-22 mo	M	18 wks	Rat (Fischer 344)	No effect on long-term clearance of radiolabeled tracer particles.	Mauderly et al. (1990)
10	Continuous 7 days	NR	NR	Rat (NR)	High influx of PMNs in the lung (BALF) after 24 h of exposure, reversed for macrophages; no change in the lymphocyte population.	Pagani et al. (1994)
10	35 days	NR	NR	Guinea pig	63% increase in epithelial cells positive for macrophage congregation.	Sherwin et al. (1968)
10	4 h	F	NR	Mouse (Swiss)	Increase in total pulmonary cells in animals infected with some species of bacteria.	Jakab (1988)
10 25	24 h	M	12-13 wks	Rat (Sprague-Dawley)	Decreased phagocytosis at 25 ppm only.	Katz and Laskin (1976)

ppm	EXPOSURE	GENDER	AGE	SPECIES (STRAIN)	EFFECTS	REFERENCE
<i>Clearance</i>						
3 9	6 h/day, 6 days/wk, for 2 wks	F	NR	Guinea Pig	Significant, dose-dependent decrease in ciliary activity, significant at 3 ppm (12%) and 9 ppm (30%), and increase in eosinophil accumulation on epithelium and submucosal layer.	Ohashi et al. (1994)
10 20	14 h/day, for 15 days, 20 or 25 days	M	NR	Mouse (C57BL/5)	20 ppm NO ₂ induced an increased mucus production due to goblet cell hyperplasia in the central airways.	Wegman and Herz (2002)
<i>Alveolar Macrophage Endpoints</i>						
0.5	8 h/day, 5 days/wk, for 0.5, 1, 5, or 10 days	M	NR	Rat (Sprague-Dawley)	Acute depression of pulmonary arachidonate metabolism observed. Unstimulated AM synthesis of LTB ₄ depressed within 1 day and also on day 5 of exposure. Acute depression of AM synthesis of TxB ₂ , LBT ₄ , and 5-HETE on stimulation by the calcium ionophore, A23187, within 1 day of exposure but not with longer exposure, while 5-HETE increased significantly at 10 days of exposure only. Suggests rapid depression of cyclooxygenase and 5-lipoxygenase activities. ZAS-stimulated LTB ₄ production delayed until 5 days and remained lower at 10 days. AM superoxide production stimulated by PMA was rapidly and continuously depressed throughout the study. BAL fluid levels of LTB ₄ and TxB ₂ paralleled ex vivo depression of AM production.	Robinson et al. (1993)
0.2 0.5 2.0	Continuous, presumably 7 days/wk, up to 12 wks	F	Neonates or 5 wks old	Rat (Brown-Norway)	Animals were exposed during embryonic or weanling (5-wks old) period. ROS generation was significantly suppressed at 0.5 and 2.0 ppm NO ₂ in animals exposed during the weanling period. Cytokine level measurement in AM culture mediums indicated that inflammatory reactions (significant increases in TFN α and IFN γ) were initiated at 8 wks and terminated at 12 wks in animals exposed during the embryonic period while inflammatory reactions (significantly increased TFN α level) were not initiated at 8 wks but take place at 12 wks in animals exposed as weanlings. Results suggest that NO ₂ exposure from the weanling period has stronger effects on AM activity.	Kumae and Arakawa (2006)

Table AX4.4. Lung permeability and inflammation.

ppm	EXPOSURE	GENDER	AGE	SPECIES (STRAIN)	EFFECTS	REFERENCE
0.8 5 10	Presumably continuous, 1 day or 3 days	M	NR	Rat (Sprague-Dawley)	BAL protein content significantly increased in a concentration- and exposure duration-dependent manner, with the change becoming significant at 5 ppm for 3 days and 10 ppm for ≥1 day of exposure.	Muller et al. (1994)
5 10	24 h or 24 h/day for 7 days	M	NR	Rat (CD Cobs)	Exposure induced inflammatory response in the lungs. At 10 ppm, influx of PMN, maximal at 24 h, but no influx observed after 7 days of exposure, a trend that was also observed with protein content in BAL fluid. In contrast, no influx of macrophages was observed, but the influx was maximal after 7 days of exposure. No significant changes in lymphocyte counts at any exposure concentration and protein content in BAL fluid not significantly affected at 5 ppm. Protein content of BAL fluid increased significantly only after 24 h of exposure to 10 ppm NO ₂ .	Pagani et al. (1994)
5 25	6 h/day for 1, 3, or 5 days	NR	NR	Mouse (C57BL/6)	Exposure to 5 ppm NO ₂ did not cause any lung inflammation or injury. Exposure to 25 ppm NO ₂ induced acute lung injury (characterized by increases in protein, LDH, macrophages, and neutrophils recovered by BAL) that peaked after 3 days, lesions within terminal bronchioles, and AHR. OVA-sensitized animals exposed to 25 ppm, but not 5 ppm, NO ₂ showed augmentation of eosinophilic inflammation and terminal bronchiolar lesions, which extended significantly into the alveoli. No increased expression of mucus cell-associated gene products in non-sensitized or OVA-sensitized animals exposed at any concentration.	Poynter et al. (2006)
5 20	3 h	M	NR	Mouse (BALB/c)	Exposure of OVA-challenged animals to 20 ppm produced BHR and caused significant increase in neutrophils and fibronectin concentration, significant reduction in eosinophil count, and exudation and release of IL-5 in BAL fluid 24 h and/or 72 h after exposure. Exposure to 5 ppm did not modify BHR, but significantly reduced pulmonary eosinophilic inflammation (reduced eosinophilic count and eosinophil peroxidase activity) and the production of IL-5 in the BAL fluid. Exposure to NO ₂ did not cause any significant changes in IgE anti-OVA antibody in exposed animals, while IgG1 titers were significantly increased in animals exposed only to 5 ppm NO ₂ , compared to controls. There was no development of mucosal metaplasia in any NO ₂ exposed group compared to controls.	Proust et al. (2002)
5 10 20	24 h/day, for 3 or 25 days	M	NR	Rat (Sprague-Dawley)	Exposure to NO ₂ exhibited concentration- and exposure duration-dependent, and tissue localization-specific differences in Clara cell proliferation. Increased proliferation (measured as BrdU-LI) in both bronchial and bronchiolar epithelium of all exposed groups, with significance starting at exposure to 5 ppm for 3 or 25 days. Exposure to 5 and 10 ppm NO ₂ for 3 days showed significantly higher proliferative activity in bronchiolar epithelium than in the bronchial epithelium for corresponding exposure groups, while the difference in proliferation between proximal and distal airways diminished after 25 days of exposure. Clara cell proliferation was not accompanied by a change in Clara cell numbers in any of exposure groups, a finding the authors explained by the assumption that the process of proliferation takes place at the same rate as Clara cell differentiates into other cells, a transition that leads to the loss of phenotypic Clara properties in differentiating cells.	Barth and Muller (1999)
1.2	24 h/day, for 3 days	M	NR	Rat (Sprague-Dawley)	No significant differences in cell viability and percentages of pulmonary AMs or PMNs between animals exposed to 1.2 ppm NO ₂ and controls.	Bermudez (2001)

ppm	EXPOSURE	GENDER	AGE	SPECIES (STRAIN)	EFFECTS	REFERENCE
10 20	14 h/day, for 15 days, 20 or 25 days	M	NR	Mouse (C57BL/5)	Exposure to 10 ppm for 15 days – the only exposure duration used for this concentration – did not significantly affect influx of inflammatory cells (leukocyte subpopulations and macrophages). 20 ppm NO ₂ induced airway and parenchymal inflammation – dominated by a significant influx of macrophages and neutrophils –, peaking at 15 days of exposure and declining at day 25.	Wegman and Herz (2002)
3.6 7.2 10.8 14.4	24 h, 12h, 8h, and 6 h, respectively, for 3 days, giving a C H T of 86.4 ppm-h	M	NR	Rat (Sprague-Dawley)	Significant cell proliferation (increased labeling index) in peripheral airways compared to controls, regardless of concentration or exposure duration. Suggests Haber's law (c H t = k) was not followed over the concentration ranges studied. No proliferative response was observed in alveolar epithelium.	Rajini et al. (1993)
0.5	8 h/day, 5 days/wk, for 0.5, 1, 5, or 10 days	M	NR	Rat (Sprague-Dawley)	No effect on weight gain. No effects on neutrophil, lymphocyte macrophage/monocyte levels or cell population percentages in BAL. Suggests no significant influx of inflammatory cells into lung airways and alveolar spaces.	Robinson et al. (1993)
5 10 20	24 h/day, for 3 or 25 days	M	NR	Rat (Sprague-Dawley)	<p>Compared to controls, proliferative activity significantly increased, but with no concentration-dependence in respiratory bronchiolar epithelium at 5 ppm and above after 3-day exposure, but increase was concentration-dependent, with significance at ≥10 ppm following 25-day exposure. Proliferative activity increased in a concentration-dependent manner in bronchial epithelium, with significance only at 20 ppm after 3 days of exposure and at ≥10 ppm following 25 days of exposure.</p> <p>Concentration-dependent thickening of alveolar septa and bronchiolar walls, significant only at ≥10 ppm after 3- and 25-day exposure, but 5 ppm caused significant thickening only in bronchiolar walls after 25 days, but not after 3 days, of exposure compared to controls.</p> <p>Statistically significant reduction in alveoli surface density at ≥10 ppm after 25 days of exposure and at 20 ppm only after 3 days of exposure, while alveolar circumference increased statistically significantly at ≥10 ppm after 25 days of exposure and at 20 ppm following 3 days of exposure. 5 ppm did not significantly affect these endpoints after 3 or 25 days of exposure compared to controls. Data suggest concentration- and exposure duration-dependent development of emphysema, significant only at ≥10 ppm, but not at 5 ppm, after 3 or 25 days of exposure. Alveolar duct length increased significantly at ≥10 ppm after 25 days and at 20 ppm after 3 days of exposure; no effect at 5 ppm.</p> <p>Radial alveolar count values decreased significantly at 20 ppm after 3 and 25 days and at 10 ppm after 25 days exposure; no effect at 5 ppm. Increase in avg medial thickness at 10 ppm with significance only after 25 days of exposure and at 20 ppm with significance after 3 and 25 days of exposure. In contrast, 5 ppm caused significant increase at both 3 and 25 days of exposure. Authors suggested effect at 5 ppm was due a reduction of pulmonary arterial mass and not as a result of vasodilation induced by nitrogen oxide.</p>	Barth et al. (1994b)

ppm	EXPOSURE	GENDER	AGE	SPECIES (STRAIN)	EFFECTS	REFERENCE
0, 1.0, 2.0, 4.0	24 h/day, for 12 wks	M	10 wks	Rat (Wistar) Guinea Pig (Hartley)	<p>No change in body weight or absolute lung weight in any exposed group compared to controls, but relative lung weight was significantly increased in animals exposed to 4.0 ppm NO₂. Number of lung cells from animals exposed to ≥2.0 ppm significantly reduced (but extent of reduction at 4.0 ppm < 2.0 ppm), whereas number of mast cells not significantly different in exposed animals compared to controls. IgE-mediated histamine release from lung mast cells significantly reduced at 2.0 ppm NO₂ but not at 4.0 ppm or 1.0 ppm, but no difference observed in A23187-stimulated histamine release in lung mast cells in any exposed group compared to controls. Results from histamine release suggest that NO₂ exposure to rat lung mast cells did not induce histamine-releasing activity.</p> <p>No change in body weight or absolute or relative lung weight in any exposed group compared to controls. Number of lung cells or mast cells was not significantly different in exposed animals compared to controls. Increasing trend observed in IgE-mediated histamine release from lung mast cells, the change becoming significant only at 4.0 ppm. No significant change in ionophore A2318-stimulated histamine release in exposed groups compared to controls. Data suggest NO₂ exposure in guinea pigs enhanced histamine-releasing activity in lung mast cells.</p>	Fujimaki and Nohara (1994)
0.2 0.5 2	Continuous, presumably 7 days/wk, up to 12 wks	F	Neonates or 5 wks old	Rat (Brown-Norway)	<p>Rats were exposed from embryonic or weanlings (5 wks old) period up to 12 wks of age. Significantly decreased levels of AM + Mo in weanling animals exposed to 0.5 and 2.0 ppm, and significantly increased levels of neutrophils in animals exposed to 2.0 ppm at 12 wks. Levels of AM + Mo significantly increased in animals exposed to 0.5 ppm during embryonic period while levels of neutrophil population significantly decreased, compared to controls, at 12 wks. [Changes in cell populations in BAL fluid not investigated in animals exposed to 2.0 ppm during the embryonic period due to loss of sample.] Mean level of lymphocytes significantly increased in the embryonic group exposed to 0.2 ppm and in the weanling group exposed to 0.5 and 2.0 ppm, but increase not concentration-dependent in the weanling group. Except for exposure to 0.2 ppm, NO₂ exposure appeared to improve allergic conditions in the BAL fluid of the embryonic group, but caused inflammatory changes in the BAL fluid of the weanling group.</p> <p>Data suggest NO₂ exposure from the weanling period has stronger effects on AM activity.</p>	Kumae and Arakawa (2006)

AHR = Airway hyperresponsiveness
AM = Alveolar macrophage
BAL = Bronchoalveolar lavage
BHR = Bronchopulmonary hyperreactivity
BrdU-LI = Bromodeoxyuridine-labelling index

LDH = Lactate dehydrogenase
Mo = Monocytes
OVA = Ovalbumin
PMN = Polynorphonuclear neutrophil

Table AX4.5. Immune responses.

ppm	EXPOSURE	GENDER	AGE	SPECIES (STRAIN)	EFFECTS	REFERENCES
0.5 0.1 base + 0.25, 0.5, or 1.0 peak	Continuous Continuous base + 3 h/day, 5 days/wk peak for 1, 3, 6, 9, 12 mos	NR	NR	Mouse	Suppression of splenic T and B cell responsiveness to mitogens variable and not related to concentration or duration, except for the 940 µg/m ³ continuous group, which had a linear decrease in PHA-induced mitogenesis with NO ₂ duration.	Maigetter et al. (1978)
0.25	7 h/day, 5 days/wk, 7wks	F	6 wks	Mouse (AKR/cum)	Reduced percentage of total T-cell population and trend towards reduced percentage of certain T-cell subpopulations; no reduction of mature T cells or natural killer cells.	Richters and Damji (1988)
0.25	7 h/day, 5 days/ wk, 36 wks	F	5 wks	Mouse (AKR/cum)	Reduced percentage of total T-cell population and percentages of T helper/inducer cells on days 37 and 181.	Richters and Damji (1990)
0.35	7 h/day, 5 days/ wk, 12 wks	M	6 wks	Mouse (C57BL/6J)	Trend towards suppression in total percentage of T-cells. No effects on percentages of other T-cell subpopulations.	Richters and Damji (1988)
0.4 1.6	24 h/day 4 wks	M	7 wks	Mouse (BALB/c)	Decrease in primary PFC response at ≥ 752 µg/m ³ . Increase in secondary PFC response at 3010 µg/m ³ .	Fujimaki et al. (1982)
0.5 base + 1.5 peak	22 h/day, 7 days/wk base + 6 h/day, 5 days/wk peak for 1, 3, 13, 52, 78 wks	M	10 wks	Rat (Fischer 344)	No effect on splenic or circulatory B or T cell response to mitogens. After 3 weeks of exposure only, decrease in splenic natural killer cell activity. No histological changes in lymphoid tissues.	Selgrade et al. (1991)
0.5 base + 2.0 peak	24 h/day, 5 days/wk base + 1 h/day, 5 days/wk peak for 3 mos	M	6 wks	Mouse (CD-1)	Vaccination with influenza A2/Taiwan virus after exposure. Decrease in serum neutralizing antibody; hemagglutination inhibition antibody titers unchanged. Before virus challenge, NO ₂ exposure decreased serum IgA and increased IgG1, IgM, and IgG2; after virus, serum IgA unchanged and IgM increased.	Ehrlich et al. (1975)
0.5	8 h/day, 5 days/wk, for 0.5, 1, 5, or 10 days	M	NR	Rat (Sprague-Dawley)	Levels of TxB2, LTB4, and PGE2 in BAL fluid were depressed within 4 h of exposure. Suggests acute depression of pulmonary arachidonate metabolism observed in BAL fluid. Unstimulated AM synthesis of LTB4 was depressed within 1 day and also on day 5 of exposure. The AM synthesis of TxB2, LTB4, and 5-HETE on stimulation by the calcium ionophore, A23187, was acutely depressed within 1 day of exposure but not with longer exposure, while 5-HETE was significantly increased at 10 days. Suggests rapid depression of cyclooxygenase and 5-lipoxygenase activities. ZAS-stimulated LTB4 production was delayed until 5 days and remained lower at 10 days. BAL fluid levels of LTB4 and TxB2 paralleled ex vivo depression of AM production. AM superoxide production stimulated by PMA was rapidly and continuously depressed throughout the study.	Robinson et al. (1993)

ppm	EXPOSURE	GENDER	AGE	SPECIES (STRAIN)	EFFECTS	REFERENCES
5	3 h	F	7 wks	Rat (Brown-Norway)	<p>Rats were immunized intraperitoneally and challenged intratracheally with house mite dust. Animals were exposed to NO₂ after sensitization or challenge or after sensitization and challenge (double exposure). A single exposure after sensitization or challenge caused a significant decrease in antigen-specific IgG in BAL fluid, single exposure after sensitization caused significant increase in serum IgE, while exposure only after challenge caused significant decrease in antigen-specific IgA levels in BAL fluid. Double NO₂ exposure caused significantly higher levels of antigen-specific serum IgE and local IgA, IgG, and IgE antibody, and significant increase in lymphocyte responsiveness to antigen in the spleen and mediastinal lymph nodes. Double exposure also significantly increased the ratio of inflammatory cells to alveolar macrophages without affecting the total number of lavageable cells.</p> <p>Data suggest a 3-h exposure to 5 ppm NO₂ after intraperitoneal sensitization and pulmonary challenge with house dust mite allergen was necessary to enhance specific immune responses to the allergen and increased the number of inflammatory cells in the lungs. Additionally, data suggest an upregulation of specific immune responses and subsequent immune-mediated pulmonary inflammation.</p>	Gilmour et al. (1996)
5 20	3 h	M	NR	Mouse (BALB/c)	<p>Animals were sensitized and challenged with the antigen OVA to generate airway inflammation before being exposed to NO₂.</p> <p>Exposure of OVA-challenged animals to 20 ppm produced BHR and caused significant increase in neutrophils and fibronectin concentration, significant reduction in eosinophil count, and exudation and release of IL-5 in bronchoalveolar fluid 24 h and/or 72 h after exposure. Exposure to 5 ppm did not modify BHR, but significantly reduced pulmonary eosinophilic inflammation (reduced eosinophilic count and eosinophil peroxidase activity) and the production of IL-5 in the BAL fluid. Authors suggested that potentiation of BHR by 20 ppm NO₂ in allergic mice may be accounted for by an increased vascular/epithelial permeability, facilitating the allergen availability and accelerating the inflammatory process.</p> <p>Exposure to NO₂ did not cause any significant changes in IgE anti-OVA antibody in exposed animals, while IgG1 titers were significantly increased in animals exposed only to 5 ppm NO₂, compared to controls. There was no development of mucosal metaplasia in any NO₂ exposed group compared to controls.</p>	Proust et al. (2002)
4	2 h/day	M and F	From birth until 3 mos of age	Rabbit (NZW)	No effect on mortality, health, behavior, body weight, or basal pulmonary function (lung resistance, dynamic compliance, respiration rates, tidal volume, and minute volumes) in animals immunized against house mite dust compared to littermates exposed to air. Immune parameters were not evaluated.	Douglas et al. (1994)
4.76	4 h/day, 5 days/wk, for 6 wks (30 exposures, total)	M	NR	Guinea Pig (Hartley)	Animals were intraperitoneally sensitized twice and then challenged pulmonarily with <i>C. albicans</i> . Animals were exposed, from the first day of sensitization, and throughout the study period. Exposure to NO ₂ resulted in significantly increased respiratory rate (tachypnea) (2.3-2.7 times/s) 15 h after antigen challenge compared to controls, but did not significantly affect the expiration/inspiration ratio. Authors indicated that delayed-type dyspneic symptoms in this study were increased by exposure to NO ₂ .	Kitabatake et al. (1995)

ppm	EXPOSURE	GENDER	AGE	SPECIES (STRAIN)	EFFECTS	REFERENCES
0.06 0.5 1 2 4	24 h/day, for 6 or 12 wks	M	NR	Guinea Pig (Hartley)	Concentration- and exposure duration-dependent increases in airway responsiveness to inhaled histamine aerosol, significant at 1.0 ppm and above in animals exposed for 12 wks and at 2 ppm and above in those exposed for 6 wks. No significant increase in specific airway resistance (sRaw) values at any NO ₂ concentration at 6 wks of exposure, but there was a concentration-dependent increase in this parameter at 12 wks of exposure, with significance at 2.0 ppm and above. Authors concluded NO ₂ could be a potent risk factor for alteration of pulmonary function and airway responsiveness.	Kobayashi and Miura (1995)
1 2 4	24 h/day, for 12 wks	M M	10 wks 10 wks	Rat (Wistar) Guinea Pig (Hartley)	No change in body weight or absolute lung weight in any exposed group compared to controls, but relative lung weight significantly increased in animals exposed to 4.0 ppm NO ₂ . Number of lung cells from animals exposed to ≥ 2.0 ppm significantly reduced (but extent of reduction at 4.0 ppm < 2.0 ppm), but number of mast cells not significantly different in exposed animals compared to controls. IgE-mediated histamine release from lung mast cells significantly reduced at 2.0 ppm NO ₂ but not at 4.0 ppm or 1.0 ppm, but no difference observed in A23187-stimulated histamine release in lung mast cells in any exposed group compared to controls. Results from histamine release suggest that NO ₂ exposure to rat lung mast cells did not induce histamine-releasing activity in rats. No change in body weight or absolute or relative lung weight in any exposed group compared to controls. Number of lung cells or mast cells not significantly different in exposed animals compared to controls. Increasing trend observed in IgE-mediated histamine release from lung mast cells, the change becoming significant only at 4.0 ppm. No significant change in ionophore A2318-stimulated histamine release in exposed groups compared to controls. Data suggest NO ₂ exposure in guinea pigs enhanced histamine-releasing activity in lung mast cells. Thus, species differences exist between the rat and guinea pig in response to induction of histamine-releasing activity following NO ₂ exposure.	Fujimaki and Nohara (1994)
5 25	6 h/day for 1, 3, or 5 days	NR	NR	Mouse (C57BL/6)	Exposure to 25 ppm, but not 5 ppm, NO ₂ induced acute lung injury (characterized by increases in protein, LDH, macrophages, and neutrophils recovered by bronchoalveolar lavage) that peaked after 3 days, lesions within terminal bronchioles, and AHR. OVA-sensitized animals exposed to 25 ppm, but not 5 ppm, NO ₂ showed augmentation of eosinophilic inflammation and terminal bronchiolar lesions, which extended significantly into the alveoli. There was no increased expression of mucus cell-associated gene products in non-sensitized or OVA-sensitized animals exposed at any concentration.	Poynter et al. (2006)

1.0 2.5 5.0	6 h/day, 6 days	NR	4-6 wks	Mouse (CD-1)	Cytomegalovirus	Increase in virus susceptibility at 5.0 ppm only.	Rose et al. (1988, 1989)
1.5- 50	2 h	NR	NR	Mouse (NR) Hamster (NR) Monkey (Squirrel)	K. pneumoniae	Increased mortality in mice, hamsters, and monkeys at ≥3.5, ≥35, and 50 ppm NO ₂ , respectively	Ehrlich (1980)
1.5	Continuous or intermittent, 7 h/day, 7 days/wk, up to 15 days	F	NR	Mouse (CD-1)	Streptococcus sp.	After 1 wk, mortality with continuous exposure was greater than that for intermittent after 2 wks, no significant difference between continuous and intermittent exposure.	Gardner et al. (1979) Coffin et al. (1977)
3.5						Increased mortality with increased duration of exposure; no significant difference between continuous and intermittent exposure; with data adjusted for total difference in C H T, mortality essentially the same.	
1.5 base + 4.5 peak	Continuous 64 h, then peak for 1, 3.5, or 7 h, then continuous 18 h base	F	NR	Mouse (CD-1)	Streptococcus sp.	Mortality increased with 3.5- and 7-h single peak when bacterial challenge was after an 18 h baseline exposure.	Gardner (1980) Gardner (1982) Graham et al. (1987)
4.5	1, 3.5, or 7 h					Mortality proportional to duration when bacterial challenge was immediate, but not 18 h postexposure.	
1.5	7 h/day, 4, 5, and 7 days	NR	NR	Mouse (NR)	Streptococcus sp.	Elevated temperature (32°C) increased mortality after 7 days.	Gardner (1982)
1.9 3.8 7.0 9.2 14.8	4 h	M	NR	Mouse (NR)	S. aureus	Physical removal of bacteria unchanged by exposure. Bactericidal activity decreased by 7, 14, and 50%, respectively, in three highest NO ₂ -exposed groups.	Goldstein et al. (1973)
1.5- 5.0	3 h	F	6-10 wks	Mouse (CF-1, CD2F1)	Streptococcus sp.	Increased mortality in mice exposed to ≥2.0 ppm	Ehrlich et al. (1977) Ehrlich (1980)

ppm	EXPOSURE	GENDER	AGE	SPECIES (STRAIN)	INFECTIVE AGENT	EFFECTS	REFERENCES
1.5 2.5 3.5 5.0 10 15	2 h	NR	6-8 wks	Mouse (Swiss Webster)	K. pneumoniae	No effect at 1.5 or 2.5 ppm; increased mortality at 3.5 ppm and above. Increase in mortality when K. pneumoniae challenge 1 and 6 h after 5 or 10 ppm NO ₂ exposure; when K. pneumoniae challenge 27 h following NO ₂ exposure, effect only at 15 ppm.	Purvis and Ehrlich (1963) Ehrlich (1979)
2.0	1.5 h/day, 5 days/wk for 1, 2, and 3 wks	NR	2 wks	Hamster (Golden Syrian) (in vitro)	A/PR/8/34 influenza virus	Peak virus production in tracheal explants occurred earlier.	Schiff (1977)
2.5 4.0 5.0 10 15	4 h	F	NR	Mouse (Swiss)	S. aureus, Proteus mirabilis, Pasteurella pneumotropica	Concentration-related decrease in bactericidal activity at ≥ 4.0 ppm with S. aureus when NO ₂ exposure after bacterial challenge; when NO ₂ exposure was before challenge, effect at 10 ppm; NO ₂ concentrations >5.0 ppm required to affect bactericidal activity for other tested microorganisms.	Jakab (1987, 1988)
5.0 10	Continuous, 2 mos Continuous, 1 mo	M	NR	Monkey (Squirrel)	K. pneumoniae or A/PR/8 influenza virus	Increased viral-induced mortality (1/3). Increase in Klebsiella-induced mortality (2/7); no control deaths. Increased virus-induced mortality (6/6) within 2-3 days after infection; no control deaths. Increase in Klebsiella-induced mortality (1/4), no control deaths.	Henry et al. (1970)
5.0 10	4 h	M/F	6-10 wks	Mouse (C57BL6N, C3H/HeN)	Mycoplasma pulmonis	NO ₂ increased incidence and severity of pneumonia lesions and decreased the number of organisms needed to induce pneumonia; no effect on physical clearance; decreased mycoplasmal killing and increased growth; no effect on specific IgM in serum; C57B1/6N mice generally more sensitive than C3H/HeN mice. At 10 ppm, one strain (C57B1/6N) of mice had increased mortality.	Parker et al. (1989)
10 15 35 50	2 h	M/F	NR	Monkey (Squirrel)	K. pneumoniae	Clearance of bacteria from lungs of 10-, 15-, and 35-ppm groups delayed or prevented. All three animals in highest exposed group died.	Henry et al. (1969)
5	NR	NR	NR	Mice (NR)	Parainfluenza (murine sendei virus)	Altered the severity but not the course of the infection	Jakab (1988)

Table AX4.7. Lung structure.

ppm	EXPOSURE	GENDER	AGE	SPECIES (STRAIN)	EFFECTS	REFERENCE
3 9	6 h/day, 6 days/wk, for 2 wks	F	NR	Guinea Pig	Morphological changes observed at both concentrations. Ciliated cells displayed pathological changes such as cytoplasmic vacuolation and protrusion at 3 ppm, but eosinophils displayed normal morphology. Minor to major changes in epithelial cells (decreased number of specific granules, cytoplasmic vacuolization, and morphological changes in specific granules) and ciliated cells showed compound cilia, cytoplasmic vacuolization, and sloughing) at 9 ppm.	Ohashi et al. (1994)
5 25	6 h/day for 1, 3, or 5 days	NR	NR	Mouse (C57BL/6)	No lung inflammation or injury observed at 5 ppm at any time, compared to controls. 25 ppm NO ₂ induced acute lung injury (characterized by increases in protein, LDH, macrophages, and neutrophils recovered by BAL) at 25 ppm that peaked after 3 days, lesions within terminal bronchioles, and AHR. Another group of mice exposed for 5 days to 25 ppm and allowed to recover in room air for 20 days demonstrated resolution of the pattern of acute lung injury in these animals.	Poynter et al. (2006)
5 10 20	24 h/day, for 3 days	M	NR	Rat (Sprague-Dawley)	Significant alteration in morphology of Clara cells (loss of apical intra-luminal projects and damaged epithelium covered by a layer of CC10-reactive material) at ≥5 ppm.	Barth and Muller (1999)
5 10 20	24 h/day, for 25 days	M	NR	Rat (Sprague-Dawley)	No significant alteration of morphology of Clara cells compared to controls.	Barth and Muller (1999)
5 10 20	24 h/day, for 25 days	M	NR	Rat (Sprague-Dawley)	Exposure to 5 ppm showed no significant qualitative changes of the lung tissue, but animals exhibited slight fibrosis of the centroacinar alveolar septa, respiratory bronchioli, and interstitium, and irregularly shaped alveolar spaces at ≥10 ppm. Morphometric analysis showed significantly diminished alveolar surface density at ≥10 ppm. Suggests development of emphysema at ≥10 ppm. The avg medial thickness of the pulmonary artery was significantly increased at ≥10 ppm, but at 5 ppm, this parameter was significantly decreased, compared to controls. Authors reported negative correlation between avg medial thickness and alveolar surface density.	Barth et al. (1995)
5 10 20	24 h/day, for 3 days	M	NR	Rat (Sprague-Dawley)	Histopathology revealed structural alterations extending from slight interstitial edema after exposure to 5 ppm, to epithelial necrosis and interstitial inflammatory infiltration after exposure to 10 ppm, and an additional intra-alveolar edema after 20 ppm. Light microscopic examination did not confirm the qualitative histological changes, particularly muscularization of intra-acinar vessels. Exposure to ≥10 ppm for 25 days caused emphysema and slight centrilobular interstitial fibrosis. Morphometric analysis showed significantly diminished alveolar surface density at 10 ppm after 25 days of exposure and at 20 ppm after 3 and 25 days of exposure. Avg medial thickness of the pulmonary artery significantly increased at ≥10 ppm, but at 5 ppm, this parameter was significantly decreased both during after 3-day and 25-day exposures, compared to controls. Authors regarded the decrease in the medial thickness at 5 ppm as reflecting a reduction of pulmonary arterial mass and not as a result of vasodilation. Avg medial thickness and alveolar surface density were negatively correlated. Study indicates exposures to as low as 5 ppm is not likely to induce structural changes in the lung of rats. Effect on the morphometry of the alveolar region appeared to be time-dependent, since significant changes were seen at 10 ppm after 25 days, but only at 20 ppm in the 3-day exposure study.	Barth et al. (1995)

ppm	EXPOSURE	GENDER	AGE	SPECIES (STRAIN)	EFFECTS	REFERENCE
10 20	14 h/day, for 15 days, 20 or 25 days	M	NR	Mouse (C57/BL/5)	Initial dose response experiment identified 20 ppm NO ₂ as concentration causing lung injury and air inflammation (marked influx of inflammatory cells in the airways, predominated by macrophages and neutrophils and to a lesser extent by lymphocytes) for exposure that lasted 15 days, whereas 10 ppm did not induce significant increase in leukocyte amount in BAL fluid. Actual study using 20 ppm NO ₂ observed induction of air space enlargement (evidenced by a significant increase in mass-specific lung volume and volume-weighted alveolar volume). No significant changes in total alveolar surface area.	Wegman and Herz (2002)
0.8 5 10	24 h/day, for 1 or 3 days	M	NR	Rat (Sprague-Dawley)	Significant increase in Type II cell proliferation (evidenced by increases in AgNOR-number and BrdU-LI) after exposure to 5 ppm NO ₂ for 3 days and 10 ppm for 1 and 3 days. Significant increase in bronchiolar epithelial proliferation (increases in AgNOR-number and BrdU-LI) at ≥0.8 ppm for 1 and 3 days. In the bronchial epithelium, statistically significant increase in proliferation as increase in AgNOR-number at 10 ppm only after 3 days of exposure and as increase in BrdU-LI after exposure to 5 and 10 ppm for ≥1 day. Results showed highest rate of epithelial proliferation in the bronchiolar epithelium compared to bronchial epithelium and Type II cells. Study indicates cell proliferation changes beginning at concentrations as low 0.8 ppm NO ₂ following a single day of exposure.	Barth et al. (1994a)
5 10 20	24 h/day, for 3 or 25 days	M	NR	Rat (Sprague-Dawley)	<p>Compared to controls, proliferative activity (evidenced by increase in AgNOR-number) significantly increased, but with no concentration-dependence in respiratory bronchiolar epithelium at 5 ppm and above after 3-day exposure, but the increase was concentration-dependent, with significance at ≥10 ppm following 25-day exposure. Activity was increased in a concentration-dependent manner in bronchial epithelium with significance only at 20 ppm after 3 days of exposure and at ≥10 ppm following 25 days of exposure.</p> <p>Concentration-dependent thickening of alveolar septa and bronchiolar walls, significant only at ≥10 ppm after 3- and 25-day exposure, but 5 ppm caused significant thickening only in bronchiolar walls after 25 days, but not 3 days, of exposure compared to controls.</p> <p>Statistically significant reduction in alveoli surface density at ≥10 ppm after 25 days of exposure and at 20 ppm only after 3 days of exposure, while alveolar circumference increased statistically significantly at ≥10 ppm after 25 days of exposure and at 20 ppm following 3 days of exposure. 5 ppm did not significantly affect these endpoints after 3 or 25 days of exposure compared to controls. Data suggest concentration- and exposure duration-dependent development of emphysema, significant only at ≥10 ppm, but not at 5 ppm, after 3 or 25 days of exposure.</p> <p>Alveolar duct length increased significantly at ≥10 ppm after 25 days and at 20 ppm after 3 days of exposure; no effect at 5 ppm.</p> <p>Radial alveolar count values decreased significantly at 20 ppm after 3 and 25 days and at 10 ppm after 25 days exposure; no effect at 5 ppm.</p> <p>Increase in avg medial thickness at 10 ppm with significance only after 25 days of exposure and at 20 ppm with significance after 3 and 25 days of exposure. However, 5 ppm caused significant decrease at both 3 and 25 days of exposure. Authors suggested effect at 5 ppm was due to vasodilation induced by nitrogen oxide.</p>	Barth et al. (1994b)

ppm	EXPOSURE	GENDER	AGE	SPECIES (STRAIN)	EFFECTS	REFERENCE
25 50 75 100 150 200 250	5, 15, or 30 min 2, 5, 15, or 30 min 2, 5, or 15 min	M	NR	Rat (Fischer-344)	Animals exposed to ≥ 200 ppm NO ₂ for 30 min died within 24 h after exposure. NO ₂ exposure induced proportional increases in LWW, indicative of pulmonary edematous responses, over the same exposure period after the 15-min exposures. Animals exposed to 25 ppm NO ₂ did not produce observable lung injury (i.e., occurrence of alveolar fibrin and Type II cell hyperplasia) on exposure for 5 min. Animals exposed to all exposure concentrations for 15 min showed alveolar fibrin, while Type II hyperplasia occurred at 50 ppm and its level of expression correlated with exposure concentration. After 30 min of exposure, the occurrence of fibrin increased as a function of exposure concentration, while over a concentration range of 25-150 ppm NO ₂ , the Type II cell hyperplastic response increased with increasing exposure concentration. Data suggest exposure concentration was evidently more important than exposure time in terms of causing lung injury when high concentrations of NO ₂ are inhaled.	Lehnert et al. (1994)
3.6 7.2 10.8 14.4	24 h, 12 h, 8 h, and 6 h, respectively, for 3 days, giving a C H T of 86.4 ppm h	M	NR	Rat (Sprague-Dawley)	Short-term exposure was not sufficient to produce significant type I alveolar cell necrosis or a significant migration of inflammatory cells across the interstitium and alveolar epithelium.	Rajini et al. (1993)
0.5 base + 1.5 peak	Base presumably continuous, two 1-h peaks/day, for 9 wks	M	7 wks	Rat (Fischer-344)	No significant differences in thickness of the alveolar septal components, between controls and exposed group. Analysis of parenchymal cell populations showed no significant differences in the avg volumes of different cell types or in their surface areas. Total number of fenestrae in the lungs of NO ₂ -exposed animals occurred at a greater frequency than in controls, but no significant alterations were found in the connective tissue matrix or interstitial cell population, suggesting that connective tissue matrix and interstitial cells of the lung parenchyma did not undergo significant degeneration on exposure to the low level of NO ₂ used in this study.	Mercer et al. (1995)

Annex 5. Clinical Studies: Exposure to NO_x

AX5.1. Introduction

This annex summarizes the effects of NO_x on human volunteers exposed under controlled conditions. The goal is to review the scientific literature on human clinical studies of NO_x exposure published since the 1993 NO_x Air Quality Criteria Document (AQCD) (EPA 1993). The primary focus was on NO₂ because it is the most abundant NO_x species in the atmosphere and there are few human studies of exposure to other NO_x species.

Clinical summary conclusions from the 1993 AQCD are provided below:

- NO₂ causes decrements in lung function, particularly increased airway resistance in healthy subjects at concentrations exceeding 2.0 ppm for 2 h.
- NO₂ exposure results in increased airway responsiveness in healthy, nonsmoking subjects exposed to concentrations exceeding 1.0 ppm for 1 hour or longer.
- NO₂ exposure at levels above 1.5 ppm may alter numbers and types of inflammatory cells in the distal airways or alveoli, but these responses depend upon exposure concentration, duration, and frequency. NO₂ may alter function of cells within the lung and production of mediators that may be important in lung host defenses.
- NO₂ exposure of asthmatics causes, in some subjects, increased airway responsiveness to a variety of provocative mediators, including cholinergic and histaminergic chemicals, SO₂ and cold air. However, the presence of these responses appears to be influenced by the exposure protocol, particularly whether or not the exposure includes exercise.
- Modest decrements in spirometric measures of lung function (3 to 8%) may occur in some asthmatics and COPD patients under certain NO₂ exposure conditions.
- Nitric acid levels in the range of 50 to 200 ppb may cause some pulmonary function responses in adolescent asthmatics, but not in healthy adults. Other commonly occurring NO_x species do not appear to cause any pulmonary function responses at concentrations expected in the ambient environment, even at higher levels than in worst-case scenarios. However, not all NO_x acid species have been studied sufficiently.
- No association between lung function responses and respiratory symptom responses were observed. Furthermore, there is little evidence of a concentration-response relationship for changes in lung function, airway responsiveness, or symptoms at the NO₂ levels that are reviewed here.

In the summary and integration chapter of the 1993 NO_x criteria document, one of the key health effects at near ambient concentrations of NO₂ was increased airway responsiveness or hyperresponsiveness in asthmatic individuals after short-term exposures. The 1993 AQCD notes the absence of a concentration-response relationship for NO₂ exposure and airway responsiveness in asthmatics. For example, most responses to NO₂ that had been observed in asthmatics occurred at concentrations between 0.2 and 0.5 ppm. However, other studies showed an absence of effects on airway responsiveness or hyperresponsiveness at much higher concentrations, up to 4 ppm. Since 1993, additional studies have suggested that exposure to low concentrations of NO₂, either alone or in

combination with other pollutants such as SO₂, may enhance allergen responsiveness in asthmatic subjects.

In the years since the preparation of the 1993 AQCD, many studies from a variety of disciplines have convincingly demonstrated that exposure to particulate air pollution increases the risk for cardiovascular events. In addition, a number of epidemiological studies have shown associations between ambient NO₂ levels and adverse cardiovascular outcomes, at concentrations well below those shown to cause respiratory effects. However, to date there remain very few clinical studies of NO₂ that include endpoints relevant to cardiovascular disease.

AX5.1.1. Considerations in Controlled Human Clinical Studies

Human clinical studies attempt to engineer laboratory atmospheric conditions relevant to ambient pollutant atmospheres, with careful control of concentrations, duration, timing, and other conditions which may impact responses. These studies provide the opportunity to measure symptoms and physiological markers of health effects that result from breathing the atmospheres. The carefully controlled environment allows investigators to identify responses to individual pollutants, to characterize exposure-response relationships, to examine interactions among pollutants, and to study the effects of other variables such as exercise, humidity, or temperature. Susceptible populations can participate, including individuals with acute and chronic respiratory and cardiovascular diseases, with appropriate limitations based on subject comfort and protection from risk. Endpoint assessment traditionally has included symptoms and pulmonary function, but more recently a variety of markers of pulmonary, systemic, and cardiovascular function have been used to assess pollutant effects.

Human clinical studies have limitations. For practical and ethical reasons, studies must be limited to relatively small groups, to short durations of exposure, and to pollutant concentrations that are expected to produce only mild and transient responses. Findings from the short-term exposures in clinical studies may provide limited insight into the health effects of chronic or repeated exposures.

Specific issues of protocol design in human clinical studies have been reviewed (Frampton, Pietropaoli et al. 2006), and will not be considered further here, except in the context of specific studies of NO₂ exposure described in the following pages.

In clinical studies, humans are the species of interest, so findings have particular relevance to risk assessment. However, the utility of clinical studies in risk assessment is tempered by the obvious need to avoid adverse health effects of the study itself. This usually means selecting subjects that are not the most susceptible to the pollutant being studied. Furthermore, clinical studies depend on outcome markers with variable relevance or validation as markers of true health effects. The statement from the American Thoracic Society, “What constitutes an adverse health effect?” (American Thoracic Society 2000) addresses issues relevant to selection and interpretation of outcome markers in clinical studies.

The 1993 NO_x AQCD included a description of key outcome measures that had been in use up to that date. These included primarily respiratory outcomes, including pulmonary function tests such as spirometry, lung volumes, and airway resistance, and tests of pulmonary clearance of inhaled aerosols. A brief description of bronchoalveolar lavage was also included, which had come into use prior to 1993 to assess airway inflammation and changes in the epithelial lining fluid in response to NO₂ exposure.

AX5.2. Effects of NO₂ in Healthy Subjects

Table AX5.2-1 summarizes the key clinical studies of NO₂ exposure in healthy subjects since 1993, with a few key studies included prior to that date.

AX5.3. Effects of NO_x Exposure in Sensitive Subjects

Table AX5.3-1 summarizes studies of potentially sensitive subjects. The potential for NO₂ exposure to enhance responsiveness to allergen challenge in asthmatics deserves special mention. Several recent studies, summarized in Table AX5.3-2, have reported that low-level exposures to NO₂, both at rest and with exercise, enhance the response to specific allergen challenge in mild asthmatics.

These recent studies involving allergen challenge suggest that NO₂ may enhance the sensitivity to allergen-induced decrements in lung function, and increase the allergen-induced airway inflammatory response.

AX5.4. Effects of Mixtures Containing NO_x

Table AX5.4-1 summarizes human clinical studies of NO₂-containing mixtures or sequential exposures that are most relevant to ambient exposure scenarios.

Table AX5.2-1. Clinical studies – healthy subjects.

STUDY	LOCATION	PARTICIPANTS	METHODS	FINDINGS	COMMENTS
Avissar et al. (2000)	Rochester, NY, USA	21 healthy nonsmokers	Measurements of extracellular glutathione peroxidase (eGPx) activity and protein levels in epithelial lining fluid from NO ₂ exposure study described in Frampton et al. (2002) (see below).	No effects of NO ₂ exposure on eGPx activity and protein concentrations. (O ₃ exposure decreased eGPx activity and protein concentrations.)	NO ₂ up to 1.5 ppm for 3 h did not deplete this mode of antioxidant defense in the epithelial lining fluid.
Azadniv et al. (1998)	Rochester, NY, USA	2 studies, 12 healthy nonsmokers in each	Air vs. 2 ppm NO ₂ for 6 h with intermittent exercise. Phase 1: BAL 18 h after exposure; Phase 2: BAL immediately after exposure.	Increased BAL neutrophils, decreased blood CD8+ and null T lymphocytes 18 h after exposure. No effects on symptoms or lung function.	2 ppm NO ₂ for 6 h caused mild inflammation.
Blomberg et al. (1997)	Sweden	30 healthy nonsmokers	Air vs. 2 ppm NO ₂ for 4 h, with intermittent exercise.	Increased neutrophils and interleukin-8 in bronchial wash. Increases in specific lymphocyte subsets in BAL fluid. Symptoms/lung function not reported.	2 ppm NO ₂ for 4 h caused airway inflammation.
Blomberg et al. (1999)	Sweden	12 healthy nonsmokers	Air vs. 2 ppm NO ₂ for 4 h on 4 days, with intermittent exercise.	After 4 days of NO ₂ , increased neutrophils in bronchial wash but decreased neutrophils in bronchial biopsy. 2% decrease in FEV1 after first exposure to NO ₂ , attenuated with repeated exposure. Symptoms not reported.	Decreased lung function, not confirmed in other studies at this concentration. Conflicting information on airway inflammation.

STUDY	LOCATION	PARTICIPANTS	METHODS	FINDINGS	COMMENTS
Devlin et al. (1999; Frampton, Boscia et al. 2002)	Chapel Hill, NC, USA	8 healthy nonsmokers	Air and 2.0 ppm NO ₂ for 4 h with intermittent exercise.	Increased bronchial lavage neutrophils, IL-6, IL-8, alpha1-antitrypsin, and tissue plasminogen activator. Decreased alveolar macrophage phagocytosis and superoxide production. No effects on pulmonary function. Symptoms not reported.	2 ppm NO ₂ for 4 h caused airway inflammation.
Drechsler-Parks (1995)	Santa Barbara, CA, USA	8 older healthy nonsmokers	4 2-h exposures with intermittent exercise: air, 0.60 ppm NO ₂ , 0.45 ppm O ₃ , and 0.60 ppm NO ₂ + 0.45 ppm O ₃ .	Significant reduction in cardiac output during exercise, estimated using noninvasive impedance cardiography, with NO ₂ + O ₃ . Symptoms and pulmonary function not reported.	Suggests cardiac effects of NO ₂ + O ₃ . Small number of subjects limits statistical power, has not been replicated.
Frampton et al. (1991)	Rochester, NY, USA	39 healthy nonsmokers	3 protocols, all for 3 h with control air exposure: (1) continuous 0.06 ppm NO ₂ , (2) baseline 0.05 ppm NO ₂ with peaks of 2.0 ppm, and (3) continuous 1.5 ppm NO ₂ .	No symptoms or direct effects on pulmonary function. Increased airways responsiveness to carbachol after 1.5 ppm NO ₂ .	Evidence for increased nonspecific airways responsiveness with NO ₂ as low as 1.5 ppm for 3 h.
Frampton et al. (2002)	Rochester, NY, USA	21 healthy nonsmokers	Exposure to air, 0.6, 1.5 ppm NO ₂ for 3 h with intermittent exercise.	Dose-related decrease in hematocrit, hemoglobin, blood lymphocytes, and T lymphocytes. Mild increase in neutrophils recovered in bronchial portion of BAL fluid. In vitro viral challenge of bronchial epithelial cells showed increased cytotoxicity after NO ₂ . No effects on symptoms or pulmonary function.	Indicates NO ₂ causes airway inflammation. Suggest subtle effects on red blood cells, possibly RBC destruction (hemolysis).
Gong et al. (2005)	Downey, CA, USA	6 healthy nonsmokers and 18 ex-smokers with COPD	2 h exposures with intermittent exercise to: (1) air, (2) 0.4 ppm NO ₂ , (3) 200 µg/m ³ concentrated ambient particulate matter (CAPs), (4) NO ₂ + CAPs.	Reduced maximum mid-expiratory flow rate and oxygen saturation with CAPs exposures; no effects of NO ₂ alone or additive effect with CAPs.	Exposures not fully randomized. Small number of healthy subjects limits interpretation for healthy group.
Helleday et al. (1994)	Sweden	8 healthy smokers, 8 healthy nonsmokers	3.5 ppm NO ₂ for 20 min with 15 min exercise. BAL 24 h after exposure compared with non-exposure control BAL.	Different inflammatory cell increases in smokers and nonsmokers. No effects on symptoms. Pulmonary function not reported.	Lack of control air exposure with exercise is problematic.
Helleday et al. (1995)	Sweden	24 healthy nonsmokers, 8 in each of 3 groups	Bronchoscopic assessment of mucociliary activity: (1) 45 min after 1.5 ppm NO ₂ for 20 min, (2) 45 min after 3.5 ppm NO ₂ for 20 min, and (3) 24 h after 3.5 ppm NO ₂ for 4 h.	Complete abolition of mucociliary activity 20 min after NO ₂ ; increased activity 24 h after NO ₂ . Symptoms/ pulmonary function not reported.	No true air control exposure, order of procedures not randomized, subjects not blinded.
Jörres et al. (1995)	Germany	8 healthy nonsmokers & 12 mild asthmatics	Air or 1 ppm NO ₂ exposure for 3 h with intermittent exercise.	In asthmatics, 2.5% decrease FEV1 after NO ₂ vs. 1.3% decrease after air, p = 0.01. FEV1 decreased 20% in 1 subject after NO ₂ . No significant lung function effect in healthy subjects. Changes in eicosanoids (more pronounced in asthmatics), but not inflammatory cells, in BAL fluid.	Lung function effects consistent with other studies, suggesting some asthmatics susceptible. Evidence for mild airway inflammation.

STUDY	LOCATION	PARTICIPANTS	METHODS	FINDINGS	COMMENTS
Kim et al. (1991)	Seattle, WA, USA	9 healthy athletes	Air, 0.18, and 0.30 ppm NO ₂ for 30 min with exercise.	No effects on pulmonary function. Symptoms not reported.	Small number of subjects limits conclusions.
Morrow et al. (1992)	Rochester, NY, USA	20 COPD subjects (14 current smokers) and 20 elderly healthy (13 never-smokers, 4 former smokers, 3 current smokers)	Air vs. 0.3 ppm NO ₂ for 4 h with intermittent exercise.	COPD: small declines in FVC and FEV1 with NO ₂ . Healthy: No symptoms or pulmonary function effects for group as a whole. Healthy smokers showed a 2.3% decline in FEV1 with NO ₂ , and differed from nonsmokers.	Mild lung function effects of 0.3 ppm for 4 h in exercising patients with COPD. Small number of healthy smoking subjects limits conclusions regarding this group.
Pathmanathan et al. (2003)	United Kingdom	12 healthy nonsmokers	Air vs. 2 ppm NO ₂ for 4 h on 4 days, with intermittent exercise. Bronchoscopy and biopsy 1 h after exposure.	Epithelial expression of IL-5, IL-10, IL-13, and ICAM-1 increased following NO ₂ exposure. No data on inflammatory cells in BAL fluid.	Supportive evidence for pro-allergic airway inflammation favoring following NO ₂ exposure.
Posin et al. (1978)	Downey, CA, USA	10 healthy nonsmokers	3 daily exposures for 2.5 h. 1st day: air; 2nd and 3rd days: 1 or 2 ppm NO ₂ . Intermittent exercise. Subsequent control series of 3 daily air exposures.	Reduced hemoglobin and hematocrit, and red blood cell acetyl cholinesterase.	Suggests red blood cell effects of NO ₂ (see Frampton et al., 2002). Exposures not randomized.
Rasmussen et al. (1992)	Denmark	14 healthy nonsmokers	Air vs. 2.3 ppm NO ₂ for 5 h.	Small increases in FVC and FEV1. Reduced lung permeability and blood glutathione peroxidase after exposure.	Only 1 wk between exposures may have confounded results.
Rigas et al. (1997)	State College, PA, USA	12 healthy nonsmokers	2 h of 0.36 ppm NO ₂ , 0.75 ppm NO ₂ , 0.36 ppm SO ₂ , or 0.36 ppm O ₃ . Boluses of O ₃ every 30 min to measure O ₃ absorption.	NO ₂ and SO ₂ increased O ₃ absorption by increasing biochemical substrates.	Suggests breathing mixtures of NO ₂ and O ₃ would increase O ₃ dose to airways.
Sandström et al. (1990)	Sweden	32 healthy nonsmokers, 4 groups of 8 subjects	4 ppm NO ₂ for 20 min with 15 min exercise. BAL 4, 8, 24, 72 h after exposure, compared with non-exposure control BAL.	Increase in BAL mast cells and lymphocytes 4-24 h after exposure.	Study weakened by lack of control air exposure.
Sandström et al. (1991)	Sweden	18 healthy nonsmokers	2.25, 4.0, 5.5 ppm NO ₂ for 20 min with light exercise. BAL 24 h after exposure, compared with non-exposure control BAL.	Increase in BAL mast cells (all concentrations) and lymphocytes (4.0 and 5.5 ppm).	Study weakened by lack of control air exposure.
Sandström et al. (1992a)	Sweden	10 healthy nonsmoking men	4 daily exposures to 4 ppm NO ₂ for 20 min with 15 min exercise. BAL 24 h after exposure, compared with non-exposure control BAL.	Reduction in alveolar macrophages, NK cells, and CD8 lymphocytes in BAL; reduction in total lymphocytes in blood.	Study weakened by lack of control air exposure.
Sandström et al. (1992b)	Sweden	8 healthy nonsmokers	1.5 ppm NO ₂ for 20 min with 15 min exercise, every 2nd day H 6. BAL 24 h after exposure compared with non-exposure control BAL.	Reduced CD8+ T lymphocytes and NK cells in BAL fluid.	Study weakened by lack of control air exposure.

STUDY	LOCATION	PARTICIPANTS	METHODS	FINDINGS	COMMENTS
Solomon et al.(2000)	San Francisco, CA, USA	15 healthy nonsmokers	Air or 2.0 ppm NO ₂ with intermittent exercise, for 4 h daily H 4. BAL 18 h after exposure.	Increased neutrophils in bronchial lavage decreased CD4+ T lymphocytes in BAL. No changes in blood.	Airway inflammation with 2 ppm NO ₂ for 4 daily 4 h exposures.
Vagaggini et al. (1996)	Italy	7 healthy nonsmokers	Air vs. 0.3 ppm NO ₂ for 1 h with intermittent exercise.	Mild increase in symptoms. No effects on lung function, nasal lavage, or induced sputum.	Small number of subjects limits statistical power.

Table AX5.3-1. Subjects with respiratory disease.

REFERENCE	LOCATION	PARTICIPANTS	APPROACH & METHODS	FINDINGS	COMMENTS
Gong et al. (2005)	Downey, CA, USA	6 healthy nonsmokers and 18 ex-smokers with COPD	2 h exposures with intermittent exercise to: (1) air, (2) 0.4 ppm NO ₂ , (3) 200 µg/m ³ concentrated ambient particulate matter (CAPs), (4) NO ₂ + CAPs.	Reduced maximum mid-expiratory flow rate and oxygen saturation with CAPs exposures; no effects of NO ₂ alone or additive effect with CAPs.	Exposures not fully randomized. Small number of subjects limits interpretation for healthy group.
Hackney et al. (1992)	Downey, CA, USA	26 smokers with symptoms and reduced FEV ₁	Personal monitoring and chamber exposure to air and 0.3 ppm NO ₂ for 4 h with intermittent exercise.	No significant effects on lung function.	
Jörres and Magnussen (1991)	Germany	11 mild asthmatics	Air vs. 0.25 ppm NO ₂ for 30 min with 10 min exercise.	No effects on lung function or airways responsiveness to methacholine.	
Jörres et al. (1995)	Germany	8 healthy nonsmokers & 12 mild asthmatics	Air or 1 ppm NO ₂ exposure for 3 h with intermittent exercise.	In asthmatics, 2.5% decrease FEV ₁ after NO ₂ vs. 1.3% decrease after air, p = 0.01. FEV ₁ decreased 20% in 1 subject after NO ₂ . No significant lung function effect in healthy subjects. Changes in eicosanoids (more pronounced in asthmatics), but not inflammatory cells, in BAL fluid.	Lung function effects consistent with other studies, suggesting some asthmatics susceptible. Evidence for mild airway inflammation. Small number of healthy subjects limits statistical power.
Morrow et al. (1992)	Rochester, NY, USA	20 COPD, 20 healthy elderly	Air vs. 0.3 ppm NO ₂ for 4 h with intermittent exercise.	Equivocal reduction in FVC with COPD patients, but not healthy subjects.	
Strand et al. (1997)	Sweden	19 mild asthmatics	Air vs. 0.26 ppm NO ₂ for 30 min with intermittent exercise.	Increased airway responsiveness to histamine 5 h after exposure. No effects on lung function.	Suggests increased nonspecific airways responsiveness at much lower concentration than healthy subjects. Differs from findings in Jörres and Magnussen (1991).
Vagaggini et al. (1996)	Italy	8 mild asthmatics, 7 COPD	Air vs. 0.3 ppm NO ₂ for 1 h with intermittent exercise.	Mild decrease in FEV ₁ in COPD subjects in comparison with air exposure, but not with baseline. No effects on nasal lavage or induced sputum.	No convincing effect of NO ₂ in this study. Small number of subjects limits statistical power.

Table AX5.3-2. Inhaled allergen.

REFERENCE	LOCATION	PARTICIPANTS	APPROACH & METHODS	FINDINGS	COMMENTS
Barck et al. (2002)	Sweden	13 mild asthmatics, 4 ex-smokers	30 min exposures to air and 0.26 ppm NO ₂ (at rest?), allergen challenge 4 h and BAL 19 h after exposure. Randomized, crossover, double blind.	Increased PMN in bronchial wash and BAL fluid, increased eosinophil cationic protein in bronchial wash, and reduced cell viability and BAL volume with NO ₂ + allergen. No effects on lung function response to allergen.	Key study suggesting that NO ₂ enhances inflammatory response to allergen in mild asthmatics.
Barck et al. (2005)	Sweden	18 mild asthmatics, 4 ex-smokers	Day 1: 15 min exposures, Day 2: 2 15-min exposures to air and 0.26 ppm NO ₂ separated by 1 h, at rest. Allergen challenge 4 h after exposure on day 1 and 3 h after exposure on day 2. Sputum induction before exposure on days 1 & 2, and morning of day 3. Randomized, crossover, single blind.	Increased eosinophilic cationic protein in sputum and blood, and increased myeloperoxidase in blood with NO ₂ + allergen. No differences in lung function or sputum cells.	Provides supporting evidence that NO ₂ enhances the airway inflammatory response to allergen.
Barck et al. (2005)	Sweden	16 mild asthmatics with rhinitis	30 min exposures to air and 0.26 ppm NO ₂ at rest, nasal allergen challenge 4 h after exposure. Nasal lavage before and at intervals after exposure and challenge.	No significant differences between air and NO ₂ exposure.	0.26 ppm NO ₂ did not enhance nasal inflammatory response to allergen challenge.
Devalia et al. (1994)	United Kingdom	8 mild asthmatics	6 h exposures to combination of 0.4 ppm NO ₂ and 0.2 ppm SO ₂ .	Increased allergen responsiveness 10 min after exposure to combination of NO ₂ and SO ₂ , but not to individual gases.	Small number of subjects limits statistical power.
Jenkins et al. (1999)	United Kingdom	11 mild asthmatics	(1) 6-h exposures to air, 0.1 ppm O ₃ , 0.2 ppm NO ₂ , and combination followed by allergen challenge; (2) 3-h exposures to air, 0.2 ppm O ₃ , 0.4 ppm NO ₂ , and combination; All exposures with intermittent exercise.	All of the second exposure scenarios (O ₃ , NO ₂ , and combination), but none of the first exposure scenarios, resulted in reduced concentration of allergen causing a 20% decline in FEV1. Authors conclude that concentration more important than total inhaled pollutant.	Suggests 0.4 ppm for 3 h with intermittent exercise increases allergen responsiveness.
Rusznak et al. (1996)	United Kingdom	13 mild asthmatics	6 h exposures to combination of 0.4 ppm NO ₂ and 0.2 ppm SO ₂ .	Increased allergen responsiveness to combination of NO ₂ and SO ₂ , 10 min, 24, and 48 h after exposure.	Confirms findings of Devalia et al. (1994), that NO ₂ + SO ₂ for 6 h increases allergen responsiveness.
Strand et al. (Strand, Rak et al. 1997)	Sweden	18 patients with mild asthma, age 18-50 yrs	Exposure to 0.26 ppm NO ₂ for 30 min at rest, allergen challenge 4 h after exposure.	Late phase, but not early phase, response to allergen enhanced by NO ₂ .	Suggests 0.26 ppm NO ₂ for 30 min at rest increases late response.
Strand et al. (1998)	Sweden	16 patients with mild to moderate asthma, age 21-52 yrs	4 daily repeated exposures to 0.26 ppm NO ₂ for 30 min at rest.	Significant increases in both early and late phase response to allergen after 4th day of exposure.	Suggests repeated 0.26 ppm NO ₂ at rest increases allergen response.
Tunnicliffe et al. (1994)	United Kingdom	10 nonsmoking mild asthmatics age 16-60 yrs. 8 subjects completed.	Exposure to air, 0.1 ppm, and 0.4 ppm NO ₂ for 1 h at rest, separated by at least 1 wk, followed by allergen challenge.	Post-challenge reduction in FEV1 after 0.4 ppm NO ₂ was greater than after air, for both the early (p < 0.009) and late (p < 0.02) responses. No difference in nonspecific airway responsiveness.	Suggests threshold for allergen responsiveness effect is between 0.1 and 0.4 ppm for 1 h resting exposure.

REFERENCE	LOCATION	PARTICIPANTS	APPROACH & METHODS	FINDINGS	COMMENTS
Wang et al. (1995)	United Kingdom	2 groups of 8 subjects with allergic rhinitis	Exposure to 0.4 ppm NO ₂ (at rest?) for 6 h followed by nasal allergen challenge and nasal lavage.	Increase in myeloperoxidase and eosinophil cationic protein in nasal lavage fluid following allergen challenge.	Suggests enhanced nasal inflammatory response to allergen with 0.4 ppm.
Wang et al. (1999)	United Kingdom	16 subjects with allergic rhinitis	Treatment with nasal fluticasone or placebo for 4 wks followed by exposure to 0.4 ppm NO ₂ for 6 h, allergen challenge, and nasal lavage.	Fluticasone suppressed the NO ₂ and allergen-induced increase in eosinophil cationic protein in nasal lavage fluid.	Confirms earlier findings of this group that 0.4 ppm NO ₂ enhances nasal allergen response.

Table AX5.4-1. NO₂ and other pollutants.

STUDY	LOCATION	PARTICIPANTS	METHODS	FINDINGS	COMMENTS
Devalia et al. (1994)	United Kingdom	8 mild asthmatics	6 h exposures to combination of 0.4 ppm NO ₂ and 0.2 ppm SO ₂ .	Increased allergen responsiveness 10 min after exposure to combination of NO ₂ and SO ₂ , but not to individual gases.	Small number of subjects limits statistical power.
Drechsler-Parks (1995)	Santa Barbara, CA, USA	8 older healthy nonsmokers	4 2-h exposures with intermittent exercise: air, 0.60 ppm NO ₂ , 0.45 ppm O ₃ , and 0.60 ppm NO ₂ + 0.45 ppm O ₃ .	Significant reduction in cardiac output during exercise, estimated using noninvasive impedance cardiography, with NO ₂ + O ₃ . Symptoms and pulmonary function not reported.	Suggests cardiac effects of NO ₂ + O ₃ . Small number of subjects limits statistical power, has not been replicated.
Gong et al. (2005)	Downey, CA, USA	6 healthy nonsmokers and 18 ex-smokers with COPD	2 h exposures with intermittent exercise to: (1) air, (2) 0.4 ppm NO ₂ , (3) 200 µg/m ³ concentrated ambient particulate matter (CAPs), (4) NO ₂ + CAPs.	Reduced maximum mid-expiratory flow rate and oxygen saturation with CAPs exposures; no effects of NO ₂ alone or additive effect with CAPs.	Exposures not fully randomized. Small number of healthy subjects limits interpretation for healthy group.
Hazucha et al. (1994)	Chapel Hill, NC, USA	21 healthy female nonsmokers	2 h exposure to air or 0.6 ppm NO ₂ followed 3 h later by exposure to 0.3 ppm O ₃ , with intermittent exercise.	NO ₂ enhanced spirometric responses and airways responsiveness following subsequent O ₃ exposure.	0.6 ppm NO ₂ enhanced ozone responses.
Jörres and Magnussen (1990)	Germany	14 nonsmoking mild asthmatics	30 min exposures to air, 0.25 ppm NO ₂ , or 0.5 ppm SO ₂ at rest followed 15 min later by 0.75 ppm SO ₂ hyperventilation challenge.	NO ₂ but not SO ₂ increased airways responsiveness to SO ₂ challenge.	Findings contrast with Rubenstein et al. (1990).
Koenig et al. (1994)	Seattle, WA, USA	28 asthmatic adolescents; 6 subjects did not complete.	Exposure for 90 min with intermittent exercise to: (1) 0.12 ppm ozone + 0.3 ppm NO ₂ , (2) 0.12 ppm ozone + 0.3 ppm NO ₂ + 68 µg/m ³ H ₂ SO ₄ , or (3) 0.12 ppm ozone + 0.3 ppm NO ₂ + 0.05 ppm nitric acid.	No effects on pulmonary function.	Absence of lung function effects of 0.3 ppm NO ₂ consistent with other studies; no effects of mixtures.
Rubenstein et al. (1990)	San Francisco, CA, USA	9 stable asthmatics	30 min exposures to air or 0.3 ppm NO ₂ with 20 min exercise, followed 1 h later by SO ₂ inhalation challenge.	No effects on pulmonary function or SO ₂ responsiveness.	Findings contrast with Jörres and Magnussen et al. (1990).

STUDY	LOCATION	PARTICIPANTS	METHODS	FINDINGS	COMMENTS
Rudell et al. (1999)	Sweden	10 healthy nonsmokers	Air and diesel exhaust for 1 h, with and without particle trap. NO ₂ concentration 1.2-1.3 ppm. BAL 24 h after exposures.	Increased neutrophils in BAL fluid, no significant reduction in effect with particle trap.	Filter only partially trapped particles. Unable to draw conclusions about role of NO ₂ in causing effects.
Rusznak et al. (1996)	United Kingdom	13 mild asthmatics	6 h exposures to combination of 0.4 ppm NO ₂ and 0.2 ppm SO ₂ .	Increased allergen responsiveness to combination of NO ₂ and SO ₂ , 10 min, 24, and 48 h after exposure.	Confirms findings of Devalia et al. (1994), that NO ₂ + SO ₂ for 6 h increases allergen responsiveness.

Annex 6. Epidemiologic Studies Related to Ambient Exposure to NO_x

This annex provides supplemental information on various epidemiologic methods and studies that are referenced in the 2008 NO_x ISA. The first section describes considerations in the interpretation of epidemiologic studies. This is followed by a section on cardiovascular effects that are related to short-term exposure to NO₂. This topic is discussed in the ISA, but more detail is provided in this annex due to inconsistency with supporting studies. The second section of this annex presents tables detailing the epidemiologic studies presented in the ISA. In general, these tables are divided into sections based on the endpoint of concern. Tables AX6.3-1 through AX6.3-5 cover respiratory endpoints, while tables AX6.3-6 to AX6.3-9 address cardiovascular disease. The two tables, AX6.3-10 and AX6.3-11 summarize heart rate variability. Tables AX6.3-12 through AX6.3-14 address birth outcomes: birthweight, pre-term births, and lung growth, respectively, and tables AX6.3-15 through AX6.3-19 look at the long-term effects associated with NO₂ exposure (i.e., lung function, asthma, respiratory symptoms, lung cancer, and mortality). Lastly, table AX6.3-20 summarizes the effects of NO₂ on asthmatics.

AX6.1. Interpretation of Epidemiologic Studies

This section mainly focuses on the topics of exposure assessment and model specification in air pollution epidemiologic studies. The initial discussion addresses potential biases that may result from NO₂ exposure measurement error and from the choice of exposure index and lag period. The remaining discussion highlights model specification issues and potential confounding by temporal factors, meteorological effects, seasonal trends, and copollutants.

AX6.1.1. Exposure Assessment and Measurement Error

In many air pollution epidemiologic studies, especially time-series studies that use administrative data on mortality and hospitalization outcomes, air pollution data from central ambient monitoring sites are used as the estimate of exposure. Personal exposures of individual study subjects, usually, are not directly measured in epidemiologic studies. The relationship between NO₂ concentrations from ambient monitors and personal NO₂ exposures was discussed previously (Annex AX3). Routinely collected ambient monitor data, though readily available and convenient, may not represent true personal exposure, which includes both ambient and nonambient (i.e., indoor) source exposures. Also, personal exposure measurements and ambient measurements are subject to different types of artifacts and measurement error. Therefore, they may not be measuring the same quantities.

As discussed thoroughly in the 2004 PM AQCD (Section 8.4.5), the resulting exposure measurement error and its effect on the estimates of relative risk is an important consideration for interpreting epidemiologic study results. In theory, there are three components to exposure measurement error in time-series studies as described by Zeger et al. (2000): (1) the use of average population rather than individual exposure data; (2) the difference between average personal ambient exposure and ambient concentrations at central monitoring sites; and (3) the difference between true and measured ambient concentrations. The first error component, having aggregate rather than individual exposure data, is a Berksonian measurement error, which in a simple linear model increases the standard error, but does not bias the risk estimate. The second error component, which results from the difference between community average personal ambient exposure and outdoor ambient concentration level, has the greatest potential to

introduce bias. If the error is of a fixed amount (i.e., absolute differences do not change with increasing concentrations), there is no bias. However, if the error is not a fixed difference, this error will likely attenuate the NO₂ risk estimate as personal NO₂ exposures are generally lower than ambient NO₂ concentrations in homes without sources, while they are higher in homes with sources. The third error component, the instrument measurement error in the ambient levels, is referred to as nondifferential measurement error and is unlikely to cause substantial bias, although it can lead to a bias toward the null.

The impact of exposure measurement error on NO₂ effect estimates was demonstrated in a study by Kim et al. (2006), which is a longitudinal study that investigated personal exposures to NO₂, PM_{2.5}, and CO for cardiac compromised individuals in Toronto, Canada. The mean (SD) personal exposure for NO₂ was 14 ppb (6). NO₂ personal exposures were less than central-fixed-site ambient measurements. Ambient NO₂ was correlated with the personal exposure to NO₂ (median Spearman's correlation coefficient of 0.57). Personal exposures to PM_{2.5} were correlated with the personal exposure to NO₂ (median Spearman's correlation coefficient of 0.43). This study suggests that central-fixed-site measurements of PM_{2.5} and NO₂ may be treated as surrogates for both exposure to PM_{2.5} and NO₂ in time-series epidemiology studies, and that NO₂ is a potential confounder of PM_{2.5} and vice versa. As described in Chapter 2, Nerriere et al. (2005) provided additional data from European cities, noting that season, city, and land use dependence were important factors affecting the relationship between personal exposure to ambient NO₂ and corresponding ambient monitoring site concentrations, and recommended a site-specific analysis for a specific study. Zidek (1997) noted that a statistical analysis must balance bias and imprecision (error variance). Ignoring measurement error in air pollution epidemiologic studies often results in underestimated risk estimates and standard errors.

In addition, the use of ambient NO₂ concentrations may obscure the presence of thresholds in epidemiologic studies at the population level due to the overestimation of exposure and the resulting underestimation of effects. Using PM_{2.5} as an example, Brauer et al. (2002) examined the relationship between ambient concentrations and mortality risk in a simulated population with specified common individual threshold levels. They found that no population threshold was detectable when a low threshold level was specified. Even at high-specified individual threshold levels, the apparent threshold at the population level was much lower than the specified threshold. Brauer et al. (2002) concluded that surrogate measures of exposure (i.e., those from centrally-located ambient monitors) that were not highly correlated with personal exposures obscured the presence of thresholds in epidemiologic studies at the population level, even if a common threshold exists for individuals within the population.

As discussed in Chapter 2, NO₂ concentrations measured at central ambient monitors may explain, at least partially, the variance of individual personal exposures; however, this relationship is influenced by factors such as air exchange rates in housing and time spent outdoors, which may vary by city. Other studies conducted in various cities observed that the daily averaged personal NO₂ exposures from the population were well correlated with monitored ambient NO₂ concentrations, although substantial variability existed among the personal measurements. Thus, there is supportive evidence that ambient NO₂ concentrations from central monitors may serve as valid surrogate measures for mean personal NO₂ exposures experienced by the population, which is of most relevance to time-series studies (See Chapter 2). Respiratory hospital visit and admission studies are influenced by the visits and admission of asthmatics. In children, for whom asthma is more prevalent, ambient monitors may correlate, to some extent, with personal exposure to NO₂ of ambient origin because children spend more time outdoors in the warm season and have an increased potential for exposure due to traffic. However, of some concern for mortality and hospitalization time-series studies is the extent to which ambient NO₂ concentrations are representative of personal NO₂ exposures in another particularly susceptible group of individuals, the debilitated elderly. To date, the correlation between the two measurements has not been examined in this population. A better understanding of the relationship between ambient concentrations and personal exposures, as well as the factors that affect the relationship will improve the interpretation of the ambient concentration-population health response associations observed.

Existing epidemiologic models may not fully take into consideration all of the biologically relevant exposure history or reflect the complexities of all the underlying biological processes. Using ambient

concentrations to determine exposure may overestimate true personal NO₂ exposures (depending on indoor sources), resulting in biased descriptions of underlying concentration-response relationships (i.e., in attenuated risk estimates). The implication is that the effects being estimated occur at exposures that are uncertain and the potency of NO₂ is different than these effect estimates indicate. As very few studies evaluating NO₂ health effects with personal NO₂ exposure measurements exist in the literature, effect estimates determined from ambient NO₂ concentrations must be evaluated and used with caution to assess the health risks of NO₂.

The ultimate goal of the NO₂ NAAQS is to set a standard for the ambient level, not personal exposure level, of NO₂. Confidence in the use of ambient concentrations in epidemiologic studies is greatly strengthened if they are shown to be associated with personal exposures. However, until more information on personal NO₂ exposure becomes available, the use of routinely monitored ambient NO₂ concentrations as a surrogate for personal exposures is not generally expected to change the principal conclusions from NO₂ epidemiologic studies.

AX6.1.2. NO₂ Exposure Indices Used

The NO₂-related effect estimates for mortality and morbidity health outcomes are usually presented in this document as relative risk, i.e., the risk rate relative to a baseline mortality or morbidity rate. Relative risks are based on an incremental change in exposure. To enhance comparability between studies, presenting these relative risks by a uniform exposure increment is needed. However, determining a standard increment is complicated by the use of different NO₂ exposure indices in the existing health studies. The daily NO₂ exposure indices that most often appear in the literature are the maximum 1-h average within a 24-h period (1-h max) and 24-h avg (24-h avg) concentrations. As levels are lower and less variable for the longer averaging times, relative risk of adverse health outcomes for a specific numeric concentration range are not directly comparable across metrics. Using the nationwide distributional data for NO₂ monitors in U.S. Metropolitan Statistical Areas, increments representative of a low-to-high change in NO₂ concentrations were approximated on the basis of annual mean to 95th percentile differences (Langstaff, 2006):

Daily Exposure Index	
Exposure Increment	ppb
1-h avg NO ₂	30
24-h avg NO ₂	20
2-wk avg NO ₂	20

Efforts were made to standardize the NO₂ risk estimates using these increments throughout the ISA, except as noted. The specified incremental change for each daily NO₂ exposure index ensures that risk estimates are comparable across the different metrics. The different increments for each NO₂ exposure index do not represent inconsistencies; rather, they are appropriately scaled to facilitate comparisons between the various studies that used different indices. Note that in the Chapter 6 Annex Tables (see Annex Section AX6.3), effect estimates are not standardized; there, the results are presented in the tables as reported in the published papers.

AX6.1.3. Lag Time: Period between Exposure and Health Effect

Exposure lags may reflect the distribution of effects across time in a population and the potential mechanisms of effects. The choice of lag days for the relationship between exposure and health effects depends on the hypothesis being tested and the mechanism involved in the expression of the outcome.

Effects can occur acutely with exposure on the same or previous day, cumulatively over several days, or after a delayed period of a few days. With knowledge of the mechanism of effect, the choice of lag days can be determined prior to analysis. As one example, one would expect cough to occur acutely after exposure with a lag of 0 or 1 day, given that NO₂ can act as a short-term irritant. However, an NO₂-related inflammatory response may not lead to asthma exacerbation until several days later. An asthmatic may be impacted by NO₂ on the first day of exposure, have further effects triggered on the second day, and then report to the emergency room for an asthmatic attack three days after exposure. Further, within a population of asthmatics, exacerbation of asthma symptoms may be observed over a period of several days, since each asthmatic may have varying individual aspects of the disease and may be affected by the exposure differently depending on his/her sensitivity and disease severity. The results from controlled human studies may be useful in assessing the adequacy of lags for some respiratory health outcomes.

The concepts of lags are well discussed in the O₃ AQCD (2006) and are only briefly reviewed here, as the concept for O₃ pertains to NO₂ as well. Selection of lag periods should depend on the hypothesis of the study and the potential mechanism of the effect. When the mechanism of the health effect is unknown, investigating the association between outcome and exposure using cumulative distributed lag models may be informative. Analyzing a large number of lags and simply choosing the largest and most significant results may bias the air pollution risk estimates towards or away from the null. Most studies have shown that NO₂ has a fairly consistent, immediate effect on health outcomes, including respiratory hospitalizations and mortality. Several studies also observed significant NO₂ effects over longer cumulative lag periods, suggesting that in addition to single-day lags, multiday lags should be investigated to fully capture a delayed NO₂ effect on health outcomes. In this document, discussion largely focuses on effect estimates from 0- and 1-day lags, with some consideration of cumulative, multiday lag effects. It is not straightforward to compare and contrast results from single-day versus multiday lag models, because the parameters estimated from these models are not the same. These complications need to be taken into consideration when interpreting results from various lag models.

AX6.1.4. Model Specification for Temporal Trends and Meteorological Effects

Several challenges are encountered with respect to designing and interpreting time-series studies. The principal challenge facing the analyst in the daily time-series context is avoiding bias due to confounding by short-term temporal factors operating over time scales from days to seasons, thus adjusting for long-term trends in the evaluation of acute or short-term associations. In the current regression models used to estimate short-term effects of air pollution, two major potential confounders generally need to be considered: (1) seasonal trend and other “long-wave” temporal trends; and (2) weather effects. Both of these variables tend to predict a significant fraction of fluctuations in time-series analyses.

Current weather models used in time-series analyses can be classified by their use of: (1) quantile (e.g., quartile, quintile) indicators; (2) parametric functional forms such as V- or U-shape functions; and (3) parametric (e.g., natural splines) or nonparametric (e.g., locally estimated smoothing splines [LOESS]) smoothing functions. More recent studies tend to use smoothing functions. While these methods provide flexible ways to fit health outcomes as a function of temperature and other weather variables, there are two major issues that need further examination to enable more meaningful interpretation of NO₂ morbidity and mortality effects.

The first issue is the interpretation of weather or temperature effects. Most researchers agree that extreme temperatures (i.e., heat waves or cold spells) contribute to morbidity and mortality effects. However, as extreme hot or cold temperatures, by definition, happen rarely, much of the health effects occur in the mild or moderate temperature range. Given the significant correlation between NO₂ and temperature, ascribing the association between temperature and health outcomes solely to temperature effects may underestimate the effect of NO₂. The second issue deals with the fact that weather model

specifications are fitted for year-round data in most studies. Such models will ignore the correlation structure that can change across seasons, resulting in inefficiency and model mis-specification. This is particularly important for NO₂, which appears to change its relationship with temperature as well as with other pollutants across seasons.

This changing relationship between NO₂ and temperature, as well as between NO₂ and other pollutants across seasons, and its potential implications for health effects modeling have not been examined thoroughly in the time-series literature. Even the flexible smoother-based adjustments for seasonal and other time-varying variables cannot fully take into account these complex relationships. One way to alleviate or avoid this complication is to analyze data by season. While this practice reduces sample size, the reduction would not be as serious as for PM (which is collected only every sixth day in most locations) because NO₂ is collected daily. An alternative approach is to include separate NO₂ concentration variables for each season (e.g., by multiplying NO₂ concentrations by a season indicator variable). However, this approach assumes that all effects in the model that are not indicated to be season-specific do not vary seasonally.

In locations where seasonal variability may be a factor, NO₂ effect estimates calculated using year-round data can be misleading, as the changing relationship between NO₂, temperature, and other pollutants across seasons may have a significant influence on the estimates. Analyses have indicated that confounding from seasonal variability may be controlled effectively by stratifying the data by season.

AX6.1.5. Confounding Effects of Copollutants

Extensive discussion of issues related to confounding effects among air pollutants in time-series studies are provided in Section 8.4.3 of the 2004 PM AQCD (U.S. Environmental Protection Agency, 2004). Since the general issues discussed there are applicable to all pollutants, such discussions are not repeated here.

AX6.1.6. Generalized Estimating Equations

Since the publication of the 1993 NO₂ AQCD (U.S. Environmental Protection Agency, 1993), methods to analyze panel and longitudinal studies have improved. The general mixed model method of Stiratelli et al. (1984) was an improvement over the method of Korn and Whittemore (1979) in that all the data could be used, including that from subjects with insufficient data to permit fitting of a separate logistical regression model. Generalized Estimating Equations, Liang and Zeger (1986) is an extension of generalized linear models. The joint distribution of the subject's observations does not have to be specified to derive the estimating equations. This is avoided by assuming a marginal distribution at each time. However, a covariate that is constant for a subject cannot be included in this model. Besides Gaussian outcome variables, the method can also be used for binomial or Poisson variables.

AX6.1.7. Hypothesis Testing and Model Selection

Epidemiologic studies investigated the association between various measures of NO₂ (e.g., multiple lags, different metrics, etc.) and various health outcomes using different model specifications. Statistically testing a null hypothesis (i.e., there is no effect of NO₂) requires one to calculate the value of a test statistic (i.e., the t-value). If the observed test statistic exceeds a critical value (oftentimes the 95th percentile) or is outside a range of values, the null hypothesis is rejected. However, when multiple testing is done using a critical value determined for a single test, the chance that at least one of the hypotheses is significant may be greater than the specified error rate. Procedures are available to ensure that the rejection error rate does not exceed the expected error rate (usually 5%) when conducting multiple

hypothesis testing. However, often the multiple hypotheses being tested are not statistically independent, thus some corrections, such as the Bonferroni adjustment, may be overly conservative.

Multiple hypothesis testing and model selection also contribute to publication bias. Publication bias is the tendency of investigators to submit manuscripts or editors to accept manuscripts for publication based on the strength of the study findings. Although publication bias commonly exists for many topics of research, it may be present to a lesser degree in the air pollution literature. Several air pollutants often are examined in a single study, leading to the publication of significant, as well as nonsignificant, individual pollutant results. For example, many air pollution papers with a focus on PM health effects also published NO₂ results. NO₂ was largely considered a potentially confounding copollutant of PM; thus, NO₂ effect estimates were often presented regardless of the statistical significance of the results. Another aspect of publication bias is only selecting the largest or statistically strongest effect estimate to report and not the array of models evaluated. See a full discussion in the O₃ AQCD (U.S. Environmental Protection Agency, 2006).

The summary of health effects in this ISA was vulnerable to the errors of publication bias and multiple testing. Efforts have been made to reduce the impact of multiple testing errors on the conclusions in this document. To address multiple hypothesis testing, emphasis was placed in this document on a priori hypotheses. As identifying a priori hypotheses is difficult in the majority of the studies, the most common hypotheses were considered. For example, although many studies examined multiple single-day lag models, priority was given to effects observed at 0- or 1-day lags rather than at longer lags. Both single- and multiple-pollutant models that include NO₂ were considered and examined for robustness of results. Analyses of multiple model specifications for adjustment of temporal or meteorological trends were considered sensitivity analyses. Sensitivity analyses were not granted the same inferential weight as the original hypothesis-driven analysis; however, these analyses are discussed in this document as appropriate given their valuable insights that may lead scientific knowledge in new directions.

AX6.1.8. Generalized Additive Models

Generalized Additive Models (GAM) have been widely utilized for epidemiologic analysis of the health effects attributable to air pollution. The impact of the GAM convergence issue was thoroughly discussed in Section 8.4.2 of the 2004 PM AQCD. Reports have indicated that using the default convergence criteria in the Splus software package for the GAM function can lead to biased regression estimates for PM and an underestimation of the standard error of the effect estimate (Dominici et al., 2002; Ramsay et al., 2003). The GAM default convergence criterion in the Splus software package is 10 with a maximum number of 10 iterations. The user can specify convergence criteria, that is orders of magnitude smaller than the default value and can also allow for many more iterations before terminating the program. The use of the default convergence criterion was found to be a problem when the estimated relative risks were small and two or more nonparametric smoothing curves were included in the GAM (Dominici et al., 2002). The magnitude and direction of the bias depend in part on the concavity of the independent variables in the GAM and the magnitude of the risk estimate. Recent focus has been on the influence of the GAM function on effect estimates for PM.

The GAM convergence problem appears to vary depending on data sets, and likely depends upon the intercorrelation among covariates and the magnitude of the risk estimate; thus, its impact on the results of individual studies cannot be known without a reanalysis. Consistent with the approach used in the 2004 PM AQCD, the results from studies that analyzed data using GAM with the default convergence criterion and at least two nonparametric smoothing terms are generally not considered in this chapter, with some exceptions as noted.

AX6.2. Cardiovascular Effects Related to Short-Term NO₂ Exposure

AX6.2.1. Hospital Admissions and ED Visits: All CVD

Results of studies of short-term NO₂ exposure and hospitalization or Emergency Department visits for cardiovascular disease are summarized in Figure AX6.2-1. Studies of both 1-h max NO₂ level and 24-h avg NO₂ level are included. With the exception of lag 1 results reported by Jalaludin et al. (2006), most point estimates are positive with confidence limits excluding the null value. Jalaludin et al. report a lag 0 cool season relative risk (not pictured) of 1.09 (95%CI: 1.05, 1.13) per 30 ppb increase in 1-h max NO₂ level (Jalaludin et al., 2006). (Note that the IQR reported by Jalaludin et al. is 9.3 ppb so the 30-ppb increase into which the results were standardized may be unlikely in Sydney, where the study was conducted.) Although results for cardiovascular diseases were not tabulated for a reanalysis of GAM impacted study of Los Angeles and Cook County hospital admissions, authors note that they observed an association of NO₂ with CVD hospital admissions in the reanalyses (Moolgavkar, 2003). The association was diminished with the use of increasingly stringent convergence criteria, however (Moolgavkar, 2003).

Ischemic Heart Disease

Studies that further narrowed the cardiac disease grouping to evaluate Ischemic Heart Diseases (IHD) are summarized in Figure AX6.2-2. Several US studies examined the association of ambient NO₂ level with IHD (Ito, 2004; Mann et al. 2002; Metzger et al. 2004; Peel et al. 2007). Ito (2004) reported a null association of 24-h avg NO₂ level with IHD admissions in Ontario where the mean ambient level was 21.3 ppb. Mann et al. (2002) examined the association of 24-h avg NO₂ level with IHD and secondary diagnoses of arrhythmia, IHD and secondary diagnosis of CHF, IHD and no secondary diagnosis, and all IHD regardless of secondary diagnosis in single-pollutant models. The authors noted that the strongest effect observed (IHD with secondary diagnosis of CHF) may have been driven by the MI primary diagnoses. The 24-h avg NO₂ level in the South Coast Air Basin of California, where this study was conducted was approximately 37 ppb. This study was novel in that exposure level was assigned based on the zip code of the health insurance participant and proximity to the monitoring station (Mann et al., 2002). A non-significant increased risk of ED visit for IHD was observed in single-pollutant models, among those with hypertension but not diabetes in a study conducted in Atlanta where the daily 1-h max NO₂ level was approximately 46 ppb (Peel et al., 2007).

Two studies of IHD and hospital admissions conducted in Europe have produced conflicting results (Atkinson et al., 1999a; Poloniecki et al., 1997). Atkinson et al. (1999a) reported a significant increase in IHD admission in a study in London. A study conducted in Helsinki reported an association of NO with both hospitalization and ED visits for IHD while no association with NO₂ was observed (Pönkä and Virtanen, 1996). In addition, Several Australian studies, including two multicity studies, supported an association of hospital admissions and emergency visits for IHD and ambient NO₂ level among older adults in single-pollutant models (Jalaludin et al., 2006; Barnett et al., 2006; Simpson et al., 2005a,b). One study conducted in Hong Kong reports slightly elevated non-significant association of IHD with 24-h avg NO₂ level (Wong et al., 1999). In addition, Lee et al. (2003a) reported an increase in IHD admissions associated with 24-h avg NO₂ level at lag 5.

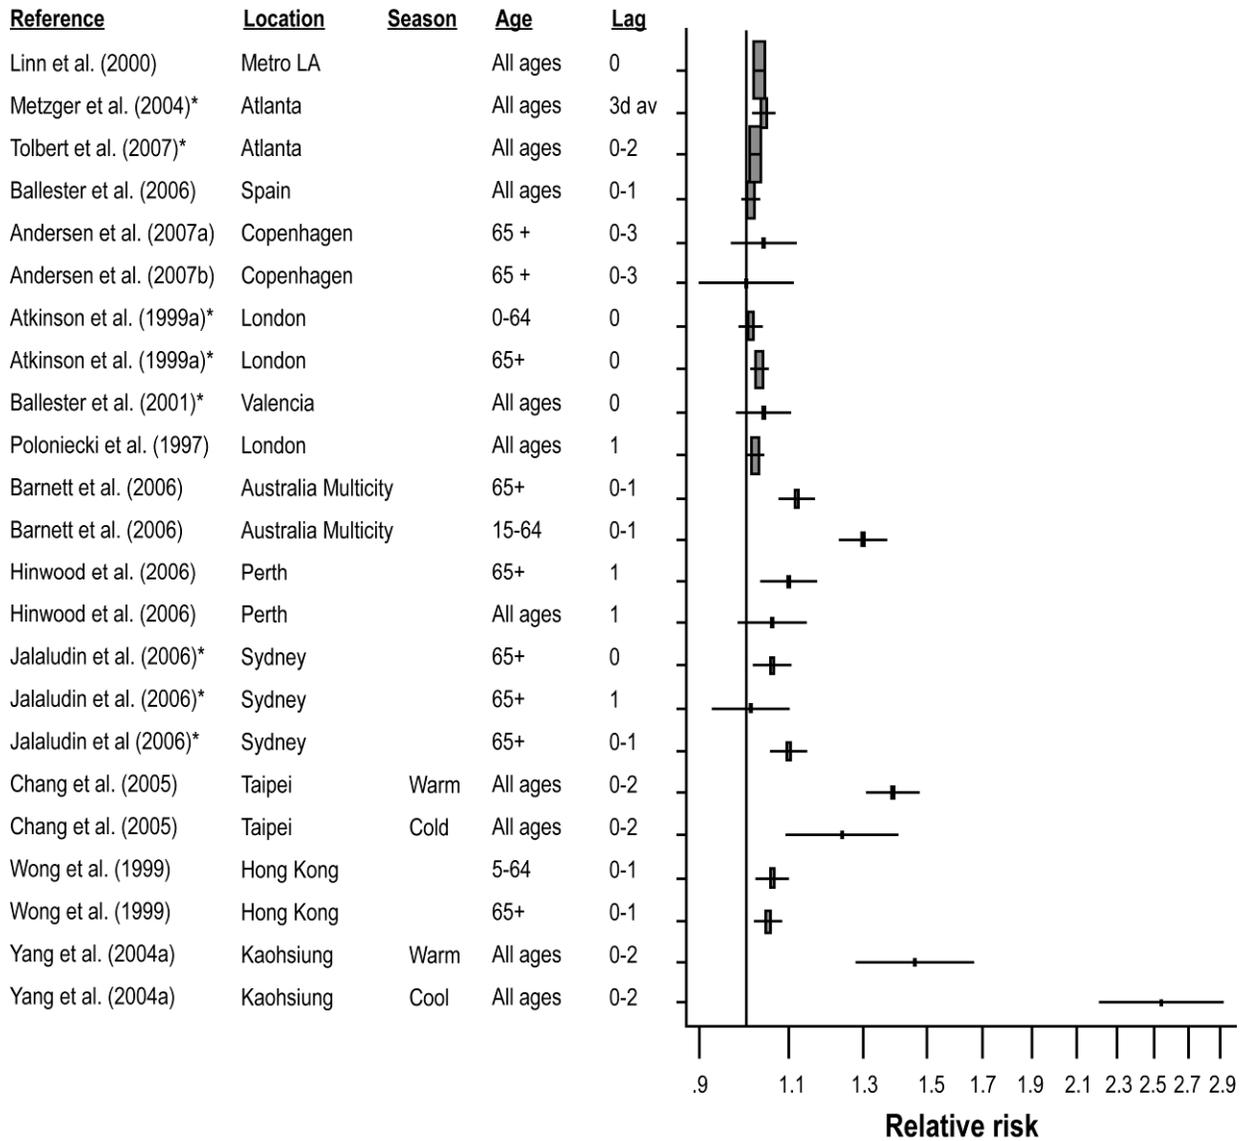

Figure AX6.2-1. Relative risks (95% CI) for associations of 24-h NO₂ (per 20 ppb) and daily 1-h max NO₂* with hospitalizations or emergency department visits for all cardiovascular diseases (CVD). Primary author and year of publication, city, stratification variable(s), and lag are listed. Results for lags 0 or 1 are presented, as available. *NO₂ 1 h max; all others 24 h avg.

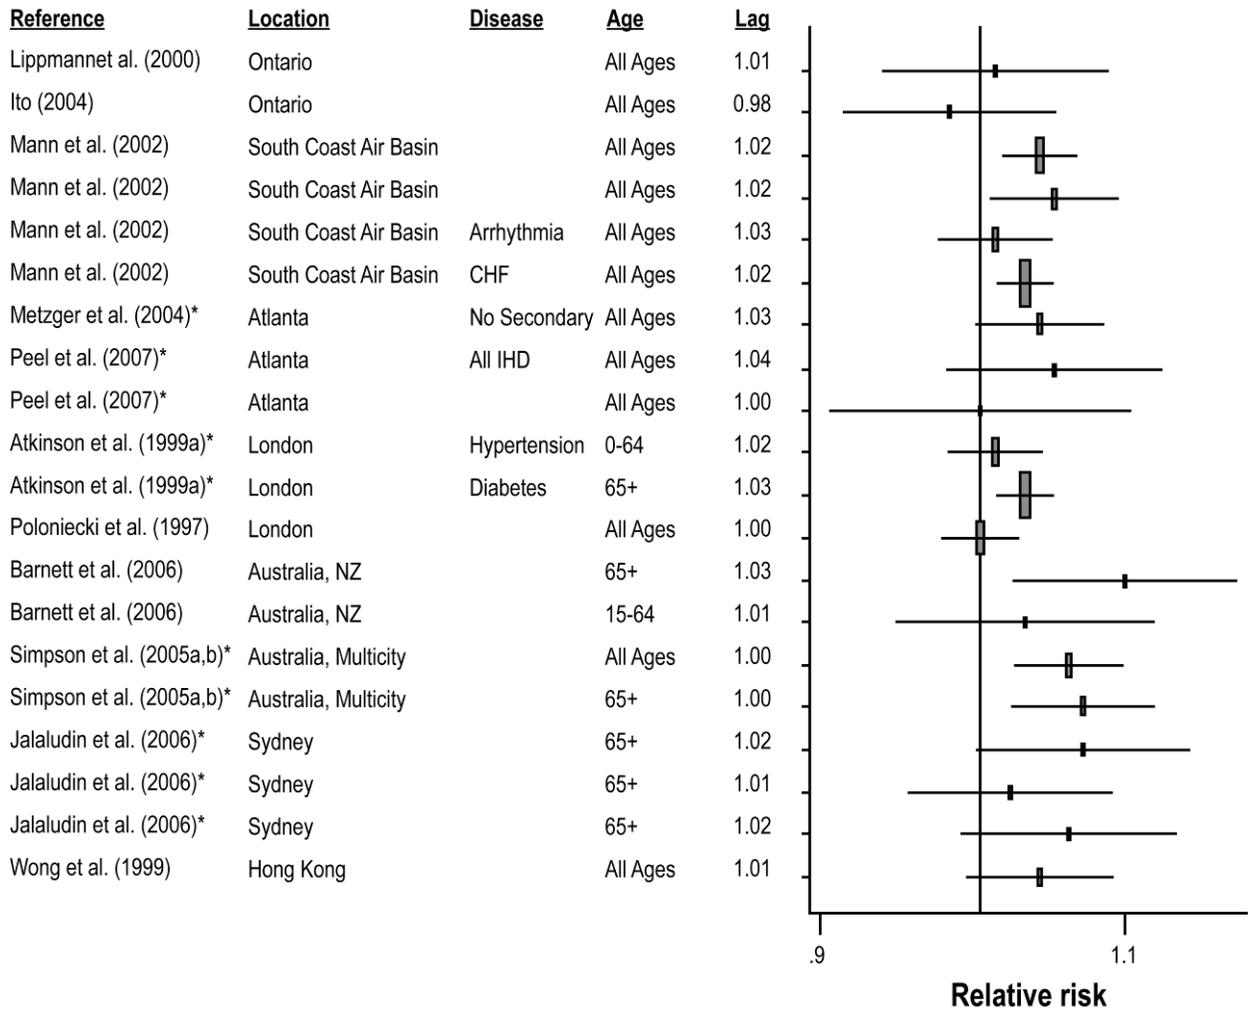

Figure AX6.2-2. Relative risks (95% CI) for associations of 24-h NO₂ (per 20 ppb) and daily 1-h max NO₂* (per 30 ppb) with hospitalizations for Ischemic Heart Disease (IHD). Primary author and year of publication, city, stratification variable(s), and lag are listed. Results for lags 0 or 1 are presented, as available. *NO₂ 1 h max; all others 24 h avg.

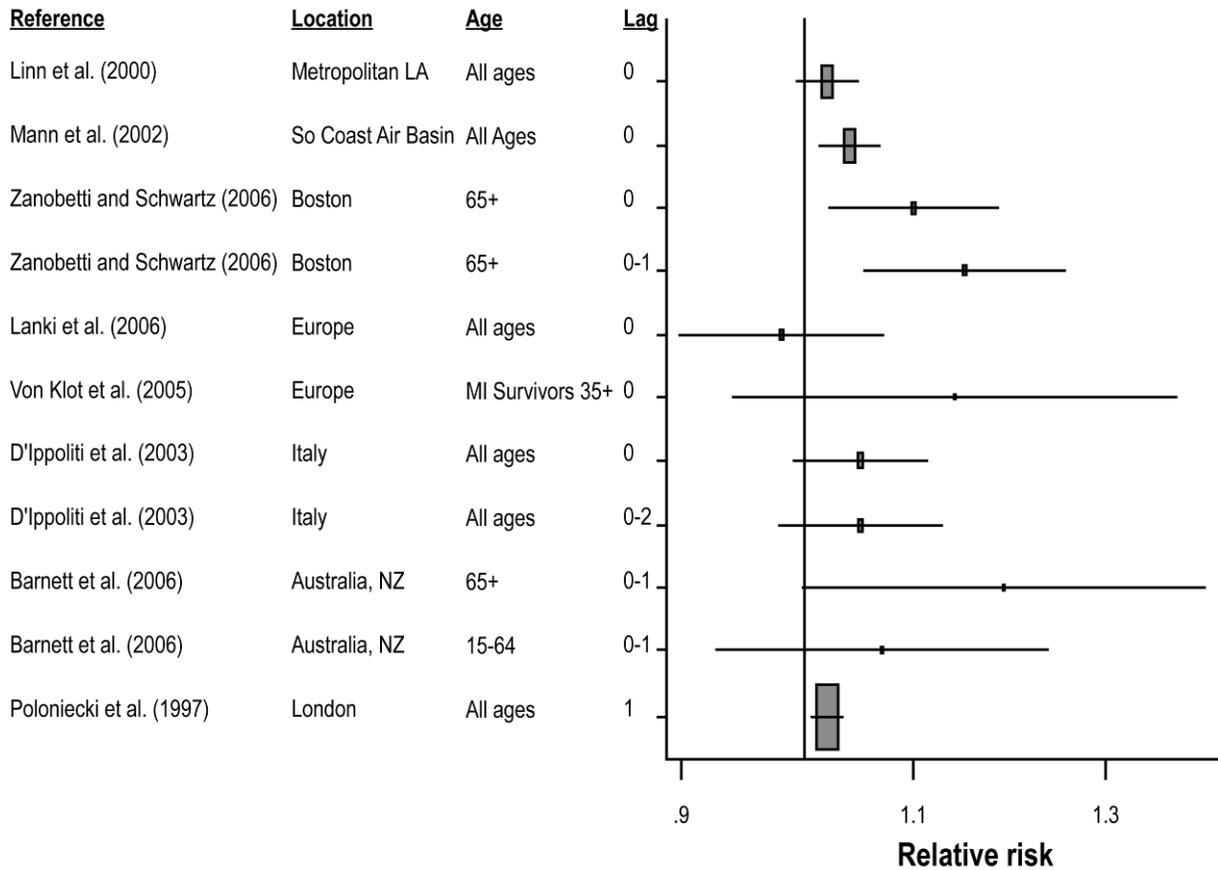

Figure AX6.2-3. Relative risks (95% CI) for associations between 24-h avg NO₂ (per 20 ppb) and hospitalizations for myocardial infarction (MI). Primary author and year of publication, city, stratification variable(s), and lag are listed. Results for lags 0 or 1 are presented as available. *NO₂ 1 h max; all others 24 h avg.

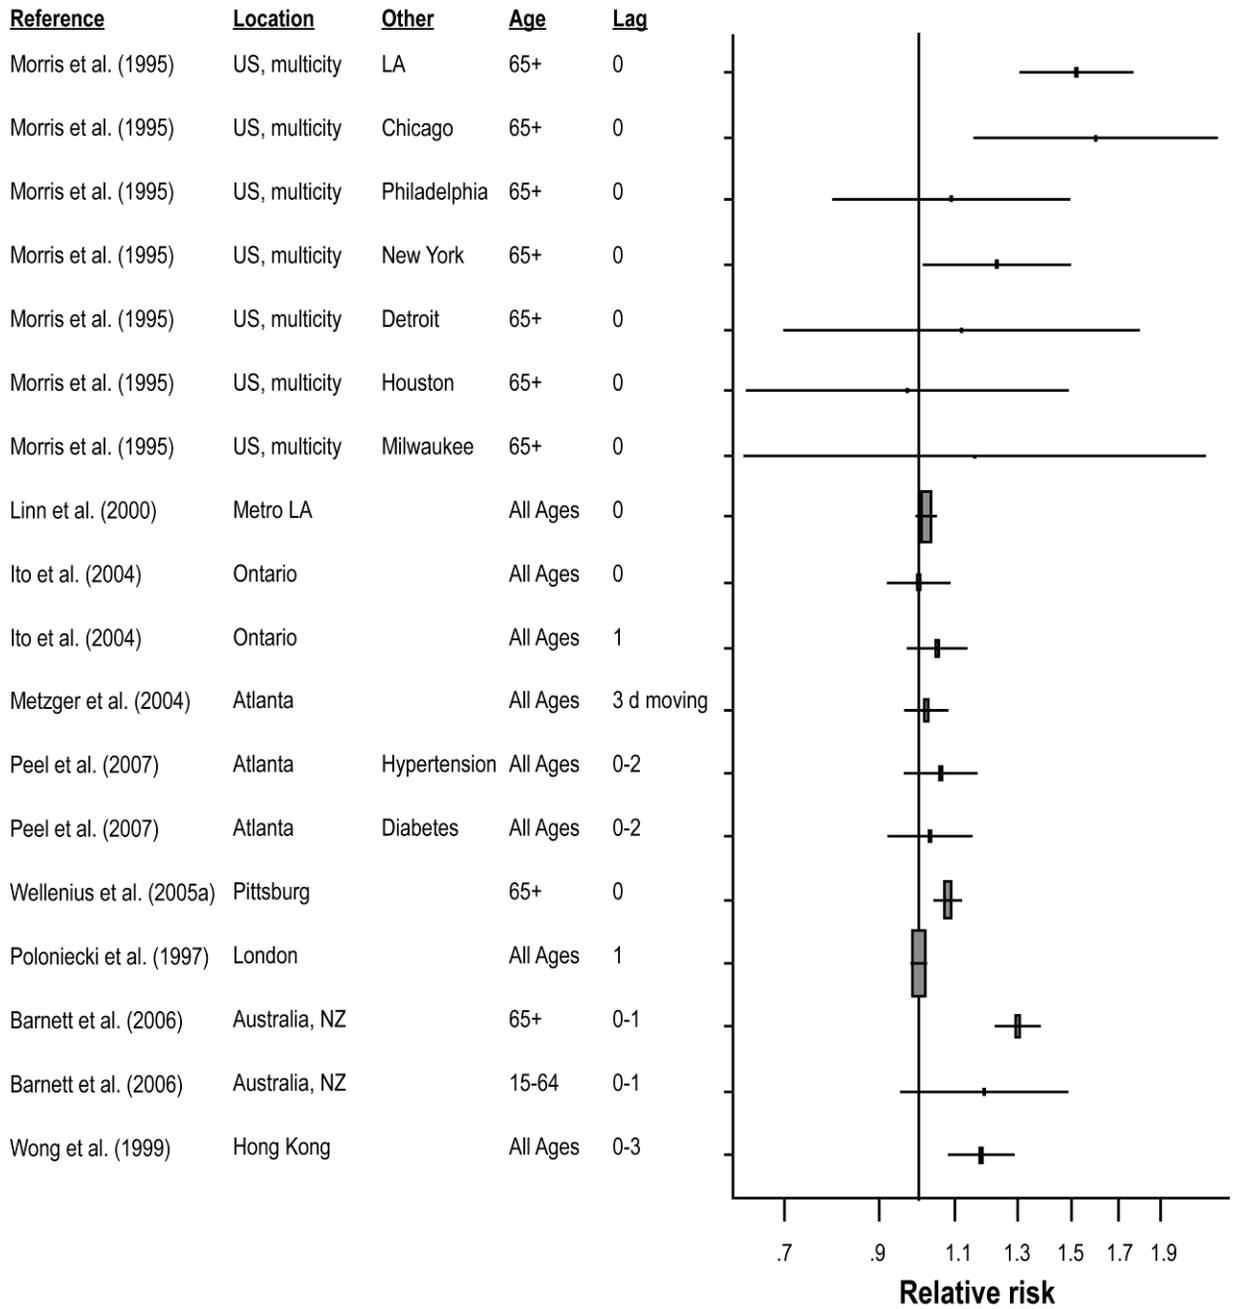

Figure AX6.2-4. Relative risks (95% CI) for associations of 24-h avg NO₂ (per 20 ppb) and 1-h max NO₂* with hospitalizations for congestive heart failure (CHF). Primary author and year of publication, city, stratification variable(s), and lag are listed. Results for lags 0 or 1 are presented as available.

AX6.2.2. Hospital Admissions and ED Visits: Myocardial Infarction (MI)

Studies of hospital admissions for MI are summarized in Figure AX6.2-3. In the United States, positive single-pollutant associations for emergency admissions for MI and increases in ambient NO₂ level were reported in Boston (Zanobetti and Schwartz, 2006) and California (Linn et al., 2000; Mann et al., 2002).

Pooled results from two European multicity studies are inconsistent. Von Klot et al. (2005) reported an increase in MI readmissions at lag 0 while Lanki et al. (2006) reported a null effect at lag 1. The NO₂ levels were similar in the cities studied with Lanki et al. (2006) reporting the 24-h avg level of 23 ppb and Von Klot et al. (2005) reporting a range in 24-h avg across the cities studied of 12-37 ppb. A single-city study in Italy (D'Ippoliti et al., 2003) found positive significant associations between 24-h avg NO₂ level and admission for the first episode of MI. The 24-h avg NO₂ level reported by D'Ippoliti was approximately 45 ppb. A study conducted in London reported a positive association of ED visit for MI with 24-h avg NO₂ where the 24-h avg reported was approximately 35 ppb. Finally, positive associations were reported for MI in a multicity study conducted in Australia and New Zealand among older adults and adults from 15 to 64 years old (Barnett et al., 2006). The 24-h avg NO₂ level ranged from approximately 7-12 ppb in the Australian cities studied (Barnett et al., 2006).

AX6.2.3. Hospital Admissions and ED Visits: Arrhythmia and Congestive Heart Failure (CHF)

Hospital or ED admissions for arrhythmia were inconsistently associated with increases in ambient NO₂ level. Some studies reported positive associations (Rich et al., 2006a; Mann et al., 2002; Barnett et al., 2006) while others reported null associations (Metzger et al., 2004; Lippmann et al., 2000; reanalysis Ito, 2004). Single-pollutant models of hospital admissions and ED visits for CHF have also produced mixed results (Figure AX6.2-4). A seven city study conducted in the U.S. among the elderly found positive associations in Los Angeles (RR: = 1.52 [1.35, 1.71]), Chicago (RR: = 1.60 [1.24, 2.07]) and New York (RR: = 1.23 [1.05, 1.43]) per 30-ppb increase in NO₂ (Morris et al., 1995). Estimates were close to the null value in Philadelphia, Detroit, Houston, and Milwaukee and only the estimate for New York remained significant in multi-pollutant models (Morris et al., 1995). The 1-h max NO₂ level in the cities studied ranged from 40 ppb in Milwaukee to 77 ppb in Los Angeles (Morris et al., 1995). Ito, 2004 reported null associations for CHF and NO₂ in Ontario where the 24-h avg NO₂ level is approximately 21 ppb (Ito, 2004). Elevated but non-significant associations were reported in Atlanta (Metzger et al., 2004; Peel et al., 2007) and elevated significant associations were reported in Pittsburgh (Wellenius et al., 2005a). Null associations were reported in London (Poloniecki et al., 1997) while positive significant associations were reported in a multicity study in Australia and New Zealand (Barnett et al., 2006) and in Hong Kong (Wong et al., 1999).

AX6.2.4. Hospital Admissions and ED Visits: Cerebrovascular Disease

AX6.2.4.1. Vaso-Occlusion in Sickle Cell

A recent study evaluated the association of pain in Sickle Cell patients, which is thought to be caused by vaso-occlusion, with air pollution (Yallop et al., 2007). A time series analysis was performed to link daily hospital admissions for acute pain among sickle cell patients with daily air pollution levels in London using the cross correlation function. No association was reported for NO₂. However, Yallop et al. (2007) observed an association (CCF = -0.063, lag 0) for NO, CO, and O₃.

AX6.2.5. Hospital Admissions and ED Visits: Multipollutant Modeling Results

Multipollutant models may have limited utility to distinguish the independent effects of specific pollutants if model assumptions are not met. However, these models are widely used in air pollution research and results for CVD hospital admissions and ED visits are summarized in Figure AX6.2-5. This figure includes only those studies that present two-pollutant results in tabular form. Studies with qualitative descriptions or figures summarizing two-pollutant results are discussed in the text that follows (Linn et al., 2000; Mann et al., 2002; Metzger et al., 2004; Tolbert et al., 2007; Zanobetti and Schwartz, 2006; Jalaludin et al., 2006; Von Klot et al., 2005; Ballester et al., 2006; Wong et al., 1999). In addition, we included text discussion of studies that simultaneously adjust for several pollutants (Morris et al., 1995; Llorca et al., 2005) and several cerebrovascular disease studies that report multipollutant results (Ballester et al., 2001; Villeneuve et al., 2006; Tsai et al., 2003a; Chan et al., 2006).

A U.S. study showed a diminishment of the relative risk for CHF in two-pollutant models (Wellenius et al., 2005a). Morris et al. (1995) also observed a similar diminishment of the CHF association in multipollutant models containing SO₂, CO, and Ozone (Morris et al., 1995). The association of cardiac disease admissions with NO₂ in several non-U.S. studies was not robust in two-pollutant models (Simpson et al., 2005a,b; Poloniecki et al., 1997; Barnett et al., 2006; Ballester et al., 2006). Llorca et al. (2005) reported a similar lack of robustness in models containing NO₂, TSP, H₂S, NO, and SO₂. Estimates from studies conducted in Taiwan reporting relatively high associations of NO₂ with CVD in single-pollutant models remained robust in two-pollutant models during the cool (Yang et al., 2004a) or warm (Chang et al., 2005) seasons only. In an Australian study of older adults (65+ years), the effect estimate for NO₂ was robust to simultaneous adjustment for O₃ and particles (Morgan et al., 1998a).

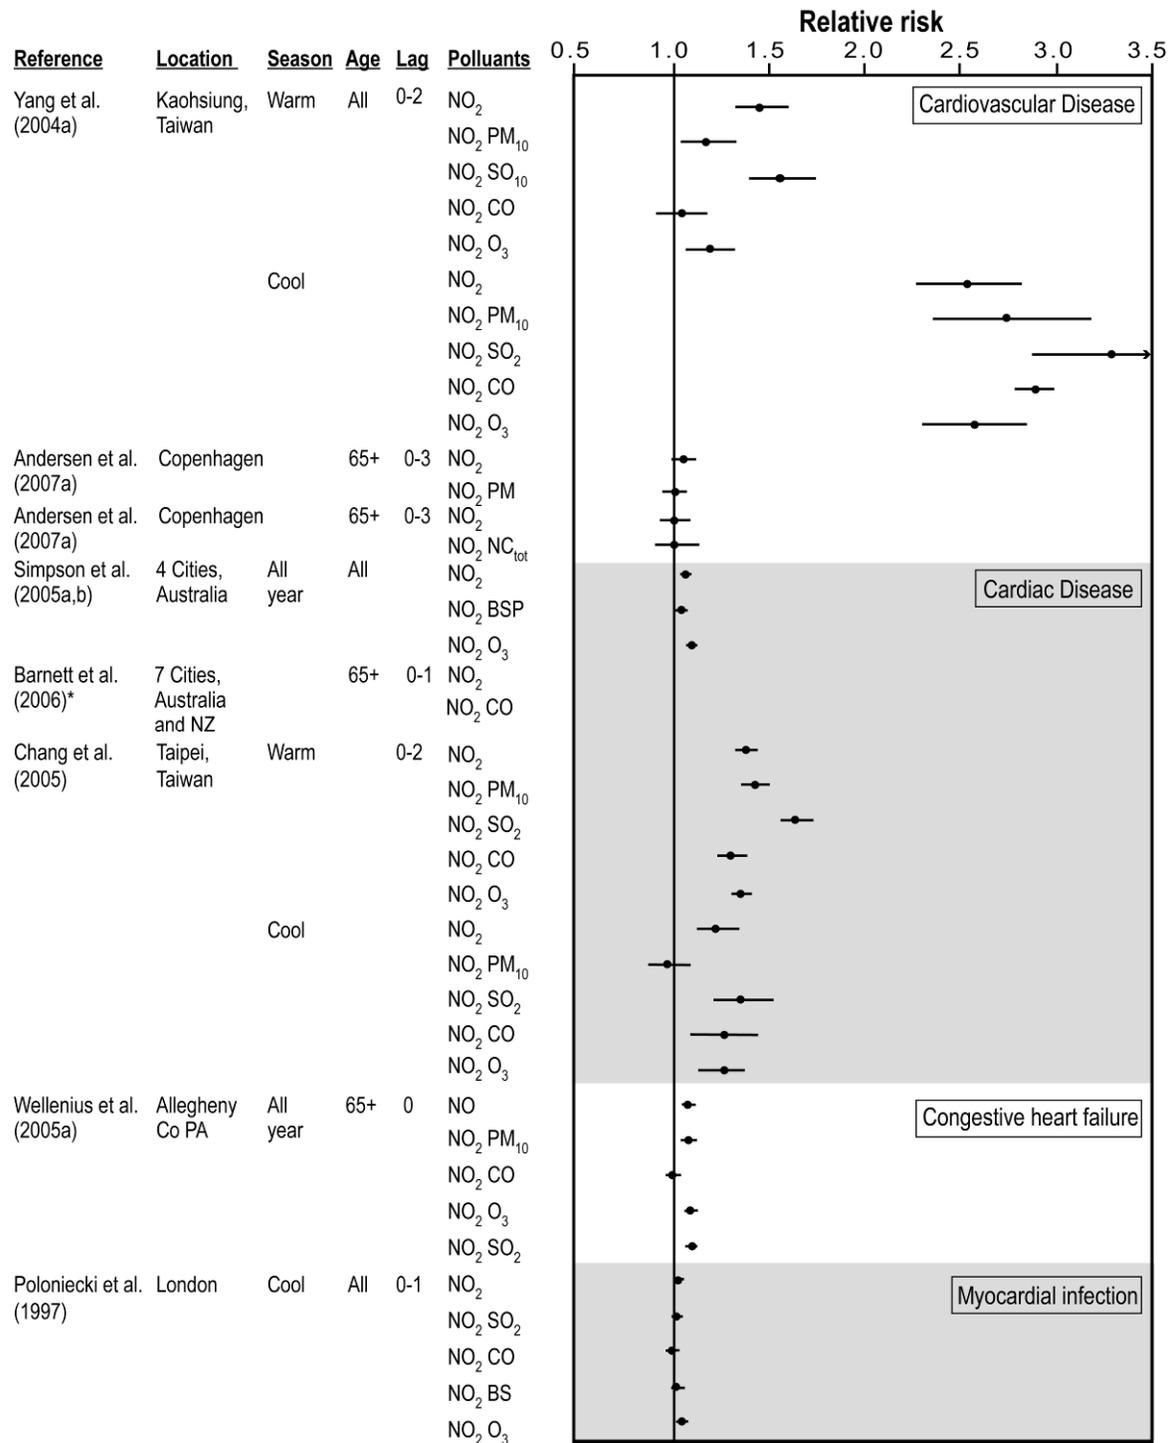

Figure AX6.2-5. Relative risks (95% CI) for associations of 24-h avg NO₂ exposure (per 20 ppb) and daily 1-h max NO₂* (per 30 ppb) with hospitalizations or emergency department visits for CVD. Studies with 2 pollutant model results. Primary author and year of publication, city, stratification variable(s), and lag are listed. Results for lags 0 or 1 are presented as available.

In two additional U.S. studies, investigators provided text descriptions of multipollutant model results and indicated that their analyses were unable to distinguish the effects of NO₂ from PM, CO, and other traffic pollutants (Linn et al., 2000; Mann et al., 2002.) In both studies, CO was more highly correlated with NO₂ than PM. In a Canadian study in which default GAM procedures were used, the significant association of NO₂ with ED visits for cardiac disease was reduced and non-significant in multipollutant models (Stieb et al., 2000). Further, in a study of emergency department visits to Atlanta hospitals, Metzger et al., 2004 observed a diminishment of the effect of NO₂ on visits for cardiovascular disease when CO was modeled with NO₂, while the effect of CO remained robust. This finding was repeated in an analysis that included several additional years of data (Tolbert et al., 2007). In this paper, Tolbert et al. (2007) discussed the limitations of multipollutant models in detail and conclude that these models may help researchers identify the strongest predictor of disease but may not isolate the independent effect of each pollutant. In an Australia study (Jalaludin et al., 2006) and a Spanish multicity study (Ballester et al., 2006) presenting multipollutant results, the association of NO₂ with cardiac disease was not robust to adjustment for other pollutants (CO, SO₂, particles). However, in a European multicity study investigators reported that the effect of NO₂ on cardiac readmissions among MI survivors was not diminished in multipollutant models (Von Klot et al., 2005).

Burnett et al. (1997a) reported robust estimates for cardiac disease hospital admissions and NO₂, whereas the observed association for cardiac hospitalizations and PM were explained by gaseous pollutants. In another multicity study conducted in the same area, associations of NO₂ with cardiac disease were not attenuated when CO, SO₂, and PM variables were included in the models (Burnett et al., 1999).

The association of NO₂ with stroke was not robust to adjustment for CO in a Canadian study (Villeneuve et al., 2006). The association of NO₂ with all cerebrovascular disease was not robust to adjustment for BS and SO₂ in a Spanish single city study (Ballester et al., 2001). Although results from a Taiwanese study indicated that the effect of NO₂ on stroke admissions is not diminished in two-pollutant models, the authors noted that the association of NO₂ with stroke may not be causal if NO₂ is a surrogate other components of the air pollution mixture (Tsai et al., 2003a).

Studies using alternative methods to investigate the influence of copollutants on observed associations of NO₂ with cardiovascular disease are few in number. In an study of emergency admissions for MI and ambient pollution in Boston investigators attempt to distinguish traffic from non-traffic related pollutants through their definition of an exposure metric for non-traffic PM (residuals in model of PM_{2.5} regressed against BC) but found NO₂, PM_{2.5} and non-traffic PM each may trigger MI during the warm season (Zanobetti and Schwartz, 2006). In a study conducted in Hong Kong, investigators looked at the association of NO₂ with CVD during high PM₁₀ and high ozone days (Wong et al., 1999). An interaction between NO₂ and ozone was observed (in the single-pollutant model NO₂ associated with heart failure, RR: 1.18 95% CI: 1.10, 1.26 per 20 ppb, lag 0-3).

AX6.2.6. Heart Rate Variability

Liao et al. (2004) investigated short-term associations between ambient pollutants and cardiac autonomic control from the fourth cohort examination (1996 to 1998) of the population-based Atherosclerosis Risk in Communities (ARIC) Study. PM₁₀, NO₂, and other gaseous air pollutants were examined in this study. PM₁₀ (24-h avg) and NO₂ (24-h avg) 1 day prior to the randomly allocated examination date were used. The mean ± SD NO₂ level was 21 ± 8 ppb. PM₁₀ concentrations measured 1 day prior to the HRV measurements were inversely associated with both frequency- and time-domain HRV indices. Ambient NO₂ concentrations were inversely associated with high-frequency power and SDNN. In single-pollutant models, a 20-ppb increase in ambient NO₂ was associated with a 5% reduction (95% CI: 0.7, 9.2), in mean SDNN. Consistently more pronounced associations were suggested between PM₁₀ and HRV among persons with a history of hypertension.

Various measures of HRV have been examined in relation to daily levels of ambient air pollution in other studies (Chan et al., 2005; Wheeler et al., 2006; Holguín et al., 2003; Luttmann-Gibson et al., 2006; Schwartz et al., 2005). Chan et al. (2005) recruited 83 patients from the cardiology section of a hospital in Taiwan. Patients included 39 with coronary heart disease (CHD) and 44 with more than one risk factor for CHD. The authors reported finding significant associations between increases in NO₂ and decline in SDNN (NO₂ lagged 4 to 8 h) and LF (NO₂ lagged 5 or 7 h) (see Annex Table AX6.3-10 for quantitative results). There were no significant associations for r-MSSD or HF and NO₂. None of the other pollutants tested (PM₁₀, CO, SO₂, O₃) were significantly associated with any of the HRV measured. Wheeler et al. (2006) examined HRV and ambient air pollution in Atlanta in 12 patients who had an MI from 3 to 12 months prior to enrollment and 18 COPD patients. The results in the two patient groups were quite different: increasing concentration of NO₂ in the previous 4-h significantly reduced SDNN in MI patients and significantly increased SDNN in COPD patients (see Annex Table AX6.10). Similar significant associations were seen with increases in 4-h ambient PM_{2.5}. The PM_{2.5} concentrations were moderately correlated with NO₂ levels ($r = 0.4$).

In contrast, Holguín et al. (2003) found PM_{2.5} concentrations were moderately correlated with NO₂ levels ($v = 0.04$) in 34 elderly adults in Mexico City and found no significant associations with increases in NO₂, but did find significant effects of PM_{2.5} on HF, particularly among hypertensive subjects. Similarly, Luttmann-Gibson et al. (2006) also found significant effects of PM_{2.5} and SO₄ on HRV measured in a panel of 32 senior adults in Steubenville, OH, but observed no effect of increasing NO₂. Likewise, Schwartz et al. (2005) found significant effects of increases in PM_{2.5} on measures of HRV, while no associations with NO₂ were observed. A population-based study of air pollutants and HRV was conducted in Boston, MA on 497 men from the VA Normative Aging Study (NAS) (Park et al., 2005). The mean \pm SD 24-h avg NO₂ concentration was 22.7 ± 6.2 ppb. Associations with HRV outcomes were observed with a 4-h moving avg of O₃ and PM_{2.5} concentrations, but not with NO₂.

AX6.2.7. Repolarization Changes

A prospective panel study, conducted in East Germany, analyzed 12 repeat ECG recordings for 56 males with IHD (Henneberger et al., 2005). Ambient air pollutants measured at fixed monitoring sites were used to assign individual exposures for 0 to 5, 5 to 11, 12 to 17, 18 to 23, 0 to 23 h and for 2 to 5 days prior to the EEG. Pollutants considered were ultrafine particles (UFP), accumulation mode particle (ACP), PM_{2.5}, elemental carbon (EC), organic carbon (OC), SO₂, NO₂, NO, and CO. Associations were observed between (1) QT duration and EC and OC; (2) T-wave amplitude and UFP, ACP and PM_{2.5}; and (3) T-wave complexity and PM₁₀, EC, and OC. NO ($r = 0.83$) and NO₂ (0.76) were highly correlated with UFP but were not associated with repolarization abnormalities.

AX6.2.8. Arrhythmias Recorded on Implantable Cardioverter Defibrillators (ICDs)

In a pilot study, Peters et al. (2000a) abstracted device records for 3 years for each of 100 patients with ICDs. Defibrillator discharge events were positively associated with the previous day and 5-day mean NO₂ concentrations: each 20-ppb increase in the previous day's NO₂ level was associated with an increased risk of a discharge event (OR = 1.55 [95% CI: 1.05, 2.29]) (see Annex Table AX6.3-1 for the increase associated with a 20-ppb increase in NO₂).

Three papers by the same team of investigators examined the association between air pollution and the incidence of ventricular arrhythmias (Dockery et al., 2005; Rich et al., 2005) and PAF episode (Rich et al., 2006b) in Boston. A total of 203 patients with ICDs who lived within 25 miles of the ambient monitoring site were monitored. Data included a total of 635 person-years of follow-up or an average of 3.1 years per subject. The median (IQR) 48-h avg NO₂ concentration was 22.7 (7.7) ppb. In the study by

Dockery et al. (2005), significant positive associations were observed between ventricular arrhythmias within 3 days of a prior event, and a 2-day mean exposure to several air pollutants including PM_{2.5}, BC, NO₂, CO, and SO₂. Rich et al. (2005) examined associations between ambient air pollution levels less than 24 h before the occurrence of a ventricular arrhythmia to make use of the precise time definition available from the implantable cardioverter defibrillator (Rich et al., 2005). In single-pollutant models, each 20-ppb increase in the mean NO₂ level over the previous 2 days was associated with an increased likelihood of ventricular arrhythmia, OR = 1.54 (95% CI: 1.11, 2.18). The association with NO₂ was not significant in two-pollutant models with PM_{2.5}, but remained marginally significant in models with O₃ (2.0-ppb increase in 24-h moving avg NO₂ was associated with an OR = 1.36 [95% CI: 1.00, 1.80]). There was a strong association between an increase of NO₂ (by 20 ppb) and ventricular arrhythmia in the presence of ventricular arrhythmia within the previous 72 h (OR = 2.09 [95% CI: 1.26, 3.51]). Increased but non-significant associations were observed in this population between NO₂ levels and PAF, as well as fine particles and black carbon (Rich et al., 2006b).

A study conducted in St. Louis, which also examined the association of air pollutant level within 24 h of a ventricular arrhythmia, reports non-significant increases for NO₂ and elemental carbon, while SO₂ was significantly associated with increased occurrence of arrhythmia (Rich et al., 2006a). Metzger et al. (2007) examined the association of ventricular tachyarrhythmias with air pollutants in the largest study to date (N = 518), which was conducted in Atlanta. These investigators reported “suggestive” findings for coarse particulate but generally no evidence of an association of NO₂ and other pollutants with tachyarrhythmias (Metzger et al., 2007).

AX6.2.9. Markers of Cardiovascular Disease

In a large cross-sectional study of 7,205 office workers in London, Pekkanen et al. (2000) collected blood samples and analyzed the association between plasma fibrinogen, a risk factor for CVD, and ambient levels of air pollution. In models adjusting for weather, demographic, and socioeconomic factors, there was an increased likelihood of blood levels of fibrinogen >3.19 g/l (90th percentile) for each 20-ppb increase in NO₂ lagged by 3 days (OR = 1.14 [95% CI: 1.03, 1.25]). The correlation between daily NO₂ and other traffic-related pollutants were high: daily levels of black smoke (r = 0.75), PM₁₀ (r = 0.76), SO₂ (r = 0.62), CO (r = 0.81). The authors proposed that the increased concentrations of fibrinogen, a mediator of cardiovascular morbidity and mortality, may be an indicator of inflammatory reactions caused by air pollution.

Schwartz (2001) examined the association between fibrinogen, platelet count, and white blood cell (WBC) count in the Third National Health and Nutrition Examination Survey (NHANES III). In single-pollutant models NO₂ was associated with platelet counts and fibrinogen. However, in a two-pollutant model with PM₁₀ these associations became negative.

Pekkanen et al. (2002) enrolled a panel of 45 adults with coronary heart disease in order to examine associations between heart function as measured by risk of ST-segment depression and particulate pollution. Level of particulate and gaseous pollutants, including NO₂, lagged by 2 days was found to have the strongest effect on risk of ST-segment depression during mild exercise tests (OR = 14.1 [95% CI: 3.0, 65.4] for ST-segment depression of >0.1mV with a 20-ppb increase in NO₂ lagged by 2 days). A large (n = 863) cross-sectional study of resting heart rate (HR) of adults in France found significant associations between elevated levels of NO₂ within 8-h of measurement and resting HR of ≥75 beats per minute (bpm) (OR = 2.7 [95% CI: 1.2, 5.4] for resting HR >75 bpm for each 20-ppb increase in NO₂) (Ruidavets et al., 2005).

In a population based study of participants in the Atherosclerosis Risk in Communities (ARIC) study, Liao et al., 2005 did not observe differences in White Blood Cell (WBC) count, Factor VIII C, fibrinogen, Von Willibrand Factor (VWF) or albumin depending on 24-h avg NO₂ level lagged 1 to 3 days prior to the examination date. However, PM₁₀ was associated with factor VIII-C in this cohort. An

association between PM₁₀ and serum albumin was observed only among persons with a history of CVD (Liao et al., 2005).

Ruckerl et al. (2006) examined several markers of inflammation, cell adhesion, and coagulation among a panel of 57 male patients with CHD. These authors primary hypothesis was that C-reactive protein (CRP) would be increased with increases in air pollution. They also investigated the effect of air pollution on other markers including serum amyloid A (SAA), E-selectin, von Willebrand factor antigen, intercellular adhesion molecule 1 (ICAM-1), fibrinogen, factor VII, prothrombin fragment 1+2, and D-dimer. A significant association was observed for NO₂ with CRP greater than the 90th percentile but the strongest effect on CRP was observed for ultrafine particles.

Steinvil et al. (2007) investigated the association of air pollutants with several markers of inflammation (fibrinogen, CRP, and WBC). Significant decreases in fibrinogen associated with increases of 13 ppb in ambient NO₂ were reported among men (all lags 0-7 and 7 day avg) and women (lag 0, 7 day avg). The absolute change in fibrinogen ranged from 7.9 to 16.7 mg/dL (Steinvil et al., 2007). The mean NO₂ level was 19.5 ppb (Steinvil et al., 2007). PM₁₀ was significantly associated with increased fibrinogen only at day 7. No correlations with CRP and WBC were observed (Steinvil et al., 2007).

Baccarelli et al. (2007) investigated the effect of ambient NO₂ with prothrombin time (PT) and activated partial thromboplastin time (APTT) in 1218 normal subjects in Italy. Both NO₂ (coefficient = -0.08 95%CI: -0.15, 0.00) and PM₁₀ (coefficient = -0.08 95% CI: -0.14, -0.01) on the same day and the average for 30 days prior to the examination were negatively correlated with PT (e.g., PT became shorter indicating hypercoagulability), while no effect on APTT was reported (Baccarelli et al., 2007).

Table AX6.3-19. Effects of acute NO_x exposure on mortality. Risk estimates are standardized for per 20 ppb 24-h avg NO₂ increment.

REFERENCE, STUDY LOCATION, AND PERIOD	OUTCOME MEASURE	MEAN NO ₂ LEVELS	COPOLLUTANTS CONSIDERED	LAG STRUCTURE REPORTED	METHOD/DESIGN	EFFECT ESTIMATES
META ANALYSIS						
Stieb et al. (2002), re-analysis (2003) meta-analysis of estimates from multiple countries.	All cause	24-h avg ranged from 13 ppb (Brisbane, Australia) to 38 ppb (Santiago, Chile). "Representative" concentration: 24 ppb	PM ₁₀ , O ₃ , SO ₂ , CO	The lags and multiday averaging used in these estimates varied	Meta-analysis of Time-series study results	Single-pollutant model (11 estimates): 0.8% (95% CI: 0.2, 1.5); Multipollutant model estimates (3 estimates): 0.4% (95% CI: -0.2, 1.1)
UNITED STATES						
Samet et al. (2000a,b) (reanalysis Dominici et al., 2003) 90 U.S. cities (58 U.S. cities with NO ₂ data) 1987-1994	All cause; cardiopulmonary	Ranged from 9 ppb (Kansas City) to 39 ppb (Los Angeles), 24-h avg	PM ₁₀ , O ₃ , SO ₂ , CO; two-pollutant models	0, 1, 2	Poisson GAM, reanalyzed with stringent convergence criteria; Poisson GLM. Time-series study.	24-h avg NO ₂ (per 20 ppb): Posterior means: All cause: Lag 1: 0.50% (0.09, 0.90) Lag 1 with PM ₁₀ and SO ₂ : 0.48% (-0.54, 1.51)
Kinney and Özkaynak (1991) Los Angeles County, CA 1970-1979	All cause; respiratory; circulatory	69 ppb, 24-h avg	KM (particle optical reflectance), NO ₂ , SO ₂ , CO; multipollutant models	1	OLS (Ordinary Least Squares) on high-pass filtered variables. Time-series study.	All cause: Exhaustive multipollutant model: 0.5% (-0.1, 1.2); Two-pollutant with OX: 0.7% (0.5, 1.0)
Kelsall et al. (1997) Philadelphia, PA, 1974-1988	All cause; respiratory; cardiovascular;	39.6 ppb, 24-h avg	TSP, CO, SO ₂ , O ₃	0 (AIC presented for 0 through 5)	Poisson GAM	All cause: Single-pollutant: 0.3% (-0.6, 1.1); With TSP: -1.2% (-2.2, -0.2)
Ostro et al. (2000) Coachella Valley, CA 1989-1998	All cause; respiratory; cardiovascular; cancer; other	20 ppb, 24-h avg	PM ₁₀ , PM _{2.5} , PM _{10-2.5} , O ₃ , CO	0-4	Poisson GAM with default convergence criteria. Time-series study.	Lag 0 day: All cause: 5.5% (1.0, 10.3) Respiratory: 1.8% (-10.3, 15.5) Cardiovascular: 3.7% (-1.7, 9.3)
Fairley (1999; reanalysis Fairley, 2003) Santa Clara County, CA 1989-1996	All cause; respiratory; circulatory	28 ppb, 24-h avg	PM ₁₀ , PM _{2.5} , PM _{10-2.5} , SO ₂ , coefficient of haze, NO ₃ ⁻ , O ₃ , SO ₂ ;	0, 1	Poisson GAM, reanalyzed with stringent convergence criteria; Poisson GLM. Time-series study.	Lag 1: All cause: 1.9% (0.2, 3.7); Cardiovascular: 1.4% (-1.7, 4.5); Respiratory: 4.8% (-0.3, 10.2)

REFERENCE, STUDY LOCATION, AND PERIOD	OUTCOME MEASURE	MEAN NO2 LEVELS	COPOLLUTANTS CONSIDERED	LAG STRUCTURE REPORTED	METHOD/DESIGN	EFFECT ESTIMATES
Gamble (1998) Dallas, TX 1990-1994	All cause; cardiopulmonary	15 ppb, 24-h avg	PM ₁₀ , O ₃ , SO ₂ , CO; two-pollutant models	Avg 4-5	Poisson GLM. Time-series study.	All cause: 4.4% (0.0, 9.0) Cardiovascular: 1.9% (-4.6, 9.0) Respiratory: 13.7% (-2.0, 32.0)
Dockery et al. (1992) St. Louis, MO and Eastern Tennessee 1985-1986	All cause	St. Louis: 20 ppb; Eastern Tennessee: 12.6 ppb, 24-h avg	PM ₁₀ , PM _{2.5} , SO ₄ , H ⁺ , O ₃ , SO ₂	Lag 1	Poisson with GEE. Time-series study.	All cause: St. Louis, MO: 0.7% (-3.5, 5.1) Eastern Tennessee: 3.9% (-8.7, 18.2)
Moolgavkar (2003) Cook County, IL and Los Angeles County, CA, 1987-1995	All cause; cardiovascular	Cook County: 25 ppb; Los Angeles: 38 ppb, 24-h avg	PM _{2.5} , PM ₁₀ , O ₃ , SO ₂ , CO; two- pollutant models	0, 1, 2, 3, 4, 5	Poisson GAM with default convergence criteria. Time-series study.	All cause: Lag 1: Cook County: Single-pollutant: 2.2% (1.3, 3.1); with PM ₁₀ : 1.8% (0.7, 3.0); Los Angeles: Single-pollutant: 2.0% (1.6, 2.5); with PM _{2.5} : 1.8% (0.1, 3.6).
Moolgavkar (2000a,b,c); re-analysis (2003). Cook County, IL; Los Angeles County, CA, and Maricopa County, AZ, 1987-1995	Cardiovascular; cerebrovascular; COPD	Cook County: 25 ppb; Los Angeles: 38 ppb; Maricopa County: 19 ppb, 24-h avg	PM _{2.5} , PM ₁₀ , O ₃ , SO ₂ , CO; two- and three-pollutant models	0, 1, 2, 3, 4, 5	Poisson GAM with default convergence criteria in the original Moolgavkar (2000); GAM with stringent convergence criteria and GLM with natural splines in the 2003 re-analysis. The 2000 analysis presented total death risk estimates only in figures.	GAM, Lag 1: Cardiovascular: Cook County: 1.1% (-0.5, 2.8); Los Angeles: 2.8% (2.0, 3.6); Maricopa Co.: 4.6% (0.5, 9.0); Re-analysis, GLM: Total deaths: 2.5% (1.5, 3.6)
Lippmann et al. (2000); reanalysis Ito, (2003, 2004) Detroit, MI 1985-1990 1992-1994	All cause; respiratory; circulatory; cause-specific	1985-1990: 23.3 ppb, 24-h avg 1992-1994: 21.3 ppb, 24-h avg	PM ₁₀ , PM _{2.5} , PM _{10-2.5} , SO ₄ ²⁻ , H ⁺ , O ₃ , SO ₂ , CO; two-pollutant models	0, 1, 2, 3, 0-1, 0-2, 0-3	Poisson GAM, reanalyzed with stringent convergence criteria; Poisson GLM. Numerical NO ₂ risk estimates were not presented in the re- analysis. Time-series study.	Poisson GAM: All cause: Lag 1: 1985-1990: 0.9% (-1.2, 3.0) 1992-1994: 1.3% (-1.5, 4.2)
Lipfert et al. (2000) Seven counties in Philadelphia, PA area 1991-1995	All cause; respiratory; cardiovascular; all ages; age 65+ yrs; age <65 yrs; various subregional boundaries	20.4 ppb, 24-h avg	PM ₁₀ , PM _{2.5} , PM _{10-2.5} , SO ₄ , O ₃ , other PM indices, NO ₂ , SO ₂ , CO; two-pollutant models	0-1	Linear with 19-day weighted avg Shumway filters. Time-series study. Numerous results.	All-cause, avg of 0- and 1-day lags, Philadelphia: 2.2% (p > 0.05)

REFERENCE, STUDY LOCATION, AND PERIOD	OUTCOME MEASURE	MEAN NO2 LEVELS	COPOLLUTANTS CONSIDERED	LAG STRUCTURE REPORTED	METHOD/DESIGN	EFFECT ESTIMATES
Chock et al. (2000) Pittsburgh, PA 1989-1991	All cause; age <74 yrs; age 75+ yrs	Not reported.	PM ₁₀ , NO ₂ , SO ₂ , CO; two-, five-, and six-pollutant models	0, plus minus 3 days	Poisson GLM. Time-series study. Numerous results	All cause, lag 0, age 0-74: 0.5% (-2.4, 3.5); age 75+: 1.0% (-1.9, 4.0)
De Leon et al. (2003) New York City, NY 1985-1994	Circulatory and cancer with and without contributing respiratory causes	40.6 ppb, 24-h avg	PM ₁₀ , O ₃ , SO ₂ , CO; two-pollutant models	0 or 1	Poisson GAM with stringent convergence criteria; Poisson GLM. Time-series study.	Gaseous pollutants results were given only in figures. Circulatory: Age < 75: ~1% Age 75+: ~2%
Klemm and Mason (2000); Klemm et al. (2004) Atlanta, GA Aug 1998-July 2000	All cause; respiratory; cardiovascular; cancer; other; age <65 yrs; age 65+ yrs	51.3 ppb, max 1-h.	PM _{2.5} , PM _{10-2.5} , EC, OC, O ₃ , SO ₄₂₋ , NO ₃ , SO ₂ , CO	0-1	Poisson GLM using quarterly, moly, or biweekly knots for temporal smoothing. Time-series study.	All cause, age 65+ yrs: avg 0-1 days Quarterly knots: 1.0% (-4.2, 6.6); Moly knots: 3.1% (-3.0, 9.7); Bi-wkly knots: 0.9% (-5.9, 8.2)
Gwynn et al. (2000) Buffalo, NY Time-series study.	All cause; respiratory; circulatory	24-h avg 21 ppb	PM ₁₀ , CoH, O ₃ , SO ₂ , CO, H ⁺ , SO ₄₂₋		Poisson GAM with Default convergence criteria.	All cause (lag 3): 2.1% (-0.3, 4.6); Circulatory (lag 2): 1.3% (-2.9, 5.6); Respiratory (lag 1): 6.4% (-2.5, 16.2)
CANADA						
Burnett et al. (2004) 12 Canadian cities 1981-1999	All cause	24-h avg ranged from 10 (Saint John) to 26 (Calgary) ppb.	PM _{2.5} , PM _{10-2.5} , O ₃ , SO ₂ , CO	1, 0-2	Poisson GLM. Time-series study.	Lag 0-2, single-pollutant: 2.0% (1.1, 2.9); with O ₃ : 1.8% (0.9, 2.7) Days when PM indices available, lag 1, single-pollutant: 2.4% (0.7, 4.1); with PM _{2.5} : 3.1% (1.2, 5.1)
Burnett et al. (2000); re-analysis (2003) 8 Canadian cities 1986-1996	All cause	24-h avg ranged from 15 (Winnipeg) to 26 (Calgary) ppb.	PM _{2.5} , PM ₁₀ , PM _{2.5-10} , SO ₂ , O ₃ , CO	0, 1, 0-2	Poisson GAM with default convergence criteria. Time-series study. The 2003 re-analysis did not consider gaseous pollutants.	Days when PM indices available, lag 1, single-pollutant: 3.6% (1.6, 5.7); with PM _{2.5} : 2.8% (0.5, 5.2)
Burnett et al. (1998a), 11 Canadian cities 1980-1991	All cause	24-h avg ranged from 14 (Winnipeg) to 28 (Calgary) ppb.	SO ₂ , O ₃ , CO	0, 1, 2, 0-1, 0-2 examined but the best lag/averaging for each city chosen	Poisson GAM with default convergence criteria. Time-series study.	Single-pollutant: 4.5% (3.0, 6.0); with all gaseous pollutants: 3.5% (1.7, 5.3)
Burnett et al. (1998b), Toronto, 1980-1994	All cause	24-h avg 25 ppb	SO ₂ , O ₃ , CO, TSP, COH, estimated PM ₁₀ , estimated PM _{2.5}	0, 1, 0-1	Poisson GAM with default convergence criteria. Time-series study.	Single-pollutant (lag 0): 1.7% (0.7, 2.7); with CO: 0.4% (-0.6, 1.5)

REFERENCE, STUDY LOCATION, AND PERIOD	OUTCOME MEASURE	MEAN NO2 LEVELS	COPOLLUTANTS CONSIDERED	LAG STRUCTURE REPORTED	METHOD/DESIGN	EFFECT ESTIMATES
Vedal et al. (2003) Vancouver, British Columbia, Canada 1994-1996	All cause; respiratory; cardiovascular	17 ppb, 24-h avg	PM ₁₀ , O ₃ , SO ₂ , CO	0, 1, 2	Poisson GAM with stringent convergence criteria. Time-series study. By season.	Results presented in figures only. NO ₂ showed associations in winter but not in summer.
Villeneuve et al. (2003) Vancouver, British Columbia, Canada 1986-1999	All cause; respiratory; cardiovascular; cancer; socioeconomic status	19 ppb, 24-h avg	PM _{2.5} , PM ₁₀ , PM _{10-2.5} , TSP, coefficient of haze, SO ₄₂₋ , SO ₂ , O ₃ , CO	0, 1, 0-2	Poisson GLM with natural splines. Time-series study.	All yr: All cause Lag 1: 4.0% (0.9, 7.2) Respiratory: Lag 0: 2.1% (-3.0, 7.4) Cardiovascular: Lag 0: 4.3% (-4.2, 13.4)
Goldberg et al. (2003) Montreal, Quebec, Canada 1984-1993	Congestive Heart Failure (CHF) as underlying cause of death vs. those classified as having congestive heart failure 1 yr prior to death	22 ppb, 24-h avg	PM _{2.5} , coefficient of haze, SO ₄₂₋ , SO ₂ , O ₃ , CO	0, 1, 0-2	Poisson GLM with natural splines. Time-series study.	CHF as underlying cause of death: Lag 1: 1.0% (-5.1, 7.5) Having CHF 1 yr prior to death: Lag 1: 3.4% (0.9, 6.0)
EUROPE						
Samoli et al. (2006) 30 APHEA2 cities. Study periods vary by city, ranging from 1990 to 1997	All cause, respiratory; cardiovascular	1-h max ranged from 24 (Wroclaw) to 81 (Milan) ppb	BS, PM ₁₀ , SO ₂ , O ₃	01	Poisson model with penalized splines.	All-cause: single: 1.8% (1.3, 2.2); with SO ₂ : 1.5% (1.0, 2.0) Cardiovascular: single: 2.3% (1.7, 3.0); with SO ₂ : 1.9% (1.1, 2.7) Respiratory: single: 2.2% (1.0, 3.4); with SO ₂ : 1.1% (-0.4, 2.6)
Samoli et al. (2005) 9 APHEA2 cities. Period not reported.	All-cause	The selected cities had 1-h max medians above 58 ppb and the third quartiles above 68.	None	01	Poisson model with either non-parametric or cubic spline smooth function in each city, and combined across cities.	No numeric estimate presented. The concentration-response was approximately linear.

REFERENCE, STUDY LOCATION, AND PERIOD	OUTCOME MEASURE	MEAN NO2 LEVELS	COPOLLUTANTS CONSIDERED	LAG STRUCTURE REPORTED	METHOD/DESIGN	EFFECT ESTIMATES
Touloumi et al. (1997) Six European cities: London, Paris, Lyon, Barcelona, Athens, Koln. Study periods vary by city, ranging from 1977 to 1992	All cause	Ranged from 37 (Paris) to 70 (Athens) ppb, 1-h max	BS, O ₃ ; two-pollutant models	0, 1, 2, 3, 0-1, 0-2, 0-3 (best lag selected for each city)	Poisson autoregressive. Time-series study.	All-cause: Single-pollutant model: 1.0% (0.6, 1.3); With BS: 0.5% (0.0, 0.9).
Zmirou et al. (1998) Four European cities: London, Paris, Lyon, Barcelona Study periods vary by city, ranging from 1985-1992	Respiratory; cardiovascular	Ranged from 24 (Paris) to 37 (Athens) ppb in cold season and 23 (Paris) to 37 (Athens) ppb in warm season, 24-h avg	BS, TSP, SO ₂ , O ₃	0, 1, 2, 3, 0-1, 0-2, 0-3 (best lag selected for each city)	Poisson GLM. Time-series study.	Western Europe: Respiratory: 0.0% (-1.1, 1.1) Cardiovascular: 0.8% (0.0, 1.5)
Biggeri et al. (2005) 8 Italian cities, Period variable between 1990-1999	All cause; respiratory; cardiovascular	24-h avg ranged from 30 (Verona) to 51 (Rome) ppb	Only single-pollutant models; O ₃ , SO ₂ , CO, PM ₁₀	0-1	Poisson GLM. Time-series study.	All cause: 3.6% (2.3, 5.0) Respiratory: 5.6% (0.2, 11.2) Cardiovascular: 5.1% (3.0, 7.3)
Anderson et al. (1996) London, England 1987-1992	All cause; respiratory; cardiovascular	37 ppb, 24-h avg	BS, O ₃ , SO ₂ ; two-pollutant models	0, 1	Poisson GLM. Time-series study.	All cause (Lag 1): 0.6% (-0.1, 1.2); Respiratory (lag 1): -0.7% (-2.3, 1.0) Cardiovascular: 0.5% (-0.4, 1.4)
Bremner et al. (1999) London, England 1992-1994	All cause; respiratory; cardiovascular; all cancer; all others; all ages; age specific (0-64, 65+, 65-74, 75+ yrs)	34 ppb, 24-h avg	BS, PM ₁₀ , O ₃ , SO ₂ , CO; two-pollutant models	Selected best from 0, 1, 2, 3, (all cause); 0, 1, 2, 3, 0-1, 0-2, 0-3 (respiratory, cardiovascular)	Poisson GLM. Time-series study.	All cause (lag 1): 0.9% (0.0, 1.9) Respiratory (lag 3): 1.9% (-0.3, 4.2) Cardiovascular (lag 1): 1.9% (0.6, 3.2)
Anderson et al. (2001) West Midlands region, England 1994-1996	All cause; respiratory; cardiovascular.	37 ppb, 1-h max	PM ₁₀ , PM _{2.5} , PM _{2.5-10} , BS, SO ₂ , O ₃ , SO ₂ , CO	0-1	Poisson GAM with default convergence criteria. Time-series study.	All cause: 1.7% (-0.5, 3.8) Respiratory: 3.3% (-1.9, 8.8) Cardiovascular: 3.1% (-0.2, 6.4)
Prescott et al. (1998) Edinburgh, Scotland 1992-1995	All cause; respiratory; cardiovascular; all ages; age <65 yrs; age ≥ 65 yrs	26 ppb, 24-h avg	BS, PM ₁₀ , O ₃ , SO ₂ , CO; two-pollutant models	0	Poisson GLM. Time-series study.	Results presented as figures only. Essentially no associations in all categories. Very wide confidence intervals.

REFERENCE, STUDY LOCATION, AND PERIOD	OUTCOME MEASURE	MEAN NO2 LEVELS	COPOLLUTANTS CONSIDERED	LAG STRUCTURE REPORTED	METHOD/DESIGN	EFFECT ESTIMATES
Le Tertre et al. (2002) Le Havre, Lyon, Paris, Rouen, Strasbourg, and Toulouse, France Study periods vary by city, ranging from 1990-1995	All cause; respiratory; cardiovascular	Ranged from 15 (Toulouse) to 28 (Paris) ppb, 24-h avg	BS, O ₃ , SO ₂	0-1	Poisson GAM with default convergence criteria. Time-series study.	Six-city pooled estimates: All cause: 2.9% (1.6, 4.2) Respiratory: 3.1% (-1.7, 8.0) Cardiovascular: 3.5% (1.1, 5.9)
Zeghnoun et al. (2001) Rouen and Le Havre, France 1990-1995	All cause; respiratory; cardiovascular	24-h avg 18 ppb in Rouen; 20 ppb in Le Havre	SO ₂ , BS, PM13, O ₃	0, 1, 2, 3, 0-3,	Poisson GAM with default convergence criteria. Time-series study.	All cause in Rouen (lag 1): 5.5% (0.2, 11.1) ; in Le Havre (lag 1): 2.4% (-3.4, 8.5)
Dab et al. (1996) Paris, France 1987-1992	Respiratory	24 ppb, 24-h avg	BS, PM13, O ₃ , SO ₂ , CO	0	Poisson autoregressive. Time-series study.	Lag1: 2.1% (3.1, 7.7)
Zmirou et al. (1996) Lyon, France 1985-1990	All cause; respiratory; cardiovascular; digestive	37 ppb, 24-h avg	PM13, SO ₂ , O ₃	Selected best from 0, 1, 2, 3	Poisson GLM. Time-series study.	All cause (lag 1): 1.5% (-1.5, 4.6) Respiratory (lag 2): -2.3% (-15.6, 13.0) Cardiovascular (lag 1): 0.8% (-2.7, 4.3)
Sartor et al. (1995) Belgium Summer 1994	All cause; age <65 yrs; age 65+ yrs	24-h avg NO ₂ : Geometric mean: During heat wave (42 day period): 17 ppb Before heat wave (43 day period): 15 ppb After heat wave (39 day period): 13 ppb	TSP, NO, O ₃ , SO ₂	0, 1, 2	Log-linear regression for O ₃ and temperature. Time-series study.	Only correlation coefficients presented for NO ₂ . Unlike O ₃ , NO ₂ was not particularly elevated during the heat wave.
Hoek et al. (2000); reanalysis Hoek, (2003) The Netherlands: entire country, four urban areas 1986-1994	All cause; COPD; pneumonia; cardiovascular	24-h avg median: 17 ppb in the Netherlands; 24 ppb in the four major cities	PM ₁₀ , BS, SO ₄ ²⁻ , NO ₃ ⁻ , O ₃ , SO ₂ , CO; two-pollutant models	1, 0-6	Poisson GAM, reanalyzed with stringent convergence criteria; Poisson GLM.
