United States Environmental Protection Agency

February 2012
EPA/600/R-10/075B

Integrated Science Assessment for Lead

National Center for Environmental Assessment-RTP Division
Office of Research and Development
U.S. Environmental Protection Agency
Research Triangle Park, NC

DISCLAIMER

This document is the second external review draft for review purposes only and does not constitute U.S. Environmental Protection Agency policy. Mention of trade names or commercial products does not constitute endorsement or recommendation for use.

CONTENTS

Lead Project Team

Executive Direction

Dr. John Vandenberg (Director)—National Center for Environmental Assessment-RTP Division, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Debra Walsh (Deputy Director)—National Center for Environmental Assessment-RTP Division, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Mary Ross (Branch Chief)—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Doug Johns (Acting Branch Chief)—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Scientific Staff

Dr. Ellen Kirrane (Pb Team Leader)—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. James Brown—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. Allen Davis—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Jean-Jacques Dubois—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Tara Greaver—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Erin Hines—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Dennis Kotchmar—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Meredith Lassiter—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Stephen McDow—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Qingyu Meng—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Elizabeth Oesterling Owens—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Molini Patel—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr Joseph P. Pinto—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Jennifer Richmond-Bryant—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Lindsay Stanek—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. David Svendsgaard—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Lisa Vinikoor-Imler—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Technical Support Staff

Mr. Kenneth J. Breito–Senior Environmental Employment Program, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Ellen Lorang—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. J. Sawyer Lucy–Student Services Authority, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Deborah Wales—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. Richard N. Wilson–National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Barbara Wright—Senior Environmental Employment Program, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Authors, Contributors, and Reviewers

Authors

Dr. Ellen Kirrane (Pb Team Leader)—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Robyn Blain— Energy, Environment and Transportation, Environmental Science & Policy, ICF International, Lexington, MA

Dr. James Brown—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. Allen Davis—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Gary Diamond—Syracuse Research Corporation, Akron, NY

Dr. Rodney Dietert—Cornell University College of Veterinary Medicine, Veterinary Medical Center, Ithaca, NY

Dr. Jean-Jacques Dubois—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Anne Fairbrother—Exponent, Inc., Bellevue, WA

Dr. Jay Gandy—Department of Environmental and Occupational Health, University of Arkansas for Medical Sciences, Little Rock, AR

Dr. Harvey Gonick—David Geffen School of Medicine, University of California-Los Angeles, Los Angeles, CA

Dr. Margaret Graham—School of Geosciences, University of Edinburgh, Edinburgh, Scotland

Dr. Tara Greaver—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Erin Hines—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Dennis Kotchmar—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Meredith Lassiter—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Stephen McDow—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Qingyu Meng—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Bill Mendez—Energy, Environment and Transportation, Environmental Science & Policy, ICF International, Fairfax, VA

Dr. Howard Mielke—Center for Bioenvironmental Research, Tulane/Xavier Universities, New Orleans, LA

Ms. Chandrika Moudgal— Energy, Environment and Transportation, Environmental Science & Policy, ICF International, Dublin, CA

Dr. Elizabeth Oesterling Owens—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Katherine Palmquist—Exponent, Inc., Bellevue, WA

Dr. Molini Patel—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr Joseph P. Pinto—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Jennifer Richmond-Bryant—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Stephen Rothenberg—National Institute of Public Health, Cuernavaca, Morelos, Mexico

Dr. MaryJane Selgrade—Energy, Environment and Transportation, Environmental Science & Policy, ICF International, RTP, NC

Dr. Lindsay Stanek—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. David Svendsgaard—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Lisa Vinikoor-Imler—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Virginia Weaver—Johns Hopkins Bloomberg School of Public Health, Baltimore, MD

Dr. Marc Weisskopf—Department of Environmental Health and Department of Epidemiology, Harvard School of Public Health, Harvard University, Boston, Massachusetts

Dr. John Pierce Wise, Sr.—Maine Center for Toxicology and Environmental Health, Department of Applied Medical Sciences, Portland, ME

Dr. Rosalind Wright—Harvard Medical School and School of Public Health, Harvard University, Boston, MA

Dr. Robert Wright—Harvard Medical School and School of Public Health, Harvard University, Boston, MA

Contributors

Mr. Brian Adams—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Halil Cakir— Office of Air Quality Planning and Standards, Office of Air and Radiation, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Ye Cao—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Laura Datko—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. Josh Drukenbrod—Office of Air Quality Planning and Standards, Office of Air and Radiation, U.S. Environmental Protection Agency, RTP, NC

Mr. Mark Schmidt—Office of Air Quality Planning and Standards, Office of Air and Radiation, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Katie Shumake—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Kaylyn Siporin—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Lauren Tuttle—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Adrien Wilkie—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Brianna Young—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Reviewers

Dr. Christal Bowman—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. David Buchwalter—Department of Toxicology, North Carolina State University, Raleigh, NC

Dr. Barbara Buckley—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. Kevin Cavender—Office of Air Quality Planning and Standards, Office of Air and Radiation, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Rebecca C. Dzubow—Office of Children's Health Protection, U.S. Environmental Protection Agency, Washington, DC

Dr. David DeMarini—National Health and Environmental Effects Research Laboratory, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Pam Factor-Litvak—Department of Epidemiology, Mailman School of Public Health, New York, NY

Dr. Gabriel Filippelli—Department of Earth Sciences, Indiana University-Purdue University, Indianapolis, IN

Dr. Andrew Friedland—Environmental Studies Program, Darmouth College, Hanover, NH

Dr. Barbara Glenn—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Washington, DC

Dr. Jeff Herrick—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Marion Hoyer—Office of Transportation and Air Quality, Office of Air and Radiation, U.S. Environmental Protection Agency, Ann Arbor, MI

Dr. Douglas Johns—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Thomas Luben—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Karen Martin—Office of Air Quality Planning and Standards, Office of Air and Radiation, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Connie Meacham—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Marie Lynn Miranda—Environmental Sciences and Policy, Nicholas School of the Environment, Duke University, Durham, NC

Dr. Deirdre Murphy—Office of Air Quality Planning and Standards, Office of Air and Radiation, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Paul Mushak—PB Associates, Durham NC

Dr. Kris Novak—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. David Orlin—Air and Radiation Law Office, Office of General Counsel, U.S. Environmental Protection Agency, Washington, DC

Dr. Meredith Pedde—Office of Transportation and Air Quality, Office of Air and Radiation, U.S. Environmental Protection Agency, Ann Arbor, MI

Dr. Pradeep Rajan—Office of Air Quality Planning and Standards, Office of Air and Radiation, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Joanne Rice—Office of Air Quality Planning and Standards, Office of Air and Radiation, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Mary Ross—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Joel Schwartz—Department of Environmental Health, Harvard School of Public Health, Boston, MA

Mr. Jason Sacks—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Ginger Tennant—Office of Air Quality Planning and Standards, Office of Air and Radiation, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Jay Turner—Environmental and Chemical Engineering Department, Washington University, St. Louis, MO

Dr. John Vandenberg—National Center for Environmental Assessment-RTP Division, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Robert W. Vanderpool—National Exposure Research Laboratory, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Nosratola Vaziri—Division of Nephrology and Hypertension, School of Medicine, University of California, Irvine

Ms. Debra Walsh—National Center for Environmental Assessment-RTP Division, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Nasser Zawia—Department of Biomedical and Pharmaceutical Sciences, University of Rhode Island

Clean Air Scientific Advisory Committee Lead NAAQS Review Panel

Chair of the Environmental Protection Agency's Clean Air Scientific Advisory Committee

Dr. Jonathan M. Samet*, Department of Preventive Medicine at the Keck School of Medicine, and Director of the Institute for Global Health at the University of Southern California, Los Angeles, CA

Chair of the Lead Review Panel

Dr. Christopher H. Frey*, North Carolina State University, Raleigh, NC

Lead Review Panel Members

Dr. George A. Allen*, Northeast States for Coordinated Air Use Management (NESCAUM), Boston, MA

Dr. Herbert Allen, University of Delaware, Newark, DE

Dr. Richard Canfield, Cornel University, Ithaca, NY

Dr. Deborah Cory-Slechta, University of Rochester, Rochester, NY

Dr. Cliff Davidson, Syracuse University, Syracuse, NY

Dr. Philip E. Goodrum, Environmental Resources Management (ERM), Dewitt, NY

Dr. Sean Hays, Summit Toxicology, Allenspark, CO

Dr. Philip Hopke, Clarkson University, Potsdam, NY

Dr. Susan Korrick, Harvard Medical School, Boston, MA

Dr. Michael Kosnett, University of Colorado Health Sciences Center, Denver, CO

Dr. Roman Lanno, Ohio State University, Columbus, OH

Dr. Richard L. Poirot, Vermont Agency of Natural Resources, Waterbury, VT

Dr. Joel Pounds, Battelle-Pacific Northwest National Laboratory, Richland, WA

Dr. Michael Rabinowitz, Harvard University, Newport, RI

Dr. William Stubblefield, Oregon State University, Corvallis, OR

Dr. Ian von Lindern, TerraGraphics Environmental Engineering, Inc., Moscow, ID

Dr. Gail Wasserman, Columbia University, New York, NY

Dr. Michael Weitzman, New York University School of Medicine, New York, NY

* Members of the statutory Clean Air Scientific Advisory Committee (CASAC) appointed by the EPA Administrator

Science Advisory Board Staff

Mr. Aaron Yeow, Designated Federal Officer, Office of Administration, Science Advisory Board Staff Office, U.S. Environmental Protection Agency, Washington, DC 20004. Phone: 202-564-2050, Email: yeow.aaron@epa.gov

Acronyms and Abbreviations

α	alpha
αT	the extent of DNA denaturation per cell
Å	Ångström (10^{-10} meter)
AA	African American; arachidonic acid, atomic absorption
AALM	All Ages Lead Model
AAS	atomic absorption (spectrophotometry, spectrometry, spectroscopy)
Ab	amyloid-beta peptide
ABL	atmospheric boundary layer
ACE	angiotensin converting enzyme
ACh	acetylcholine
ACP	acid phosphatase
ACR	acute to chronic ratio
Acyl-Co	acyl-coenzyme A
AD	axial diffusivity
ADHD	attention deficit hyperactivity disorder
ADP	adenosine diphosphate
AE	anion exchanger
AF	absorbed fraction; absorption fraction
A/G	albumin/globulin
Ag	silver
A-horizon: Topsoil horizon (surface soil)	
AKI	acute kidney injury
Al	aluminum
ALA	aminolevulinic acid
ALAD	aminolevulinic acid dehydratase;
ALAD 1-1: aminolevulinate delta-dehydratase 1-1	
ALAD-2	aminolevulinate delta-dehydratase-2
ALD	aldehyde dehydrogenase
ALM	Adult Lead Methodology
ALP	alkaline phosphatase
ALT	alanine aminotransferase
AM	Alveolar macrophages
AMF	arbuscular mycorrhizal fungi
AMP	adenosine monophosphate
ANC	acid neutralizing capacity; absolute neutrophil counts
ANF	atrial natriuretic factor
AngII	renal angiotensin II
ANOVA	analysis of variance
ANPR	advance notice of proposed rulemaking
AP-1	activator protein-1
ApaI	polymorphism of the VDR in humans
APC	antigen-presenting cell
APOE	Apolipoprotein E
APRT	adenine phosphoribosyltransferase
AQCD	Air Quality Criteria Document
AQS	(U.S. EPA) Air Quality System (database)
As	arsenic
AST	aspartate aminotransferase
ASV	anode stripping voltammetry
ATLD	ataxia-telangiectasia-like disorder
ATOFMS	aerosol time-of-flight mass spectrometry
ATP	adenosine-triphosphate
ATPase	adenosine triphosphatase; adenosine triphosphate synthase
ATSDR	Agency for Toxic Substances and Disease Research
Au	gold
avg	average
AVS	acid-volitile sulfides
a-wave	initial negative deflection in the electroretinogram
AWQC	Ambient Water Quality Criteria
β	Beta; Beta coefficient; regression coefficient; standardized coefficient
3β-HSD	3-beta-hydroxysteroid dehydrogenase
17β-HSD: 17-beta-hydroxysteroid dehydrogenase	
Ba	barium
BAF	bioaccumulation factors
BAL	2,3-dimercaptopropanol
BASC	Behavior Assessment System for Children

BASC-PRS: Behavior Assessment System for Children-Parent Ratings Scale

BASC-TRS: Behavior Assessment System for Children-Teacher Rating Scale

BCB blood cerebrospinal fluid barrier

B-cell Bone marrow-derived lymphocytes, B lymphocyte

BCF bioconcentration factors

Bcl-x member of the B-cell lymphoma-2 protein family

Bcl-xl B-cell lymphoma-extra large

B-horizon: subsoil horizon

bio biological

Bi_2S_3 bismuth (III) sulfide

BK biokinetics

BLM biotic ligand model

BMD benchmark dose; bone mineral density

BMDL benchmark dose limit

BMI body mass index

BMP bone morphogenetic protein

BMS Baltimore Memory Study

BMW battery manufacturing workers

BP blood pressure

BR bronchial responsiveness

BrdU bromo-2'-deoxyuridine

8-Br-GMPc: 8-bromo-cyclic guanosine monophosphate

Bs-horizon; subsoil horizon with accumulation of sesquioxides

BSI Brief Symptom Inventory

BSID-II Bayley Scale for Infant Development-II

BsmI polymorphism of the VDR in humans

Bt20 birth to 20 cohort

BUN blood urea nitrogen

bw body weight

b-wave initial positive deflection in the electroretinogram

C carbon; Celsius; soil or dry sediment Pb concentration; Caucasian; Cysteine

Ca calcium

Ca^{2+} calcium ion

CAA Clean Air Act

CaBP calcium binding protein

$CaCl_2$ calcium chloride

$CaCO_3$ calcium carbonate; calcite

CaEDTA calcium ethylenediaminetetraacetic acid

CaMKII calmodulin-dependent protein kinase II

cAMP cyclic adenosine monophosphate

CASAC Clean Air Scientific Advisory Committee

CASM Comprehensive Aquatic Systems Model

$CaSO_4$ calcium sulfate

$CaSO_4.2H_2O$: gypsum

CAT catalase

CBLI cumulative blood lead index

CBSA core based statistical area

CD cluster of differentiation

Cd cadmium

Cd(II) cadmium (II)

Cd^{2+} cadmium ion

CD3+ T lymphocyte

CD4+ T helper cell

CDC Centers for Disease Control

CEA carcinoembryonic antigen

CEC cation exchange capacity

cent central

cert. certiorari

cf correction factor; latin abbreviation for conferre (used as "compared with)

CFL contanst flux layer

CFR Code of Federal Regulations

cGMP cyclic guanosine monophosphate

ChAT chlorine acetyltranferase

CHD coronary heart disease

CHL Chinese hamster lung

CHO Chinese hamster ovary cell line

C-horizon: Soil horizon underneath A- and B-horizons, may contain lumps or shelves of rock and parent material

CHV79 Chinese hamster lung cell line

CI confidence interval

Cir. circuit

CKD chronic kidney disease

CKD-EPI: Chronic Kidney Disease Epidemiology Collaboration

CL confidence limit

Cl chlorine

Cl^- chlorine ion

Cl_2 molecular chlorine

CLACE 5: Fifth Cloud and Aerosol Characterization Experiment in the Free Troposphere campaign

CLS Cincinnati Lead Study

CO carbon monoxide

CO_2 carbon dioxide

CO_3^{2-} carbonate ion

Co cobalt

CoA coenzyme A

COD coefficient of difference

Coeff coefficient

COMP aT: The percentage of sperm with increased sensitivity to DNA denaturation

Con control

Conc. concentration

Cong. congress

Corr correlation

COX cyclooxygenase; cytochrome oxidase subunits

COX-2 cyclooxygenase-2

$cPLA_2$ cytosolic phopholipidase A_2

CPRS-R Conners' Parent Rating Scale-Revised

Cr chromium; creatine

Cr III chromium III

CRAC Ca^{2+} release activated calcium

CRACI calcium release activated calcium influx

CREB cyclic adenosinemonophosphate (cAMP) response element-binding

CRP C-reactive protein

CSF colony-stimulating factor

CSN Chemical Speciation Network

CT zinc-adequate control

Cu copper

Cu(II) copper (II)

CV coefficient of variation

CVD cardiovasicular disease

CYP cytochrome

CYP 1A1, Cyp1A1: cytochrome P450 family 1 member A1

CYP 1A2, Cyp1A2: cytochrome P450 family 1 member A2

CYP P450: cytochrome P450

Δ delta, difference, change

Δ5-3β-HSD : delta-5-3-beta-hydroxysteroid dehydrogenase

δ-ALA 5-aminolevulinic acid; delta-aminolevulinic acid

δ-ALAD : delta-aminolevulinic acid dehydratase

D_2, D_3 dopamine receptors

D50 size at 50% efficiency

d day(s); depth

db, dB decibel

DbH dopamine beta-hyrdoxylase

DBP diastolic blood pressure

dep dependent

dev. deviation

DEX exogenous dexamethasone

DG degenerate gyrus

2-dG 2-deoxyguanosine

DHAA dehydroascorbate

diff differentiation

DIT developmental immunotoxicity

DMPS 2,3-dimercaptopropane-l-sulfonic acid

DMSA dimercaptosuccinic acid

DMSO dimethyl sulfoxide

DNA deoxyribonucleic acid

DoAD developmental origins of adult disease

DOC dissolved organic carbon

DOM dissolved organic matter

DP-109 metal chelator

DP-460 metal chelator

DR diet-restricted

DRD4 dopamine 4 receptor

DRD4.7 dopamine 4 receptor repeat alleles

DRUM Davis Rotating Unit for Monitoring

D-serine neuronal signal

DSM-IV Diagnostic Statistical Manual-IV

DTH delayed-type hypersensitivity

DTPA diethylene triamine pentaacetic acid; techetium-diethylenetriamine-pentaacetic acid

E east; expression for exposure

E2 estradiol

e exponential function

EC endothelial cell

EC_{10} effect concentration for 10% of test population

EC_{20} effect concentration for 20% of test population

EC_{50} effect concentration for 50% of test population

ECG electrocardiography; electrocardiogram

ECOD 7-ethoxycoumarin-o-deethylase

Eco-SSLs: ecological soil screening levels

ED_{10} effect dose for 10% of population

EDTA ethylenediaminetetraacetic acid

EFS electrical field stimulus

EGF epidermal growth factor

EGFR epidermal growth factor receptor

eGFR estimated glomerular filtration rate

Eh electrochemical potential

E-horizon: soil horizon with eluviated or leached of mineral and/or organic content

EI-MS electron impact ionization mass spectrometry

eNOS endothelial nitric oxide synthase

EOG end-of-grade

EPA U.S. Environmental Protection Agency

EPT ephemeroptera, plecoptera, trichoptera

ER endoplasmic reticulum

Erg-1 ether-a-go-go related gene

ERG electroretinogram

ERK extracellular signal regulated kinase

ERK1/2 extracellular signal-regulated kinases 1 and 2

EROD 7-ethoxyresorufin-o-deethylase

ESCA electron spectroscopy for chemical analysis

ESI-MS electrospray ionization mass spectrometry

ESRD end stage renal disease

ET endothelin

ET-1 vasoconstrictor endothelin-1

ET_A-type receptors : endothelin type A receptors

EU European Union

EURO European emission standard

eV electronvolts

EXAFS X-ray absorption fine structure spectroscopy

F_0 filial 0 generation

F_1 first offspring generation

F_2 second offspring generation

FAA Federal Aviation Agency

FAI free androgen index

FAS apoptosis stimulating fragment

Fas-L apoptosis stimulating fragment ligand

Fe iron

Fe(III) iron III

FEM Federal equivalence method

FEV1 forced expiratory volume in 1 second

FI fixed interval

FI-Ext fixed interval with extinction

Fl fluoride

FokI polymorphism of the VDR in humans

FR Federal Register (Notice)

FrA fractional anisotropy

FR-FI fixed ratio-fixed interval

FRM Federal reference method

FSH follicle-stimulating hormone

FSIQ full scale intelligence quotient (IQ)

FT3 free triodothyronine

FT4 free thyroxine

G pregnancy; guanine

G2 gap 2 Phase

g, mg, kg, µg, ng, pg: Gram(s), milligram(s), microgram(s), kilogram(s), nanogram(s), picogram(s)

G93A mouse model

GABA γ-aminobutyric acid; gamma aminobutyric acid

GABAergic: gamma aminobutyric acid-ergic

GAD generalized anxiety disorder

GC gas chromatography

G-CSF granulocyte colony-stimulating factor

GD gestational day

GEE generalized estimating equations

GFAAS graphite furnace atomic absorption spectrometry

GFAP glial fibrillary acidic protein

GFR glomerular filtration rate

GGT gamma-glutamyl transpeptidase

GH growth hormone

GI gastrointestinal

GIS Geographic Information System

G+L pregnancy plus lactation

GLE gestationally-lead exposed

GM geometric mean

GMR geometric mean blood lead ratio

GnRH gonadotropin-releasing hormone

G6PD glucose-6-phosphate dehydrogenase

GPEI glutathione transferase P (GST-P) enhancer I

GPT glutamate pyruvate transaminase

GPx glutathione peroxidase

GPX1 gene encoding for glutathione peroxidase 1

GR glutathione reductase

GRP78 glucose-regulated protein 78

GRP94 glucose-regulated protein 94

Grp glucose-regulated protein

GSD geometric standard deviation

GSH glutathione

GSSG glutathione disulfide

GST glutathione S-transferase

GSTM1 glutathione S-transferase Mu 1

GST-P glutathione transferase P

GTP guanosine-5'-triphosphate; guanine triphosphate

H hydrogen

H^+ hydrogen ion

h hour(s)

ha hectare

HAD hydroxyalkenals

Hb hemoglobin

HC_5 acute toxicity hazardous concentration for 5% of species

HC_{10} acute toxicity hazardous concentration for 10% of species

HCl hydrochloric acid

HCO_3^- bicarbonate; hydrogen carbonate

Hct hematocrit

HDL high-density lipoprotein

HF hydrogen fluoride

HFE hemochromatosis gene

HFE C282Y: hemochromatosis gene with C282Y mutation

HFE H63D : hemochromatosis gene with H63D mutation

Hg mercury

$HgCl_2$ mercury(II) chloride

5-HIAA 5-hydroxyindoleacetic acid

HIV human immunodeficiency virus

HLA-DRB: human leukocyte antigen genes

HMEC human dermal microvascular endothelial cells

HMGR 3-hydroxy-3-methylglutaryl-CoA reductase

HMOX-1: heme oxygenase-1

HNO_3 nitric acid

HO-1 heme oxygenase; heme oxidase-1

H_2O water

H_2O_2 hydrogen peroxide

HOME Home Observation for Measurement of the Environment

HPA hypothalamic-pituitary-adrenal

HPb, h-Pb: high lead

HPG hypothalamic-pituitary-gonadal

HPLC high-performance liquid chromatography

HPRT hypoxanthine-guanine phosphoribosyltransferase

HPT hyperparathyroidism; hypothalamic-pituitary-thyroid

HR heart rate; hazard ratio

HRV heart rate variability

hsp heat shock proteins

5HT serotonin

5-HT 5-hydroxytryptamine

5-HT2B 5-hydroxytryptamine receptor 2B

hTERT telomerase reverse transcriptase

HVA homovanillic acid

I interstate

IARC International Agency for Research on Cancer

IC_{50} half maximal inhibitory concentration

ICAP inductively coupled argon plasma

ICP-AES inductively coupled plasma atomic emission spectroscopy

ICPMS, ICP-MS: Inductively coupled plasma mass spectrometry

ICR imprinting control region

ICRP International Commission on Radiological Protection

ID identification

IDA iron-deficiency anemia

IDE insulin-degrading enzyme

IEPA Illinois Environmental Protection Agency

IEUBK Integrated Exposure Uptake Biokinetic

IFN-γ interferon-gamma

Ig immunoglobulin

IgA immunoglobulin A

IgE immunoglobulin E

IGF-1 insulin-like growth factor 1

IgG immunoglobulin G

IgM immunoglobulin M

IHD ischemic heart disease

IL interleukin

IL-1β interleukin-1 Beta

IL-2 interleukin-2

IL-4 interleukin-4

IL-5 interleukin-5

IL-6 interleukin-6

IL-8 interleukin-8

IL-10 interleukin-10

IL-12 interleukin-12

IMPROVE: Interagency Monitoring of Protected Visual Environment

IMT intimal medial thickening

INL inner neuroblastic layers of the retina

iNOS inducible nitric oxide synthase

i.p. intraperitoneal (route)

IQ intelligence quotient

IQR interquartile range

IRE1 inositol-requiring enzyme-1

ISA Integrated Science Assessment

ISF intake slope factor

ISL inertial sublayer

ISO International Standards Organization

i.v. intravenous

IVBA in vitro bioaccessibility

IVF in vitro fertilization

JNK jun N-terminal kinase

K Kelvin; potassium; resupsension factor

K^+ potassium ion

$K_{0.5}$ concentration of free metal giving half maximal metal-dependent release

KART Karters of American Racing Triad

K_d dissociation constant

Kd partition coefficient; ratio of the metal concentration in soil to that in soil solution

kDa, kD kiloDalton

KEDI-WISC: Korean Educational Development Institute-Wechsler Intelligence Scale for Children

6-keto-PGF1α: 6-keto-prostaglandin F1α (vasodilatory prostaglandin)

keV kiloelectron volt

Ki-67 antigen, cell cycle and tumor growth marker

Kim-1 kidney injury molecule-1

Kinder-KITAP : Kinder-Testbatterie zur Aufmerksamkeitsprüfung für Kinder

K-ras specific protooncogene

Λ lambda; resuspension rate

L length

L, mL, dL: liter(s), milliliter(s), deciliter(s)

LA-ICP-MS: laser ablation inductively coupled plasma mass spectrometry

LC_{50} lethal concentration (at which 50% of exposed organisms die)

LD_{50} lethal dose (at which 50% of exposed organisms die)

LDH lactate dehydrogenase

LDL low-density lipoproteins

LFH-horizons: organic soil horizons located above well-drained surface soil

PIH	pregnancy induced hypertension
PIQ	performance intelligence quotient (IQ)
PIR	poverty-income ratio
PIXE	particle induced X-Ray emission; proton-induced x-ray emission
PKC	protein kinase C
PLP	proteolipid protein
PM	particulate matter
PM_X	Particulate matter of a specific size range not defined for regulatory use. Usually X refers to the 50% cut point, the aerodynamic diameter at which the sampler collects 50% of the particles and rejects 50% of the particles. The collection efficiency, given by a penetration curve, increases for particles with smaller diameters and decreases for particles with larger diameters. The definition of PM_X is sometimes abbreviated as "particles with a nominal aerodynamic diameter less than or equal to X μm" although X is usually a 50% cut point.

PM_{10}	In general terms, particulate matter with a nominal aerodynamic diameter less than or equal to 10 μm; a measurement of thoracic particles (i.e., that subset of inhalable particles thought small enough to penetrate beyond the larynx into the thoracic region of the respiratory tract) in regulatory terms, particles with an upper 50% cut-point of 10± 0.5 μm aerodynamic diameter (the 50% cut point diameter is the diameter at which the sampler collects 50% of the particles and rejects 50% of the particles) and a penetration curve as measured by a reference method based on Appendix J of 40 CFR Part 50 and designated in accordance with 40 CFR Part 53 or by an equivalent method designated in accordance with 40 CFR Part 53.
$PM_{2.5}$	In general terms, particulate matter with a nominal aerodynamic diameter less than or equal to 2.5 μm; a measurement of fine particles in regulatory terms, particles with an upper 50% cut-point of 2.5 μm aerodynamic diameter (the 50% cut point diameter is the diameter at which the sampler collects 50% of the particles and rejects 50% of the particles) and a penetration curve as measured by a reference method based on Appendix L of 40 CFR Part 50 and designated in accordance with 40 CFR Part 53, by an equivalent method designated in accordance with 40 CFR Part 53, or by an approved regional method designated in accordance with Appendix C of 40 CFR Part 58.
$PM_{10\text{-}2.5}$	In general terms, particulate matter with a nominal aerodynamic diameter less than or equal to 10 μm and greater than a nominal 2.5 μm; a measurement of thoracic coarse particulate matter or the coarse fraction of PM10 in regulatory terms, particles with an upper 50% cut-point of 10 μm aerodynamic diameter and a lower 50% cut-point of 2.5 μm aerodynamic diameter (the 50% cut point diameter is the diameter at which the sampler collects 50% of the particles and rejects 50% of the particles) as measured by a reference method based on Appendix O of 40 CFR Part 50 and designated in accordance with 40 CFR Part 53 or by an equivalent method designated in accordance with 40 CFR Part 53.
PM_{10C}	The $PM_{10\text{-}2.5}$ concentration of $PM_{10\text{-}2.5}$ measured by the 40 CFR Part 50 Appendix O reference method which consists of currently operated, collocated low-volume (16.7 Lpm) PM_{10} and $PM_{2.5}$ reference method samplers.
p38MAPK	p38 mitogen-activated protein kinase(s)
PMN	polymorphonuclear leukocyte
P5N	pyrimidine 5'-nucleotidase
PND	post natal day
POC	particulate organic carbon
PP	polypropylene; pulse pressure
ppb	parts per billion
ppm	parts per million

S. Rep. Senate Report
SRIXE synchrotron radation induced X-ray emission
StAR steroidogenic acute regulatory protein
STAT signal transducer and activator of transcription
STAT3 signal transducer and activator of transcription 3
STAT5 signal transducer and activator of transcription 5
STD. Standard
ST Interval: measured from the J point to the end of the T wave in an ECG
Syb synaptobrevin
Syn synaptophysin
Syt synaptotagmin
SZn supplemental zinc
T, t time
T_3, T3 triiodothyronine
T_4, T4 thyroxine
$t_{1/2}$ half-life (-lives); time required to reduce the initial concentration by 50%
TBARS thioBarbituric acid reactive substances; thiobarbituric acid-reactive species
T cell, T-cell: T lymphocyte
TE trace elements
TEC threshold effect concentrations
TF ratio of the metal concentration in plant to that in soil; transferrin
TFIIIA transcription factor IIIA
Tg transgenic
TGF transforming growth factor
TGF-β β transforming growth factor
TGFβ1, TGF-β1: β1 transforming growth factor
TH tyrosine hydroxylase
TH1, Th1: T-derived lymphocyte helper 1
TH2, Th2: T-derived lymphocyte helper 2
Th T-helper lymphocyte
TIMP-1 tissue inhibitor of metalloproteinases-1
TIMS thermal ionization mass spectrometry
TLC Treatment of Lead-exposed Children (study)
T/LH testosterone/luteinizing hormone - measure of Leydig cell function
TNF tumor necrosis factor (e.g., TNF-α)
TNP-Ficoll: trinitrophenyl-ficoll
TNP-OVA: trinitrophenyl-ovalabumin
TPR total peripheral vascular resistance
TS transferrin saturation
TSH thyroid stimulating hormone; total sulfhydryl
TSP total suspended particles
TSS total suspended solids

PREAMBLE

Process of ISA Development

This preamble outlines the general process for developing an Integrated Science Assessment (ISA) including the framework for evaluating weight of evidence and drawing scientific conclusions and causal judgments. The ISA provides a concise review, synthesis, and evaluation of the most policy-relevant science to serve as a scientific foundation for the review of the National Ambient Air Quality Standards (NAAQS). The general process for NAAQS reviews is described at http://www.epa.gov/ttn/naaqs/review.html; information for individual NAAQS reviews is available at www.epa.gov/ttn/naaqs. This preamble is a general discussion of the basic steps and criteria used in developing an ISA; for each ISA, specific details and considerations are included in the introductory section for that assessment.

The fundamental process for developing an ISA includes:

- literature searches;
- study selection;
- evaluation and integration of the evidence; and
- development of scientific conclusions and causal judgments.

An initial step in this process is publication of a call for information in the Federal Register that invites the public to provide information relevant to the assessment, such as new publications on health or welfare[1] effects of the pollutant, or from atmospheric and exposure sciences fields. EPA maintains an ongoing literature search process for identification of relevant scientific studies published since the last review of the NAAQS. Search strategies are designed for pollutants and scientific disciplines and iteratively modified to optimize identification of pertinent publications. Papers are identified for inclusion in several additional ways: specialized searches on specific topics; independent review of tables of contents for journals in which relevant papers may be published; independent identification of relevant literature by expert scientists; review of citations in previous assessments and identification by the public and CASAC during the external review process. References considered for inclusion in the ISA can be found at http://hero.epa.gov/; the references cited in the ISA include a hyperlink to each reference.

[1] Welfare effects as defined in Clean Air Act (Section 302(h) [42:U.S.C.:7602(h)]) include, but are not limited to, "effects on soils, water, crops, vegetation, man-made materials, animals, wildlife, weather, visibility and climate, damage to and deterioration of property, and hazards to transportation, as well as effects on economic values and on personal comfort and well-being."

Studies that have undergone scientific peer review and have been published or accepted for publication and reports that have undergone review are considered for inclusion in the ISA. Analyses conducted by EPA using publicly available data are also considered for inclusion in the ISA. All relevant epidemiologic, controlled human exposure, toxicological, and ecological and welfare effects studies published since the last review are considered, including those related to exposure-response relationships, mode(s) of action (MOA), and potentially at-risk populations and lifestages. Studies on atmospheric chemistry, environmental fate and transport, dosimetry, toxicokinetics and exposure are also considered for inclusion in the document, as well as analyses of air quality and emissions data.

Each ISA builds upon the conclusions of previous assessments for the criteria pollutant under review. EPA focuses on peer reviewed literature published following the completion of the previous review and on any new interpretations of previous literature, integrating the results of recent scientific studies with previous findings. Important older studies may be discussed in detail to reinforce key concepts and conclusions or for reinterpretation in light of newer data. Older studies also are the primary focus in some areas of the document where research efforts have subsided, or if these older studies remain the definitive works available in the literature.

Selection of studies for inclusion in the ISA is based on the general scientific quality of the study, and consideration of the extent to which the study is informative and policy-relevant. Policy relevant and informative studies include those that provide a basis for or describe the relationship between the criteria pollutant and effects, including studies that offer innovation in method or design and studies that reduce uncertainty on critical issues, such as analyses of confounding or effect modification by copollutants or other variables, analyses of concentration-response or dose-response relationships, or analyses related to time between exposure and response. Emphasis is placed on studies that examine effects associated with pollutant concentrations relevant to current population and ecosystem exposures, and particularly those pertaining to concentrations currently found in ambient air. Other studies are included if they contain unique data, such as a previously unreported effect or MOA for an observed effect, or examine multiple concentrations to elucidate exposure-response relationships. In general, in assessing the scientific quality and relevance of health and welfare effects studies, the following considerations have been taken into account when selecting studies for inclusion in the ISA.

- Are the study populations, subjects, or animal models adequately selected, and are they sufficiently well defined to allow for meaningful comparisons between study or exposure groups?

- Are the statistical analyses appropriate, properly performed, and properly interpreted? Are likely covariates adequately controlled or taken into account in the study design and statistical analysis?
- Are the air quality data, exposure, or dose metrics of adequate quality and sufficiently representative of information regarding ambient conditions?
- Are the health, ecological or welfare effect measurements meaningful, valid and reliable?
- Do the analytical methods provide adequate sensitivity and precision to support conclusions?

Considerations specific to particular disciplines include the following. In selecting epidemiologic studies, EPA considers whether a given study: (1) presents information on associations with short- or long-term pollutant exposures at or near conditions relevant to ambient exposures; (2) addresses potential confounding by other pollutants; (3) assesses potential effect modifiers; (4) evaluates health endpoints and populations not previously extensively researched; and (5) evaluates important methodological issues related to interpretation of the health evidence (e.g., lag or time period between exposure and effects, model specifications, thresholds, mortality displacement).

Considerations for the selection of research evaluating controlled human exposure or animal toxicological studies includes a focus on studies conducted using relevant pollutant exposures. For both types of studies, relevant pollutant exposures are considered to be those generally within one or two orders of magnitude of ambient concentrations. Studies in which higher doses were used may also be considered if they provide information relevant to understanding MOA or mechanisms, as noted below.

Evaluation of controlled human exposure studies focuses on those that approximated expected human exposure conditions in terms of concentration and duration. Studies should include control exposures to filtered air, as appropriate. In the selection of controlled human exposure studies, emphasis is placed on studies that: (1) investigate potentially at-risk populations and lifestages such as people with asthma or cardiovascular diseases, children or older adults; (2) address issues such as concentration-response or time-course of responses; and (3) have sufficient statistical power to assess findings.

Review of the animal toxicological evidence focuses on studies that approximate expected human dose conditions, which vary depending on the dosimetry, toxicokinetics and biological sensitivity of the particular laboratory animal species or strains studied. Emphasis is placed on studies that: (1) investigate animal models of disease that can

provide information on populations potentially at increased risk of effects; (2) address issues such as concentration-response or time-course of responses; and (3) have sufficient statistical power to assess findings. Due to resource constraints on exposure duration and numbers of animals tested, animal studies typically utilize high-concentration exposures to acquire data relating to mechanisms and assure a measurable response. Emphasis is placed on studies using doses or concentrations generally within 1-2 orders of magnitude of current levels. Studies with higher concentration exposures or doses are considered to the extent that they provide useful information to inform our understanding of interspecies differences and potential differences between healthy and susceptible human populations. Results from in vitro studies may also be included if they provide mechanistic insight or further support for results demonstrated in vivo.

These criteria provide benchmarks for evaluating various studies and for focusing on the policy-relevant studies in assessing the body of health, ecological and welfare effects evidence. As stated initially, the intent of the ISA is to provide a concise review, synthesis, and evaluation of the most policy-relevant science to serve as a scientific foundation for the review of the NAAQS, not extensive summaries of all health, ecological and welfare effects studies for a pollutant. Of most relevance for inclusion of studies is whether they provide useful qualitative or quantitative information on exposure-effect or exposure-response relationships for effects associated with pollutant exposures at doses or concentrations relevant to ambient conditions that can inform decisions on whether to retain or revise the standards.

In developing an ISA, EPA reviews and summarizes the evidence from: studies of atmospheric sciences and exposure; the health effects evidence from toxicological, controlled human exposure and epidemiologic studies; and ecological and welfare effects evidence. In the process of developing the first draft ISA, EPA may convene a public workshop in which EPA and non-EPA experts review the scientific content of preliminary draft materials to ensure that the ISA is up to date and focused on the most policy-relevant findings, and to assist EPA with integration of evidence within and across disciplines.

EPA integrates the evidence from across scientific disciplines or study types and characterizes the weight of evidence for relationships between the pollutant and various outcomes. The integration of evidence on health, and ecological or welfare effects, involves collaboration between scientists from various disciplines. As an example, an evaluation of health effects evidence would include the integration of the results from epidemiologic, controlled human exposure, and toxicological studies, and application of the causal framework (described below) to draw conclusions. Using the causal framework described in the following section, EPA scientists consider aspects such as

strength, consistency, coherence, and biological plausibility of the evidence, and develop draft causality determinations on the nature of the relationships. Causality determinations often entail an iterative process of review and evaluation of the evidence. Two drafts of the ISA are typically released for review by the CASAC and the public, and comments received on the characterization of the science as well as the implementation of the causal framework are carefully considered in revising and completing the final ISA.

EPA Framework for Causal Determination

EPA has developed a consistent and transparent basis to evaluate the causal nature of air pollution-related health or welfare effects for use in developing ISAs. The framework described below establishes uniform language concerning causality and brings more specificity to the findings. This standardized language was drawn from sources across the federal government and wider scientific community, especially the National Academy of Sciences (NAS) Institute of Medicine (IOM) document, *Improving the Presumptive Disability Decision-Making Process for Veterans (2008)*, a comprehensive report on evaluating causality. This framework:

- describes the kinds of scientific evidence used in establishing a general causal relationship between exposure and health effects;
- characterizes the evidence necessary to reach a conclusion about the existence of a causal relationship;
- identifies issues and approaches related to uncertainty; and
- provides a framework for classifying and characterizing the weight of evidence in support of a general causal relationship.

Approaches to assessing the separate and combined lines of evidence (e.g., epidemiologic, controlled human exposure, and animal toxicological studies) have been formulated by a number of regulatory and science agencies, including the IOM of the NAS (2008), International Agency for Research on Cancer (2006b), U.S. EPA (2005c), and Centers for Disease Control and Prevention (2004). Causal inference criteria have also been described for ecological effects evidence (U.S. EPA, 1998; Fox, 1991). These formalized approaches offer guidance for assessing causality. The frameworks are similar in nature, although adapted to different purposes, and have proven effective in providing a uniform structure and language for causal determinations.

Evaluating Evidence for Inferring Causation

The 1964 Surgeon General's report (*Smoking and health: Report of the advisory committee to the surgeon general of the public health service*) defined "cause" as a "significant, effectual relationship between an agent and an associated disorder or disease in the host" (HEW, 1964), more generally, a cause is defined as an agent that brings about an effect or a result. An association is the statistical relationship among variables; alone, however, it is insufficient proof of a causal relationship between an exposure and a health outcome. Unlike an association, a causal claim supports the creation of counterfactual claims, that is, a claim about what the world would have been like under different or changed circumstances (Samet and Bodurow, 2008).

Many of the health and environmental outcomes reported in these studies have complex etiologies. Diseases such as asthma, coronary heart disease (CHD) or cancer are typically initiated by multiple agents. Outcomes depend on a variety of factors, such as age, genetic susceptibility, nutritional status, immune competence, and social factors (Samet and Bodurow, 2008; Gee and Payne-Sturges, 2004). Effects on ecosystems are often also multifactorial with a complex web of causation. Further, exposure to a combination of agents could cause synergistic or antagonistic effects. Thus, the observed risk may represent the net effect of many actions and counteractions.

In estimating the causal influence of an exposure on health or environmental effects, it is recognized that scientific findings incorporate uncertainty. "Uncertainty" can be defined as having limited knowledge to exactly describe an existing state or future outcome, e.g., the lack of knowledge about the correct value for a specific measure or estimate. Uncertainty analysis may be qualitative or quantitative in nature. In many cases, the analysis is qualitative, and can include professional judgment or inferences based on analogy with similar situations. Quantitative uncertainty analysis may include use of simple measures (e.g., ranges) and analytical techniques. Quantitative uncertainty analysis might progress to more complex measures and techniques, if needed for decision support. Various approaches to evaluating uncertainty include classical statistical methods, sensitivity analysis, or probabilistic uncertainty analysis, in order of increasing complexity and data requirements. However, data may not be available for all aspects of an assessment and those data that are available may be of questionable or unknown quality. Ultimately, the assessment is based on a number of assumptions with varying degrees of uncertainty. The ISA generally evaluates uncertainties qualitatively in assessing the evidence from across studies; in some situations quantitative analysis approaches, such as meta-regression, may be used.

Publication bias is a source of uncertainty regarding the magnitude of health risk estimates. It is well understood that studies reporting non-null findings are more likely to

be published than reports of null findings, and publication bias can also result in overestimation of effect estimate sizes (Ioannidis, 2008). For example, effect estimates from single-city epidemiologic studies have been found to be generally larger than those from multicity studies (Bell et al., 2005).

Consideration of Evidence from Scientific Disciplines

Moving from association to causation involves the elimination of alternative explanations for the association. The ISA focuses on evaluation of the findings from the body of evidence, drawing upon the results of all studies determined to meet the criteria described previously. Causality determinations are based on the evaluation and synthesis of evidence from across scientific disciplines. The relative importance of different types of evidence varies by pollutant or assessment, as does the availability of different types of evidence for causality determination. Three general types of studies inform consideration of human health effects: controlled human exposure, epidemiologic and toxicological studies. Evidence on ecological or welfare effects may be drawn from a variety of experimental approaches (e.g., greenhouse, laboratory, field) and numerous disciplines (e.g., community ecology, biogeochemistry and paleological/historical reconstructions).

Direct evidence of a relationship between pollutant exposures and human health effects comes from controlled human exposure studies. Controlled human exposure studies experimentally evaluate the health effects of administered exposures in human volunteers under highly controlled laboratory conditions. Also referred to as human clinical studies, these experiments allow investigators to expose subjects to known concentrations of air pollutants under carefully regulated environmental conditions and activity levels. In some instances, controlled human exposure studies can also be used to characterize concentration-response relationships at pollutant concentrations relevant to ambient conditions. Controlled human exposures are typically conducted using a randomized crossover design, with subjects exposed both to the pollutant and a clean air control. In this way, subjects serve as their own controls, effectively controlling for many potential confounders. However, controlled human exposure studies are limited by a number of factors, including small sample size and short exposure time. For example, exposure patterns relevant to understanding real-world exposures, especially long-term exposures, are generally not practical to replicate in a laboratory setting. In addition, although subjects do serve as their own controls, personal exposure to pollutants in the hours and days preceding the controlled exposures may vary significantly between and within individuals. Finally, controlled human exposure studies require investigators to adhere to stringent health criteria for subjects included in the study, and therefore the results often cannot be generalized to an entire population. Although some controlled human exposure studies have included health-compromised individuals such as those with respiratory or

cardiovascular disease, these individuals must also be relatively healthy and may not represent the most sensitive individuals in the population. In addition, the study design is limited to exposures and endpoints that are not expected to result in severe health outcomes. Thus, not observing an effect in controlled human exposure studies does not necessarily mean that a causal relationship does not exist. While controlled human exposure studies provide important information on the biological plausibility of associations observed in epidemiologic studies, observed effects in these studies may underestimate the response in certain populations.

Epidemiologic studies provide important information on the associations between health effects and exposure of human populations to ambient air pollution. In epidemiologic or observational studies of humans, the investigator generally does not control exposures or intervene with the study population. Broadly, observational studies can describe associations between exposures and effects. These studies fall into several categories: e.g., cross-sectional, prospective cohort, panel and time-series studies. "Natural experiments" offer the opportunity to investigate changes in health related to a change in exposure, such as closure of a pollution source.

In evaluating epidemiologic studies, consideration of many study design factors and issues must be taken into account to properly inform their interpretation. One key consideration is evaluation of the potential contribution of the pollutant to a health outcome when it is a component of a complex air pollutant mixture. Reported effect estimates in epidemiologic studies may reflect: independent effects on health outcomes; effects of the pollutant acting as an indicator of a copollutant or a complex ambient air pollution mixture; effects resulting from interactions between that pollutant and copollutants.

In the evaluation of epidemiologic evidence, one important consideration is potential confounding. Confounding is "… a confusion of effects. Specifically, the apparent effect of the exposure of interest is distorted because the effect of an extraneous factor is mistaken for or mixed with the actual exposure effect (which may be null)" (Rothman and Greenland, 1998). One approach to remove spurious associations due to possible confounders is to control for characteristics that may differ between exposed and unexposed persons; this is frequently termed "adjustment." Scientific judgment is needed to evaluate likely sources and extent of confounding, together with consideration of how well the existing constellation of study designs, results, and analyses address this potential threat to inferential validity. A confounder is associated with both the exposure and the effect; for example, confounding can occur between correlated pollutants that are associated with the same effect.

Several statistical methods are available to detect and control for potential confounders, with none of them being completely satisfactory. Multivariable regression models constitute one tool for estimating the association between exposure and outcome after adjusting for characteristics of participants that might confound the results. The use of multipollutant regression models has been the prevailing approach for controlling potential confounding by copollutants in air pollution health effects studies. Finding the likely causal pollutant from multipollutant regression models is made difficult by the possibility that one or more air pollutants may be acting as a surrogate for an unmeasured or poorly measured pollutant or for a particular mixture of pollutants. In addition, more than one pollutant may exert similar health effects, resulting in independently observed associations for multiple pollutants. The number and degree of diversity of covariates, as well as their relevance to the potential confounders, remain matters of scientific judgment. Despite these limitations, the use of multipollutant models is still the prevailing approach employed in most air pollution epidemiologic studies and provides some insight into the potential for confounding or interaction among pollutants.

Confidence that unmeasured confounders are not producing the findings is increased when multiple studies are conducted in various settings using different subjects or exposures, each of which might eliminate another source of confounding from consideration. For example, multicity studies which use a consistent method to analyze data from across locations with different levels of covariates can provide insight on potential confounding by copollutants. Intervention studies, because of their quasi-experimental nature, can be particularly useful in characterizing causation.

Another important consideration in the evaluation of epidemiologic evidence is effect modification, which occurs when the effect differs between subgroups or strata; for example, effect estimates that vary by age group or potential risk factor. “Effect-measure modification differs from confounding in several ways. The main difference is that, whereas confounding is a bias that the investigator hopes to prevent or remove from the effect estimate, effect-measure modification is a property of the effect under study … . In epidemiologic analysis one tries to eliminate confounding but one tries to detect and estimate effect-measure modification” (Rothman and Greenland, 1998). When a risk factor is a confounder, it is the true cause of the association observed between the exposure and the outcome; when a risk factor is an effect modifier, it changes the magnitude of the association between the exposure and the outcome in stratified analyses. For example, the presence of a pre-existing disease or indicator of low socioeconomic status may be an effect modifier in causing increased risk of effects related to air pollution exposure. It is often possible to stratify the relationship between health outcome and exposure by one or more of these potential effect modifiers. For variables that modify the association, effect estimates in each stratum will be different from one another

and different from the overall estimate, indicating a different exposure-response relationship may exist in populations represented by these variables.

Another key consideration for ambient air pollution epidemiologic studies is exposure measurement error. There are several components that contribute to exposure measurement error in these epidemiologic studies, including the difference between true and measured ambient concentrations, the difference between average personal exposure to ambient pollutants and ambient concentrations at central monitoring sites, and the use of average population exposure rather than individual exposure estimates.

The third main type of health effects evidence, animal toxicological studies, provides information on the pollutant's biological action under controlled and monitored exposure circumstances. Taking into account physiological differences of the experimental species from humans, these studies inform characterization of health effects of concern, exposure-response relationships and MOAs. Further, animal models can inform determinations of at-risk or susceptible populations. These studies evaluate the effects of exposures to a variety of pollutants in a highly controlled laboratory setting and allow exploration of toxicological pathways or mechanisms by which a pollutant may cause effects. Understanding the biological mechanisms underlying various health outcomes can prove crucial in establishing or negating causality. In the absence of human studies data, extensive, well-conducted animal toxicological studies can support determinations of causality, if the evidence base indicates that similar responses are expected in humans under ambient exposure conditions.

Interpretations of animal toxicological studies are affected by limitations associated with extrapolation between animal and human responses. The differences between humans and other species have to be taken into consideration, including metabolism, hormonal regulation, breathing pattern, and differences in lung structure and anatomy. Also, in spite of a high degree of homology and the existence of a high percentage of orthologous genes across humans and rodents (particularly mice), extrapolation of molecular alterations at the gene level is complicated by species-specific differences in transcriptional regulation. Given these differences, there are uncertainties associated with quantitative extrapolations of observed pollutant-induced pathophysiological alterations between laboratory animals and humans, as those alterations are under the control of widely varying biochemical, endocrine, and neuronal factors.

For ecological effects assessment, both laboratory and field studies (including field experiments and observational studies) can provide useful data for causality determination. Because conditions can be controlled in laboratory studies, responses may be less variable and smaller differences easier to detect. However, the control conditions may limit the range of responses (e.g., animals may not be able to seek alternative food

sources), so they may not reflect responses that would occur in the natural environment. In addition, larger-scale processes are difficult to reproduce in the laboratory.

Field observational studies measure biological changes in uncontrolled situations, and describe an association between a disturbance and an ecological effect. Field data can provide important information for assessments of multiple stressors or where site-specific factors significantly influence exposure. They are also often useful for analyses of larger geographic scales and higher levels of biological organization. However, because conditions are not controlled, variability is expected to be higher and differences harder to detect. Field surveys are most useful for linking stressors with effects when stressor and effect levels are measured concurrently. The presence of confounding factors can make it difficult to attribute observed effects to specific stressors.

Intermediate between laboratory and field are studies that use environmental media collected from the field to examine response in the laboratory, and experiments that are performed in the natural environment while controlling for some environmental conditions (i.e., mesocosm studies). This type of study in manipulated natural environments can be considered a hybrid between a field experiment and laboratory study since some aspects are performed under controlled conditions but others are not. They make it possible to observe community and/or ecosystem dynamics, and provide strong evidence for causality when combined with findings of studies that have been made under more controlled conditions.

Application of Framework for Causal Determination

In its evaluation of the scientific evidence on health or welfare effects of criteria pollutants, EPA determines the weight of evidence in support of causation and characterizes the strength of any resulting causal classification. EPA also evaluates the quantitative evidence and draws scientific conclusions, to the extent possible, regarding the concentration-response relationships and the loads to ecosystems, exposure doses or concentrations, duration and pattern of exposures at which effects are observed.

To aid judgment, various "aspects"[1] of causality have been discussed by many philosophers and scientists. The 1964 Surgeon General's report on tobacco smoking discussed criteria for the evaluation of epidemiologic studies, focusing on consistency, strength, specificity, temporal relationship, and coherence (HEW, 1964). Sir Austin Bradford Hill (1965) articulated aspects of causality in epidemiology and public health that have been widely used (Samet and Bodurow, 2008; IARC, 2006b; U.S. EPA, 2005c; CDC, 2004). These aspects (Hill, 1965) have been modified (Table I) for use in causal

[1] The "aspects" described by Hill (1965) have become, in the subsequent literature, more commonly described as "criteria." The original term "aspects" is used here to avoid confusion with "criteria" as it is used, with different meaning, in the Clean Air Act.

determinations specific to health and welfare effects for pollutant exposures (U.S. EPA, 2009).[1] Although these aspects provide a framework for assessing the evidence, they do not lend themselves to being considered in terms of simple formulas or fixed rules of evidence leading to conclusions about causality (Hill, 1965). For example, one cannot simply count the number of studies reporting statistically significant results or statistically nonsignificant results and reach credible conclusions about the relative weight of the evidence and the likelihood of causality. Rather, these aspects are taken into account with the goal of producing an objective appraisal of the evidence, informed by peer and public comment and advice, which includes weighing alternative views on controversial issues. In addition, it is important to note that the aspects in Table I cannot be used as a strict checklist, but rather to determine the weight of the evidence for inferring causality. In particular, not meeting one or more of the principles does not automatically preclude a determination of causality [see discussion in (CDC, 2004)].

1 The Hill aspects were developed for interpretation of epidemiologic results. They have been modified here for use with a broader array of data, i.e., epidemiologic, controlled human exposure, ecological, and animal toxicological studies, as well as in vitro data, and to be more consistent with EPA's Guidelines for Carcinogen Risk Assessment.

Table I Aspects to aid in judging causality

Consistency of the observed association	An inference of causality is strengthened when a pattern of elevated risks is observed across several independent studies. The reproducibility of findings constitutes one of the strongest arguments for causality. If there are discordant results among investigations, possible reasons such as differences in exposure, confounding factors, and the power of the study are considered.
Coherence	An inference of causality from one line of evidence (e.g., epidemiologic, clinical or animal studies) may be strengthened by other lines of evidence that support a cause-and-effect interpretation of the association. Evidence on ecological or welfare effects may be drawn from a variety of experimental approaches (e.g., greenhouse, laboratory, and field) and subdisciplines of ecology (e.g., community ecology, biogeochemistry and paleontological/historical reconstructions). The coherence of evidence from various fields greatly adds to the strength of an inference of causality. In addition, there may be coherence in demonstrating effects across multiple study designs or related health endpoints within one scientific line of evidence.
Biological plausibility.	An inference of causality tends to be strengthened by consistency with data from experimental studies or other sources demonstrating plausible biological mechanisms. A proposed mechanistic linking between an effect and exposure to the agent is an important source of support for causality, especially when data establishing the existence and functioning of those mechanistic links are available.
Biological gradient (exposure-response relationship)	A well-characterized exposure-response relationship (e.g., increasing effects associated with greater exposure) strongly suggests cause and effect, especially when such relationships are also observed for duration of exposure (e.g., increasing effects observed following longer exposure times).
Strength of the observed association	The finding of large, precise risks increases confidence that the association is not likely due to chance, bias, or other factors. However, it is noted that a small magnitude in an effect estimate may represent a substantial effect in a population.
Experimental evidence	Strong evidence for causality can be provided through “natural experiments” when a change in exposure is found to result in a change in occurrence or frequency of health or welfare effects.
Temporal relationship of the observed association	Evidence of a temporal sequence between the introduction of an agent, and appearance of the effect, constitutes another argument in favor of causality.
Specificity of the observed association	Evidence linking a specific outcome to an exposure can provide a strong argument for causation. However, it must be recognized that rarely, if ever, does exposure to a pollutant invariably predict the occurrence of an outcome, and that a given outcome may have multiple causes.
Analogy	Structure activity relationships and information on the agent’s structural analogs can provide insight into whether an association is causal. Similarly, information on mode of action for a chemical, as one of many structural analogs, can inform decisions regarding likely causality.

Determination of Causality

In the ISA, EPA assesses the body of relevant literature, building upon evidence available during previous NAAQS reviews, to draw conclusions on the causal relationships between relevant pollutant exposures and health or environmental effects. ISAs use a

five-level hierarchy that classifies the weight of evidence for causation[1]. In developing this hierarchy, EPA has drawn on the work of previous evaluations, most prominently the IOM's *Improving the Presumptive Disability Decision-Making Process for Veterans* (Samet and Bodurow, 2008), EPA's *Guidelines for Carcinogen Risk Assessment* (U.S. EPA, 2005c), and the U.S. Surgeon General's smoking report (CDC, 2004), *The Health Consequences of Smoking: A Report of the Surgeion General*. This weight of evidence evaluation is based on various lines of evidence from across the health and environmental effects disciplines. These separate judgments are integrated into a qualitative statement about the overall weight of the evidence and causality. The five descriptors for causal determination are described in Table II.

Determination of causality involves the evaluation of evidence for different types of health, ecological or welfare effects associated with short- and long-term exposure periods. In making determinations of causality, evidence is evaluated for major outcome categories and then conclusions are drawn based upon the integration of evidence from across disciplines and also across the spectrum of related endpoints. In making causal judgments, the ISA focuses on major outcome categories (e.g., respiratory effects, vegetation growth), by evaluating the coherence of evidence across a spectrum of related endpoints (e.g., health effects ranging from inflammatory effects to respiratory mortality) to draw conclusions regarding causality. In discussing the causal determination, EPA characterizes the evidence on which the judgment is based, including strength of evidence for individual endpoints within the major outcome category.

[1] The Center for Disease Control (CDC) and IOM frameworks use a four-category hierarchy for the strength of the evidence. A five-level hierarchy is used here to be consistent with the EPA Guidelines for Carcinogen Risk Assessment and to provide a more nuanced set of categories.

Table II Weight of evidence for causal determination

	Health Effects	Ecological and Welfare Effects
Causal relationship	Evidence is sufficient to conclude that there is a causal relationship with relevant pollutant exposures (i.e., doses or exposures generally within one to two orders of magnitude of current levels). That is, the pollutant has been shown to result in health effects in studies in which chance, bias, and confounding could be ruled out with reasonable confidence. For example: a) controlled human exposure studies that demonstrate consistent effects; or b) observational studies that cannot be explained by plausible alternatives or are supported by other lines of evidence (e.g., animal studies or mode of action information). Evidence includes replicated and consistent high-quality studies by multiple investigators.	Evidence is sufficient to conclude that there is a causal relationship with relevant pollutant exposures i.e., doses or exposures generally within one to two orders of magnitude of current levels). That is, the pollutant has been shown to result in effects in studies in which chance, bias, and confounding could be ruled out with reasonable confidence. Controlled exposure studies (laboratory or small- to medium-scale field studies) provide the strongest evidence for causality, but the scope of inference may be limited. Generally, determination is based on multiple studies conducted by multiple research groups, and evidence that is considered sufficient to infer a causal relationship is usually obtained from the joint consideration of many lines of evidence that reinforce each other.
Likely to be a causal relationship	Evidence is sufficient to conclude that a causal relationship is likely to exist with relevant pollutant exposures, but important uncertainties remain. That is, the pollutant has been shown to result in health effects in studies in which chance and bias can be ruled out with reasonable confidence but potential issues remain. For example: a) observational studies show an association, but copollutant exposures are difficult to address and/or other lines of evidence (controlled human exposure, animal, or mode of action information) are limited or inconsistent; or b) animal toxicological evidence from multiple studies from different laboratories that demonstrate effects, but limited or no human data are available. Evidence generally includes replicated and high-quality studies by multiple investigators.	Evidence is sufficient to conclude that there is a likely causal association with relevant pollutant exposures. That is, an association has been observed between the pollutant and the outcome in studies in which chance, bias and confounding are minimized, but uncertainties remain. For example, field studies show a relationship, but suspected interacting factors cannot be controlled, and other lines of evidence are limited or inconsistent. Generally, determination is based on multiple studies in multiple research groups.
Suggestive of a causal relationship	Evidence is suggestive of a causal relationship with relevant pollutant exposures, but is limited. For example, (a) at least one high-quality epidemiologic study shows an association with a given health outcome but the results of other studies are inconsistent; or (b) a well-conducted toxicological study, such as those conducted in the National Toxicology Program (NTP), shows effects in animal species.	Evidence is suggestive of a causal relationship with relevant pollutant exposures, but chance, bias and confounding cannot be ruled out. For example, at least one high-quality study shows an effect, but the results of other studies are inconsistent.
Inadequate to infer a causal relationship	Evidence is inadequate to determine that a causal relationship exists with relevant pollutant exposures. The available studies are of insufficient quantity, quality, consistency or statistical power to permit a conclusion regarding the presence or absence of an effect.	The available studies are of insufficient quality, consistency or statistical power to permit a conclusion regarding the presence or absence of an effect.

	Health Effects	Ecological and Welfare Effects
Not likely to be a causal relationship	Evidence is suggestive of no causal relationship with relevant pollutant exposures. Several adequate studies, covering the full range of levels of exposure that human beings are known to encounter and considering at-risk populations, are mutually consistent in not showing an effect at any level of exposure.	Several adequate studies, examining relationships with relevant exposures, are consistent in failing to show an effect at any level of exposure.

In drawing judgments regarding causality for the criteria air pollutants, the ISA focuses on evidence of effects in the range of relevant pollutant exposures or doses, and not on determination of causality at any dose. Emphasis is placed on evidence of effects at doses (e.g., blood lead concentration) or exposures (e.g., air concentrations) that are relevant to, or somewhat above, those currently experienced by the population. The extent to which studies of higher concentrations are considered varies by pollutant and major outcome category, but generally includes those with doses or exposures in the range of one to two orders of magnitude above current or ambient conditions. Studies that use higher doses or exposures may also be considered to the extent that they provide useful information to inform our understanding of mode of action, interspecies differences or factors that may increase risk of effects for a population. Thus, a causality determination is based on weight of evidence evaluation for health, ecological or welfare effects, focusing on the evidence from exposures or doses generally ranging from current levels to one or two orders of magnitude above current levels.

In addition, EPA evaluates evidence relevant to understand the quantitative relationships between pollutant exposures and health, ecological or welfare effects. This includes evaluation of the form of concentration-response or dose-response relationships and, to the extent possible, drawing conclusions on the levels at which effects are observed. The ISA also draws scientific conclusions regarding important exposure conditions for effects and populations that may be at greater risk for effects, as described in the following section.

Quantitative Relationships: Effects on Human Populations

Once a determination is made regarding the causal relationship between the pollutant and outcome category, important questions regarding quantitative relationships include:

- What is the concentration-response, exposure-response, or dose-response relationship in the human population?
- What is the interrelationship between incidence and severity of effect?

- What exposure conditions (dose or exposure, duration and pattern) are important?
- What populations and lifestages appear to be differentially affected (i.e., more at risk of experiencing effects)?

To address these questions, the entirety of quantitative evidence is evaluated to characterize pollutant concentrations and exposure durations at which effects were observed for exposed populations, including populations and lifestages potentially at increased risk. To accomplish this, evidence is considered from multiple and diverse types of studies, and a study or set of studies that best approximates the concentration-response relationships between health outcomes and the pollutant may be identified. Controlled human exposure studies provide the most direct and quantifiable exposure-response data on the human health effects of pollutant exposures. To the extent available, the ISA evaluates results from across epidemiologic studies that use various methods to characterize the form of relationships between the pollutant and health outcomes and draws conclusions on the shape of these relationships. Animal data may also inform evaluation of concentration-response relationships, particularly relative to MOAs and characteristics of susceptible populations.

An important consideration in characterizing the public health impacts associated with exposure to a pollutant is whether the concentration-response relationship is linear across the range of concentrations or if nonlinear relationships exist along any part of this range. Of particular interest is the shape of the concentration-response curve at and below the level of the current standards. Various sources of variability and uncertainty, such as low data density in the lower concentration range, possible influence of exposure measurement error, and variability between individuals in susceptibility to air pollution health effects, tend to smooth and "linearize" the concentration-response function, and thus can obscure the existence of a threshold or nonlinear relationship. Since individual thresholds vary from person to person due to individual differences such as genetic level susceptibility or preexisting disease conditions (and even can vary from one time to another for a given person), it can be difficult to demonstrate that a threshold exists in a population study. These sources of variability and uncertainty may explain why the available human data at ambient concentrations for some environmental pollutants (e.g., particulate matter [PM], ozone [O_3], lead [Pb], environmental tobacco smoke [ETS], radiation) do not exhibit thresholds for cancer or noncancer health effects, even though likely mechanisms include nonlinear processes for some key events. These attributes of human population dose-response relationships have been extensively discussed in the broader epidemiologic literature (Rothman and Greenland, 1998).

Finally, identification of the population groups or lifestages that may be at greater risk of health effects from air pollutant exposures contributes to an understanding of the public health impact of pollutant exposures. In the ISA, the term "at-risk population" is used to encompass populations or lifestages that have a greater likelihood of experiencing health effects related to exposure to an air pollutant due to a variety of factors. These factors may be intrinsic, such as genetic or developmental factors, race, gender, lifestage, or the presence of pre-existing diseases, or they may be extrinsic, such as socioeconomic status (SES), activity pattern and exercise level, reduced access to health care, low educational attainment, or increased pollutant exposures (e.g., near roadways). Epidemiologic studies can help identify populations potentially at increased risk of effects by evaluating health responses in the study population. Examples include testing for interactions or effect modification by factors such as gender, age group, or health status. Experimental studies using animal models of susceptibility or disease can also inform the extent to which health risks are likely greater in specific population groups.

Quantitative Relationships: Effects on Ecosystems or Public Welfare

Key questions for understanding the quantitative relationships between exposure (or concentration or deposition) to a pollutant and risk to ecosystems or the public welfare include:

- What elements of the ecosystem (e.g., types, regions, taxonomic groups, populations, functions, etc.) appear to be affected, or are more sensitive to effects? Are there differences between locations or materials in welfare effects responses, such as impaired visibility or materials damage?
- Under what exposure conditions (amount deposited or concentration, duration and pattern) are effects seen?
- What is the shape of the concentration-response or exposure-response relationship?

Evaluations of causality generally consider the probability of quantitative changes in ecological and welfare effects in response to exposure. A challenge to the quantification of exposure-response relationships for ecological effects is the great regional and local spatial variability, as well as temporal variability, in ecosystems. Thus, exposure-response relationships are often determined for a specific ecological system and scale, rather than at the national or even regional scale. Quantitative relationships therefore are available site by site and may differ greatly between ecosystems.

Concepts in Evaluating Adversity of Health Effects

In evaluating health evidence, a number of factors can be considered in delineating between adverse and nonadverse health effects resulting from exposure to air pollution. Some health outcomes, such as hospitalization for respiratory or cardiovascular diseases, are clearly considered adverse. It is more difficult to determine the extent of change that constitutes adversity in more subtle health measures. These include a wide variety of responses, such as alterations in markers of inflammation or oxidative stress, changes in pulmonary function or heart rate variability, or alterations in neurocognitive function measures. The challenge is determining the magnitude of change in these measures when there is no clear point at which a change become adverse; for example, what percentage change in a lung function measure represents an adverse effect. What constitutes an adverse health effect may vary between populations. Some changes that may not be considered adverse in healthy individuals would be potentially adverse in more susceptible individuals.

For example, the extent to which changes in lung function are adverse has been discussed by the American Thoracic Society (ATS) in an official statement titled *What Constitutes an Adverse Health Effect of Air Pollution?* (2000). An air pollution-induced shift in the population distribution of a given risk factor for a health outcome was viewed as adverse, even though it may not increase the risk of any one individual to an unacceptable level. For example, a population of asthmatics could have a distribution of lung function such that no identifiable individual has a level associated with significant impairment. Exposure to air pollution could shift the distribution such that no identifiable individual experiences clinically relevant effects. This shift toward decreased lung function, however, would be considered adverse because individuals within the population would have diminished reserve function and therefore would be at increased risk to further environmental insult. The committee also observed that elevations of biomarkers, such as cell number and types, cytokines and reactive oxygen species, may signal risk for ongoing injury and clinical effects or may simply indicate transient responses that can provide insights into mechanisms of injury, thus illustrating the lack of clear boundaries that separate adverse from nonadverse effects.

The more subtle health outcomes may be connected mechanistically to health events that are clearly adverse. For example, air pollution may affect markers of transient myocardial ischemia such as ST-segment abnormalities and onset of exertional angina. These effects may not be apparent to the individual, yet may still increase the risk of a number of cardiac events, including myocardial infarction and sudden death. Thus, small changes in physiological measures may not appear to be clearly adverse when considered alone, but may be a part of a coherent and biologically plausible chain of related health outcomes

that range up to responses that are very clearly adverse, such as hospitalization or mortality.

Concepts in Evaluating Adversity of Ecological Effects

Adversity of ecological effects can be understood in terms ranging in scale from the cellular level to the individual organism and to the population, community and ecosystem levels. In the context of ecology, a population is a group of individuals of the same species, and a community is an assemblage of populations of different species interacting with one another that inhabit an area. An ecosystem is the interactive system formed from all living organisms and their abiotic (physical and chemical) environment within a given area (IPCC, 2007). The boundaries of what could be called an ecosystem are somewhat arbitrary, depending on the focus of interest or study. Thus, the extent of an ecosystem may range from very small spatial scales to, ultimately, the entire Earth (IPCC, 2007).

Effects on an individual organism are generally not considered to be adverse to public welfare. However if effects occur to enough individuals within a population, then communities and ecosystems may be disrupted. Changes to populations, communities and ecosystems can in turn result in an alteration of ecosystem processes. Ecosystem processes are defined as the metabolic functions of ecosystems including energy flow, elemental cycling, and the production, consumption and decomposition of organic matter (U.S. EPA, 2002b). Growth, reproduction, and mortality are species-level endpoints that can be clearly linked to community and ecosystem effects and are considered to be adverse when negatively affected. Other endpoints such as changes in behavior and physiological stress can decrease ecological fitness of an organism, but are harder to link unequivocally to effects at the population, community and ecosystem level. The degree to which pollutant exposure is considered adverse may also depend on the location and its intended use (i.e., city park, commercial cropland). Support for consideration of adversity beyond the species level by making explicit the linkages between stress-related effects at the species and effects at the ecosystem level is found in *A Framework for Assessing and Reporting on Ecological Condition: an SAB report* (U.S. EPA, 2002b). Additionally, the National Acid Precipitation Assessment Program (NAPAP) uses the following working definition of *adverse ecological effects* in the preparation of reports to Congress mandated by the Clean Air Act: “any injury (i.e. loss of chemical or physical quality or viability) to any ecological or ecosystem component, up to and including at the regional level, over both long and short terms.”

On a broader scale, ecosystem services may provide indicators for ecological impacts. Ecosystem services are the benefits that people obtain from ecosystems (UNEP, 2003). According to the *Millennium Ecosystem Assessment*, ecosystem services include:

"provisioning services such as food and water; regulating services such as regulation of floods, drought, land degradation, and disease; supporting services such as soil formation and nutrient cycling; and cultural services such as recreational, spiritual, religious and other nonmaterial benefits." For example, a more subtle ecological effect of pollution exposure may result in a clearly adverse impact on ecosystem services if it results in a population decline in a species that is recreationally or culturally important.

PREFACE

Legislative Requirements for the NAAQS Review

Two sections of the Clean Air Act (CAA) govern the establishment and revision of the NAAQS. Section 108 (42:U.S.C.:7408) directs the Administrator to identify and list certain air pollutants and then to issue air quality criteria for those pollutants. The Administrator is to list those air pollutants that in her "… judgment, cause or contribute to air pollution which may reasonably be anticipated to endanger public health or welfare; …" and, "… the presence of which in the ambient air results from numerous or diverse mobile or stationary sources;" and, "… for which … [the Administrator] plans to issue air quality criteria…. ." Air quality criteria are intended to "accurately reflect the latest scientific knowledge useful in indicating the kind and extent of all identifiable effects on public health or welfare which may be expected from the presence of [a] pollutant in the ambient air …" (42:U.S.C.:7408([b]). Section 109 (42:U.S.C.:7409) directs the Administrator to propose and promulgate "primary" and "secondary" NAAQS for pollutants for which air quality criteria are issued. Section 109(b)(1) defines a primary standard as one "…the attainment and maintenance of which in the judgment of the Administrator, based on such criteria and allowing an adequate margin of safety, are requisite to protect the public health." The legislative history of Section 109 indicates that a primary standard is to be set at "… the maximum permissible ambient air level … which will protect the health of any [sensitive] group of the population," and that for this purpose "… reference should be made to a representative sample of persons comprising the sensitive group rather than to a single person in such a group…" (S. Rep. No. 91:1196, 91st Cong., 2d Sess. 10 [1970]). A secondary standard, as defined in Section 109(b)(2), must "… specify a level of air quality the attainment and maintenance of which, in the judgment of the Administrator, based on such criteria, is requisite to protect the public welfare from any known or anticipated adverse effects associated with the presence of [the] pollutant in the ambient air." Welfare effects (as defined in Section 302(h); 42:U.S.C.:7602[h]) include, but are not limited to, "… effects on soils, water, crops, vegetation, man-made materials, animals, wildlife, weather, visibility and climate, damage to and deterioration of property, and hazards to transportation, as well as effects on economic values and on personal comfort and well-being."

The requirement that primary standards provide an adequate margin of safety was intended to address uncertainties associated with inconclusive scientific and technical information available at the time of standard setting. It was also intended to provide a reasonable degree of protection against hazards that research has not yet identified (Lead Industries Association v. EPA, 647:F.2d:1130-1154 [D.C.Cir 1980]; American Petroleum

Institute v. Costle, 665:F.2d:1176-1186 [D.C.Cir. 1981]; American Farm Bureau Federation v. EPA, 559:F.3d:512-533 [D.C. Cir. 2009]; Association of Battery Recyclers v. EPA, 604:F.3d:613, 617-618 [D.C. Cir. 2010]). Both kinds of uncertainties are components of the risk associated with pollution at levels below those at which human health effects can be said to occur with reasonable scientific certainty. Thus, in selecting primary standards that provide an adequate margin of safety, the Administrator is seeking not only to prevent pollution levels that have been demonstrated to be harmful but also to prevent lower pollutant levels that may pose an unacceptable risk of harm, even if the risk is not precisely identified as to nature or degree. The CAA does not require the Administrator to establish a primary NAAQS at a zero-risk level or at background concentration levels (Lead Industries v. EPA, [647:F.2d:at 1156 n.51]), but rather at a level that reduces risk sufficiently so as to protect public health with an adequate margin of safety.

In addressing the requirement for an adequate margin of safety, the EPA considers such factors as the nature and severity of the health effects involved, the size of sensitive population(s) at risk, and the kind and degree of the uncertainties that must be addressed. The selection of any particular approach to providing an adequate margin of safety is a policy choice left specifically to the Administrator's judgment (Lead Industries Association v. EPA, [647:F.2d:1161-1162]; Whitman v. American Trucking Associations, [531:U.S.:457-495 (2001)]).

In setting standards that are "requisite" to protect public health and welfare as provided in Section 109(b), EPA's task is to establish standards that are neither more nor less stringent than necessary for these purposes. In so doing, EPA may not consider the costs of implementing the standards (see generally, Whitman v. American Trucking Associations, [531:U.S.:457, 465-472, 475-476 (2001)]). Likewise, "… [a]ttainability and technological feasibility are not relevant considerations in the promulgation of national ambient air quality standards." (American Petroleum Institute v. Costle, [665:F.2d:1185]).

Section 109(d)(1) requires that "not later than December 31, 1980, and at 5-year intervals thereafter, the Administrator shall complete a thorough review of the criteria published under section 108 and the national ambient air quality standards … and shall make such revisions in such criteria and standards and promulgate such new standards as may be appropriate … ." Section 109(d)(2) requires that an independent scientific review committee "shall complete a review of the criteria … and the national primary and secondary ambient air quality standards … and shall recommend to the Administrator any new … standards and revisions of existing criteria and standards as may be appropriate

… .” Since the early 1980's, this independent review function has been performed by the Clean Air Scientific Advisory Committee (CASAC).

History of the NAAQS for Pb

On October 5, 1978, EPA initially promulgated primary and secondary NAAQS for Pb under Section 109 of the Act (43 FR 46246). Both primary and secondary standards were set at a level of 1.5 micrograms per cubic meter ($\mu g/m^3$), measured as Pb in total suspended particles (Pb-TSP), not to be exceeded by the maximum arithmetic mean concentration averaged over a calendar quarter. These standards were based on the 1977 Air Quality Criteria for Lead (U.S. EPA, 1977).

The first review of the Pb standards was initiated in the mid-1980s. The scientific assessment for that review is described in the 1986 Air Quality Criteria for Lead (U.S. EPA, 1986a), the associated Addendum (U.S. EPA, 1986c) and the 1990 Supplement (U.S. EPA, 1990a). As part of the review, the Agency designed and performed human exposure and health risk analyses (U.S. EPA, 1989), the results of which were presented in a 1990 Staff Paper (U.S. EPA, 1990b). Based on the scientific assessment and the human exposure and health risk analyses, the 1990 Staff Paper presented recommendations for consideration by the Administrator (U.S. EPA, 1990b). After consideration of the documents developed during the review and the significantly changed circumstances since Pb was listed in 1976, the Agency did not propose any revisions to the 1978 Pb NAAQS. In a parallel effort, the Agency developed the broad, multi-program, multimedia, integrated U.S. Strategy for Reducing Lead Exposure (U.S. EPA, 1991). As part of implementing this strategy, the Agency focused efforts primarily on regulatory and remedial clean-up actions aimed at reducing Pb exposures from a variety of non-air sources judged to pose more extensive public health risks to U.S. populations, as well as on actions to reduce Pb emissions to air, such as bringing more areas into compliance with the existing Pb NAAQS (U.S. EPA, 1991).

The most recent review of the Pb air quality criteria and standards was initiated in November, 2004 (69 FR 64926) and the Agency’s plans for preparation of the *Air Quality Criteria Document* and conduct of the NAAQS review were contained in two documents: *Project Work Plan for Revised Air Quality Criteria for Lead* (U.S. EPA, 2005e)*;* and *Plan for Review of the National Ambient Air Quality Standards for Lead* (U.S. EPA, 2006e). The schedule for completion of this review was governed by a judicial order in *Missouri Coalition for the Environment v. EPA* (No. 4:04CV00660 ERW, Sept. 14, 2005; and amended on April 29, 2008 and July 1, 2008), which specified a schedule for the review of duration substantially shorter than five years.

The scientific assessment for the review is described in the 2006 *Air Quality Criteria for Lead* [2006 Pb AQCD; (U.S. EPA, 2006b)], multiple drafts of which received review by CASAC and the public. EPA also conducted human exposure and health risk assessments and a pilot ecological risk assessment for the review, after consultation with CASAC and receiving public comment on a draft analysis plan (U.S. EPA, 2006d). Drafts of these quantitative assessments were reviewed by CASAC and the public. The pilot ecological risk assessment was released in December 2006 (ICF, 2006) and the final health risk assessment report was released in November 2007 (U.S. EPA, 2007g). The policy assessment based on both of these assessments, air quality analyses and key evidence from the AQCD was presented in the Staff Paper (U.S. EPA, 2006f), a draft of which also received CASAC and public review. The final Staff Paper presented OAQPS staff's evaluation of the public health and welfare policy implications of the key studies and scientific information contained in the 2006 Criteria Document and presented and interpreted results from the quantitative risk/exposure analyses conducted for this review. Based on this evaluation, the Staff Paper presented OAQPS staff recommendations that the Administrator give consideration to substantially revising the primary and secondary standards to a range of levels at or below 0.2 $\mu g/m^3$.

Immediately subsequent to completion of the Staff Paper, EPA issued an advance notice of proposed rulemaking (ANPR) that was signed by the Administrator on December 5, 2007 (72 FR 71488).[1] CASAC provided advice and recommendations to the Administrator with regard to the Pb NAAQS based on its review of the ANPR and the previously released final Staff Paper and risk assessment reports. The proposed decision on revisions to the Pb NAAQS was signed on May 1, 2008 and published in the Federal Register on May 20, 2008 (73 FR 29184). Members of the public provided both written and, at two public hearings, oral comments and the CASAC Pb Panel also provided advice and recommendations to the Administrator based on its review of the proposal notice. The final decision on revisions to the Pb NAAQS was signed on October 15, 2008 and published in the Federal Register on November 12, 2008 (73 FR 66964).

The November 2008 notice described EPA's decision to revise the primary and secondary NAAQS for Pb from a level of 1.5 $\mu g/m^3$ to a level of 0.15 $\mu g/m^3$. EPA's decision on the level for the primary standard was based on the much-expanded health effects evidence on neurocognitive effects of Pb in children. The level of 0.15 $\mu g/m^3$ was established to protect against air Pb-related health effects, including IQ loss, in the most highly exposed children, those exposed at the level of the standard. Results of the quantitative risk assessment were judged supportive of the evidence-based framework

1 The ANPR was one of the features of the revised NAAQS review process that EPA instituted in 2006. :In 2009, this component of the process was replaced by reinstatement of the OAQPS policy assessment (previously termed the Staff Paper).

estimates. The averaging time was revised to a rolling three-month period with a maximum (not-to-be-exceeded) form, evaluated over a three-year period. As compared to the previous averaging time of calendar quarter, this revision was considered to be more scientifically appropriate and more health protective. The rolling average gives equal weight to all three-month periods, and the new calculation method gives equal weight to each month within each three-month period. Further, the rolling average yields 12 three-month averages each year to be compared to the NAAQS versus four averages in each year for the block calendar quarters pertaining to the previous standard. The indicator of Pb-TSP was retained, reflecting the evidence that Pb particles of all sizes pose health risks. The secondary standard was revised to be identical in all respects to the revised primary standards.[1]

Revisions to the NAAQS were accompanied by revisions to the data handling procedures, the treatment of exceptional events, and the ambient air monitoring and reporting requirements; as well as emissions inventory reporting requirements.2 One aspect of the new data handling requirements is the allowance for the use of Pb-PM_{10} monitoring for Pb NAAQS attainment purposes in certain limited circumstances at non-source-oriented sites. The monitoring network requirements resulted in a substantial number of new monitors being required as of January 2010, Subsequent to the 2008 rulemaking, additional revisions were made to the monitoring network requirements, which required additional monitors as of December 2011; the complete current requirements are described in Section 3.4.

On February 26, 2010 (75 FR 8934), EPA formally initiated its current review of the air quality criteria for Pb, requesting the submission of recent scientific information on specified topics. Soon after, a science policy workshop was held to identify key policy issues and questions to frame the review of the Pb NAAQS (75 FR 20843). Drawing from the workshop discussions, a draft IRP [*Integrated Review Plan for the National Ambient Air Quality Standards for Lead (U.S. EPA, 2011d)]*, was developed and made available in late March, 2011 for public comment and consultation with CASAC and was discussed by the CASAC via a publicly accessible teleconference consultation on May 5, 2011 (76 FR 20347, 76 FR 21346). The final IRP (U.S. EPA, 2011c) was released in November, 2011 (76 FR 76972).

As part of the science assessment phase of the current review, EPA held a workshop in December 2010 (75 FR 69078) to discuss, with invited scientific experts, preliminary

1 The 2008 NAAQS for Pb are specified at 40 CFR 50.16.
2 The 2008 federal regulatory measurement methods for Pb are specified in 40 CFR 50, Appendix G and 40 CFR part 53. Consideration of ambient air measurements with regard to judging attainment of the standards is specified in 40 CFR 50, Appendix R. The Pb monitoring network requirements are specified in 40 CFR 58, Appendix D, section 4.5. Guidance on the approach for implementation of the new standards was described in the Federal Register notices for the proposed and final rules (73 FR 29184; 73 FR 66964).

draft materials prepared during the ongoing development of the Pb ISA. The first external review draft ISA for Lead was released on May 6, 2011 (U.S. EPA 2011). The CASAC Pb Review Panel met at a public meeting on July 20, 2011 to review the draft ISA (76 FR 36120). Subsequently, on December 9, 2011, the CASAC panel provided a consensus letter for their review to the Administrator of the EPA (U.S. EPA 2011). The current document, the second external review draft *ISA for Lead*, will be discussed at a public meeting of the CASAC Pb Review Panel, and timely public comments received will be provided to the CASAC panel. A Federal Register notice will inform the public of the exact date and time of that CASAC meeting.

CHAPTER 1 EXECUTIVE SUMMARY

1.1 Introduction

This Integrated Science Assessment (ISA) is a synthesis and evaluation of the most policy-relevant science that forms the scientific foundation for the review of the primary (health-based) and secondary (welfare-based) national ambient air quality standard (NAAQS) for Lead (Pb). In 2008, the levels of the the primary and secondary NAAQS for Pb were lowered ten-fold, from the 1978 level of 1.5 $\mu g/m^3$, to a level of 0.15 $\mu g/m^3$. The averaging time was revised to a rolling three-month period with a maximum (not-to-be-exceeded) form, evaluated over a three-year period. EPA's decision on the level for the primary standard was based on the much-expanded health effects evidence on neurocognitive effects of Pb in children. The revised standard was established to protect against air Pb-related health effects, including IQ loss, in the most highly exposed children.

EPA has developed a process for evaluating the scientific evidence and drawing conclusions and causal judgments regarding air pollution-related health and environmental effects. The ISA development process includes literature search strategies, criteria for selecting and evaluating studies, approaches for evaluating weight of the evidence, and a framework for making causality determinations. The ISA uses a five-level hierarchy that classifies the weight of evidence for causation:

- Causal relationship
- Likely to be a causal relationship
- Suggestive of a causal relationship
- Inadequate to infer a causal relationship
- Not likely to be a causal relationship

The process and causality framework are described in more detail in the Preamble to the ISA. Considerations that are specific to the causal determinations drawn for the health and ecological effects of Pb are described in Section 2.1 of the document.

1.2 Lead Sources, Fate and Transport in the Environment, Human Exposure and Dose

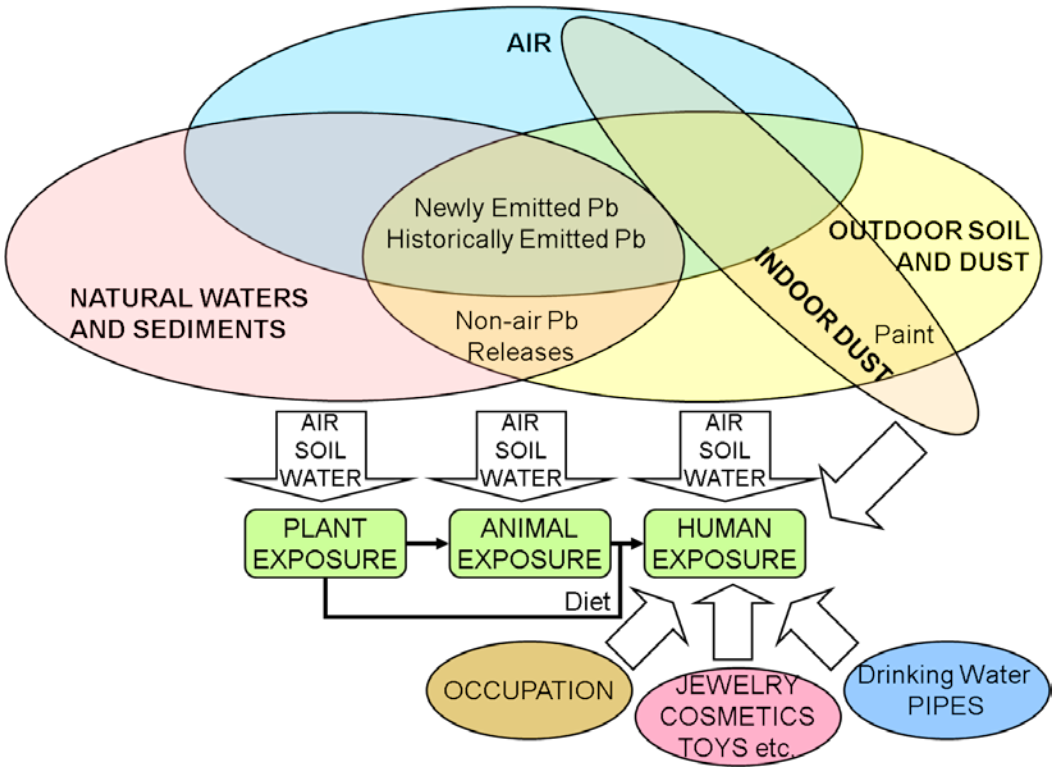
Emissions of Pb to ambient air have declined by more than two orders of magnitude over the period 1970 to 2008 following the ban on alkyl-Pb additives for on-road gasoline and tightened industrial standards. Emissions were estimated to be 970 tons in 2008, with more than half emitted from piston-engine aircraft. Other sources of ambient air Pb (beginning with the largest) include metals processing, fossil fuel combustion, other industrial sources, roadway related sources, and historic Pb. During the same period that saw this dramatic decrease in Pb emissions, ambient air Pb concentrations have also declined. The median annual concentrations in 2010 (0.03 $\mu g/m^3$) were approximately thirty times lower than they were in 1980. The sharpest drop in Pb concentration occurred during 1980-1990 and concentrations continued to decline through 2010. Concentrations near Pb sources as well as concentrations away from Pb sources have shown a sharp decline (Section 2.2.2).

The indicator for the Pb NAAQS is Pb in total suspended particles (Pb-TSP). The Pb-TSP indicator was retained in 2008 in recognition of the role of all PM sizes in ambient air Pb exposures. The Federal Reference Method (FRM) Pb-TSP sampler's size selective performance is known to be affected by wind speed and direction, and collection efficiency has been demonstrated to decline with particle size. The size distribution of Pb-bearing particulate matter (PM) varies substantially depending on the nature of Pb sources and proximity of the monitors to the Pb sources. Coarse Pb-bearing PM deposits to a great extent near its source, contributing to local soil Pb concentrations, while fine Pb-bearing PM (e.g. aircraft emissions) can be transported long distances, potentially contributing Pb to remote areas. Depending on local conditions, deposited particles may be resuspended and redeposited multiple times before further transport becomes unlikely. In regulatory Pb monitoring, ambient Pb sampled using the FRM for Pb-PM_{10} is allowed in certain instances where the expected Pb concentration does not approach the NAAQS and no sources of ultracoarse Pb are nearby.

Atmospheric deposition has led to measurable Pb concentrations observed in rain, snowpack, soil, surface waters, sediments, agricultural plants, livestock, and wildlife across the world, with the highest concentrations near Pb sources, such as metal smelters. After the phase-out of Pb from on-road gasoline, Pb concentrations have decreased considerably in rain, snowpack, and surface waters. In contrast, Pb is retained in soils and sediments, where it provides a historical record of deposition and associated concentrations. In remote lakes, sediment profiles indicate higher Pb concentrations in near surface sediment as compared to pre-industrial era sediment from greater depth and indicate peak concentrations between 1960 and 1980 (when leaded on-road gasoline was

at peak use). Ingestion and water intake are the major routes of Pb exposure for aquatic organisms, and food, drinking water, and inhalation are major routes of exposure for livestock and terrestrial wildlife.

Human exposure to Pb involves multiple pathways (Figure 1-1) and is difficult to assess because Pb has multiple sources in the environment. Air-related pathways of Pb exposure are the focus of this assessment. In addition to inhalation of Pb from ambient air, air-related Pb exposure pathways include inhalation and ingestion of Pb from indoor dust and/or outdoor soil that originated from recent or historic ambient air. Non-air-related exposures to humans include occupational exposures, hand-to-mouth contact with Pb-containing consumer goods, hand-to-mouth contact with dust or chips of peeling Pb-containing paint, or ingestion of Pb in drinking water conveyed through Pb pipes. Soil can act as a reservoir for deposited Pb emissions and exposure to soil contaminated with deposited Pb can occur through resuspended PM as well as shoe tracking and hand-to-mouth contact, which is the main pathway of childhood exposure to Pb. Infiltration of Pb dust into indoor environments has been suggested, and Pb dust has been shown to persist in indoor environments even after repeated cleanings. Measurements of particle-bound Pb exposures reported in this assessment have shown that personal exposure measurements of Pb concentration are typically higher than are indoor or outdoor ambient Pb concentrations.



Note: The Venn diagram is used to illustrate the passage of Pb through multiple environmental media compartments through which exposure can occur.

Figure 1-1 Conceptual model of multimedia Pb exposure.

The majority of Pb in the body is found in bone (roughly 90% in adults, 70% in children); only about 1% of Pb is found in the blood. Pb in blood is primarily (~99%) bound to RBCs. The burden of Pb in the body may be viewed as that divided between a dominant slow compartment (bone) and smaller fast compartment(s) (soft tissues). Pb uptake and elimination in soft tissues is much faster than it is in bone. Pb accumulates in bone regions undergoing the most active calcification at the time of exposure. Pb in bone becomes distributed in trabecular (e.g. patella) and the more dense cortical bone (e.g. tibia).

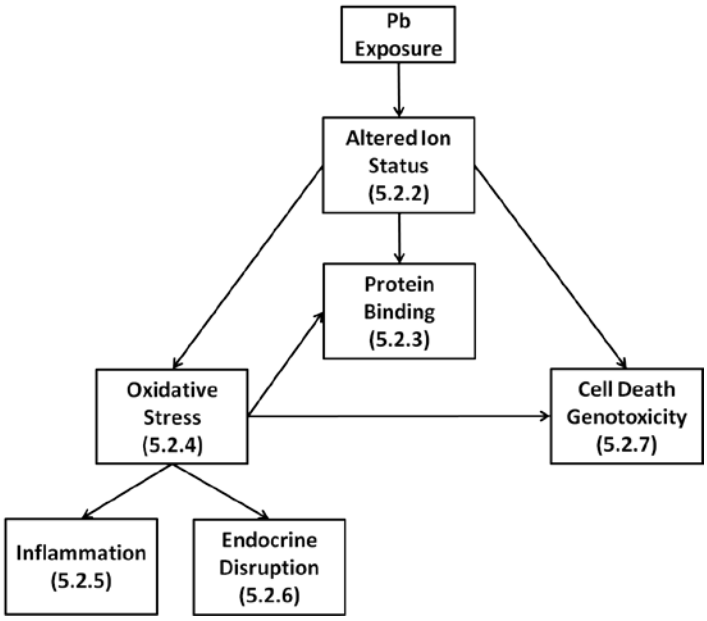
Blood Pb is the most common metric of Pb dose or exposure used in epidemiologic studies of Pb health effects. Overall, blood Pb levels have been decreasing among U.S. children and adults over the past twenty years. The median blood Pb level for the entire U.S. population is 1.2 µg/dL with a 95th percentile blood Pb level of 3.7 µg/dL based on the 2007-2008 NHANES (National Health and Nutrition Examination Survey) data. Among children aged 1-5 years, the median and 95th percentiles are slightly higher at 1.4 µg/dL and 4.1 µg/dL, respectively. Other common metrics of Pb dose or exposure used in

epidemiologic studies are Pb in bone (a metric of cumulative exposure) and Pb cord blood (a metric of prenatal exposure).

Blood Pb is dependent on both the recent exposure history of the individual, as well as the long-term exposure history that determines body burden and Pb in bone. The contribution of bone Pb to blood Pb changes in an individual depending on the duration and intensity of the exposure, age, and various other physiological stressors that may affect bone remodeling (e.g., nutritional status, pregnancy, menopause, extended bed rest, hyperparathyroidism) beyond that which normally and continuously occurs. In children, largely due to faster exchange of Pb to and from bone, blood Pb is both an index of recent exposure and potentially an index of body burden. In adults and children whose current exposure to Pb has effectively ceased or greatly decreased, a slow decline in blood Pb concentrations mainly reflects the gradual release of Pb from bone. Generally, bone Pb is an index of cumulative exposure and body burden. Pb is sequestered in two bone compartments; with Pb in trabecular bone exchanging more rapidly with the blood, than Pb in cortical bone. Therefore, Pb in cortical bone a better marker of cumulative exposure and Pb in trabecular bone more likely to be correlated with blood Pb, in adults and children. There is evidence for maternal-to-fetal transfer of Pb in humans. Transplacental transfer of Pb may be facilitated by an increase in the plasma/blood Pb concentration ratio during pregnancy. Maternal-to-fetal transfer of Pb appears to be related partly to the mobilization of Pb from the maternal skeleton.

1.3 Integrative Overview of Health and Ecological Effects

There is substantial overlap between the ecological and health endpoints related to Pb exposure in that they can be mediated through multiple, interconnected modes of action (Table 2-5). The principal cellular/subcellular effects contributing to modes of action for human health and ecological endpoints are altered ion status, protein binding, oxidative stress, inflammation, endocrine disruption and cell death/genotoxicity (Figure 1-2). The commonalities with regard to the endpoints and modes of action allowed the integration of the evidence across disciplines (Table 2-4). The mechanisms of Pb toxicity are likely conserved from invertebrates to vertebrates, including humans in some organ systems. See Section 2.8.1 for additional details.



Note: The subsections where these MOAs are discussed are indicated in parentheses.

Figure 1-2 Schematic representation of the relationships between the various MOAs by which Pb exerts its effects.

1.3.1 Health Effects of Lead

Evidence from epidemiologic and toxicological studies was considered in combination with the evidence from other disciplines such as exposure sciences and toxicokinetics in determining the causal relationships for the health outcomes discussed in this assessment. The evidence related to the specific endpoints comprising the weight of the evidence for the organ system-specific causal determination are summarized in Table 1-1 below. Table 1-1 also specifies the sections sections in Chapter 2 and Chapter 5 where detailed information can be found.

Table 1-1 Summary of causal determinations between exposure to Pb and health outcomes

Outcome[a]	Causality Determination
Nervous System Effects (Section 2.6.1)	Causal Relationship
Cardiovascular Effects (Section 2.6.2)	Causal Relationship
Renal Effects (Section 2.6.3)	Causal Relationship
Immune System Effects (Section 2.6.4)	Causal Relationship
Effects on Heme Synthesis and Red Blood Cell Function (Section 2.6.5)	Causal Relationship
Reproductive and Developmental Effects (Section 2.6.6)	Causal Relationship
Cancer (Section 2.6.7)	Likely Causal Relationship

[a]Based upon the framework described in the Preamble, a determination of causality was made for a broad outcome category (e.g., nervous system effects) by evaluating the coherence of evidence across disciplines and across a spectrum of related endpoints. However, the evidence on which the causal judgment is based, including the strength of evidence for the individual endpoints within the major outcome category, is characterized within the discussion. Causal determinations were made within approximately 1-2 orders of magnitude of current levels.

Nervous System Effects

Recent epidemiologic and toxicological studies substantiated the strong body of evidence presented in the 2006 Pb AQCD that Pb exposure is associated with nervous system effects. The weight of evidence clearly supports associations of increases in blood Pb levels with decrements in cognitive function in children, i.e., full-scale IQ and various measures of learning and memory. Several studies find that there is a larger incremental effect of Pb on cognition at lower blood Pb levels. Studies have not provided evidence of a threshold for Pb-related impaired cognition. Epidemiologic and toxicological evidence also clearly demonstrates Pb-associated increases in behavioral problems, in particular, inattention and impulsivity in children. In epidemiologic studies, associations with cognitive function and behavior were observed after adjustment for a range of potential confounding variables, but most commonly, parental IQ, parental education, and other SES-related variables. In children, the weight of evidence supports cognitive function decrements and behavioral problems in association with concurrent blood Pb levels. Associations also are observed with prenatal, early childhood, and childhood average blood Pb levels, thus uncertainty remains regarding the lifestage of exposure within childhood that is associated with the greatest risk. The weight of toxicological evidence demonstrates neurodevelopmental effects with prenatal and early postnatal Pb exposures that can have effects persisting to adulthood. The biological plausibility for epidemiologic and toxicological findings for effects on cognitive function and behavior is provided by evidence characterizing underlying mechanisms, including Pb-induced

changes in neurogenesis, synaptogenesis and synaptic pruning, long term potentiation, and neurotransmitter function. Based most heavily on cognitive function decrements and inattention in children, the collective body of evidence integrated across epidemiologic and toxicological studies is sufficient to conclude that there is a causal relationship between Pb exposures and nervous system effects (Section 2.6.1).

Cardiovascular Effects

The 2006 Pb AQCD concluded that there was a relationship between blood Pb and bone Pb and cardiovascular effects in adults, in particular increased blood pressure (BP) and increased incidence of hypertension. Building on this strong body of evidence, recent epidemiologic and toxicological studies substantiated the evidence that long-term Pb exposure is associated with cardiovascular effects in adults with the largest body of evidence demonstrating associations of Pb with increased BP and hypertension. The epidemiologic evidence is strengthened by several recent prospective studies that find associations between biomarkers of Pb and BP and hypertension and by effect estimates that are observed after adjustment for multiple potential confounding factors. However, there is uncertainty regarding the level, timing, frequency, and duration of Pb exposure contributing to the observed associations since the populations studied were likely to have higher past than recent Pb exposure. Animal toxicological studies provide mechanistic evidence to support the biological plausibility of Pb-induced hypertension, including Pb-induced oxidative stress, activation of renin-angiotensin aldosterone system (RAAS), altered sympathetic activity, and vasomodulator imbalance. Collectively, the evidence integrated across epidemiologic and toxicological studies as well as across the spectrum of other cardiovascular endpoints examined is sufficient to conclude that there is a causal relationship between Pb exposures and cardiovascular health effects (Section 2.6.2).

Renal Effects

New epidemiologic and toxicological studies evaluated in the current review support or expand upon the strong body of older evidence on the effect of Pb on the renal system presented in the 2006 Pb AQCD. The weight of epidemiologic evidence consistently demonstrates a relationship between higher blood Pb level and kidney dysfunction (e.g., lower creatinine clearance, higher serum creatinine, and lower glomerular filtration rate [GFR]) in nonoccupationally-exposed adults. Associations between Pb biomarker levels and renal function are observed after adjustment for multiple potential confounding factors such as age, sex, comorbid cardiovascular conditions, body mass index, smoking, and alcohol use; however, there is uncertainty regarding the level, timing, frequency, and

duration of Pb exposure contributing to the observed associations, since the populations studied were likely to have higher past exposure than recent exposure. Coherence for epidemiologic findings is provided by observations from animal models that Pb exposure for longer than 6 months decreases GFR and increases serum creatinine. The weight of evidence from animal studies indicates that Pb induces histopathological changes, including tubular atrophy and sclerosis. By demonstrating Pb-induced renal oxidative stress, inflammation, mitochondrial dysfunction, apoptosis, and glomerular hypertrophy, toxicological studies provide biological plausibility for the associations observed in epidemiologic studies between blood Pb levels and kidney dysfunction. Collectively, the evidence integrated across epidemiologic and toxicological studies as well as across the spectrum of renal outcomes is sufficient to conclude that there is a causal relationship between Pb exposures and renal health effects (Section 2.6.3).

Immune System Effects

As described in the 2006 Pb AQCD, rather than producing overt cytotoxicity or pathology, Pb exposure was found to be associated with alterations in several subclinical parameters related to cellular and humoral immunity (Figure 5-42). The principal findings are Pb-induced increased production of Th2 cytokines, suppressed production of Th1 cytokines, increased inflammation, and elevated IgE, with the weight of evidence provided by toxicological studies. Collectively, these findings are coherent with the observed effects of Pb exposure on decreasing responses to antigens (e.g., DTH, bacterial resistance) in animals. Both toxicological studies in animals and epidemiologic studies in children provide evidence for Pb-associated increases in IgE. The toxicological and epidemiologic findings for the Pb-induced effects on Th2 cytokines, IgE, and inflammation provide biological plausibility for the associations observed for blood Pb levels with asthma and allergic conditions in children. Associations with asthma and allergy were observed after considering potential confounding by several factors, including, SES and allergen exposure. The blood Pb levels and Pb exposure lifestage, magnitude, frequency, and duration associated with immune effects are not well characterized in children or adults. Epidemiologic studies of children and adults primarily examined concurrent blood Pb levels. The consistency and coherence of findings across the continuum of related immune parameters that demonstrate a stimulation of Th2 responses in toxicological studies combined with the supporting epidemiologic evidence in children are sufficient to conclude that there is a causal relationship between Pb exposures and immune system effects (Section 2.6.4).

Heme Synthesis and Red Blood Cell Function

Recent epidemiologic and toxicological studies support findings from the 2006 Pb AQCD which concluded that Pb exposure was associated with effects on developing red blood cells (RBCs) as well as heme synthesis in children and occupationally exposed adults. The principal findings for RBC survival and function from recent studies are the consistent Pb-induced alterations in several inter-connected hematological parameters such as hemoglobin (Hb), hematocrit (Hct), and mean corpuscular volume (MCV) observed across multiple studies. The effects on heme synthesis occurred through the inhibition of multiple key enzymes, most notably aminolevulinic acid dehydratase (ALAD), the enzyme that catalyzes the second, rate-limiting step in heme biosynthesis. For heme synthesis, the largest body of evidence indicates decreased ALAD activity in association with Pb exposure or blood Pb levels in occupationally-exposed adults or in children (3-12 years old), respectively. Evidence for oxidative stress, an important mode of action by which Pb may exert effects, primarily comes from studies of occupationally-exposed adults and of children. the level, frequency, timing and duration of exposure associated with altered RBC survival and function, heme synthesis, or the state of oxidative stress in RBCs is uncertain in both adults and in children. The consistency of findings in epidemiologic studies investigating effects in occupationally-exposed adults and children, and the coherence of findings in the toxicological literature and coherence across the disciplines is sufficient to conclude that there is a causal relationship exists between Pb exposures and effects on heme synthesis and RBC function (Section 2.6.5).

Reproductive and Developmental Effects

Supporting conclusions from the 2006 Pb AQCD, recent toxicological and epidemiologic literature provides strong evidence that Pb exposure is associated with effects on reproduction and development, and expands evidence for additional endpoints. The weight of the evidence supports the association of Pb exposure with delayed onset of puberty in both males and females; and detrimental effects on sperm and semen quality in occupationally-exposed males and in laboratory animals. In cross-sectional epidemiologic studies of girls (ages 6-18 years) consistent associations with delayed pubertal development (measured by age at menarche, pubic hair development, and breast development) were observed. In boys (ages 8-15 years), fewer studies were conducted but associations with delayed puberty were observed in most. There is uncertainty with regard to the exposure frequency, timing, duration and level that contributed to these observed association in studies of adolescents. The collective body of evidence integrated across epidemiologic and toxicological studies (which examined Pb-induced detrimental effects on sperm and on delayed onset of puberty), is sufficient to conclude that there is a

causal relationship between Pb exposures and reproductive and developmental effects (Section 2.6.6).

Cancer

The previous epidemiologic studies included in the 2006 Pb AQCD provided very limited evidence suggestive of Pb exposure associations with cancers of the lung and stomach and genotoxic effects in humans. The conclusions of the 2006 Pb AQCD were consistent with those of International Agency for Research on Cancer (IARC) and the National Toxicology Program. The animal toxicological literature continues to provide the strongest evidence for an association between cancer and Pb exposure, with some supporting evidence provided by the epidemiologic literature. Evidence from toxicological studies demonstrates a relationship between Pb and cancer, genotoxicity/clastogenicity or epigenetic modification. Carcinogenicity in previous animal toxicology studies with Pb exposure has been reported in the kidneys, testes, brain, adrenals, prostate, pituitary, and mammary gland, albeit at high doses of Pb. Epidemiologic studies of cancer incidence and mortality reported inconsistent results. Recent occupational studies of Pb exposure and lung cancer reported no associations. The majority of epidemiologic studies of brain cancer had null results overall, but positive associations between Pb exposure and brain cancer were observed among individuals with certain genotypes (e.g. ALAD2). The collective body of evidence integrated across toxicological and epidemiologic studies is sufficient to conclude that there is a likely causal relationship between Pb exposure and cancer (Section 2.6.7).

1.3.2 Ecological Effects of Lead

The 2006 Pb AQCD and previous assessments found that the most commonly observed effects in terrestrial organisms included decreased survival, reproduction and growth as well as development and behavior. In aquatic invertebrates, effects of Pb exposures included inhibition of ALAD, reduced reproduction, growth and survival. Evidence of toxicity to fish (e.g. heme formation, alterations in brain receptors, effects on blood chemistry and hormonal systems, and decreases in some enzyme activities) was also observed. The effects of Pb can be observed in endpoints common to both terrestrial and aquatic biota. These effects can be observed at multiple levels of biological organization, starting at the cellular and subcellular level, then at the whole organism level, and finally at the community and ecosystem level. Effects of Pb on physiological stress, blood, and neurobehavior may increase susceptibility to other stressors and impact fitness of individual organisms. Effects on development, reproduction, growth and survival may

lead to effects on communities and ecosystems. The relationship of exposure and responses is difficult to quantitatively characterize because of the influence of multiple environmental variables on both Pb bioavailability and toxicity, and the substantial species and lifestage differences in Pb sensitivity.

A brief discussion of the conclusions regarding Pb effects on physiological stress, hematology, neurobehavior, development, reproduction, growth, survival and community and ecosystem level effects is provided below and summarized in Table 1-2. Causal determinations were based on consideration and integration of information on biogeochemistry, bioavailability, biological effects, and exposure-response relationships of Pb in terrestrial and aquatic environments. A detailed discussion for all relevant welfare effects is provided in Chapters 2 and 7.

Table 1-2 Summary of Pb causal determinations for plants, invertebrates and vertebrates

Effect[a]	Terrestrial	Aquatic[b]
Physiological Stress-All organisms (Section 2.7.3.1)	Causal	Causal
Hematological Effects-Invertebrates (Section 2.7.3.2)	Inadequate	Causal
Hematological Effects-Vertebrates (Section 2.7.3.2)	Causal	Causal
Neurobehavioral Effects-Invertebrates and Vertebrates (Section 2.7.3.3)	Likely Causal	Likely Causal
Developmental and Reproductive Effects-Plants (Section 2.7.3.4)	Inadequate	Inadequate
Developmental and Reproductive Effects-Invertebrates and Vertebrates (Section 2.7.3.4)	Causal	Causal
Growth-Plants (Section 2.7.3.5)	Causal	Causal
Growth-Invertebrates (Section 2.7.3.5)	Inadequate	Causal
Growth-Vertebrates (Section 2.7.3.5)	Inadequate	Inadequate
Survival-Plants (Section 2.7.3.6)	Inadequate	Inadequate
Survival- Invertebrates and Vertebrates (Section 2.7.3.6)	Causal	Causal
Community and Ecosystem Level Effects (Section 2.7.3.7)	Likely Causal	Likely Causal

[a]Effects observed at or near ambient levels of Pb were emphasized, and studies generally within 1-2 orders of magnitude above current conditions were considered in the body of evidence for terrestrial and aquatic ecosystems.

[b]Causal determinations for aquatic biota are based primarily on evidence from freshwater organisms.

Effects on physiological stress

Upregulation of antioxidant enzymes and increased lipid peroxidation are considered to be reliable biomarkers of stress. Alterations in these biomarkers are associated with Pb exposure in plants, invertebrates and vertebrates, and they may be indicative of increased susceptibility to other stressors, and of reduction in individual fitness. Markers of oxidative damage and antioxidant activity have been observed in a wide range of species

in terrestrial and aquatic environments when Pb is present, and following laboratory exposures. Evidence is sufficient to conclude that there is a causal relationship between Pb exposures and physiological stress in terrestrial and aquatic plants, invertebrates and vertebrates (Section 2.7.3.1).

Hematological Effects

Changes in hematological variables including ALAD activity, blood cell counts and serum profiles are associated with Pb exposure in both aquatic and terrestrial animal taxa. Evidence from both field and laboratory studies suggest that ALAD is an indicator for Pb exposure across a wide range of biota, and it is commonly recognized as such. Studies conducted across the last two decades have indicated that hematological responses are associated with Pb in the environment. Evidence is sufficient to conclude that there is a causal relationship between Pb exposures and hematological effects in aquatic invertebrates and vertebrates. Evidence is inadequate to establish a causal relationship between Pb exposures and hematological effects in terrestrial invertebrates (Section 2.7.3.2).

Neurobehavioral Effects

Historical and recent evidence from Pb-exposed animals indicates that Pb affects behaviors such as food consumption, avoidance and escape from predators, behavioral thermoregulation, and prey capture. Alterations to these behaviors may decrease the overall fitness of the organism. Evidence from laboratory studies has shown effects of Pb on nervous system endpoints in both aquatic and terrestrial animal taxa. Overall, the evidence from terrestrial and aquatic systems is sufficient to conclude that there is a likely causal relationship between Pb exposures and neurobehavioral effects in terrestrial and aquatic invertebrates and vertebrates (Section 2.7.3.3).

Effects on Development and Reproduction

Various endpoints measured in multiple taxa of terrestrial and aquatic organisms have documented effects of Pb on development, fecundity and hormone homeostasis. In plants, few studies have addressed reproductive effects of Pb exposure. Decreased reproduction at the organismal level can result in declining abundance and/or extirpation of populations, decreased taxa richness, and decreased relative or absolute abundance at the community level. Among the animal species tested, aquatic invertebrates were the most sensitive to Pb with respect to reproduction. Effects of Pb on reproduction in invertebrates and vertebrates indicate that Pb is affecting fecundity of Pb-exposed

organisms in both aquatic and terrestrial habitats, and the evidence is sufficient to conclude that there is a causal relationship between Pb exposures and reproductive effects in terrestrial and aquatic invertebrates and vertebrates. The evidence is inadequate to conclude that there is a causal relationship between Pb exposures and reproductive effects in plants (Section 2.7.3.4).

Effects on Growth

Effects on growth observed at the species level may translate into effects at the ecosystem level. Exposure to Pb has been shown to have effects on growth in plants and in some species of invertebrates and vertebrates. Evidence for effects of Pb on growth is strongest in plants, although they are typically observed in laboratory studies with high exposure concentrations or in field studies near point sources. Evidence for Pb effects on growth in invertebrates has been observed most extensively in freshwater aquatic taxa, with inhibition in sensitive species occurring near the current range of Pb in surface waters. In general, juvenile organisms are more sensitive than are adults. There are limited data on growth effects in vertebrates. Evidence is sufficient to conclude that there is a causal relationship between Pb exposures and growth effects in aquatic and terrestrial plants and aquatic invertebrates. Evidence is inadequate to to conclude that there is a causal relationship between Pb exposures and growth effects in terrestrial invertebrates and in terrestrial and aquatic vertebrates (Section 2.7.3.5).

Effects on Survival

Decreased survival of individuals within a population can have ecosystem-level impacts. Pb is generally not toxic to aquatic or terrestrial plants at concentrations found in the environment away from point sources, probably due to the fact that plants often sequester large amounts of Pb in roots, with little translocation to other parts of the plant. Aquatic invertebrates are generally more sensitive to Pb exposure than other taxa, with survival adversely impacted in a few species at concentrations occurring near point sources, or at concentrations near common ambient levels. Terrestrial invertebrates typically tolerate higher concentrations of Pb. Limited studies with vertebrates indicated adverse effects of Pb on survival at concentrations typically higher than ambient Pb in the environment, although juvenile organisms appear to be more sensitive than adults. The evidence is inadequate to conclude that there is a causal relationship between Pb exposure and survival in terrestrial and aquatic plants. Evidence is sufficient to conclude that there is a causal relationship between Pb exposures and survival in terrestrial and aquatic invertebrates and vertebrates (Section 2.7.3.6).

Community and Ecosystem Effects

At higher levels of ecological organization, exposure to Pb may alter community and ecosystem structure and function. Decreases in abundance, reduced species diversity and shifts in community composition have been observed following Pb exposure in laboratory and field experiments, but considerable uncertainties exist in generalizing to natural ecosystem level effects. Assessment of Pb-specific exposure-response relationships is difficult at the whole ecosystem level because potential confounders such as other metals, physico-chemical variables, or various stressors cannot be controlled. These factors make it difficult to quantify relationships between ambient concentrations of Pb and ecosystem responses. The cumulative evidence that has been reported for effects of Pb at the highest levels of ecological organization, and for species-level endpoints with direct relevance to population and ecosystem level effects (i.e., development and reproduction, growth, survival) is sufficient to conclude that there is a likely causal relationship between Pb exposures and the alteration of species richness, species composition and biodiversity in terrestrial and aquatic ecosystems (Section 2.7.3.7).

1.4 Policy Relevant Considerations

Public Health Significance

The concept of population risk is relevant to the interpretation of findings for the continuously-distributed subclinical health endpoints frequently studied in association with Pb biomarkers in the assessment of their public health significance. A seemingly small increase in the mean of a continuously distributed health index may push the most susceptible group in the population above a critical cut point on the continuum of disease development, such that their condition meets the clinical definition of a disease. Moreover, small changes at the population level could translate into large numbers of clinical events if a large population is affected. Pb-associated changes in subclinical indices of disease may also increase an individual's risk for health effects that are of greater clinical consequence, thus of greater public health concern. For example, a downward shift in the mean IQ value can also reduce the proportion of the population achieving very high IQ scores. Additional small increases in blood pressure or decreases in renal function that are associated with Pb biomarkers, may shift the population mean resulting in a larger proportion of the population that is diagnosed with hypertension or chronic kidney disease, respectively.

Air Lead-to-Blood Lead Relationships

A limited number of epidemiological studies evaluated relationships between air Pb and blood Pb (Section 2.9.2). Much of the pertinent earlier literature described in the 1986 Pb AQCD and more recent studies provide data from which estimates of the blood Pb-air Pb slope can be derived for children. The range of estimates from these studies is 2 to 9 µg/dL per µg/m^3. The differences in the estimates across studies may reflect model selection by the investigators (e.g., some models predict an increase in the blood Pb-air Pb slope with decreasing air Pb concentration while other models predict a constant blood Pb-air Pb slope across all air Pb concentrations) as well as inclusion parameters (e.g. soil Pb) that may account for some of the variation in blood Pb that is attributable to air Pb. Other factors that may explain the variation in the derived blood Pb-air Pb slope include differences in the populations examined and Pb sources (e.g. leaded gasoline or smelter).

Ecological Effects and Corresponding Lead Concentrations

There is limited evidence to relate ambient air concentrations of Pb to levels of deposition onto terrestrial and aquatic ecosystems and to subsequent movement of atmospherically-deposited Pb through environmental compartments (e.g., soil, sediment, water, and biota) (Section 2.9.3). Therefore, the connection between air concentration and ecosystem exposure continues to be poorly characterized for Pb and the contribution of atmospheric Pb to specific sites is not clear. Furthermore, the level at which Pb elicits a specific effect is difficult to establish in terrestrial and aquatic systems, due to the influence of other environmental variables on both Pb bioavailability and toxicity, and also to substantial species differences in Pb susceptibility. Current evidence indicates that Pb is bioaccumulated in biota; however, the sources of Pb in biota have only been identified in a few studies, and the relative contribution of Pb from all sources is usually not known. In addition, there are large differences in species sensitivity to Pb, and many environmental variables (e.g., pH, organic matter) determine the bioavailability and toxicity of Pb.

Concentration-Response Relationships for Health Effects

With each successive assessment to-date, the epidemiologic and toxicological study findings show that progressively lower blood Pb levels or Pb exposures are associated with cognitive deficits and behavioral impairments (Section 2.9.4). Compelling evidence for a steeper slope for the relationship between blood Pb level and children's IQ at lower blood Pb levels was presented in the 2006 Pb AQCD based on the international pooled analysis of seven prospective cohort studies. A subsequent reanalysis of these data focusing on the shape of the concentration-response function and several recent studies

support these findings. The majority of the epidemiologic evidence from stratified analyses comparing the lower and the higher ends of the blood Pb distributions indicates larger negative slopes at lower blood Pb levels (Figure 2-2). Several lines of toxicological evidence support the possibility of lower and higher Pb exposures acting through differential activation of mechanisms underlying cognition. The shapes of concentration-response relationships were examined in a more limited number epidemiologic studies of other effects and findings were mixed (Section 2.9.4).

Pb Exposure and Nervous System Effects in Children

Young children, do not have lengthy exposure histories and consequently the interpretation of associations with blood Pb levels for this age group may be less complicated compared to older age groups. Several lines of evidence inform the interpretation of study findings as they relate to aspects of exposure that can be attributed to the cognitive and behavioral effects of Pb observed in young children (Section 2.9.5).

Epidemiologic studies find associations of cognitive function and behavior with prenatal, early-childhood, lifetime average, and concurrent blood Pb levels as well as with childhood tooth Pb levels. However, the weight of epidemiologic evidence supports associations of concurrent blood Pb level. Studies of children up to three years of age that found associations with concurrent blood Pb levels also tended to find associations with prenatal cord or maternal blood Pb levels. Thus, both postnatal child and maternal Pb exposures may contribute to lower cognitive function in young children. Exposures that are reflected by concurrent blood Pb measured when children are older, by cumulative blood Pb levels or by tooth Pb levels have also been demonstrated to be associated with neurodevelopmental deficits throughout school-age and into adolescence. These findings are consistent with the understanding that the nervous system continues to develop throughout childhood.

Potentially At-Risk Populations

The NAAQS are intended to provide an adequate margin of safety for both the population as a whole and those groups with unique factors that make them potentially at increased risk for health effects in response to ambient air pollutant exposure. The most well-substantiated at-risk population for the effects of Pb exposure is children. Among children, the youngest age groups were observed to be most at risk of elevated blood Pb levels, with levels decreasing with increasing age of the children. Recent epidemiologic studies of infants/children detected increased risk of Pb-related health effects, and this was supported by toxicological studies. Synaptic pruning, which is active throughout early childhood (ages 1-4 years), may underlie the elevated risk of neurodevelopmental

effects in young children. Evidence is less consistent for other factors that may increase Pb-related risk including sex, genetics, pre-existing disease (e.g., hypertension), race/ethnicity, SES, nutrition, stress and co-exposure to other metals (Table 2-9).

1.5 Summary

Overall, the evidence evaluated for the current review expands upon findings of the 2006 Pb AQCD, which concluded that there was a strong body of evidence substantiating the health effects of Pb and strong evidence of effects on some ecological endpoints. Table 2-10 of Chapter 2 summarizes the main conclusions from the 2006 Pb AQCD and compares them to the findings from this assessment, including causality determinations, regarding the health and ecological effects of Pb.

Nervous system effects, specifically cognition and behavior, in children are the effects that are best substantiated as occurring at the lowest blood lead concentrations. Some new epidemiologic and toxicological findings indicate that some effects (e.g., behavioral impairments) are observed in populations of children with lower mean blood lead levels than in previous assessments (e.g. <2 μg/dL). Causal relationships were also determined between Pb exposure and several adult outcomes including renal and cardiovascular effects, for which the evidence strongly suggests that cumulative exposure plays a role. As lead exposures were generally higher in the past than they are today, uncertainties exist, regarding the relative importance of recent versus past exposure in the development of the lead-related health effects in the adult populations studied.

With regard to the ecological effects of Pb at or near concentrations currently present in the environment, there is new evidence to support previous findings of effects on growth and on reproduction and development in aquatic invertebrates as well as effects on survival in both invertebrate and vertebrate aquatic biota. These effects are observed at or near ambient levels of Pb in only a few species with greater toxicity generally associated with early lifestages. Hematological and stress related responses were also associated with elevated Pb levels in polluted areas in some terrestrial and aquatic species. In both aquatic and terrestrial systems, uptake of Pb into flora and fauna and subsequent effects on reproduction, growth and survival at the species level are likely to lead to effects at the population, community and ecosystem level of biological organization.

CHAPTER 2 INTEGRATIVE SUMMARY

2.1 ISA Development and Scope

This chapter summarizes and synthesizes the recently available scientific evidence and is intended to provide a concise synopsis of the ISA conclusions and findings that best inform the review of the NAAQS. The *Integrated Review Plan (IRP) for the National Ambient Air Quality Standards for Lead* (U.S. EPA, 2011c) identifies a series of policy-relevant questions (in Chapter 3) that provide the framework for this assessment, and which frame the entire review of the NAAQS for Pb, and thus are informed by both science and policy considerations. The plans and underlying questions for the ISA are included in the IRP. The ISA organizes, presents, and integrates the scientific evidence, which is considered along with findings from any risk analyses and policy considerations, to help the U.S. Environmental Protection Agency (EPA) address these questions during the NAAQS review for Pb. The ISA includes:

- An integration of the evidence on the human health effects associated with Pb exposure, discussion of important uncertainties identified in the interpretation of the scientific evidence, and an integration across different scientific disciplines and across individual endpoints within major outcome categories.
- An integration of the evidence on the ecological effects of Pb in aquatic and terrestrial ecosystems, discussion of endpoints common to plants, invertebrates and vertebrates and consideration of uncertainties in relating atmospheric Pb concentrations to ecological effects.
- An integration of the effects associated with exposure to Pb across the scientific disciplines for health and ecology, focusing on common modes of action.
- Discussion of policy relevant considerations, such as potentially at-risk populations and concentration-response relationships.

EPA has developed a process for evaluating the scientific evidence; and drawing conclusions and causal judgments regarding air pollution-related health and environmental effects. The ISA development process includes literature search strategies, criteria for selecting and evaluating studies, approaches for evaluating weight of the evidence, and a framework for making causality determinations. The process and causality framework are described in more detail in the Preamble to the ISA. This section provides a brief overview of the process for development of this ISA.

EPA initiated the current review of the NAAQS in April 2010 with a call for information from the public (75 FR 20843). Literature searches were conducted routinely to identify studies published since the last review, focusing on studies published from 2006 (close of previous scientific assessment) through September 2011. References that were considered for inclusion or cited in this ISA can be found at http://hero.epa.gov/lead.

This ISA evaluates relevant epidemiologic, animal toxicological, and ecological and welfare effects studies, including those related to concentration-response relationships, mode(s) of action (MOA), and susceptible populations. Additionally, air quality and emissions data, studies on environmental fate and transport, and issues related to Pb toxicokinetics and exposure were considered for inclusion in the document. Previous AQCDs (U.S. EPA, 2006b, 1986b, 1977) have included an extensive body of evidence on these topics. In this ISA, the conclusions and key findings from previous reviews are summarized at the beginning of each section, to provide the foundation for consideration of evidence from recent studies. Results of key studies from previous reviews are included in discussions or tables and figures, as appropriate, and conclusions are drawn based on the synthesis of evidence from recent studies with the extensive literature summarized in previous reviews.

The Preamble discusses the general framework for conducting the science assessment and developing an ISA, including criteria for selecting studies for inclusion in the ISA, evaluating and integrating the scientific evidence and developing scientific conclusions. In selecting the studies for inclusion in the Pb ISA, particular emphasis is placed on those studies most relevant to the review of the NAAQS.

In drawing judgments regarding causality for the criteria air pollutants, evidence of health effects in the range of relevant pollutant exposures or doses is considered. With regard to the causal determinations drawn for human health effects of Pb, population-based epidemiology studies were emphasized over occupational studies. Recent occupational studies were considered insofar as they added to the evidence base for an outcome for which sufficient numbers of population-based studies were unavailable or, to the extent that they addressed a topic area that was of particular relevance to the NAAQS review (e.g., longitudinal studies designed to examine recent versus historical Pb exposure). Evidence from toxicological studies of effects observed in experimental animals at doses that were relevant to, or somewhat above, those currently experienced by the U.S. general population were emphasized. The extent to which studies of higher concentrations were considered varied by major outcome category, but generally studies with blood Pb levels within one order of magnitude above the upper end of the distribution of U.S. blood Pb levels were considered (i.e., toxicological studies reporting blood Pb levels less than

about 100 µg/dL).[1] The majority of these studies reported blood Pb levels below approximately 30-40 µg/dL, however. Studies with higher blood Pb levels were considered to the extent that they provided useful information to inform modes of action or mechanisms or kinetics. For toxicological studies where blood Pb levels were not measured, judgments regarding how to distinguish high from the more relevant low doses were made considering the range of doses across the available body of evidence and emphasizing studies at the lower end of the range.

Relevant concentrations for drawing causality judgments for ecological effects of Pb were determined considering the range of Pb concentrations in the environment and the available evidence for concentrations at which effects were observed in biota. Effects observed at or near ambient levels of Pb were emphasized and studies generally within one to two orders of magnitude above current conditions were considered in the body of evidence for terrestrial and aquatic ecosystems. Studies at higher concentrations were used to the extent that they informed modes of action and illustrated the wide range of sensitivity to Pb across taxa. For aquatic biota, generally, the number of studies available on freshwater organisms is greater than on saltwater organisms, covering more taxa as well as more endpoints. The causal determinations for aquatic biota are, therefore, based primarily on evidence from freshwater species. When available, data from saltwater ecosystems are discussed separately under the appropriate causal endpoint. For most of the endpoints under consideration, evidence is inadequate to establish causality in saltwater species. When sufficient evidence is available for marine organisms, data on concentrations at which effects are observed are presented in Section 7.4.2.

The causal statements for terrestrial and aquatic effects are arranged according to ecologically meaningful levels of biological organization (organism, population, community, ecosystem). As recognized in EPA's Framework for Ecological Risk Assessment (U.S. EPA, 1992), and in the adverse outcome pathway (AOP) framework (Ankley et al., 2010) endpoints that are measured at one level of ecological organization may be related to an endpoint at a higher level. The AOP conceptual framework was proposed to link mechanistic data from initiating events at the molecular level through a series of higher order biological responses to survival and to developmental and reproductive endpoints that can be used in ecological risk assessment, i.e., at the population level and higher. Fecundity, growth, and survival are organism-level attributes that lead to population-level (e.g., abundance, production, extirpation), community-level (taxa richness, relative abundance) and ecosystem-level responses (Ankley et al., 2010;

1 Studies considered were generally within an order of magnitude above 10 µg/dL (i.e., 100 µg/dL), which was used to indicate the upper end of the blood Pb distribution in the U.S. population. Currently approximately 1.4% of U.S. children overall have blood Pb levels that exceed 10 µg/dL (Jones et al., 2009a); however, the proportion of individuals with blood Pb levels that exceed this concentration varies depending on factors including age and/or residence near a source of Pb exposure (Section 4.1).

Suter et al., 2005). In the case of Pb, physiological stress, hematological effects and neurobehavioral alterations may decrease the overall fitness of an organism, even though their connection to effects at higher levels of biological organization may not have been characterized. Furthermore, the effects of Pb on ecosystems necessarily begin with some initial effects at the molecular level of specific organisms within the ecosystem (U.S. EPA, 1986b). There are many different molecular and cellular level effects, and toxicity of Pb in ecosystems may be attained through multiple modes of action.

The ISA considers evidence of health effects for both short- and long-term pollutant exposures. Biomarkers are typically used in epidemiologic studies of the health effects associated with Pb as an index of exposure or dose. Consequently, the timing, frequency, level, and duration of Pb exposure(s) associated with the observed health effects are uncertain. Evidence from animal toxicological studies is also drawn upon to understand and interpret Pb exposures in epidemiologic studies. Animal toxicological studies that are relied upon to inform our understanding of the exposures needed to induce health effects in humans include chronic exposure studies (i.e., over 10% of the lifespan of the animal), long-term exposure studies (e.g., greater than 4 weeks in rodents) as well as acute or short-term exposure studies (e.g., less than 4 weeks in rodents). In this ISA, short-term human exposures are generally defined to include exposures of months (e.g., < one year) while long-term human exposures include those greater than one year in duration. In addition, information including the age of the population studied, study period and study location can be used to aid in the interpretation of findings from epidemiologic studies because Pb exposures have declined over time and exposures vary depending on proximity to Pb sources.

This ISA uses a five-level hierarchy that classifies the weight of evidence for causation:

- Causal relationship
- Likely to be a causal relationship
- Suggestive of a causal relationship
- Inadequate to infer a causal relationship
- Not likely to be a causal relationship

Beyond judgments regarding causality are questions relevant to quantifying health or environmental risks based on the understanding of the quantitative relationships between pollutant exposures and health or ecological effects. Once a determination is made regarding the causal relationship between the pollutant and outcome category, important questions regarding quantitative relationships include:

- What is the concentration-response, exposure-response, or dose-response relationship in the human population?
- What exposure conditions (dose or exposure, exposure pathways, duration and pattern) are important?
- What populations and lifestages appear to be differentially affected i.e., at greater risk of Pb-related health effects?
- What elements of the ecosystem (e.g., types, regions, taxonomic groups, populations, functions, etc.) appear to be affected or are more sensitive to effects?

This chapter summarizes and integrates the newly available scientific evidence that best informs consideration of the policy-relevant questions that frame this assessment. The organization of this chapter generally follows the organization of the document as a whole, with several additional sections including: (Section 2.1) a discussion of the assessment development and scope; (Section 2.8) an integration of the evidence across the disciplines of health and ecology; (Section 2.9) a discussion of policy-relevant considerations; and, (Section 2.10) an overall summary. This ISA itself is composed of six chapters including this integrative summary. Chapter 3 highlights key concepts or issues relevant to understanding the sources, ambient concentrations, and fate and transport of Pb in the environment. 0 summarizes key concepts and recent findings on Pb exposures, toxicokinetics, and biomarkers reflecting Pb exposure and body burden. Chapter 5 presents a discussion of the MOA of Pb and evaluates and integrates epidemiologic and animal toxicological information on health effects related to Pb exposures, including nervous system, cardiovascular, renal, immunological, reproductive and developmental, and cancer outcomes. Chapter 6 summarizes the evidence on potentially susceptible populations. Chapter 7 evaluates ecological effects evidence that is relevant to the review of the secondary NAAQS for Pb.

2.2 Ambient Lead: Source to Concentration

2.2.1 Sources, Fate and Transport of Ambient Lead

The findings of this review with respect to sources of atmospheric Pb build upon those from the 2006 Pb AQCD (U.S. EPA, 2006b), which documented the decline in ambient air Pb emissions following the ban on alkyl-Pb additives for on-road gasoline. Pb emissions declined by 98% from 1970 to 1995 and then by an additional 76% from 1995

to 2008, at which time emissions were estimated at 970 tons per year. As was the case at the time of the last Pb NAAQS review, data from the 2008 National Emissions Inventory (NEI) (U.S. EPA, 2011a) illustrate that piston-engine aircraft emissions comprise the largest share (56%) of total atmospheric Pb emissions; the 2008 NEI estimated that 550 tons of Pb were emitted from this source. Other sources of ambient air Pb, beginning with the largest, include metals processing, fossil fuel combustion, other industrial sources, roadway related sources, and historic Pb. Global atmospheric Pb deposition peaked in the 1970s, followed by a decline. See Section 3.2 for additional information.

The atmosphere is the main environmental transport pathway for Pb. On a local scale atmospheric Pb is primarily associated with coarse particulate matter (PM), and on a global scale atmospheric Pb is primarily associated with fine PM. Both wet and dry deposition are important removal mechanisms for atmospheric Pb. Because Pb in fine particles is typically fairly soluble, wet deposition is more important for fine Pb. In contrast, Pb associated with coarse particles is usually insoluble and removed by dry deposition. Pb associated with coarse PM deposits to a great extent near local industrial sources, contributing to soil Pb concentrations in those locations, while fine Pb-bearing PM can be transported long distances, contributing Pb to remote areas. Depending on local conditions, once deposited particles may be resuspended and redeposited before reaching a site where further transport is unlikely, especially for dry deposition. See Section 3.3 for additional information.

Environmental distribution of Pb occurs mainly through the atmosphere, from which it is deposited into surface waters and soil. Surface waters act as an important reservoir, with Pb lifetimes in the water column largely controlled by deposition and resuspension of Pb in sediments. Substantial amounts of Pb from vehicle wear and building materials can also be transported by runoff waters to surface waters and sediments without becoming airborne. Pb containing sediment particles can be remobilized into the water column, and sediment concentrations tend to follow those in overlying waters. See Section 3.3 for additional information.

2.2.2 Monitoring and Concentrations of Ambient Air Lead

The indicator for the Pb NAAQS is Pb in total suspended particles (Pb-TSP). The Pb-TSP indicator was retained in 2008 in recognition of the role of all PM sizes in ambient air Pb exposures. The Federal Reference Method (FRM) for Pb-TSP specifies that ambient air is drawn through a high-volume TSP sampler onto a glass fiber filter. The Pb-TSP sampler's size selective performance is known to be affected by wind speed and direction, and collection efficiency has been demonstrated to decline with particle

size with an uncertain upper size limit (Wedding et al., 1977). In recognition of the steep spatial gradients associated with sources of ultra-coarse particles, ambient Pb sampled using the FRM for Pb-PM_{10} is allowed in certain instances where the expected Pb concentration does not approach the NAAQS and no sources of ultra-coarse Pb are nearby. A new FRM for Pb-PM_{10} has been implemented in which ambient air is drawn through an inertial particle size separator for collection on a polytetrafluoroethylene (PTFE) filter. The Pb-PM_{10} FRM is free of wind direction bias. Several FEMs have also been approved. The Pb-TSP FRM is based on flame atomic absorption spectroscopy (AAS), while the Pb-PM_{10} FRM is based on x-ray fluorescense spectroscopy (XRF). Inductively-coupled plasma mass spectrometry (ICPMS) is under consideration as a new FRM for Pb-TSP. See Section 3.4.1 for additional information.

Pb monitoring requirements have experienced several changes since publication of the 2006 Pb AQCD (U.S. EPA, 2006b). The current Pb monitoring network design requirements include two types of FRM monitoring sites: source-oriented and non-source-oriented. Source-oriented FRM Pb-TSP monitoring sites are required near sources of air Pb emissions which are expected to or have been shown to contribute to ambient air Pb concentrations in excess of the NAAQS. At a minimum, monitoring is required near sources that emit 0.50 tons/year or more of Pb unless it can be determined that the source will not contribute to an ambient concentration exceeding 50% of the Pb NAAQS. With the December 2010 completion of action on regulatory requirement of Pb monitoring, one-year of Pb-TSP FRM monitoring is also required near 15 specific airports to gather additional information on the likelihood of NAAQS exceedances near airports due to combustion of leaded aviation gasoline. Non-source-oriented monitoring is also required at national core multipollutant monitoring network (NCore) sites in Core Based Statistical Areas (CBSA) with a population of at least 500,000. In addition to FRM monitoring, Pb is also routinely measured in smaller particle fractions in the chemical speciation network (CSN), interagency monitoring of protected visual environment (IMPROVE), and the national air toxics trends station (NATTS) networks. While monitoring in multiple networks provides extensive geographic coverage, measurements between networks are not directly comparable in all cases because there are differences in the methods, including the different particle size ranges sampled in the different networks. Depending on monitoring network, Pb is monitored in TSP, PM_{10}, or $PM_{2.5}$. For the purpose of analyzing data for the ISA, monitors reporting to the AQS were considered to be source-oriented if they were designated in AQS as source-oriented, or they were located within 1 mile of a 0.5 ton per year or greater source, as noted in the 2005 NEI (U.S. EPA, 2008a) or the 2008 NEI (U.S. EPA, 2011a). See Section 3.4 for additional information.

Ambient air Pb concentrations have declined drastically over the period 1980-2010. The median annual concentrations have dropped by 97% from 0.87 $\mu g/m^3$ in 1980 to 0.03 $\mu g/m^3$ in 2010. While the sharpest drop in Pb concentration occurred during 1980-1990, a declining trend was observed between 1990 and 2010. There was an 84% reduction in the median annual source-oriented Pb concentration and a 85% reduction in the median annual non-source-oriented Pb concentration for 1990-2010. Recent estimates for the natural contribution to background Pb are ~0.3 to 1 ng/m^3. These estimates exceed estimates of natural background presented in the 1986 Pb AQCD by a factor of 2 to 20. The more recent estimate still indicates that background airborne Pb concentrations are well below current ambient concentrations. See Section 3.5 for additional information.

AQS data for source-oriented and non-source-oriented FRM monitoring were analyzed for 2008-2010. For source-oriented monitors, the three-month rolling average was above the level of the NAAQS in twenty counties across the U.S. The three-month rolling average was never above the level of the NAAQS for any of the non-source-oriented FRM monitors. Pb concentrations, seasonal variations, inter-monitor correlations, and wind data were analyzed for six counties: Los Angeles County, CA; Hillsborough/Pinellas Counties, FL; Cook County, IL; Jefferson County, MO; Cuyahoga County, OH; and Sullivan County, TN. Spatial and temporal variability of Pb concentrations in each county were commonly high. Meteorology, distance from sources, and positioning of sources with respect to the monitors all appeared to influence the level of concentration variability across time and space. See Section 3.5 for additional information.

Size distribution of Pb-bearing PM varied substantially depending on the nature of Pb sources and proximity of the monitors to the Pb sources. Variation in the correlation of size fractionated Pb samples among different land use types may be related to differences in sources across land use types; for example, ultra-coarse Pb-PM has been observed near industrial sites. Additionally, Pb concentrations exhibited varying degrees of association with other criteria pollutant concentrations. Overall, Pb was moderately associated with $PM_{2.5}$, PM_{10} and NO_2. Pb was moderately associated with CO in fall and winter only. The poorest associations were observed between Pb and O_3. Among trace metals, the strongest association was with Zn. Moderate associations with Pb concentrations were observed for Br, Cu, and K. Such correlations may suggest some common sources affecting the concentrations of various pollutants. See Section 3.5 for additional information.

2.2.3 Ambient Lead Concentrations in Non-Air Media and Biota

Atmospheric deposition has led to measurable Pb concentrations observed in rain, snowpack, soil, surface waters, sediments, agricultural plants, livestock, and wildlife across the world, with highest concentrations near Pb sources, such as metal smelters. After the phase-out of Pb from on-road gasoline, Pb concentrations have decreased considerably in rain, snowpack, and surface waters. Declining Pb concentrations in tree foliage, trunk sections, and grasses, as well as surface sediments and soils in some locations, have also been observed (U.S. EPA, 2006b). In contrast, Pb is retained in soils and sediments, where it provides a historical record of deposition and associated concentrations. In remote lakes, sediment profiles indicate higher Pb concentrations in near surface sediment as compared to pre-industrial era sediment from greater depth and indicate peak concentrations between 1960 and 1980 (when leaded on-road gasoline was at peak use). Concentrations of Pb in moss, lichens, peat, and aquatic bivalves have been used to understand spatial and temporal distribution patterns of air Pb concentrations. Ingestion and water intake are the major routes of Pb exposure for aquatic organisms, and food, drinking water, and inhalation are major routes of exposure for livestock and terrestrial wildlife. Overall, Pb concentrations have decreased substantially in media through which Pb is rapidly transported, such as air and water. Substantial Pb remains in soil and sediment sinks. Although in areas less affected by major local sources, the highest concentrations are below the surface layers and reflect the phase-out of Pb from on-road gasoline and emissions reductions from other sources.

Information on ambient Pb concentrations in non-air media and biota is reported in Section 3.6, and concentrations considered in the interpretation of the ecological evidence are tabulated in Table 2-1. As noted in the preamble, the ecological causal determinations focus on studies where effects of Pb exposure are observed at or near ambient levels of Pb and studies generally within the range of one to two orders of magnitude above current or ambient conditions were also considered in the body of evidence.

Table 2-1 Ambient Pb Concentrations in Non-Air Media and Biota Considered for Ecological Assessment

Media	Pb Concentration	Years Data Obtained	References
Soil	National Average: 18.9 mg Pb/kg Range of state averages: 5-38.6 mg Pb/Kg	1961-1976	U.S. EPA (2007d, 2006b, 2003b)
Sediment[1]	Median: 28 mg Pb/kg (dry weight)	1996-2001	Mahler et al. (2006), U.S. EPA (2006b)
Fresh Surface Water (Dissolved Pb)[a]	Median: 0.5 µg Pb/L; Max: 30 µg Pb/L Range: 0.0003-0.075 µg Pb/L	2001-2003 2002-2007	U.S. EPA (2006b) Field and Sherrell (2003), Landers et al. (2008)
Saltwater[b]	Range: 0.01 – 27 µg Pb/L Range: 0.005-0.04 µg Pb/L	Dates not available	Sadiq (1992) Leland and Kuwabara (1985)
Vegetation	Lichens: 0.3-5 mg Pb/kg Grasses: 31% (percent of soil Pb in grass)	2002-2007 1980s-2000s	Landers et al. (2008) Vandenhove et al. (2009)
Vertebrate	Fish: Geometric Mean: 0.54 mg Pb/kg (dry weight) Maximum: 23 mg Pb/kg (dry weight)	2001-2003	U.S. EPA (2006b)
	Fish: 0.0033-0.97 mg Pb/kg Moose: 0.021-0.23 mg Pb/kg	2002-2007	Landers et al. (2008)

[a]Based on synthesis of NAWQA data reported in 2006 Pb AQCD (U.S. EPA, 2006b)
[b]Data from a combination of brackish and marine saltwater samples. In general, Pb in seawater is higher in coastal areas and estuaries since these locations are closer to sources of Pb contamination and loading from terrestrial systems.

2.3 Exposure to Ambient Lead

Exposure data considered in this assessment build upon the conclusions of the 2006 Pb AQCD (2006b), which found air Pb concentrations in the U.S. and associated biomarkers of exposure to have decreased substantially following the ban on Pb in on-road gasoline as well as an earlier ban on Pb in house-hold paints. Pb exposure is difficult to assess because Pb has multiple sources in the environment and passes through various media. The atmosphere is the main environmental transport pathway for Pb, and, on a global scale, atmospheric Pb is primarily associated with fine particulate matter, which can deposit to soil and water. In addition to primary emission of particle-bearing or gaseous Pb to the atmosphere, Pb can be suspended to the air from soil or dust. Air-related pathways of Pb exposure are the focus of this assessment. In addition to inhalation of Pb from ambient air, air-related Pb exposure pathways include inhalation and ingestion of Pb from indoor dust and/or outdoor soil that originated from recent or historic ambient air (e.g., air Pb that has penetrated into the residence either via the air or tracking of soil). Non-air-related exposures include occupational exposures, hand-to-mouth contact with t with dust or chips of peeling Pb-containing paint, or ingestion of Pb in drinking water conveyed through Pb pipes. Several study results indicate that exposure to Pb-containing

paint and home age (often a surrogate for the presence of Pb paint) are important residential factors that increase risk of elevated blood Pb (Sections 2.9.6.7 and 6.2.6). Most Pb biomarker studies do not indicate species or isotopic signature, and so non-air exposures are reviewed in this section because they can also contribute to Pb body burden. See Section 4.1 for additional information on exposure to ambient Pb.

A number of monitoring and modeling techniques have been employed for ambient Pb exposure assessment. Environmental Pb concentration data can be collected from ambient air Pb monitors, soil Pb samples, dust Pb samples, and dietary Pb samples to estimate human exposure. Exposure estimation error depends in part on the collection efficiency of these methods; collection efficiency for ambient air Pb FRM samplers is described in Section 3.4. Additionally, high spatial variability of the Pb concentrations in various media also can contribute to exposure error, as described in the 2009 PM ISA (U.S. EPA, 2009). Models, such as the Integrated Exposure Uptake Biokinetic (IEUBK) model, simulate human exposure to Pb from multiple sources and through various routes including inhalation, ingestion, and dermal exposure. IEUBK model inputs include soil Pb concentration, air Pb concentration, dietary Pb intake including drinking water, Pb dust ingestion, human activity, and biokinetic factors. Measurements and/or assumptions can be utilized when formulating the model inputs; error in measurements and assumptions thus have the potential to propagate through the exposure models.

Section 4.1 presents data illustrating potential exposure pathways. Soil can act as a reservoir for deposited Pb emissions and exposure to soil contaminated with deposited Pb can occur through resuspended PM as well as shoe tracking and hand-to-mouth contact, which is the main pathway of childhood exposure to Pb. Recent data by Yamamoto et al. (2006) have shown that the size distribution of particles collected on children's hands have a mode around 40 μm with the upper tail of the distribution extending to 200-300 μm. Infiltration of Pb dust into indoor environments has been suggested, and Pb dust has been shown to persist in indoor environments even after repeated cleanings. Measurements of particle-bound Pb exposures reported in this assessment have shown that personal exposure measurements of Pb concentration are typically higher than indoor or outdoor ambient Pb concentrations. These findings regarding personal exposure to Pb dust may be related to the personal cloud effect.

2.4 Toxicokinetics

The majority of Pb in the body is found in bone (roughly 90% in adults, 70% in children); only about 1% of Pb is found in the blood. Pb in blood is primarily (~99%) bound to red blood cells (RBCs). It has been suggested that the small fraction of Pb in plasma (<1%)

may be the more biologically labile and toxicologically active fraction of the circulating Pb. The relationship between Pb in blood and plasma is pseudo-linear at relatively low daily Pb intakes (i.e., <10 µg/day–kg) and at blood Pb concentrations <25 µg/dL, and becomes curvilinear at higher blood Pb concentrations due to saturable binding to RBC proteins. As blood Pb level increases and the higher affinity binding sites for Pb in RBCs become saturated, a larger fraction of the blood Pb is available in plasma to distribute to brain and other Pb-responsive tissues. See Section 4.2 for additional details.

The burden of Pb in the body may be viewed as divided between a dominant slow (i.e., uptake and elimination) compartment (bone) and smaller fast compartment(s) (soft tissues). Pb uptake and elimination in soft tissues is much faster than in bone. Pb accumulates in bone regions undergoing the most active calcification at the time of exposure. During infancy and childhood, bone calcification is most active in trabecular bone (e.g., patella); whereas, in adulthood, calcification occurs at sites of remodeling in cortical (e.g., tibia) and trabecular bone (Aufderheide and Wittmers, 1992). A high bone formation rate in early childhood results in the rapid uptake of circulating Pb into mineralizing bone; however, in early childhood bone Pb is also recycled to other tissue compartments or excreted in accordance with a high bone resorption rate (O'Flaherty, 1995). Thus, much of the Pb acquired early in life is not permanently fixed in the bone.

The exchange of Pb from plasma to the bone surface is a relatively rapid process. Pb in bone becomes distributed in trabecular and the more dense cortical bone. The proportion of cortical to trabecular bone in the human body varies by age, but on average is about 80% cortical to 20% trabecular. Of the bone types, trabecular bone is more reflective of recent exposures than is cortical bone due to the slow turnover rate and lower blood perfusion of cortical bone. Some Pb diffuses to deeper bone regions where it is relatively inert, particularly in adults. These bone compartments are much more labile in infants and children than in adults as reflected by half-times for movement of Pb from bone into the plasma (e.g., cortical half-time = 0.23 years at birth, 3.7 years at 15 years of age, and 23 years in adults; trabecular half-time = 0.23 years at birth, 2.0 years at 15 years of age, and 3.8 years in adults) (Leggett, 1993). See Section 4.2 for additional details.

Evidence for maternal-to-fetal transfer of Pb in humans is derived from cord blood to maternal blood Pb ratios. Group mean ratios range from about 0.7 to 1.0 at the time of delivery for mean maternal blood Pb levels ranging from 1.7 to 8.6 µg/dL. Transplacental transfer of Pb may be facilitated by an increase in the plasma/blood Pb concentration ratio during pregnancy. Maternal-to-fetal transfer of Pb appears to be related partly to the mobilization of Pb from the maternal skeleton. See Section 4.2 for additional details.

The dominant elimination phase of Pb kinetics in the blood, exhibited shortly after a change in exposure occurs, has a half-life of ~20-30 days. An abrupt change in Pb uptake

gives rise to a relatively rapid change in blood Pb, to a new quasi-steady state, achieved in ~75-100 days (i.e., 3-4 times the blood elimination half-life). A slower phase of Pb clearance from the blood may become evident with longer observation periods following a decrease in exposure due to the gradual redistribution of Pb among bone and other compartments. See Section 4.3 for additional details.

2.5 Lead Biomarkers

Overall, trends in blood Pb levels have been decreasing among U.S. children and adults over the past 20 years (Section 4.4). The median blood Pb level for the entire U.S. population is 1.2 μg/dL and the 95th percentile blood Pb level was 3.7 μg/dL, based on the 2007-2008 NHANES data (NCHS, 2010). Among children aged 1-5 years, the median and 95th percentiles were slightly higher at 1.4 μg/dL and 4.1 μg/dL, respectively.

Blood Pb is dependent on both the recent exposure history of the individual, as well as the long-term exposure history that determines body burden and Pb in bone. The contribution of bone Pb to blood Pb changes depending on the duration and intensity of the exposure, age, and various other physiological stressors that may affect bone remodeling (e.g., nutritional status, pregnancy, menopause, extended bed rest, hyperparathyroidism) beyond that which normally and continuously occurs. In children, largely due to faster exchange of Pb to and from bone, blood Pb is both an index of recent exposure and potentially an index of body burden. In adults and children, where exposure to Pb has effectively ceased or greatly decreased, a slow decline in blood Pb concentrations over the period of years is most likely due to the gradual release of Pb from bone. Bone Pb is an index of cumulative exposure and body burden. Even bone compartments should be recognized as reflective of differing exposure periods with Pb in trabecular bone exchanging more rapidly than Pb in cortical bone with the blood. This difference in the compartments making Pb in cortical bone a better marker of cumulative exposure and Pb in trabecular bone more likely to be correlated with blood Pb, even in adults. See Section 4.3 for additional details.

Sampling frequency is an important consideration when evaluating blood Pb and bone Pb levels in epidemiologic studies, particularly when the exposure is not well characterized. It is difficult to determine what blood Pb is reflecting in cross-sectional studies that sample blood Pb once, whether recent exposure or movement of Pb from bone into blood from historical exposures. In contrast, cross-sectional studies of bone Pb and longitudinal samples of blood Pb concentrations over time provide more of an index of cumulative exposure and are more reflective of average Pb body burdens over time. The degree to

which repeated sampling will reflect the actual long-term time-weighted average blood Pb concentration depends on the sampling frequency in relation to variability in exposure. High variability in Pb exposures can produce episodic (or periodic) oscillations in blood Pb concentration that may not be captured with low sampling frequencies. Furthermore, similar blood Pb concentrations in two individuals (or populations), regardless of their age, do not necessarily translate to similar body burdens or similar exposure histories.

The concentration of Pb in urine follows blood Pb concentration, in that it mainly reflects the exposure history of the previous few months and therefore, is likely a relatively poor index of Pb body burden. There is added complexity with Pb in urine because concentration is also dependent upon urine flow rate, which requires timed urine samples that is often not feasible in epidemiologic studies. Other biomarkers have been utilized to a lesser extent (e.g., Pb in teeth). See Section 4.3.

2.6 Health Effects

This section evaluates the evidence from toxicological and epidemiologic studies that examined the health effects associated with exposure to Pb and integrates that evidence across these disciplines. The results from the health studies are also considered in combination with the evidence from other disciplines (e.g., toxicokinetics) for the causal determinations (Section 2.1) made for the health outcomes discussed in this assessment. In the following sections a discussion of the causal determinations will be presented for the health effects for which sufficient evidence was available to conclude a causal or likely to be causal relationship (Table 2-2). A more detailed discussion of the underlying evidence used to formulate each causal determination can be found in Chapter 5 of this document.

Table 2-2 Summary of causal determinations[a] between exposure to Pb and health outcomes

Outcome	Causality Determination[a]
Nervous System Effects (Section 5.3.13)	Causal Relationship
Cardiovascular Effects (Section 5.4.7)	Causal Relationship
Renal Effects (Section 5.5.6)	Causal Relationship
Immune System Effects (Section 5.6.8)	Causal Relationship
Effects on Heme Synthesis and Red Blood Cell Function (Section 5.7.7)	Causal Relationship
Reproductive and Developmental Effects (Section 5.8.10)	Causal Relationship
Cancer (Section 5.10.6)	Likely Causal Relationship

[a]Based upon the framework described in the Preamble, a determination of causality was made for a broad outcome category (i.e., nervous system effects) by evaluating the coherence of evidence across disciplines and across a spectrum of related endpoints. However, the evidence on which the causal judgment is based, including the strength of evidence for the individual endpoints within the major outcome category, is characterized within the discussion. Causal determinations were made within approximately 1-2 orders of magnitude of current levels.

2.6.1 Nervous System Effects

Recent epidemiologic and toxicological studies substantiated the strong body of evidence presented in the 2006 Pb AQCD that Pb exposure is associated with nervous system effects. The weight of epidemiologic and toxicological evidence clearly supports associations of higher blood Pb levels with decrements in cognitive function in children, i.e., full-scale IQ and various measures of learning and memory. In epidemiologic studies, these associations were substantiated in children ages 1 to 11 years and in populations with mean blood Pb levels between 2 and 7 µg/dL. Observation of a supralinear concentration-response relationship and associations with mean (or quantile) blood Pb levels < 2 µg/dL do not provide evidence for a threshold for effects of Pb exposure on the developing nervous systems of children. Epidemiologic and toxicological evidence clearly demonstrates Pb-associated increases in behavioral problems, in particular, inattention and impulsivity (prior symptoms of ADHD). Associations are substantiated in children ages 1 to 12 years with mean concurrent blood Pb levels of 2 to 5 µg/dL. In epidemiologic studies, associations with cognitive function and behavior were observed after adjustment for a range of potential confounding variables, but most commonly, parental IQ, parental education, and other SES-related variables.

In animals, the weight of evidence demonstrates effects on cognition and behavior with prenatal and early postnatal Pb exposures that resulted in blood Pb levels of 10 to 40 µg/dL. In children, the weight of evidence supports cognitive function decrements and behavioral problems in association with concurrent blood Pb levels. Associations also are observed with prenatal, early childhood, and childhood average blood Pb levels, thus uncertainty remains regarding the lifestage of exposure within childhood that is associated with the greatest risk. The uncertainty regarding the frequency, timing duration and level of exposure contributing to the observed associations is greater in studies of older children compared to younger children. The weight of toxicological evidence demonstrates neurodevelopmental effects on cognition and behavior with prenatal and early postnatal Pb exposures that can have effects persisting to adulthood. The biological plausibility for epidemiologic and toxicological findings for effects on cognitive function and behavior is provided by evidence characterizing underlying mechanisms, including Pb-induced changes in neurogenesis, synaptogenesis and synaptic pruning, long term potentiation, and neurotransmitter function. Based most heavily on cognitive function decrements and inattention in children, the collective body of evidence integrated across epidemiologic and toxicological studies is sufficient to conclude that there is a causal relationship between Pb exposures and nervous system effects (Section 5.3.13).

New evidence demonstrates associations of blood Pb level with Attention Deficit Hyperactivity Disorder (ADHD) in children (8-17 years old) and this evidence is consistent with findings demonstrating the effect of Pb on inattention and impulsivity in children. Several new epidemiologic studies indicate associations between higher concurrent blood Pb level and higher prevalence or incidence of ADHD diagnosis and its contributing diagnostic indices, whereas previous evidence was inconsistent. The biological plausibility for associations with ADHD is strongly supported by the large epidemiologic and toxicological evidence base demonstrating Pb-associated increases in inattention and impulsivity, both of which are primary symptoms of ADHD.

The evidence for Pb-associated effects on other nervous system endpoints was also evaluated. Compared to the body of evidence on behavior and inattention, a smaller but equally consistent evidence base indicated associations of concurrent and early childhood blood Pb levels with social misconduct in children and delinquent behaviors in adolescents and young adults (Table 5-11). Associations of blood Pb levels with ADHD, misconduct, and delinquency were observed in populations of children with a wide range of blood Pb levels, 1 to 11 µg/dL, all similar in the strength of evidence. While the different behavioral indices are examined, Pb exposure also was found to affect behavior (decreased ability to escape predators or capture prey) in aquatic and terrestrial species (Section 7.2 and Section 7.3).

A few new toxicological studies augmented the evidence for Pb-related effects to the visual system by demonstrating retinal changes in male rodent offspring in association with lower blood Pb levels (<15 µg/dL) than previously examined (20 to > 100 µg/dL) (Section 5.3.4.3). A small body of epidemiologic evidence together with a large historical base of toxicological evidence indicated associations of Pb biomarkers or exposure with impaired auditory function. Associations were found in children ranging from 4 to 19 years in age and with mean concurrent blood Pb levels of 7-12 µg/dL (Section 5.3.4.1). While mood and emotional state have been examined less frequently compared with inattention and misconduct, several studies found associations of biomarkers of cumulative Pb exposure (i.e., tooth or childhood average blood Pb) and concurrent blood Pb levels with parental or teacher reports of withdrawn behavior or depression in children with mean blood Pb levels 8-28 µg/dL (Section 5.3.3.3). These findings in children are supported by a small body of toxicological studies in which prenatal plus lactational Pb exposure resulted in depression-like behavior in rodent models. Studies also reported associations of early childhood average and concurrent blood Pb levels with lower fine and gross motor function in children ages 3 to 17 years (Section 5.3.5). A common observation across studies was finding that biomarkers of Pb exposure were associated with decrements in multiple neurodevelopmental outcomes, including cognitive function, externalizing behaviors, internalizing behaviors, and motor function, within the same population. These findings in combination with previously discussed cognitive and behavioral effects indicate that Pb exposure affects a broad spectrum of neurodevelopmental effects in children.

In adults, the frequency, duration, timing and level of Pb exposure implicated in nervous system effects remain uncertain. Among occupationally-exposed adults, a spectrum of nervous system effects is associated with concurrent blood Pb level (≥ 14 µg/dL), which reflects both current and cumulative exposure. However, in adults without occupational exposure, cognitive performance is more strongly associated with tibia Pb levels than blood Pb levels, which indicates an effect of long-term, cumulative Pb exposures. Based on a smaller body of epidemiologic studies, blood and bone Pb levels were associated with essential tremor and PD, respectively, in adults (Section 5.3.7.1). However, in these case-control studies, it is difficult to establish temporality between Pb exposure and disease. Support for epidemiologic findings for PD is provided by toxicological evidence for Pb-induced decreased dopaminergic cell activity in the substantia nigra, which contributes to the primary symptoms of Parkinson’s disease. Whereas evidence for association with Alzheimer's disease in adults is weak, developmental Pb exposures of monkeys (early postnatal, PND 1-400) and rats (lactational) has been shown to induce formation of amyloid plaques, pathology that underlies Alzheimer's disease (Section 5.3.7.2). A small body of studies of behavior in adults examined and found

associations of blood and tibia Pb levels with depression and anxiety symptoms (Section 5.3.3.6).

2.6.2 Cardiovascular Effects

The 2006 Pb AQCD concluded that there was a relationship between higher blood Pb and bone Pb and cardiovascular effects in adults, in particular increased blood pressure (BP) and increased incidence of hypertension (U.S. EPA, 2006b). Building on this strong body of evidence, recent epidemiologic and toxicological studies substantiated the evidence that long-term Pb exposure is associated with cardiovascular effects in adults with the largest body of evidence demonstrating associations of Pb with increased BP and hypertension. The epidemiologic evidence is strengthened by several recent prospective studies that find associations between biomarkers of Pb and BP and hypertension and by effect estimates that are observed after adjustment for multiple potential confounding factors. The weight of epidemiologic evidence supported associations in adults with mean concurrent blood Pb levels less than 5 µg/dL. As these outcomes in epidemiologic studies were most often observed in adults with likely higher past than current Pb exposures, uncertainty exists as to the Pb exposure level, timing, frequency, and duration contributing to the observed associations. Recent epidemiologic studies found that bone Pb level, a metric of cumulative exposure, is strongly related to hypertension risk in adults with mean bone Pb levels greater than 20 µg/g. However, uncertainties also exist as to the specific Pb exposure conditions that contributed to the associations. The weight of animal evidence also demonstrates an increase in BP after long-term (i.e., greater than 4 weeks in rodents) exposure to Pb. Whereas the majority of studies examined and found increases in BP in animals with mean blood Pb levels greater than 10 µg/dL (Table 5-18), a recent study found elevated BP in animals with a mean blood Pb level of 2 µg/dL (Tsao et al. 2000). Also, animal toxicological studies provided mechanistic evidence to support the biological plausibility of Pb-induced hypertension, including Pb-induced oxidative stress, activation of RAAS (renin-angiotensin-aldosterone system), altered sympathetic activity, and vasomodulator imbalance. Collectively, the evidence integrated across epidemiologic and toxicological studies as well as across the spectrum of other cardiovascular endpoints examined is sufficient to conclude that there is a causal relationship between Pb exposures and cardiovascular health effects (Section 5.4.7).

Studies in the 2006 Pb AQCD (U.S. EPA, 2006b) also found associations between Pb biomarkers of exposure and other cardiovascular diseases such as IHD, cerebrovascular disease, peripheral vascular disease, and cardiovascular disease related mortality; however, the available evidence was limited. Recent epidemiologic and toxicological studies continue to provide evidence in adults for blood Pb-associated increased

atherosclerosis, thrombosis, IHD, PAD, arrhythmia, and cardiac contractility in populations with mean blood Pb levels >2.5 µg/dL (Table 5-19). Further, animal toxicological evidence continued to build on the evidence supporting the mechanisms leading to these cardiovascular system responses, as well as Pb-induced changes in BP and hypertension. Enhanced understanding of Pb-induced oxidative stress including ˙NO inactivation, endothelial dysfunction leading to altered vascular reactivity, activation of the RAAS, and vasomodulator imbalance provides biological plausibility for the consistent associations observed between higher blood and bone Pb levels and greater cardiovascular effects.

Recent epidemiologic studies of adults also investigated the interaction of Pb biomarkers with genetic variants in associations with cardiovascular effects. Evidence was presented for a larger blood Pb-associated increase in BP in carriers of the ALAD2 allele, which is associated with greater binding affinity for Pb in the bloodstream (Figure 5-26). Additionally, bone Pb concentration was associated with larger increases in PP, which is a good predictor of cardiovascular morbidity and mortality and an indicator of arterial stiffness, among adults with the HFE H63D and/or C282Y variant and there was evidence of HFE and transferrin gene variants, related to iron metabolism, impacting the associations of bone Pb levels with cardiovascular effects, evaluated by QT interval changes (Figure 5-26). The evidence for genetic factors to potentially increase the risk of Pb related health effects was limited (Table 6-4). New evidence extended the potential continuum of Pb-related cardiovascular effects by demonstrating associations of blood Pb and bone Pb with both cardiovascular and all-cause mortality with follow-up periods ranging between 8 and 12 years. The associations of Pb with cardiovascular morbidity observed in both epidemiologic and toxicological studies support recent epidemiologic findings of increased Pb-associated cardiovascular mortality. Since the populations enrolled in the epidemiologic studies were largely composed of adults with likely higher past than current Pb exposures, uncertainty exists as to the Pb exposure level, timing, frequency, and duration contributing to the observed associations.

2.6.3 Renal Effects

The 2006 Pb AQCD concluded that "in the general population, both circulating and cumulative Pb was found to be associated with a longitudinal decline in renal function," evidenced by increased serum creatinine and decreased creatinine clearance or eGFR over follow-up of 4 to 15 years in association with higher baseline blood and bone Pb levels (U.S. EPA, 2006b). Uncertainty remained on the contribution of past Pb exposures to associations observed in adults, the renal effects of Pb in children, and the implication of hyperfiltration. Because blood Pb level in nonoccupationally-exposed adults reflects

both recent and past Pb exposures, the magnitude, timing, frequency, and duration of Pb exposure contributing to the observed associations remains uncertain.

New epidemiologic and toxicological studies evaluated in the current review support or expand upon the strong body of evidence presented in the 2006 Pb AQCD (U.S. EPA, 2006b). The weight of epidemiologic evidence demonstrates consistently a relationship between higher blood Pb level and kidney dysfunction (e.g., lower creatinine clearance, higher serum creatinine, and lower GFR [glomerular filtration rate]) in nonoccupationally-exposed adults with mean concurrent or baseline blood Pb levels of 2-10 µg/dL. A few analyses find higher blood Pb levels to be associated with a greater longitudinal decrease in kidney function over time (4-15 years), suggesting that past Pb exposures may contribute to ongoing renal effects. The epidemiologic evidence is strengthened by associations between Pb biomarker levels and renal function that are observed after adjustment for multiple potential confounding factors such as age, sex, comorbid cardiovascular conditions, BMI (body mass index), smoking, and alcohol use. Coherence for epidemiologic findings is provided by observations in animal models that Pb exposure for greater than 6 months decreases GFR and increases serum creatinine. The weight of evidence in animal studies indicates that Pb induces histopathological changes, including tubular atrophy and sclerosis. Overall, reduced renal function and increased kidney damage in animals are observed with chronic Pb (> 4 weeks) exposure that results in blood Pb levels > 20 µg/dL. By demonstrating Pb-induced renal oxidative stress, inflammation, mitochondrial dysfunction, apoptosis, and glomerular hypertrophy, toxicological studies provide biological plausibility for the associations observed in epidemiologic studies between blood Pb levels and kidney dysfunction. Collectively, the evidence integrated across epidemiologic and toxicological studies as well as across the spectrum of renal outcomes is sufficient to conclude that there is a causal relationship between Pb exposures and renal health effects (Section 5.5.6).

In addition, data on the effects of Pb on the kidney in children were reported in a recent NHANES analysis of adolescents, ages 12-20 years, which observed an association between higher concurrent blood Pb (mean: 1.5 µg/dL) and lower cystatin C-based eGFR (Section 5.5.6). These findings are consistent with results from a rodent model study in which a low dose of Pb (50 ppm) administered from birth resulted in renal impairment (elevated serum creatinine as compared to control rats), but these observations require confirmation by measurement of GFR and renal pathology. This recent epidemiologic study along with several previous studies that included children with higher Pb exposures (due to residence near sources, Pb poisoning, or parental occupational exposure) provide evidence that renal function in children may be affected by Pb exposure. The NHANES adolescents, however, likely had higher Pb exposures earlier in childhood, thus, the magnitude, timing, frequency, and duration of Pb exposure contributing to the observed

association is uncertain. Research on the association of Pb with kidney function in the occupational setting is less consistent than that in environmentally exposed populations (Section 5.5.2.25.5.2.2). The observation of paradoxical or inverse associations (higher Pb dose with lower serum creatinine, and/or higher eGFR or calculated or measured creatinine clearance) in several of these studies reflects limitations of the study design.

2.6.4 Immune System Effects

The 2006 Pb AQCD presented consistent evidence for immune system effects associated with Pb exposure (U.S. EPA, 2006b). Rather than producing overt cytotoxicity or pathology, Pb exposure was found to be associated with alterations in several subclinical parameters related to cellular and humoral immunity (Figure 5-42). Recent toxicological and epidemiologic studies support the strong body of evidence presented in the 2006 Pb AQCD that Pb exposure may be associated with a broad spectrum of changes in both cell-mediated and humoral immunity that cumulatively promote a Th2 phenotype and hyperinflammatory state (U.S. EPA, 2006b). The principal findings are Pb-induced increased production of Th2 cytokines, suppressed production of Th1 cytokines, increased inflammation, and elevated IgE, with the weight of evidence provided by toxicological studies. Collectively, these findings are coherent with the observed effects of Pb exposure on decreasing responses to antigens (e.g., DTH, bacterial resistance) in animals. Both toxicological studies in animals and epidemiologic studies in children provide evidence for Pb-associated increases in IgE. The toxicological and epidemiologic findings for Th2 cytokines, IgE, and inflammation provide biological plausibility for the associations observed for blood Pb levels with asthma and allergic conditions in children. Associations with asthma and allergy were observed after considering potential confounding by several factors, including, SES and allergen exposure. Animal studies found a range of immune effects with prenatal exposure in juvenile animals and long-term postnatal (> 4 weeks) Pb exposures in adult animals. The blood Pb levels and Pb exposure lifestage, magnitude, frequency, and duration associated with immune effects are not well characterized in children or adults. Epidemiologic studies of children and adults primarily examined concurrent blood Pb levels. Little information was provided on concentration-response functions. In epidemiologic studies, higher IgE and higher asthma prevalence were examined and found in children with blood Pb levels > 10 µg/dL. The consistency and coherence of findings across the continuum of related immune parameters that demonstrate a stimulation of Th2 responses in toxicological studies combined with the supporting epidemiologic evidence in children are sufficient to conclude that there is a causal relationship between Pb exposures and immune system effects (Section 5.6.8).

The toxicological evidence for Pb-induced production of Th2 cytokines provides biological plausibility for the evidence linking Pb exposure with elevated IgE levels (Section 5.6.8). An increase in IL-4 from activated Th2 cells induces differentiation of B cells into antibody-producing cells, thereby amplifying B cell expansion to secrete IgE, IgA, and IgG. However, epidemiologic studies did not find blood Pb level to be associated consistently with B cell abundance. In addition to T cell responses, a prominent effect of Pb exposure, as demonstrated in an extensive historical toxicological evidence base, was the induction of macrophages into a hyperinflammatory state as characterized by enhanced production of ROS, suppressed production of NO, enhanced production of TNF-α, and excessive metabolism of arachidonic acid into immunosuppressive metabolites (e.g., PGE_2). Consistent with these observations, a previous epidemiologic study examined and found greater release of ROS and lower release of NO from macrophages, primarily in children with concurrent blood Pb levels 10.31-47.49 µg/dL (Pineda-Zavaleta et al., 2004). Misregulated inflammation represents one of the major modes of action for Pb-induced immune effects. Toxicological studies provide evidence for the modulation of inflammatory cell function, production of pro-inflammatory cytokines and metabolites, enhanced inflammatory chemical messengers, and pro-inflammatory signaling cascades. In addition to the associations reported with IL-4, epidemiologic evidence for Pb effects on inflammation is limited to a few recent studies in nonoccupationally-exposed adults in which concurrent blood Pb level was associated with other indicators of inflammation such as CRP and IL-6 (Section 5.6.5.1). The studies commonly adjusted for potential confounding by age, sex, BMI, and smoking status. However, because only concurrent blood Pb levels in adults were examined, there is uncertainty regarding the magnitude, timing, frequency, and duration of Pb exposures that contributed to the observed associations.

The effects of Pb exposure on macrophages also suggest a role for the immune system in mediating Pb-associated effects in multiple other physiological systems. A small body of new toxicological studies indicated Pb-induced changes in specialized macrophages in nonlymphoid tissue such as alveolar macrophages, testicular macrophages, and brain microglia (Section 5.6.4.5); however, these studies primarily used the i.p. route to administer Pb. Thus, the relevancy of observations to those expected from typical routes of human exposure is not clear.

In the large body of studies of adults (mostly males) with occupational Pb exposures (Section 5.6.2.5), the most consistent findings were decreased neutrophil functionality in workers with mean blood Pb levels 21-71 µg/dL. Recent epidemiologic studies provided new evidence in adults without occupational Pb exposures; however, each examined a different immune endpoint, for example, IgE, eNO, IL-6. These endpoints were associated with concurrent blood Pb levels in populations of adults with mean blood Pb

levels of 1.9 µg/dL to 7 µg/dL; however, there is uncertainty regarding the contributions of current Pb exposures and cumulative Pb stores in bone. The small body of epidemiologic studies of nonoccupationally-exposed adults examined different endpoints and found associations with concurrent blood Pb levels, which are influenced by current Pb exposures as well as cumulative Pb stores in bone (Section 5.6).

2.6.5 Heme Synthesis and Red Blood Cell Function

The 2006 Pb AQCD reported that Pb affects developing red blood cells (RBCs) in children and occupationally exposed adults as noted by anemia observed with blood Pb > 40 µg/dL. Pb-induced anemia is thought to occur due to decreased RBC life span and effects on hemoglobin (Hb) synthesis. The exact mechanism for these effects was not known, although Pb-induced changes on iron uptake or inhibition of enzymes in the heme synthetic pathway may be responsible. Pb was also observed to exert effects on heme synthesis through the inhibition of multiple key enzymes, most notably ALAD (aminolevulinic acid dehydratase), the enzyme that catalyzes the second, rate-limiting step in heme biosynthesis (Figure 5-45 presents a schematic representation of the heme biosynthetic pathway). Decreased RBC ALAD activity was concluded to be the most sensitive measure of human Pb exposure, in that measurement of ALAD activity is correlated with blood Pb levels. Oxidative stress was identified as an important potential mechanism of action by which Pb exposure induced effects on RBCs (U.S. EPA, 2006b).

Recent epidemiologic and toxicological studies support findings from the 2006 Pb AQCD. The principal finding regarding RBC survival and function are consistent Pb-induced alterations in several inter-connected hematological parameters such as Hb (hemoglobin), Hct (hematocrit), and MCV (mean corpuscular volume) across multiple studies, with the weight of evidence provided by epidemiological studies in occupationally-exposed adult populations and children. In occupationally-exposed adults, these findings are most substantiated in populations with current blood Pb levels > 20 µg/dL, although effects on hematological parameters were observed in some occupationally-exposed populations at concurrent blood Pb levels in the range of 5-7 µg/dL. The weight of evidence in adult rodents exposed long-term to Pb (i.e., ≥ 4 weeks) is coherent with epidemiologic studies regarding decrements in hematological parameters at blood Pb levels as low as 6.6-7.1 µg/dL in rats and mice. Regarding alterations in heme synthesis, the largest body of evidence again is provided by decreased ALAD activity in association with Pb exposure or blood Pb levels in occupationally-exposed adults or in children (3-12 years old), respectively. In the occupationally-exposed adult populations, the observation of decreased ALAD activity was most often observed in populations with concurrent blood Pb levels >15 µg/dL.

Animal toxicological studies also provide to the weight of evidence regarding altered ALAD activity, with effects seen in adult animals exposed for 3-4 weeks with blood Pb levels as low as 6.5 µg/dL. The weight of evidence for oxidative stress (i.e., increased lipid peroxidation or alterations in antioxidant enzyme levels) primarily comes from epidemiological studies in occupationally-exposed adults and children. The majority of evidence for increased oxidative stress in Pb-exposed adults comes from occupational cohorts with concurrent blood Pb levels >15 µg/dL. In children, concurrent blood Pb levels of 7-22 µg/dL were associated with measures of oxidative stress. The frequency, timing and duration of exposure necessary to alter RBC survival and function, heme synthesis, or the state of oxidative stress in RBCs is uncertain in both adults and children. The consistency of findings in epidemiologic studies investigating effects in occupationally-exposed adults and in children, and the coherence of findings in the toxicological literature and coherence across the disciplines, is sufficient to conclude that there is a causal relationship between Pb exposures and heme synthesis and RBC function (Section 5.7.7).

2.6.6 Reproductive and Developmental Effects

Recent toxicological and epidemiologic literature provides strong evidence that Pb exposure is associated with effects on reproduction and development supporting conclusions of the 2006 Pb AQCD and expanding evidence for additional endpoints. The weight of the evidence supports the association of Pb exposure with delayed onset of puberty in both males and females and detrimental effects on sperm and semen quality in occupationally-exposed males and in laboratory animals. In cross-sectional epidemiologic studies of girls (ages 6-18 years) with mean and/or median concurrent blood Pb levels less than 5 µg/dL consistent associations with delayed pubertal development (measured by age at menarche, pubic hair development, and breast development) were observed. Toxicological studies of rodents indicate that prenatal and lactational exposures to Pb can cause a delay in the onset of female puberty at blood Pb levels as low as 8 µg/dL. Recent studies show that pubertal onset is one of the more sensitive markers of Pb exposure with effects observed after maternal exposures leading to blood Pb levels in the pup of 3.5-13 µg/dL. In boys (ages 8-15 years), fewer studies were conducted but associations were observed in most. Male animal toxicology studies have reported delayed sexual maturity as measured with prostate weight, among other outcomes, seeing significant decrements at blood Pb levels of 34 µg/dL. There is uncertainty with regard to the exposure frequency, timing, duration and level that contributed to these observed association in these studies of adolescents. Multiple studies were performed in areas, which were contaminated with other chemicals as well as Pb.

Additionally, Pb exposure has been shown to have detrimental effects on sperm. These were observed in epidemiologic studies at population mean blood Pb levels of 30 µg/dL and greater among men occupationally exposed (mean blood Pb levels in study controls around 10 µg/dL) and in animal toxicological studies with rabbits exposed to subcutaneous Pb 3 times per week for 15 weeks with blood Pb levels of 20 µg/dL. The collective body of evidence integrated across epidemiologic and toxicological studies with a focus on the strong relationship observed with detrimental effects on sperm and delayed pubertal onset is sufficient to conclude that there is a causal relationship between Pb exposures and reproductive and developmental effects (Section 5.8.10).

The evidence on hormonal influences and fecundity are less consistent (Section 5.8.1, Section 5.8.2). Pb-mediated changes in levels or function of reproductive and growth hormones have been demonstrated in past and more recent toxicological studies; however the findings are inconsistent. Recent toxicological studies suggest that oxidative stress is a major contributor to the toxic effects of Pb on male and female reproductive systems. The effects of ROS may involve interference with cellular defense systems leading to increased lipid peroxidation and free radical attack on lipids, proteins, and DNA. Several recent studies showed an association between increased generation of ROS and germ cell injury as evidenced by destruction of germ cell structure and function. Co-administration of Pb with various antioxidant compounds either eliminated Pb-induced injury or greatly attenuated its effects. In addition, many studies that observed increased oxidative stress also observed increased apoptosis which is likely a critical underlying mechanism in Pb-induced germ cell DNA damage and dysfunction.

Consistent conclusions in the 2006 Pb ISA recent studies of pregnancy outcomes were reported mixed results. Inconsistent evidence of a relationship with Pb was available for preterm birth and little evidence was available to study the associations with spontaneous abortions (Section 5.8.6, Section 5.8.3). The 2006 Pb AQCD included a few studies that reported potential associations between Pb and neural tube defects, but the recent epidemiologic studies found no association. Some associations were observed between Pb and low birth weight (Section 5.8.7) when epidemiologic studies used measures of maternal bone Pb or air exposures, but the associations were less consistent when using maternal blood Pb or umbilical cord and placenta Pb (maternal blood Pb or umbilical cord and placenta Pb were the biomarkers most commonly used in studies of low birth weight). Effects of Pb exposure during early development on toxicological studies included reduction in litter size, implantation, birth weight and postnatal growth (Section 5.8.4). Findings from epidemiologic studies of postnatal growth are inconsistent (Section 5.8.8). Toxicological studies demonstrated that the effects of Pb exposure during early development include impairment of retinal development and alterations in the

developing hematopoietic and hepatic systems (Section 5.8.9). Negative developmental outcomes were also noted including effects on the eyes and teeth (Section 5.8.9).

2.6.7 Cancer

The previous epidemiologic studies included in the 2006 Pb AQCD (U.S. EPA, 2006b) "provide[d] only very limited evidence suggestive of Pb exposure associations with carcinogenic or genotoxic effects in humans" and the studies were summarized as follows:

> "The epidemiologic data …suggest a relationship between Pb exposure and cancers of the lung and the stomach… Studies of genotoxicity consistently link Pb-exposed populations with DNA damage and micronuclei formation, although less consistently with chromosomal aberrations."

The International Agency for Research on Cancer (IARC) classified inorganic Pb compounds as probable human carcinogens (Group 2A of IARC classifications) based on stronger evidence in animal studies than human studies, and organic Pb compounds as not classifiable (Group 3 of IARC classifications) (IARC, 2006a; Rousseau et al., 2005). Additionally, the National Toxicology Program has listed Pb and Pb compounds as "reasonably anticipated to be human carcinogens" (NTP, 2004). The typical cancer bioassays used by IARC or NTP as evidence of Pb-induced carcinogenicity used rodents that were continuously exposed to Pb-acetate in chow or drinking water for 18 months to two years in duration. These two year cancer bioassays and the doses administered are typical of cancer bioassays used with other chemicals.

The animal toxicological literature continues to provide the strongest evidence for Pb exposure and cancer with some supporting evidence provided by the epidemiologic literature. Evidence from toxicological studies demonstrates an association between Pb and cancer, genotoxicity/clastogenicity or epigenetic modification. Carcinogenicity in historical animal toxicology studies with Pb exposure has been reported in the kidneys, testes, brain, adrenals, prostate, pituitary, and mammary gland, albeit at high doses of Pb. Epidemiologic studies of cancer incidence and mortality reported inconsistent results; one large epidemiologic study demonstrated an association between blood Pb and increased cancer mortality, but the other studies reported weak or no associations. In the 2006 Pb AQCD, Pb exposure was found to be associated with stomach cancer, but there was only one recent study on stomach cancer and Pb exposure, which reported mixed findings. Similarly, some studies in the 2006 Pb AQCD reported associations between Pb exposure and lung cancer (U.S. EPA, 2006b). More recent occupational studies of Pb exposure and lung cancer reported no associations. The majority of epidemiologic studies of brain cancer had null results overall, but positive associations between Pb exposure and brain

cancer were observed among individuals with certain genotypes (e.g., ALAD2). In toxicological studies, chromosomal aberrations after Pb exposure are most often reported with Pb chromate exposure, which is likely due to toxicity of the chromate moiety. Mechanistic understanding of Pb and its effect on cancer and genotoxicity is expanding through toxicological work focusing on antioxidants and other proteins that sequester Pb or reduce its bioavailability. The collective body of evidence integrated across toxicological and epidemiologic studies is sufficient to conclude that there is a likely causal relationship between Pb exposure and cancer (Section 5.10.6).

2.7 Ecological Effects of Lead

This section evaluates the evidence from studies of ecological effects associated with exposure to Pb. Causal determinations are developed for the ecological outcomes discussed in this assessment, in combination with evidence from other disciplines (e.g., fate and transport) where relevant. Pb effects on terrestrial and aquatic systems (Section 2.7.1 and Section 2.7.2) are summarized from Chapter 7 in which the effects on terrestrial and aquatic ecosystems are presented separately. These sections are followed by a summary of the evidence for the causal determinations (Section 2.7.3) and consideration of atmospheric deposition of Pb as related to ecological effects (Section 2.9.3). The ecological causal determinations are integrated across endpoints (physiological stress, hematological effects, neurobehavioral effects, development and reproduction, growth, survival) common to both terrestrial and aquatic biota (Table 2-4). Where the causal determination varies substantially between types of organisms (typically between plants and other organisms or between aquatic and terrestrial biota), the divergence is noted.

2.7.1 Summary of Effects on Terrestrial Ecosystems

Historically, Pb poisoning is one of the earliest recognized toxicoses of terrestrial biota, occurring primarily through ingestion of spent shot by birds (Section 7.4.2.3). At the time of the 1977 Pb AQCD few studies of Pb exposure and effects in wild animals other than birds were available. A limited number of rodent trapping studies and observations from grazing animals near smelters provided evidence for differences in Pb sensitivity among species and these findings were further supported in the 1986 and 2006 Pb AQCDs (U.S. EPA, 2006b, 1986b, 1977). ALAD was recognized as a sensitive indicator of Pb exposure in rats and waterfowl in the 1977 Pb AQCD and now is regarded as a biomarker of exposure in many terrestrial organisms. According to the 2006 Pb AQCD and supported by evidence from previous Pb AQCDs, commonly observed effects of Pb on

terrestrial organisms include decreased survival, reproduction, and growth, as well as effects on development and behavior. Furthermore, the toxicity of Pb to terrestrial vertebrates and invertebrates varies with bioavailability of the metal, species and lifestage, duration of exposure, form of Pb, and soil characteristics.

In plants, Pb effects have also been studied for several decades. At the time of the 1977 Pb AQCD, it was understood that Pb uptake in plants was influenced by plant species and by the available Pb pool in the soils (U.S. EPA, 1977). Furthermore, most of the Pb taken up by plants from soil, remains in the roots and that distribution to other portions of the plant is variable among species (U.S. EPA, 1977). Plant growth was recognized as an endpoint of Pb toxicity in plants in the 1977 Pb AQCD and additional effects of Pb on growth processes were reported in subsequent Pb AQCDs (U.S. EPA, 2006b, 1986b, 1977). A study reviewed in the 1977 Pb AQCD provided evidence for Pb effects on forest-nutrient cycling and shifts in arthropod community composition in the vicinity of a smelting complex. A number of ecosystem-level effects, including decreased species diversity, changes in floral and faunal community composition, and decreasing vigor of terrestrial vegetation have subsequently been reported near Pb-point sources (U.S. EPA, 2006b, 1986b, 1977; Watson et al., 1976).

Pb in terrestrial ecosystems is either deposited directly onto plant surfaces, or incorporated into soil where it can bind with organic matter or dissolve in pore water. The amount of Pb dissolved in soil pore water determines the impact of soil Pb on terrestrial ecosystems to a much greater extent than the total amount present. It has long been established that the amount of Pb dissolved in soil solution is controlled by at least six variables: (1) solubility equilibria; (2) adsorption-desorption relationship of total Pb with inorganic compounds; (3) adsorption-desorption reactions of dissolved Pb phases on soil organic matter; (4) pH; (5) cation exchange capacity (CEC); and (6) aging. Since 2006, further details have been contributed to the understanding of the role of pH, CEC, organic matter, and aging. Smolders et al. (2009) demonstrated that the two most important determinants of both Pb solubility and toxicity in soils are pH and CEC. However, they had previously shown that experimental aging, primarily in the form of initial leaching following addition of Pb, decreases soluble metal fraction by approximately one order of magnitude (Smolders et al., 2009). Since 2006, organic matter has been confirmed as an important influence on Pb sequestration, leading to longer-term retention in soils with higher organic matter content, and also creating the potential for later release of deposited Pb. Aging, both under natural conditions and simulated through leaching, was shown to substantially decrease bioavailability to plants, microbes, and vertebrates.

There is evidence over several decades of research previously reviewed in Pb AQCDs and in recent studies reviewed in this ISA that Pb accumulates in terrestrial plants,

invertebrates and vertebrates. Studies with herbaceous plant species growing at various distances from smelters added to the existing strong evidence that atmospherically transported Pb is taken up by plants. These studies did not establish the relative proportion that originated from atmospheric Pb deposited in the soil, as opposed to that taken up directly from the atmosphere through the leaves. Multiple new studies showed that in trees, the latter is likely to be very substantial. One study attempted to quantify the proportion of atmospheric Pb up directly from the atmosphere, and suggested it amounts to 50% of the Pb contained in Scots Pine in Sweden (Klaminder et al., 2005). Studies with herbaceous plants found that in most species tested, soil Pb taken up by the roots is not translocated into the stem and leaves. Studies with trees found that soil Pb generally is translocated to other parts.

Since the 2006 Pb AQCD, various species of terrestrial snails have been found to accumulate Pb from both diet and soil (U.S. EPA, 2006b). New studies with earthworms have found that both internal concentration of Pb and mortality increase with decreasing soil pH and CEC. In addition, tissue concentration differences have been found between species of earthworms that burrow in different soil layers. The rate of accumulation in each of these species may result from differences in interacting factors such as pH and CEC between layers. Because earthworms often sequester Pb in granules, some authors have suggested that earthworm Pb is not bioavailable to their predators. There is some evidence that earthworm activity increases Pb availability in soil, but it is inconsistent. In various arthropods collected at contaminated sites, recent studies found gradients in accumulated Pb that corresponded to gradients in soil with increasing distance from point sources.

There are a few new studies of Pb bioavailability and uptake in birds since the 2006 Pb AQCD (U.S. EPA, 2006b). Several found tissue levels in birds that indicated exposure to Pb, but none of the locations for these studies was in proximity to point sources, and the origin of the Pb could not be identified. A study at the Anaconda Smelter Superfund site found increasing Pb accumulation in gophers with increasing soil Pb around the location of capture. A study of swine fed various Pb-contaminated soils showed that the form of Pb determined accumulation. New studies were able to measure Pb in the components of various food chains that included soil, plants, invertebrates, arthropods and vertebrates. They confirmed that trophic transfer of Pb is pervasive, but no consistent evidence of trophic magnification was found.

Evidence in this review further supports the findings of the previous Pb AQCDs that biological effects of Pb on terrestrial organisms vary with species and lifestage, duration of exposure, form of Pb, and soil characteristics. In photosynthetic organisms, experimental studies have added to the existing evidence of photosynthesis impairment in

plants exposed to Pb, and have found damage to photosystem II due to alteration of chlorophyll structure, as well as decreases in chlorophyll content in diverse taxa, including lichens and mosses. Evidence of oxidative stress in response to Pb exposure has also been observed in plants. Reactive oxygen species were found to increase in broad bean and tomato plants exposed to increasing concentrations of soil Pb, and a concomitant increase in superoxide dismutase, glutathione, peroxidases, and lipid peroxidation, as well as decreases in catalase were observed in the same plants. Monocot, dicot, and bryophytic taxa grown in Pb-contaminated soil or in experimentally spiked soil all responded to increasing exposure with increased antioxidant activity. In addition, reduced growth was observed in some experiments, as well as genotoxicity, decreased germination, and pollen sterility.

In terrestrial invertebrates, evidence for Pb effects has included neurological and reproductive endpoints. Recently published studies have shown neuronal damage in nematodes exposed to low concentrations of Pb (2.5 μM), accompanied by behavioral abnormalities. Reproductive adverse effects were found at lower exposure in younger nematodes, and effects on longevity and fecundity were shown to persist for several generations. Increased mortality was found in earthworms, but was strongly dependent on soil characteristics including pH, CEC, and aging. Snails exposed to Pb through either topical application or through consumption of Pb-exposed plants had increased antioxidant activity, and decreased food consumption, growth, and shell thickness. Effects on arthropods exposed through soil or diet varied with species and exposure conditions, and included diminished growth and fecundity, endocrine and reproductive anomalies, and body malformations. Within each study, increasing concentration of Pb in the exposure medium generally resulted in increased effects, but the relationship between concentration and effects varied between studies, even when the same medium, e.g., soil, was used. Evidence suggested that aging and pH are important modifiers.

Effects on amphibian and reptiles included decreased white blood cell counts, decreased testis weight, and behavioral anomalies. However, large differences in effects were observed at the same concentration of Pb in soil, depending on whether the soil was freshly amended or field-collected from contaminated areas. As in most studies where the comparison was made, effects were smaller when field-collected soils were used. In some birds, maternal elevated blood Pb level was associated in recent studies with decreased hatching success, smaller clutch size, high corticosteroid level, and abnormal behavior. Some species evidenced little or no effect of elevated blood Pb level. Effects of dietary exposure were studied in several mammalian species, and cognitive, endocrine, immunological, and growth effects were observed.

New evidence reviewed in Section 7.2.3 and Section 7.2.4 demonstrates that exposure to Pb is generally associated with negative effects in terrestrial ecosystems. It also demonstrates that many factors, including species and various soil physiochemical properties, interact strongly with Pb concentration to modify those effects. In these ecosystems, where soil is generally the main component of the exposure route, Pb aging is a particularly important factor, and one that may be difficult to reproduce experimentally. Without quantitative characterization of those interactions, characterizations of exposure-response relationships would likely not be transferable outside of experimental settings. Since the 2006 Pb AQCD, a few studies of exposure-response have been conducted with earthworms, and results have been inconsistent (U.S. EPA, 2006b).

New evidence of effects of Pb at the community and ecosystem levels of biological organization include several studies of the ameliorative effects of mycorrhizal fungi on plant growth in the presence of Pb, attributed to decreased uptake of Pb by plants, although both mycorrhizal fungus and plant were negatively affected. Most recently published research on community and ecosystem-level effects of Pb has focused on soil microbial communities, which have been shown to be impacted in both composition and activity. Many recent studies have been conducted using mixtures of metals, but have tried to separate the effects of individual metals when possible. Soil microbial activity was generally diminished, but in some cases recovered over time. Species and genotype composition were consistently altered, and those changes were long-lasting or permanent. Recent studies have addressed differences in sensitivity between species explicitly, and have clearly demonstrated high variability between related species, as well as within larger taxonomic groupings. Mammalian no observed effect concentration (NOEC) values expressed as blood Pb levels were shown to vary by a factor of 8, while avian blood NOECs varied by a factor of 50 (Buekers et al., 2009). Protective effects of dietary Ca have been found in plants, birds, and invertebrates.

2.7.2 Summary of Effects on Aquatic Ecosystems

Pb effects on aquatic biota were previously assessed in the 1977 Pb AQCD, the 1986 Pb AQCD and the 2006 Pb AQCD (U.S. EPA, 2006b, 1986a, 1977). Evidence of toxicity of Pb and other metals to freshwater organisms goes back to early observations of contamination of natural areas by Pb mining leading to extirpation of fish from streams (U.S. EPA, 1977). Observed responses of fish to Pb reported in the 1986 Pb AQCD and the 2006 Pb AQCD include inhibition of heme formation, alterations in brain receptors, effects on blood chemistry and hormonal systems, and decreases in some enzyme activities (U.S. EPA, 2006b, 1986a). In the 1986 Pb AQCD and 2006 Pb AQCD,

additional evidence for Pb toxicity was available for aquatic invertebrates. Inhibition of ALAD, and reduced reproduction, growth, and survival were reported. Few studies of Pb toxicity to saltwater organisms are reported in previous Pb AQCDs. The toxicity of Pb to saltwater and freshwater organisms varies with bioavailability of the metal, species and lifestage, duration of exposure, form of Pb, and water quality parameters (U.S. EPA, 2006b, 1986a). As reviewed in the 2006 Pb AQCD, the biotic ligand model (BLM) constitutes an attractive means of quantifying factors that affect bioavailability, such as pH, dissolved organic carbon (DOC), and alkalinity (U.S. EPA, 2006b).

The toxicity of Pb to aquatic algae and plants has been recognized in earlier agency reviews of this metal. In the 1977 Pb AQCD, differences in sensitivity to Pb among different species of algae were reported and concentrations of Pb varied among genera and within a genus, an observation subsequently found across aquatic taxa (U.S. EPA, 1977). At the time of the 1977 Pb AQCD, the information available on effects of Pb on aquatic plants was limited. For plants in general, Pb was recognized to affect photosynthesis, mitosis, and growth, but at concentrations higher than typically found in the environment (U.S. EPA, 1977). Findings from field studies of aquatic communities in the vicinity of Pb point sources include changes in species composition and species richness, predator/prey interactions, nutrient cycling and energy flow; however, Pb is often found coexisting with other metals and other stressors, which risk confounding the observed effects.

Effects of Pb observed in aquatic organisms are tied to terrestrial systems via watershed processes (Section 3.3). Atmospherically-derived Pb can enter aquatic systems through runoff from terrestrial systems or via direct deposition over a water surface. Once Pb enters surface waters, its fate and bioavailability are influenced by Ca^{2+} concentration, pH, alkalinity, total suspended solids, and dissolved organic carbon (DOC, including humic acids). In sediments, Pb bioavailability may be influenced by the presence of other metals, sulfides, Fe and Mn oxides and physical disturbance. In many, but not all aquatic organisms, Pb dissolved in the water can be the primary exposure route to gills or other biotic ligands. As recognized in the 2006 Pb AQCD and further supported in this review, chronic exposures to Pb may also include dietary uptake, and there is an increasing body of evidence showing that differences in uptake and elimination of Pb vary with species. Currently available models for predicting bioavailability focus on acute toxicity and do not consider all possible routes of uptake. They are therefore of limited applicability, especially when considering species-dependent differences in uptake and bioaccumulation of Pb.

Recent evidence supports the 2006 Pb AQCD conclusion that processes such as Pb adsorption, complexation, and chelation alter bioavailability to aquatic biota. Given the

low solubility of Pb in water, bioaccumulation by aquatic organisms may preferentially occur via exposure routes other than direct absorption from the water column; which include ingestion of contaminated food and water, uptake from sediment pore waters, or incidental ingestion of sediment (U.S. EPA, 2006b).

There are considerable differences between species in both the amount of Pb taken up from the environment and in the amount retained in the organism. Closely related species can vary greatly in bioaccumulation of Pb and other non-essential metals. Recent studies on uptake of Pb by aquatic plants and algae support the findings of previous Pb AQCDs that all plants tend to sequester larger amounts of Pb in their roots than in their shoots, and provide additional evidence for species differences in compartmentalization of sequestered Pb and in responses to Pb in water and sediments. In invertebrates, Pb can be accumulated from multiple sources, including the water column, sediment, and dietary exposure. Since the last review, new studies using stable isotopes have enabled simultaneous measurement of uptake and elimination in several aquatic organisms to assess the relative importance of water versus dietary uptake. In uptake studies of various invertebrates, Pb was mainly found in the gills and digestive gland/hepatopancreas. There is more information now on the cellular and subcellular distribution of Pb in invertebrates than there was at the time of writing the 2006 Pb AQCD. Specifically, localization of Pb at the ultrastructural level has been assessed in several species.

Recent evidence also supports the 2006 conclusions that the gill is a major site of Pb uptake in fish, and that there are species differences in the rate of Pb accumulation and distribution of Pb within the organism are supported in this review. The anterior intestine has been newly identified as a site of uptake of Pb through dietary exposure studies. There are few new studies on Pb uptake by amphibians and mammals. At the time of the publication of the 2006 Pb AQCD, trophic transfer of Pb through aquatic food chains was considered to be negligible. Measured concentrations of Pb in the tissues of aquatic organisms were generally higher in algae and benthic organisms than in consumers at higher trophic levels, indicating that Pb was bioconcentrated but not biomagnified. Some studies published since the 2006 Pb AQCD support the potential for transfer of Pb in aquatic food webs, while other studies indicate that Pb concentration decreases with increasing trophic level (U.S. EPA, 2006b).

Evidence in this ISA further supports the findings of the previous Pb AQCDs that waterborne Pb is highly toxic to aquatic organisms, with toxicity varying with species and lifestage, duration of exposure, form of Pb, and water quality characteristics. Effects of Pb on algae reported in the 2006 Pb AQCD are further supported by evidence from additional species. They include decreased growth, deformation and disintegration of cells, and blocking of the pathways that lead to pigment synthesis, thus affecting

photosynthesis. Effects on plants supported by additional evidence in this review include oxidative damage, decreased photosynthesis and reduced growth. Elevated levels of antioxidant enzymes are commonly observed in aquatic plant, algae, and moss species exposed to Pb.

Since the 2006 Pb AQCD, there is additional evidence for Pb effects on antioxidant enzymes, lipid peroxidation, stress response and osmoregulation in aquatic invertebrates. Studies of reproductive and developmental effects of Pb in this review provide further support for findings in the 2006 Pb AQCD. These new studies include reproductive endpoints for rotifers and freshwater snails as well as multigenerational effects of Pb in mosquito larvae and marine amphipods. As reviewed below, growth effects are observed at lower concentrations in some aquatic invertebrates since the 2006 Pb AQCD, especially in juvenile organisms. Behavioral effects of Pb in aquatic invertebrates reviewed in this ISA include decreased valve closing speed in scallops and slower feeding rate in blackworms.

Evidence in this ISA supports the findings of reproductive, behavioral, and growth effects in previous Pb AQCDs, as well as effects on blood parameters in aquatic vertebrates. Since the 2006 Pb AQCD, possible molecular targets for Pb neurotoxicity have been identified in fish and additional mechanisms of Pb toxicity have been elucidated in the fish gill and the fish renal system. In the 2006 Pb AQCD, amphibians were considered to be relatively tolerant to Pb. Observed responses to Pb exposure included decreased enzyme activity (e.g., ALAD reduction) and changes in behavior. Since the 2006 Pb AQCD, studies conducted at concentrations approaching environmental levels of Pb have indicated sublethal effects on tadpole endpoints including growth, deformity, and swimming ability. In fish, several recent studies on behavioral effects of Pb indicate decreased prey capture rate, slower swim speed and decline in startle response and visual contrast with Pb exposure.

Concentration-response data from plants, invertebrates and vertebrates are consistent with findings in previous AQCDs of species differences in sensitivity to Pb in aquatic systems (Section 7.3.17.4). In this ISA, as in previous AQCDs, aquatic plant growth was shown to be adversely affected by Pb exposure. The lowest EC_{50} for growth observed in marine microalgae and freshwater microalgae was in the range of 100 µg Pb/L. In the 2006 Pb AQCD, concentrations at which effects were observed in aquatic invertebrates ranged from 5 to 8,000 µg Pb/L. Several studies in this review have provided evidence of effects at lower concentrations. Among the most sensitive species, growth of juvenile freshwater snails (*L. stagnalis*) was inhibited at an EC_{20} of <4 µg Pb/L (Grosell and Brix, 2009; Grosell et al., 2006a). A chronic value of 10 µg Pb/L obtained in 28-day exposures of 2-month-old *Lampsilis siliquoidea* juveniles was the lowest genus mean chronic value

ever reported for Pb (Wang et al., 2010e). In a series of 48 hour acute toxicity tests using a variety of natural waters across North America, LC_{50} values ranged from 29 to 180 µg Pb/L tests with the cladoceran *Ceriodaphnia dubia* (Esbaugh et al., 2011).

In the 2006 Pb AQCD, adverse effects were found in freshwater fish at concentrations ranging from 10 to >5,400 µg Pb/L, generally depending on water quality variables (e.g., pH, hardness, salinity). Additional testing of Pb toxicity under conditions of varied alkalinity, DOC, and pH has been conducted since the last review. However, adverse effects in fish observed in recent studies fall within the range of concentrations observed in the previous Pb AQCD.

Since the 2006 Pb AQCD, additional evidence for community and ecosystem level effects of Pb have been observed primarily in microcosm studies or field studies near point sources (mining, effluent) with other metals present. Ecological effects associated with Pb, reported in previous Pb AQCDs, include alteration of predator-prey dynamics, species richness, species composition, and biodiversity. New studies in this ISA provide evidence in additional habitats for these community and ecological-level effects, specifically in aquatic macrophyte communities and sediment-associated communities. Different species may exhibit different responses to Pb-impacted ecosystems dependent not only upon other environmental factors (e.g., temperature, pH), but also on the species sensitivity, lifestage, or seasonally-affected physiological state. Aquatic ecosystems with low pH and low DOM are likely to be the most sensitive to the effects of atmospherically-deposited Pb.

2.7.3 Determinations of Causality for Effects on Ecosystems

Table 2-3 Summary of Pb causal determinations for plants, invertebrates and vertebrates

Effect	Terrestrial	Aquatic[a]
Physiological Stress-All organisms	Causal	Causal
Hematological Effects-Invertebrates	Inadequate	Causal
Hematological Effects-Vertebrates	Causal	Causal
Neurobehavioral Effects-Invertebrates and Vertebrates	Likely Causal	Likely Causal
Developmental and Reproductive Effects-Plants	Inadequate	Inadequate
Developmental and Reproductive Effects-Invertebrates and Vertebrates	Causal	Causal
Growth-Plants	Causal	Causal
Growth-Invertebrates	Inadequate	Causal
Growth-Vertebrates	Inadequate	Inadequate
Survival-Plants	Inadequate	Inadequate
Survival- Invertebrates and Vertebrates	Causal	Causal
Community and Ecosystem Level Effects	Likely Causal	Likely Causal

[a]Causal determinations for aquatic biota are based primarily on evidence from freshwater organisms.

2.7.3.1 Effects on Physiological Stress

Evidence is sufficient to conclude that there is a causal relationship between Pb exposures and physiological stress in terrestrial and aquatic plants, invertebrates and vertebrates (Sections 7.4.1.1 and 7.4.2.1).

Endpoints associated with physiological stress received no consideration prior to the 2006 Pb AQCD and this ISA. Studies published since the 2006 Pb AQCD support previous associations of Pb exposure with physiological stress. New evidence includes upregulation of antioxidant enzymes, production of reactive oxygen species and increased lipid peroxidation associated with Pb exposure in additional species of terrestrial and aquatic plants, invertebrates and vertebrates that support, and expand upon findings in the previous Pb AQCD (U.S. EPA, 2006b).

In this ISA and the 2006 Pb AQCD, there is strong evidence of upregulation of antioxidant enzymes and increased lipid peroxidation associated with Pb exposure in many species of plants, invertebrates and vertebrates. In plants, increases of antioxidant

enzymes with Pb exposure occur in algae, aquatic mosses, floating and rooted aquatic macrophytes, and terrestrial species. Most observations of antioxidant responses in plants typically occur at concentrations of Pb higher than found in the environment. However, in a few terrestrial plant species, increases of antioxidant enzymes occur at concentrations approaching the average Pb concentrations in U.S. soils and limited transplantation studies with aquatic plants indicate elevated antioxidant enzyme activity associated with Pb levels measured in sediments at polluted sites. There is considerable evidence for antioxidant activity in invertebrates, including gastropods, mussels, and crustaceans, in response to Pb exposure. Some recent evidence for invertebrate antioxidant responses in aquatic species indicates effects at Pb concentrations associated with polluted sites. Markers of oxidative damage are also observed in fish, amphibians and mammals, both in the laboratory and in exposed natural environments. Across all biota, there are differences in the induction of antioxidant enzymes that appear to be species-dependent.

Additional stress responses observed in terrestrial and aquatic invertebrates include elevated heat shock proteins, osmotic stress and decreased glycogen levels. Heat shock protein induction by Pb exposure has been observed in zebra mussels and mites. Tissue volume regulation is adversely affected in freshwater crabs. Glycogen levels in the freshwater snail *Biomphalaria glabrata* were significantly decreased following 96-hour exposures at near environmentally-relevant concentrations (50 µg Pb/L and higher) (Ansaldo et al., 2006).

Upregulation of antioxidant enzymes and increased lipid peroxidation are considered to be reliable biomarkers of stress, and suggest that Pb exposure induces a stress response in those organisms, which may increase susceptibility to other stressors and reduce individual fitness. The oxidative stress responses associated with Pb exposure are consistent in terrestrial biota and in aquatic organisms. Furthermore, these responses are also observed in experimental animal studies, and in humans.

2.7.3.2 Hematological Effects

Based on observations in both terrestrial and aquatic organisms and additionally supported by toxicological and epidemiological findings in laboratory animals and humans, evidence is sufficient to conclude that there is a causal relationship between Pb exposures and hematological effects in aquatic invertebrates and terrestrial and aquatic vertebrates (Section 7.4.1.2, Section 7.4.2.2). The evidence is inadequate to conclude that there is a causal relationship between Pb exposures and hematological effects in terrestrial invertebrates.

Recent studies add support to the strong body of evidence presented in previous Pb AQCDs that Pb exposure is associated with hematological responses in aquatic invertebrates and terrestrial and aquatic vertebrates. In environmental assessments of metal-impacted habitats, ALAD is a recognized biomarker of Pb exposure (U.S. EPA, 2006b). ALAD activity is negatively correlated with total Pb concentration in bivalves. Lower ALAD activity has been significantly correlated with elevated blood Pb levels in fish and mammals as well. In the 1986 Pb AQCD, decreases in RBC ALAD activity following Pb exposure were well documented in birds and mammals (U.S. EPA, 1986a). Further evidence from the 2006 Pb AQCD and this review suggests this enzyme is an indicator for Pb exposure across a wide range of taxa. Since the 2006 Pb AQCD, evidence of Pb effects on ALAD activity has been found in additional species of amphibians and fish, and has been identified in bacteria. New field studies of ALAD activity include observations in songbirds and owls near historical mining areas. In addition to consideration of ALAD activity, there is new evidence for deceased white blood cell counts in amphibians affected by Pb exposure. The consistency and coherence of these findings of effects on ALAD activity are also supported by some evidence of Pb-induced alterations of blood chemistry in fish reported in the 2006 Pb AQCD (U.S. EPA, 2006b). This evidence is strongly coherent with observations from human epidemiologic and animal toxicology studies where a causal relationship was identified between exposure to Pb and hematological effects in humans and laboratory animals (Section 2.6.5 and Section 5.7).

2.7.3.3 Neurobehavioral Effects

Overall, the evidence from terrestrial and aquatic systems is sufficient to conclude that there is a likely causal relationship between Pb exposures and neurobehavioral effects in terrestrial and aquatic invertebrates and vertebrates (Section 7.4.1.3, Section 7.4.2.3). Evidence from laboratory studies reviewed in Chapter 7 and previous Pb AQCDs have shown adverse effects of Pb on neurological endpoints in both aquatic and terrestrial animal taxa. Studies that consider mode-of-action and molecular targets of Pb toxicity in biota are now available for a few species. New studies have continued adding to the evidence from both invertebrate and vertebrate studies that Pb adversely affects behaviors such as food consumption, avoidance and escape from predators, behavioral thermoregulation, and prey capture. These changes are likely to decrease the overall fitness of the organism. New evidence in this ISA includes reports of behavioral responses across a larger variety of organisms including reptiles and fish larvae born from Pb-exposed adults, while some impairments in feeding and escaping behaviors were reported for the first time. More evidence has become available for marine organisms.

Central nervous system effects in fish recognized in previous Pb AQCDs include effects on spinal neurons and brain receptors. New evidence from this review identifies the MAPKs ERK1/2 and $p38^{MAPK}$ as possible molecular targets for Pb neurotoxicity in catfish (Leal et al., 2006). Additionally, there is new evidence for neurotoxic action of Pb in invertebrates with exposure to Pb observed to cause changes in the morphology of GABA motor neurons in nematodes (*Caenorhabditis elegans*) (Du and Wang, 2009).

Decreased food consumption of Pb-contaminated diet has been demonstrated in some invertebrates (snails) and vertebrates (lizards, pigs, fish). Behavioral effects in grunt fish *Haemulon scudderi*, occupying the top level of a simulated marine food chain included lethargy and decreased food intake in a 42-day feeding study (Soto-Jiménez et al., 2011a). These fish were fed white shrimp exposed to Pb via brine shrimp that were initially fed microalgae cultured at 20 µg Pb/L. In the same study, surfacing, reduction of motility, and erratic swimming were observed in the white shrimp after 30 days of exposure to Pb via diet. Pb may also decrease the ability of an organism to capture prey or escape predation. For example, Pb exposure has been demonstrated to adversely affect prey capture ability of certain fungal and fish species, and the motility of nematodes was adversely affected in Pb-contaminated soils (Wang and Xing, 2008). Prey capture ability was decreased in 10 day old fathead minnows born from adult fish exposed to 120 µg Pb/L for 300 days, then subsequently tested in a 21-day breeding assay (Mager et al., 2010). In a laboratory study, Pb-exposed gull chicks exhibited abnormal behaviors such as decreased walking, erratic behavioral thermoregulation and food begging that could make them more vulnerable in the wild (Burger and Gochfeld, 2005). The chicks were exposed to Pb via injection to produce feather Pb concentration approximately equivalent to those observed in wild gulls. Lizards exposed to Pb through diet in the laboratory exhibited abnormal coloration and posturing behaviors. Other behavioral effects affected by Pb exposure include increased hyperactivity in fish and hypoxia-like behavior in frogs.

These findings show strong coherence with findings from studies in laboratory animals described in Section 2.6.1 and Section 5.3 of the ISA that show that Pb induces changes in attention, increased response rates and motor function. The evidence presented in those sections is sufficient to conclude that there is a causal relationship between Pb exposure and neurobehavioral effects (Section 5.3).

2.7.3.4 Effects on Development and Reproduction

Evidence in this review and the previous Pb AQCDs from invertebrate and vertebrate studies indicate that Pb is affecting reproductive performance in multiple species. Various

endpoints have been measured in multiple taxa of terrestrial and aquatic organisms to assess the effect of Pb on development, fecundity and hormone homeostasis, and they have demonstrated the presence of adverse effects. Reproductive effects are important when considering effects of Pb because impaired fecundity at the organismal level can result in a decline in abundance and/or extirpation of populations, decreased taxa richness, and decreased relative or absolute abundance at the community level (Suter et al., 2005; U.S. EPA, 2003a). The evidence is sufficient to conclude that there is a causal relationship between Pb exposures and developmental and reproductive effects in terrestrial and aquatic invertebrates and vertebrates (Section 7.4.1.4, Section 7.4.2.4). The evidence is inadequate to conclude that there is a causal relationship between Pb exposures and developmental and reproductive effects in plants (Section 7.4.2.4).

In terrestrial invertebrates, new developmental and reproductive endpoints shown to be affected by Pb include hatching success in collembolans, increased development time in fruit flies and aphids, and disrupted hormone homeostasis in moths; however, these studies have been conducted at Pb concentrations that exceed Pb soil concentrations found in most U.S. locations. In terrestrial vertebrates, new evidence for decreased sperm count and quality in deer at a location contaminated by mining, and for decreased testis weight in lizards, support previous associations between Pb exposure and reproductive and developmental effects. Recent studies in freshwater rotifers and cladocerans provide additional evidence for reproductive and developmental effects of Pb at concentrations at or near ambient Pb levels in some aquatic species. New evidence in frogs and fish continue to support developmental and reproductive effects of Pb in aquatic vertebrates reported in earlier Pb AQCDs. Few studies are available that specifically address reproductive effects of Pb exposure in plants.

In terrestrial invertebrates, Pb can alter developmental timing, hatching success, sperm morphology, and hormone homeostasis. In fruit flies, Pb exposure increased time to pupation and decreased pre-adult development. Sperm morphology was altered in earthworms exposed to Pb-contaminated soils. Pb may also disrupt hormonal homeostasis in invertebrates as studies with moths have suggested. Evidence of multi-generational toxicity of Pb is also present in terrestrial invertebrates, specifically springtails, mosquitoes, carabid beetles, and nematodes where decreased fecundity in progeny of Pb-exposed individuals was observed. However, effects have only been studied in a small number of species and at concentrations that typically exceed Pb levels in U.S. soils.

For aquatic invertebrates, reproductive effects were reported to begin at 19 µg Pb/L for the freshwater snail *Lymnea palustris* and 27 µg Pb/L for Daphnia sp. as reported in the 1986 Pb AQCD (U.S. EPA, 1986b). Several new studies of snails, clams, and rotifers

support previous findings of adverse impacts to embryonic development. Reproductive effects have also been observed in multi-generational studies with aquatic invertebrates. Larval settlement rate and rate of population increase was decreased in rotifers and marine amphipods. Rotifers have a reduced fertilization rate associated with Pb exposure that appears to be due to decreased viability of sperm and eggs.

In aquatic vertebrates there is evidence for reproductive and developmental effects of Pb. Pb-exposure in tadpoles has been demonstrated to delay metamorphosis, decrease larval size, produce subtle skeletal malformations, and to result in slower swimming speed. Previous Pb AQCDs have reported developmental effects in fish, specifically spinal deformities in larvae at a concentration of 120 µg Pb/L. In the 2006 Pb AQCD, decreased spermatocyte development in rainbow trout was observed at 10 µg Pb/L and in fathead minnow testicular damage occurred at 500 µg Pb/L. In fish, there is new evidence in this ISA of Pb effects on steroid profiles. Reproduction in fathead minnows was affected in breeding exposures following 300-day chronic toxicity testing. However, reproductive performance was unaffected in zebrafish *Danio rerio* exposed to Pb-contaminated prey. Additional observed impacts of Pb on reproductive endpoints in fish include decreased oocyte diameter and density in toadfish, associated with elevated Pb levels in gonad.

In terrestrial vertebrates, evidence from Chapter 7 and in previous Pb AQCDs indicates an association between Pb exposure and observed adverse reproductive effects. In mammals, few studies in the field have addressed Pb specifically: most available data in wild or grazing animals are from near smelters, where animals are co-exposed to other metals. Evidence obtained using mammals in the context of human health research demonstrates adverse effects of Pb on sperm, and on onset of puberty in males and females (Chapter 5), which is coherent with the partial evidence from mammals in the wild. Other reproductive endpoints including spontaneous abortions, pre-term birth, embryo development, placental development, low birth weight, subfecundity, hormonal changes, and teratology were also affected, but less consistently. New toxicological data support trans-generational effects, a finding that is also an area of emerging interest in ecology. The evidence presented in Section 5.8 is sufficient to conclude that there is a causal relationship between Pb exposure and reproductive effects in humans and laboratory animals.

Many studies of effects on reproductive and developmental endpoints in terrestrial invertebrates and vertebrates have been conducted with soil Pb concentrations exceeding those found in most U.S. locations. Studies in this ISA include exposure-response experiments showing exposure-dependent responses with exposure increasing from background level to levels greater than near point sources. For some aquatic species,

recent evidence supports previous findings of reproductive and developmental effects of Pb and differential lifestage response at near ambient concentrations of Pb.

2.7.3.5 Effects on Growth

Evidence is sufficient to conclude that there is a causal relationship between Pb exposures and effects on growth in aquatic and terrestrial plants and aquatic invertebrates (Section 7.4.1.5, Section 7.4.2.5). Evidence is inadequate to establish a causal relationship between Pb exposures and effects on growth in terrestrial invertebrates and in terrestrial and aquatic vertebrates (Section 7.4.2.5).

Alterations in the growth of an organism can impact population, community and ecosystem level variables. Evidence for effects of Pb on growth is strongest in aquatic and terrestrial plants. In invertebrates, evidence for effects of Pb on growth has been observed most extensively in aquatic taxa, with inhibition in sensitive species occurring near the current range of Pb concentrations in surface waters. Vertebrates, particularly terrestrial, have been the object of a comparatively much smaller number of studies of the effects of Pb on growth. Growth effects observed in both invertebrates and vertebrates, however, underscore the importance of lifestage to overall Pb susceptibility. In general, juvenile organisms are more sensitive than adults. Evidence for growth effects of Pb in freshwater and terrestrial plant species is primarily supported by earlier Pb AQCDs. In aquatic invertebrates, the weight of the evidence continues to support growth effects of Pb with several new studies reporting effects at ≤ 10 µg Pb/L, specifically in snails and mussels. Also, growth effects in frogs are reported at lower concentrations in this ISA than in earlier reviews.

There is evidence over several decades of research that Pb inhibits photosynthesis and respiration in plants, both of which reduce growth (U.S. EPA, 2006b, 1977). Many laboratory and greenhouse toxicity studies have reported effects on plants. These effects are typically observed in laboratory studies with high exposure concentrations or in field studies near point sources. Pb has been shown to affect photosystem II with the hypothesized mechanism being that Pb may replace either Mg or Ca in chlorophyll, altering the pigment structure and decreasing the efficiency of visible light absorption by affected plants. Decreases in chlorophyll *a* and *b* content have been observed in various algal and plant species. Most primary producers experience EC_{50} values for growth in the range of 1,000 to 100,000 µg Pb/L with minimal inhibition of growth observed as low as 100 µg Pb/L (U.S. EPA, 2006b).

Growth effects of Pb on aquatic invertebrates are reviewed in the draft Ambient Aquatic Life Water Quality Criteria for Pb (U.S. EPA, 2008b) and the 2006 Pb AQCD. In the

2006 Pb AQCD, the LOEC for growth of freshwater amphipods *Hyalella azteca* in 42-day chronic exposure to Pb was 16 µg Pb/L (Besser et al., 2005). Recent studies provide additional evidence for effects on growth of aquatic invertebrates at ≤ 10 µg Pb/L. Growth of juvenile freshwater snails *L. stagnalis* was inhibited below the lowest concentration tested resulting in an EC_{20} <4 µg Pb/L (Grosell and Brix, 2009; Grosell et al., 2006a). In the same study, the NOEC was 12 µg Pb/L and the LOEC was 16 µg Pb/L. The authors indicated that the observed effect level for Pb was very close to the current U.S. EPA water quality criteria for Pb (3.3 µg Pb/L normalized to test water hardness) (Grosell and Brix, 2009). In the freshwater mussel, fatmucket (*L. siliquoidea*) juveniles were the most sensitive Lifestage (Wang et al., 2010e). A chronic value of 10 µg Pb/L in a 28 day exposure of 2-month-old fatmucket juveniles was the lowest genus mean chronic value ever reported for Pb. Growth effects are also reported in marine invertebrates at higher concentrations of Pb than sensitive freshwater invertebrates.

In previous Pb AQCDs, a few studies have reported growth effects of Pb on vertebrates including fish (growth inhibition), birds (changes in juvenile weight gain), and frogs (delayed metamorphosis, smaller larvae). A new study reviewed in this ISA supports findings of growth effects in frogs and suggests that these effects may be occurring at lower concentrations: the growth rate of tadpoles of the northern leopard frog exposed to 100 µg Pb/L from embryo to metamorphosis was slower than the growth rate of the controls (Chen et al., 2006b). In this study, Pb concentrations in the tissues of tadpoles were quantified and the authors reported that they were within the range of reported tissue concentrations reported in wild-caught populations. Reports of Pb-associated growth effects in fish are inconsistent.

2.7.3.6 Effects on Survival

The evidence is sufficient to conclude that there is **a** causal relationship between Pb exposures and survival in terrestrial and aquatic invertebrates and vertebrates (Section 7.4.1.6, Section 7.4.2.6). The evidence is inadequate to conclude that there is a causal relationship between Pb exposure and survival in terrestrial and aquatic plants (Section 7.4.1.6, Section 7.4.2.6). In terrestrial vertebrates and invertebrates, evidence for Pb effects on survival is primarily supported by previous Pb AQCDs with no new studies reporting effects on survival at lower concentrations. For aquatic invertebrates recent studies support previous associations between Pb exposure and mortality at concentrations near the range of Pb measured in U.S. surface waters in cladocerans, amphipods and rotifers. In aquatic vertebrates, there is new evidence for effects in fish at <100 µg Pb/L. Pb is generally not phytotoxic to aquatic or terrestrial plants at concentrations found in the environment away from point sources, probably due to the

fact that plants often sequester large amounts of Pb in roots, and that translocation to other parts of the plant is limited.

The relationship between Pb exposure and decreased survival rate has been well demonstrated in terrestrial and aquatic species, as presented in Section 7.2.5, Section 7.3.6, and Section 7.3.17.4 of this ISA (and in the previous Pb AQCDs). Toxicological studies have established LC_{50} values for some species of plants, invertebrates and vertebrates. From the LC_{50} data on Pb in this review and previous Pb AQCDs, a wide range of sensitivity to Pb is evident across taxa. LC_{50} values are usually much higher than Pb concentrations near point-sources, although physiological dysfunction that adversely impacts the fitness of an organism often occurs well below concentrations that result in mortality.

Freshwater aquatic invertebrates are generally more sensitive to Pb exposure than other taxa, with survival adversely impacted in a few species at concentrations occurring near point-sources, or at concentrations near ambient levels. These impacted species may include endangered species or candidates for the endangered species list, such as the freshwater mussel *Lampsilis rafinesqueana* (Neosho mucket), The EC_{50} for foot movement (a measure of viability) for newly transformed juveniles of this species was 188 µg Pb/L. Freshwater biota that exhibit sensitivity to Pb in the range of Pb concentrations measured in U.S. waters [median 0.50 µg Pb/L, range 0.04 to 30 µg Pb/L (U.S. EPA, 2006b)], include some species of gastropods, amphipods, cladocerans, and rotifers although the toxicity of Pb is highly dependent upon water quality variables such as DOC, hardness, and pH. Other aquatic invertebrates such as odonates may be tolerant of Pb concentrations that greatly exceed environmental levels.

Terrestrial invertebrates typically tolerate higher concentrations of Pb. In the 1986 Pb AQCD it was reported that Pb at environmental concentrations occasionally found near roadsides and smelters (10,000 to 40,000 µg Pb/g dry weight [mg Pb/kg]) can eliminate populations of bacteria and fungi on leaf surfaces and in soil. LC_{50} values for soil nematodes vary from 10-1,550 mg Pb/kg dry weight dependent upon soil OM content and soil pH (U.S. EPA, 2006b). In earthworms, 14 and 28 day LC_{50} values typically fall in the range of 2,400-5,800 mg Pb/kg depending upon the species tested.

Data on mortality of saltwater species associated with exposure to Pb is limited; however, in general, marine organisms are less sensitive to this metal than freshwater organisms and the highest toxicity is observed in juveniles. In one study, effects of Pb on survival at environmentally relevant concentrations of Pb in diet have been demonstrated though a simulated marine food chain in which the primary producer, the microalgae *T. suecica*, was exposed to 20 µg Pb/L and subsequently fed to brine shrimp *Artemia franciscana*, (mean Pb content 12 to 15 µg Pb/g) which were consumed by white-leg shrimp

Litopenaeus vannamei, itself consumed by grunt fish *H. scudderi* representing the top of the marine food chain (Soto-Jiménez et al., 2011a). Survival of brine shrimp was 25 to 35 % lower than the control and both white shrimp and grunt fish had significantly higher mortalities than controls.

In terrestrial avian and mammalian species, toxicity is observed in laboratory studies over a wide range of doses (<1 to >1,000 mg Pb/kg body weight-day) as reviewed for the development of Eco-SSL's (U.S. EPA, 2005b). The NOAELs for survival ranged from 3.5 to 3,200 mg Pb/kg • day.

In aquatic vertebrates there is considerable historic information on Pb toxicity to freshwater fish. New studies support findings in previous AQCDs of Pb effects on fish survival and indicate effects at lower concentrations in testing with juvenile lifestages. In a series of 96-hour acute toxicity tests with fathead minnow conducted in a variety of natural waters across North America, LC_{50} values ranged from 41 to 3,598 µg Pb/L and no Pb toxicity occurred in three highly alkaline waters (Esbaugh et al., 2011). Thirty day LC_{50} values for larval fathead minnows ranged from 39 to 1,903 µg Pb/L in varying concentrations of DOC, $CaSO_4$ and pH (Grosell et al., 2006a). In a recent study of rainbow trout fry at 2-4 weeks post-swim up, the 96-hour LC_{50} was 120 µg Pb/L at a hardness of 29 mg/L as $CaCO_3$, a value much lower than in testing with older fish (Mebane et al., 2008).

2.7.3.7 Community and Ecosystem Effects

More evidence for Pb toxicity to terrestrial and aquatic biota has been reported from single-species assays in laboratory studies than from whole ecosystem studies. The evidence is strong for effects of Pb on growth, reproduction and survival in very diverse species, but considerable uncertainties exist in generalizing effects observed under particular, small-scale conditions, up to the ecosystem level of biological organization. At the ecosystem level, the presence of multiple stressors, variability in field conditions, and differences in bioavailability of Pb make it difficult to measure the magnitude of effects, and to quantify relationships between ambient concentrations of Pb and ecosystem response. However, the cumulative evidence that has been reported for Pb effects at higher levels of ecological organization and for endpoints in single species with direct relevance to population and ecosystem level effects (i.e., development and reproduction, growth, survival) is sufficient to conclude that there is a likely causal relationship between Pb exposures and the alteration of species richness, species composition and biodiversity in terrestrial and aquatic ecosystems (Section 7.4.1.7, Section 7.4.2.7).

Ecosystem-level studies are complicated by the confounding of Pb exposure with other factors such as the presence of other trace metals and acidic deposition. In natural systems, Pb is often found co-existing with other stressors, and observed effects may be due to cumulative toxicity. In laboratory studies and simulated ecosystems, where it is possible to isolate the effect of Pb, this metal has been shown to alter competitive behavior of species, predator-prey interactions and contaminant avoidance. At higher levels of ecological organization, these effects may change species abundance and community structure. Uptake of Pb into aquatic and terrestrial organisms and its effects on survival, growth, physiological stress, blood, neurobehavior, and developmental and reproductive endpoints at the organism level are expected to have ecosystem-level consequences. Where evidence of effects is observed at the ecosystem level of organization, evidence from lower levels brings consistency and plausibility for causality.

Most direct evidence of community and ecosystem level effects is from near point sources where Pb concentrations are higher than typically observed in the environment. For terrestrial systems, evidence of impacts on natural ecosystems near smelters, mines, and other industrial sources of Pb has been assembled in previous decades. Those impacts include decreases in species diversity and changes in floral and faunal community composition. For aquatic systems, the literature focuses on evaluating ecological stress from Pb originating from urban and mining effluents rather than atmospheric deposition. In simulated ecosystems, where it is possible to isolate the effect of Pb, this metal has been shown to alter competitive behavior of species, predator-prey interactions and contaminant avoidance. For example, frogs and toads lack avoidance response while snails and fish avoid higher concentrations of Pb. New evidence, published since the 2006 Pb AQCD indicates that some species of worms will avoid Pb-contaminated soils (Langdon et al., 2005).These dynamics are likely to change species abundance and community structure at higher levels of ecological organization.

Recent studies continue to demonstrate associations between Pb exposures and effects at higher levels of biological organization that were shown in field and microcosm studies in previous Pb AQCDs. New studies on plant and soil microbial communities and sediment-associated and aquatic plant communities increase the total number of types of ecological associations impacted by Pb.

In terrestrial ecosystems, most studies show decreases in microorganism abundance, diversity, and function with increasing soil Pb concentration. Specifically, shifts in nematode communities, bacterial species, and fungal diversity have been observed. Furthermore, presence of arbuscular mycorrhizal fungi may protect plants growing in Pb-contaminated soils. Increased plant diversity ameliorated effects of Pb contamination on a microbial community.

In aquatic ecosystems, Pb effects reviewed in the 2006 Pb AQCD included reduced species abundance, richness and diversity, decreased primary productivity, and altered predator-prey interactions. Since the 2006 Pb AQCD, there is further evidence for effects of Pb in sediment-associated communities. Exposure to three levels of sediment Pb contamination in a microcosm experiment significantly reduced nematode diversity and resulted in profound restructuring of the community structure (Mahmoudi et al., 2007). Sediment-bound Pb contamination appears to differentially affect members of the benthic invertebrate community, potentially altering ecosystems dynamics in small urban streams (Kominkova and Nabelkova, 2005). Although surface water Pb concentrations in monitored streams were determined to be very low, concentrations of the metal in sediment were high enough to pose a risk to the benthic community (e.g., 34-101 mg Pb/kg). These risks were observed to be linked to benthic invertebrate functional feeding group, with collector-gatherer species exhibiting larger body burdens of heavy metals than benthic predators and collector-filterers.

Changes to aquatic plant community composition have been observed in the presence of elevated surface water Pb concentrations. A shift toward more Pb-tolerant species is also observed in terrestrial plant communities near smelter sites (U.S. EPA, 2006b). Certain types of plants such as rooted and submerged aquatic plants may be more susceptible to aerially-deposited Pb resulting in shifts in Pb community composition. High Pb sediment concentrations are linked to shifts in amphipod communities inhabiting plant structures.

2.8 Integration of Health and Ecological Effects

The health and ecological effects considered for causal determination are summarized in the Table 2-4. The health outcomes were nervous system, cardiovascular, renal, immune, effects on heme synthesis and RBC function, reproductive effects, and cancer. The ecological endpoints considered for causal determination were: physiological stress, hematological effects, neurobehavioral effects, developmental and reproductive effects, growth, survival, and community and ecosystem level effects. The evidence relating to specific ecological endpoints is also integrated across aquatic and terrestrial habitats. Further, the substantial overlap between the ecological and health endpoints considered in the causal determinations allowed the integration of the evidence across these disciplines.

Table 2-4 Summary of Causal Determinations[a] for Health and Ecological Effects

Outcome/Effect	Human Health Causal Determination	Ecological Receptors Causal Determination
Neurological Effects[b]	Causal Relationship	Likely Causal Relationship: Invertebrates and Vertebrates
Cardiovascular Effects	Causal Relationship	N/A[e]
Renal Effects	Causal Relationship	N/A[e]
Immune System Effects	Causal Relationship	N/A[e]
Heme Synthesis and RBC Function[c]	Causal Relationship	Causal Relationship: Terrestrial Vertebrates, Aquatic Invertebrates and Vertebrates
Reproductive Effects and Birth Outcome[d]	Causal Relationship	Causal Relationship: Invertebrates and Vertebrates Inadequate to Infer Causal Relationship: Plants
Cancer	Likely to be a causal relationship	N/A[e]
Mortality	N/A[e] (The strongest evidence of Pb-induced mortality in humans was observed for cardiovascular disease related mortality and this evidence was considered in determining the causal relationship between Pb exposure and cardiovascular effects.)	Causal Relationship: Invertebrates and Vertebrates Inadequate to Infer Causal Relationship: Plants
Growth	N/A[e] (There is evidence from toxicological and epidemiologic studies of Pb effects on fetal and postnatal growth, which was considered in determining the causal association between Pb exposure and reproductive and developmental effects.)	Causal Relationship: Plants and Aquatic Invertebrates Inadequate to Infer Causal Relationship: Vertebrates and Terrestrial Invertebrates
Physiological Stress	N/A[e] (In Human Health, oxidative stress was considered as a upstream event in the modes of action of Pb, leading downstream to various effects. Ecological literature commonly uses oxidative stress as a proxy indicator of overall fitness, and thus treats it as an effect.)	Causal Relationship
Community and Ecosystem Level Effects	N/A[e]	Likely Causal Relationship

[a]Based upon the framework described in the Preamble, a determination of causality for health effects was made for a broad outcome category (i.e., nervous system effects) by evaluating the coherence of evidence across disciplines and across a spectrum of related endpoints. However, the evidence on which the causal judgment is based, including the strength of evidence for the individual endpoints within the major outcome category, is characterized within the discussion. Causal determinations were made within approximately 1-2 orders of magnitude of current levels.

[b]In ecological receptors, the causal determination was developed considering neurobehavioral effects that can be observed in toxicological studies of animal models and studies of ecological effects in vertebrates and invertebrates. The human epidemiologic evidence evaluated included a wider range of health endpoints such as cognition.

[c]The health hematological effects considered in the determination of causality were primarily heme synthesis and RBC function. The ecological evidence considered for the causal determination included heme synthesis, blood cell count, and altered serum profiles.

[d] Reproductive health effects, including effects on sperm, as well as birth outcomes such as spontaneous abortion, were considered in the causal determination. In the ecological literature, a wide range of endpoints, including embryonic development, multigenerational studies, delayed metamorphosis, and altered steroid profiles, was considered.

[e]N/A, not applicable, i.e., for health effects no causal determination for this specific endpoint, considered within the causal determination for the larger outcome category; for ecological effects there was no comparable endpoint.

2.8.1 Modes of Action Relevant to Downstream Health and Ecological Effects

The diverse health and ecological effects of Pb are mediated through multiple, interconnected modes of action. This section summarizes the principal cellular/subcellular effects contributing to modes of action for human health endpoints associated with Pb exposure and the concentrations at which those effects are observed. Then, effects of Pb observed in aquatic and terrestrial species (Section 2.7) are evaluated along with evidence from epidemiological and laboratory animal studies to determine the extent to which common modes of action can be inferred from the observed effects. The rationale for this approach is that the mechanism of Pb toxicity is likely conserved from invertebrates to vertebrates to humans in some organ systems.

Each of the modes of action discussed in Section 5.2 has the potential to contribute to the development of a number of Pb-induced health effects (Table 2-5). Evidence for the majority of these modes of action is observed at low blood Pb levels in humans and laboratory animals, between 2 and 5 µg/dL, and at doses as low as the picomolar range in animals and cells. The concentrations eliciting the modes of action (reported in Table 2-5) are drawn from the available data and do not imply that these modes of action are not acting at lower exposure levels or that these doses represent the threshold of the effect. Also, the data in presented this table does not inform regarding the exposure frequency and duration required to elicit a particular MOA.

Table 2-5 MOAs, their related health effects, and information on concentrations eliciting the MOAs

Mode of Action [Related Health Effects (ISA Section)]	Concentrations or doses (Conditions)[a]	
	Blood Pb	Dose
Altered Ion Status [All Health Effects of Pb]	3.5 µg/dL (mean in cord blood; association with cord blood Ca^{2+}-ATPase pump activity) Huel et al. (2008)	0.00005 µM free Pb^{2+} (In vitro; 30 minutes; calmodulin activation assay) Kern et al. (2000)
Protein Binding [Renal (5.5), Heme Synthesis and RBC Function (5.7)]	17.0 µg/dL (concurrent mean in adult workers with wildtype metallothionein expression; increased BP susceptibility) Chen et al. (2010a)	50 µM Pb glutamate (In vitro; 24 hours; increased nuclear protein in neurological cell) Klann and Shelton (1989)
Oxidative Stress [All Heath Effects of Pb]	5.4 µg/dL (concurrent mean in adult male workers; decreased CAT activity in blood) Conterato et al. (In Press)	0.1 µM Pb-acetate (In vitro; 48 hours; decreased cellular GSH in neuroblastoma cells) Chetty et al. (2005)
Inflammation [Nervous System (5.3), Cardiovascular (5.4), Renal (5.5), Immune (5.6), Respiratory (5.6.4), Hepatic (5.9.1)]	2.5 µg/dL (concurrent minimum in adult males; increased serum TNF-α and blood WBC count) Kim et al. (2007)	0.01 µM Pb-acetate (In vitro; 48 hours; increased cellular PGE_2 in neuroblastoma cells) Chetty et al. (2005)
Endocrine Disruption [Reproductive and Developmental Effects (5.8), Endocrine System (5.9.3), Bone and Teeth (5.9.4)]	1.7 µg/dL (concurrent minimum in women with both ovaries removed; increased serum FSH) Krieg (2007)	10 µM Pb nitrate (In vitro; 30 minutes; displaced GHRH binding to rat pituitary receptors) Lau et al. (1991)
Cell Death/Genotoxicity [Cancer (5.10), Reproductive and Developmental Effects (5.8), Bone and Teeth (5.9.4)]	3.3 µg/dL (concurrent median in adult women; increased rate of HPRT mutation frequency) Van et al. (2004)	0.03 µM Pb-acetate (In vitro; 18 hours; increased formation of micronuclei) Bonacker et al. (2005)

[a] This table provides examples of studies that report effects with low doses or concentration; they are not the full body of evidence used to characterize the weight of the evidence. In addition, the levels cited are reflective of the data and methods available and do not imply that these modes of action are not acting at lower Pb exposure or blood Pb levels or that these doses represent the threshold of the effect. Additionally, the blood concentrations and doses (indicating Pb exposure concentrations from in vitro systems) refer to the concentrations and doses at which these modes of action were observed. While the individual modes of action are related back to specific health effects sections (e.g., Nervous System, Cardiovascular), the concentrations and doses given should not be interpreted as levels at which those specific health effects occur.

Ecosystem studies have presented evidence for the occurrence of many of these modes of action in animals, and to some degree in plants, however the connection to ecological outcomes must usually be inferred because ecological studies are typically not designed to address mode of action directly. The level at which Pb elicits a specific effect is more difficult to establish in terrestrial and aquatic systems due to the influence of environmental variables on Pb bioavailability and toxicity and substantial species differences in Pb susceptibility.

The alteration of cellular ion status (including disruption of Ca^{2+} homeostasis, altered ion transport mechanisms, and perturbed protein function through displacement of metal cofactors) appears to be the major unifying mode of action underlying all subsequent

modes of action in plants, animals, and humans (Figure 5-1). Pb can interfere with endogenous cation homeostasis, necessary as a cell signal carrier mediating normal cellular functions. Pb is able to displace metal ions, such as Zn, Mg, and Ca^{2+}, from proteins due to the flexible coordination numbers and multiple ligand binding ability of Pb, leading to abnormal conformational changes to proteins and altered protein function. Disruption of ion transport leading to increased intracellular Ca^{2+} levels is due in part to the alteration of the activity of transport channels and proteins, such as Na^{+}-K^{+} ATPase and voltage-sensitive Ca^{2+} channels. Pb can interfere with these proteins through direct competition between Pb and the native metals present in the protein metal binding domain or through disruption of proteins important in calcium-dependent cell signaling, such as PKC or calmodulin.

This competition between metals has been reported not only in human systems, but also in fish, snails, and plants. Altered Ca^{2+} channel activity and binding of Pb with Na^{+}-K^{+} ATPase in the gills of fish disrupts the Na^{+} and Cl^{-} homeostasis, which may lead to ionoregulatory failure and death. Ca^{2+} influx and ionoregulation has also been shown to be inhibited by Pb exposure in a sensitive species of snail, leading to a reduction in snail growth. In plants, substitution of the central atom of chlorophyll, Mg, by Pb prevents light-harvesting, resulting in a breakdown of photosynthesis. Pb-exposed animals also have decreased cellular energy production due to perturbation of mitochondrial function.

Disruption of ion transport not only leads to altered Ca^{2+} homeostasis, but can also result in perturbed neurotransmitter function. Evidence for these effects in Pb-exposed experimental animals and cell cultures has been linked to altered neurobehavioral endpoints and other neurotoxicity. Neurobehavioral changes that may decrease the overall fitness of the organism have also been observed in aquatic and terrestrial invertebrate and vertebrate studies. There is evidence in tadpoles and fish to suggest Pb may alter neurotransmitter concentrations, possibly resulting in some of these neurobehavioral changes.

Altered cellular ion status following Pb exposure can result in the inhibition of heme synthesis. Pb exposure is commonly associated with altered hematological responses in aquatic and terrestrial invertebrates, experimental animals, and human subjects. The proteins affected by Pb are highly conserved across species accounting for the common response seen in human health and ecological studies. This evolutionarily conserved response to Pb is likely the result of the competition of Pb with the necessary metal cofactors in the proteins involved in heme synthesis.

Although Pb will bind to proteins within cells through interactions with side group moieties, thus potentially disrupting cellular function, protein binding of Pb may represent a mechanism by which cells protect themselves against the toxic effects of Pb.

Intranuclear and intracytosolic inclusion body formation has been observed in the kidney, liver, lung, and brain following Pb exposure in experimental animals. A number of unique Pb binding proteins have been detected, constituting the observed inclusion bodies. The major Pb binding protein in blood is ALAD with carriers of the ALAD-2 allele potentially exhibiting higher Pb binding affinity. Inhibition of ALAD activity is a widely recognized response to Pb in environments where Pb is present and is considered to be biomarker of Pb exposure in both terrestrial and aquatic biota. Additionally, metallothionein is an important protein in the formation of inclusion bodies and mitigation of the toxic effects of Pb. Protein binding of Pb is a recognized mechanism of Pb detoxification in some terrestrial and aquatic biota. For example, plants can sequester Pb through binding with phytochelatin and some fish have the ability to store accumulated Pb in heat-stable proteins.

A second major mode of action of Pb is the development of oxidative stress, due in many instances to the antagonism of normal metal ion functions. Disturbances of the normal redox state of tissues can cause toxic effects and is involved in the majority of health and ecological outcomes observed after Pb exposure. The origin of oxidative stress produced after Pb exposure is likely a multi-pathway process. Studies in humans and experimental animals provide evidence to conclude that oxidative stress results from oxidation of δ-ALA, NAD(P)H oxidase activation, membrane and lipid peroxidation, and antioxidant enzyme depletion. Evidence of increased lipid peroxidation associated with Pb exposure exists for many species of plants, invertebrates, and vertebrates. Enhanced lipid peroxidation can also result from Pb potentiation of Fe^{2+} initiated lipid peroxidation and alteration of membrane composition after Pb exposure. Increased Pb-induced ROS will also sequester and inactivate biologically active $^{\bullet}NO$, leading to the increased production of the toxic product nitrotyrosine, increased compensatory NOS, and decreased sGC protein. Pb-induced oxidative stress not only results from increased ROS production but also through the alteration and reduction in activity of the antioxidant defense enzymes. The biological actions of a number of these enzymes are antagonized due to the displacement of the protein functional metal ions by Pb. Increased ROS are often followed by a compensatory and protective upregulation in antioxidant enzymes, such that this observation is indicative of oxidative stress conditions. A number of studies in plants, invertebrates, and vertebrates present evidence of increased antioxidant enzymes with Pb exposure. Additionally, continuous ROS production may overwhelm this defensive process leading to decreased antioxidant activity and further oxidative stress and injury.

In a number of organ systems Pb-induced oxidative stress is accompanied by misregulated inflammation. Pb exposure will modulate inflammatory cell function, production of proinflammatory cytokines and metabolites, inflammatory chemical

messengers, and proinflammatory signaling cascades. Cytokine production is skewed toward the production of proinflammatory cytokines like TNF-α and IL-6 as well as leading to the promotion of Th2 response and suppression of Th1cytokines and Th1-related responses.

Pb is a potent endocrine disrupting chemical. Steroid receptors and some endocrine signaling pathways are known to be highly conserved over a broad expanse of animal phylogeny. Pb will disrupt the HPG axis evidenced in humans, other mammals, and fish, by a decrease in serum hormone levels, such as FSH, LH, testosterone, and estradiol. Pb interacts with the hypothalamic-pituitary level hormone control causing a decrease in pituitary hormones, altered growth dynamics, inhibition of LH secretion, and reduction in StAR protein. Pb has also been shown to alter hormone receptor binding likely due to interference of metal cations in secondary messenger systems and receptor ligand binding and through generation of ROS. Pb disrupts hormonal homeostasis in invertebrates necessary for reproduction and development. Pb also may disrupt the HPT axis by alteration of a number of thyroid hormones, possibly due to oxidative stress. These studies have been conducted in humans and animals, including cattle; however the results of these studies are mixed and require further investigation.

Genotoxicity and cell death has been investigated after Pb exposure in humans, animals, plants, and cell models. High level Pb exposure to humans leads to increased DNA damage, however lower blood Pb levels have caused these effects in experimental animals and cells. Reports vary on the effect of Pb on DNA repair activity, however a number of studies report decreased repair processes following Pb exposure. There is some evidence in plants, earthworms, freshwater mussels and fish for DNA damage associated with Pb exposure. There is evidence of mutagenesis and clastogenicity in highly exposed humans, however weak evidence has been shown in animals and cells based systems. Human occupational studies provide limited evidence for micronucleus formation (>10 µg/dL), supported by Pb-induced effects in both animal and cell studies. Micronucleus formation has also been reported in amphibians. Animal and plant studies have also provided evidence for Pb-induced chromosomal aberrations. The observed increases in clastogenicity may be the result of increased oxidative damage to DNA due to Pb exposure, as co-exposures with antioxidants ameliorate the observed toxicities. Limited evidence of epigenetic effects is available, including DNA methylation, mitogenesis, and gene expression. Altered gene expression may come about through Pb displacing Zn from multiple transcriptional factors, and thus perturbing their normal cellular activities. Consistently positive results have provided evidence of increased apoptosis following Pb exposure.

Overall, Pb-induced health and ecological effects can occur through a number of interconnected and evolutionarily well conserved modes of action that generally originate with the alteration of ion status.

2.9 Policy Relevant Considerations

2.9.1 Public Health Significance

The weight of the epidemiologic and toxicological evidence clearly supports the causal relationship of Pb with decrements in cognitive function and behavior in young children (Section 5.3.2 and Section 5.3.13). Associations of blood Pb level with higher IgE, asthma and allergy (Section 5.6.8) and delays in the pubertal development in children (Section 5.8.10), as well as associations of blood and bone Pb with increased blood pressure, hypertension (Section 5.4.7), and kidney function (Section 5.5.6) in adults are also well-substantiated in the evidence base. These endpoints were among those comprising the weight of the evidence for determining causal relationships for the organ system effects.

The rationale for establishing the public health significance of the various health endpoints associated with Pb exposure is multifaceted. The 2006 Pb AQCD concluded that neurological effects in children and cardiovascular effects in adults were among the effects best substantiated as occurring at blood Pb levels as low as 5-10μg/dL (or possibly lower), and that these categories of effects were clearly of the greatest public health concern. Evidence of newly demonstrated immune and renal system effects in the general population was also noted to be of potential public health concern during the previous review (U.S. EPA, 2006b). No safe level of Pb exposure has been identified in current or previous assessments and any threshold for Pb neurotoxicity would have to exist at distinctly lower levels than those associated with the lowest blood Pb concentrations examined in the epidemiologic studies included in this assessment. Recent epidemiologic studies of children continue to find associations with several health endpoints in populations with lower mean blood Pb levels than previously reported (Chapter 5, Table 2-9).

The concept of population risk is relevant to the interpretation of findings for the continuously-distributed subclinical health endpoints frequently studied in association with Pb biomarkers in the assessment of their public health significance. The World Health Organization definition of “health” is “the state of complete physical, mental and social well-being and not merely the absence of disease or infirmity” (WHO, 1948). By

this definition, even decrements in health status that are not severe enough to result in the assignment of a clinical diagnosis might be undesirable if they reflect a decrement in the well-being of an individual. Further, deficits in subtle indices of health or well-being may not be observable except in aggregate, at the population level, so the critical distinction between population and individual risk is essential for interpreting the public health significance of study findings. The American Thoracic Society (ATS) discusses concepts related to understanding the shift in a population distribution of a health endpoint (ATS, 2000). As shown in Figure 2-1, a seemingly small increase in the mean of a continuously distributed health index may push the most susceptible group in the population above a critical cut point on the continuum of disease development, such that their condition meets the clinical definition of a disease. Moreover, small changes at the population level could translate into large numbers of clinical events if a large population is affected.

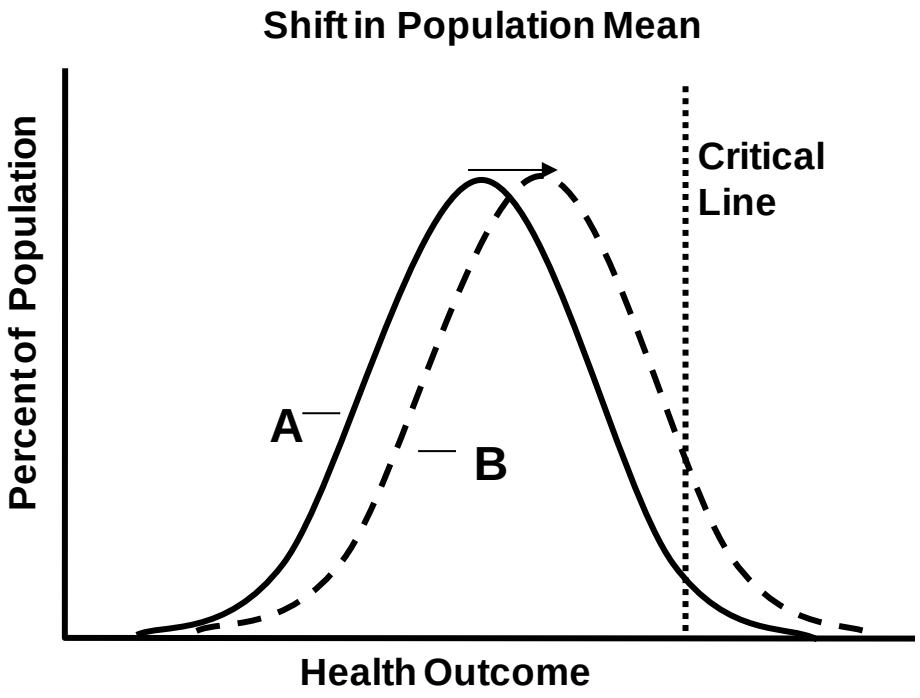


Figure 2-1 The effect of a small shift in population mean on the proportion of individuals in the population diagnosed with clinical disease (i.e., the proportion to the right of the "Critical Line.")

As shown in Table 2-6, the size of the Pb-associated effects observed in epidemiologic studies may be small relative to the effect sizes that are considered clinically relevant. Still, these small shifts in population means are often significant from a public health perspective. For example, small changes in IQ or inattention are often significant at the

population level, especially in the two tails of the outcome distribution. Further, a small shift in the population mean may result in a substantial increase in the number of individuals functioning in the low range of the IQ distribution who may fall into the IQ range associated with increase risk of educational, vocational, and social failure after experiencing a Pb-associated decrement in IQ. In cohorts of children where Pb-associated decrements in cognition and attention were observed, lower academic performance, antisocial behavior, or delinquent behavior assessed in adolescence or in early adulthood were also observed in association with blood Pb levels. Studies also find that higher blood Pb level is associated with measures of inattention and hyperactivity as well as with ADHD or other diagnostic indices used in a clinical setting (Section 5.3.3.1). A downward shift in the mean IQ value can also reduce the proportion of the population achieving very high IQ scores. It is shown that interventions that shift the population mean, in a beneficial direction, by an amount that is without clinical consequence for an individual produce substantial decreases in the proportion of individuals with clinically significant disorders. This evidence, which informs the public health significance of the evidence on the nervous system effects of Pb, is summarized in detail in Section 5.3.12.

It is also important to note that the change in a population mean observed in an epidemiologic study may be small compared to its standard error of measurement for the test. As noted in the 2006 Pb AQCD, statistics that pertain to individual-level data should not be used to draw inferences about group-level data. Measurement error affects the likelihood of detecting an association and is not relevant to the size of the association that is detected. If a study is large enough it will have adequate statistical power to detect small changes. Bias may be introduced if the measurement error of the outcome is highly correlated with the exposure and there is no evidence indicating that individuals with higher blood Pb levels test systematically lower than their true IQ.

Pb-associated changes in other subclinical indices also increase an individual's risk for health effects that are of greater clinical consequence, thus of greater public health concern. Small increases in blood pressure or decreases in GFR that are associated with Pb biomarkers, may shift the population mean resulting in a larger proportion of the population that is diagnosed with hypertension or CKD, respectively. Results from the Framingham Heart Study show that higher levels of blood pressure, even within the nonhypertensive range, impose increased rates of cardiovascular disease (Kannel, 2000a, b). A continuous graded increase in cardiovascular risk is observed as blood pressure increases, with no evidence of a threshold value. Most events arise not in the most severe cases, but mainly in those with high normal blood pressure (i.e., mild hypertension). Kannel (2000a) emphasized that systolic blood pressure exerts a strong influence on more serious cardiovascular events, as it is the primary cause of hypertension and its adverse cardiovascular sequelae. In addition to the small increases in blood pressure associated

with Pb, Pb-associated effects on cardiovascular morbidity outcomes such as ischemic heart disease (Section 5.4.3.5) and mortality (Section 5.4.5) have been observed. The high correlation between blood pressure and clinical cardiovascular outcomes combined with the high prevalence of cardiovascular disease in the U.S. adult population translate into a large increase in the prevalence of conditions in the population. In addition to the small changes in markers of kidney function, which are potentially significant from a public health perspective, Navas-Acien (2009) and Munter et al. (2003) both report increased risk of clinically significant CKD and albuminuria in association with Pb among NHANES III participants. CKD results in substantial morbidity and mortality, and, even at earlier stages than those requiring kidney dialysis or transplantation, is an important risk factor for heart disease. As kidney dysfunction can increase BP and increased BP can lead to further damage to the kidneys, Pb-induced damage to either or both renal or cardiovascular systems may result in a cycle of further increased severity of disease.

Table 2-6 Illustrative examples contrasting the effect sizes observed in epidemiologic studies to effect sizes considered significant in a clinical setting.[a]

Organ System	Endpoint and Findings from Epidemiologic Studies	Clinical Significance Context
Nervous	IQ: 1 µg/dL increase in blood Pb is typically associated with small decrement in IQ (e.g., < 3 point decrement in FSIQ score)	IQ below 70 is considered a disability by the Social Security Disability Insurance Administrationb
Cardiovascular	Systolic Blood Pressure (SBP): Doubling of blood Pb is associated with an approximate 1 mmHg increase in blood pressure (Nawrot et al., 2002)	Hypertension is defined as systolic over diastolic blood pressure that is greater than 140/90. Pre-hypertension is blood pressure that is 120 to 139/80 to 89. Hypertension is a risk factor for other cardiovascular diseases and mortality.
Renal[a]	Glomerular Filtration Rate (GFR): Increased blood Pb level is associated with reductions in GFR (e.g., Akesson et al. (2005) reports a decrease of -2.0 mL/min (95% CI: -3.2, -0.9) per 1 µg/dL increase in blood Pb)	GFR <60mL/min/1.73m2 for ≥ 3 months indicates Chronic Kidney Disease (CKD). Estimated GFR (eGFR) can be calculated using several different equations. An equation using serum cystatin C rather than serum creatinine may be a more sensitive marker of early kidney damage.
	Serum Creatinine: Increased blood Pb is associated with increased serum creatinine (e.g., (Kim et al., 1996) observed an increase 0.030 mg/g (95% CI: 0.011, 0.049) among those with peak blood Pb levels < 10 µg/dL).	Creatinine ≥ 30 mg/g creatinine indicates albuminuria.
	Creatinine Clearance: [Increased blood Pb is associated with decreased creatinine clearance (e.g., Akesson et al. (2005) reports a -1.8 mL/min (95% CI: -3.0, 0.7) per 1 µg/dL increase in blood Pb)	Normal values range from 97 to 137 mL/min (males) and 88 to 128 mL/min (females). Abnormal results indicate poor kidney function.

[a]Effect sizes based on general population studies

[b]Information on Adult Mental Disorders can be found at: http://www.socialsecurity.gov/disability/professionals/bluebook/12.00-MentalDisorders-Adult.htm

Rather than producing overt cytotoxicity or pathology, blood Pb level is associated with alterations in several subclinical parameters related to cellular and humoral immunity (Figure 5-42). Increases in IgE may contribute to more consequential health conditions including allergy and asthma and the small changes observed in epidemiologic studies may result in a population shift and increased prevalence of these conditions. Several studies found associations between blood Pb levels and asthma and allergy in children (Section 5.6.4.2). Immune changes may also be associated with autoimmune diseases later in life as well as reduced capacity to combat certain viral infections and cancer. Although the public health significance of a delay in onset of puberty is less clear, there is some limited evidence that delay in puberty is associated with other health outcomes (Gilsanz et al., 2011; Naves et al., 2005).

There is a new body of literature suggesting there may be relationship between maternal bone Pb, cord Pb and/or concurrent blood Pb and cardiovascular effects in children including increased blood pressure, Total Peripheral Resistance (TPR) responses to acute stress tasks, and acute stress-induced autonomic and cardiovascular dysregulation (Section 5.4.4). This evidence, however, is difficult to interpret with respect to the risk

for health effects because cardiovascular and renal effects are associated with long-term exposures to Pb and there is uncertainty regarding the frequency, timing, duration and level of exposure associated with the effects. There is some evidence that the pathogenesis of CVD begins in childhood (Kapuku et al., 2006). Although compensatory mechanisms may be more active in children compared to adults, these early cardiovascular effects may persist and worsen if Pb exposure persists over the long-term. A recent study that strengthens the evidence of an association between blood Pb and altered renal function in children is included in this review. This NHANES analysis in adolescents found that association between higher blood Pb and lower cystatin C-based eGFR (Section 5.5.6). This association is reported in a population with mean blood Pb levels less than 5 μg/dL; however, those enrolled in the study were likely to have higher past than recent Pb exposure and the pattern and level of their exposure was not assessed in the study.

In addition to the long-term effects of Pb, early life exposure to Pb (postnatally) may permanently alter normal development of the CNS to increase risk of pathology in adults (Section 5.3.2.2). For example connections between developmental exposure to Pb with early life programming and the resulting inflammation-associated DNA damage with neurodegeneration have been demonstrated in rats. Additionally, there is animal toxicological evidence for a Pb exposure contribution to Alzheimer's disease pathology through the generation of neuronal plaques is in early life (Section 5.3.7.2). Early life Pb exposure is also associated with impaired auditory function (Section 5.3.4.3).

2.9.2 Air Lead-to-Blood Lead Relationships

The 1986 Pb AQCD described epidemiological studies of relationships between air Pb and blood Pb. Much of the pertinent earlier literature described in the 1986 Pb AQCD was drawn from a meta-analysis by Brunekreef (1984). Based on the studies available at that time that considered multiple air-related Pb exposure pathways in the aggregate, the 1986 Pb AQCD concluded that "the blood Pb versus air Pb slope β is much smaller at high blood and air levels." This is to say that the slope β was much smaller for occupational exposures where high blood Pb levels (>40 μg/dL) and high air Pb levels (much greater than 10 $\mu g/m^3$) prevailed relative to lower environmental exposures which showed lower blood Pb and air Pb concentrations (<30 μg/dL and <3 $\mu g/m^3$). For those environmental exposures, it was concluded that the relationship between blood Pb and air Pb "…for direct inhalation appears to be approximately linear in the range of normal ambient exposures (0.1-2.0 $\mu g/m^3$)" (pp 1–98 of the 1986 Pb AQCD). In addition to the meta-analysis of Brunekreef (1984), more recent studies have provided data from which estimates of the blood Pb-air Pb slope can be derived for children (Table 2-7, Table

4-11). The range of estimates from these studies is 2-9 µg/dL per µg/m^3, which encompasses the estimate from the Brunekreef (1984) meta-analysis of (3-6 µg/dL per µg/m^3). Most studies have described the blood Pb-air Pb relationship as either log-log (Schnaas et al., 2004; Hayes et al., 1994; Brunekreef, 1984), which predicts an increase in the blood Pb-air Pb slope with decreasing air Pb concentration or linear (Hilts, 2003; Tripathi et al., 2001; Schwartz and Pitcher, 1989), which predicts a constant blood Pb-air Pb slope across all air Pb concentrations. These differences may simply reflect model selection by the investigators; alternative models are not reported in these studies.

The blood Pb-air Pb slope may also be affected in some studies by the inclusion of parameters (e.g., soil Pb) that may account for some of the variance in blood Pb attributable to air Pb. Other factors that likely contribute to the derived blood Pb-air Pb slope include differences in the populations examined and Pb sources, which varied among individual studies. See Section 4.5.1 for a detailed discussion of studies that inform air Pb-to blood-Pb relationships.

Table 2-7 Summary of Estimated Slopes for Blood Pb to Air Pb Relationships in Humans

Reference	Study Methods	Model Description	Blood Pb–Air Pb Slope[a]
Children Populations			
Brunekreef et al. (1984)	**Location:** Various countries **Years:** 1974-1983 **Subjects:** Children (varying age ranges, n>190,000) **Analysis:** Meta analysis of 18 studies	**Model:** Log-Log **Blood Pb:** 5-41 µg/dL (mean range for studies) **Air Pb:** 0.1-24 µg/m^3 (mean range for studies)	**All children:** 4.6 (1.5)[c] **Children <20 µg/dL:** 4.8 (0.54)[d]
Hayes et al. (1994)	**Location:** Chicago, IL **Years:** 1974-1988 **Subjects:** 0.5-6 yr (n = 9,604) **Analysis:** Regression of quarterly median blood Pb and quarterly mean air Pb	**Model:** Log-Log **Blood Pb:** 12-30 µg/dL (annual median range) **Air Pb:** 0.05-1.2 µg/m^3 (annual mean range)	8.2 (0.62)[e]
Hilts et al. (2003)	**Location:** Trail, BC **Years:** 1989-2001 **Subjects:** 0.5-6 yr (Estimated n = 220-460, based on 292-536 blood Pb measurements/yr with 75-85% participation). **Analysis:** Regression of blood Pb screening and community air Pb following upgrading of a local smelter	**Model:** Linear Blood Pb: 4.7-11.5 µg/dL (annual geometric mean range) **Air Pb:** 0.03-1.1 µg/m^3 (annual geometric mean range)	6.5 (0.48)[f]
Ranft et al. (2008)	**Location:** Germany **Years:** 1983-2000 **Subjects:** 6-11 yr (n = 843) **Analysis:** Pooled regression 5 cross-sectional studies	**Model:** Multivariate Log-Linear **Blood Pb:** 2.2-13.6 µg/dL (5th-95th percentile) **Air Pb:** 0.03-0.47 µg/m^3 (5th-95th percentile)	3.2 (0.1)[g]
Schnaas et al. (2004)	**Location:** Mexico City **Years:** 1987-2002 **Subjects:** 0.5-10 yr (n = 321) **Analysis:** Regression of lifetime blood Pb from longitudinal blood Pb measurements and annual average air Pb data	**Model:** Log-Log **Blood Pb**: 5-12 µg/dL (annual GM range) **Air Pb**: 0.07-2.8 µg/m^3 (annual mean range in yr of birth)	2.2 (0.4)[h]
Schwartz and Pitcher (1989), U.S. EPA (1986a)	**Location:** Chicago, IL **Years:** 1976-1980 **Subjects**: Black children, 0-5 yr (n = 5,476) **Analysis:** Chicago blood Pb screening, gasoline consumption data, and Pb concentrations in gasoline	**Model:** Linear **Blood Pb:** 18-27 µg/dL (mean range) **Air Pb:** 0.36-1.22 µg/m^3 (annual maximum quarterly mean)[b]	8.6 (0.75)[i]
Tripathi et al. (2001)	**Location:** Mumbai, India **Years:** 1984-1996 **Subjects:** 6-10 yr (n = 544) **Analysis:** Regression of blood Pb and air Pb data	**Model:** Linear **Blood Pb:** 8.6-14.4 µg/dL (regional GM range) **Air Pb:** 0.11-1.18 µg/m^3 (regional GM range)	3.6 (0.45)[j]

Reference	Study Methods	Model Description	Blood Pb–Air Pb Slope[a]
Adult Populations			
Rodrigues et al. (2010)	**Location:** New England, U.S. **Years:** 1994-1995 **Subjects:** Adult bridge painters (n=84, 1 female) **Analysis:** Regression analysis of blood Pb and air Pb data (personal monitors) collected during work performing various job-related tasks	**Model:** Log-log **Blood Pb:** 16.1 µg/dL (GM, 1,7 GSD) **Air Pb**: 58 µg/m^3 (GM, 2.8 GSD)	0.01 (58)[k]
Mixed Child-Adult Populations			
Schwartz and Pitcher (1989), U.S. EPA (1986a)	**Location:** U.S. **Years:** 1976-1980 **Subjects:** 0.5-74 yr (n = 9,987) **Analysis:** NHANES blood Pb, gasoline consumption data and Pb concentrations in gasoline	**Model:** Linear **Blood Pb:** 11-18 µg/dL (mean range) **Air Pb:** 0.36-1.22 µg/m^3 (annual maximum quarterly mean)	9.3 (0.75)[l]

[a]Slope is predicted change in blood Pb (µg/dL per µg/m3) evaluated at ± 0.01 µg/m3 from central estimate of air Pb for the study (shown in parentheses)
[b]Based on data for U.S. (1986 Pb AQCD).
[c]ln(PbB) = ln(PbA) × 0.3485 + 2.853
[d]ln(PbB) = ln(PbA) × 0.2159 + 2.620
[e]ln(PbB) = ln(PbA) × 0.24 +3.17
[f]PbB = PbA × 6.5
[g]PbB =1.5 × EXP(0.9361 × (PbA-0.1)/0.44), where 1.5 µg/dL is the background PbB, and 0.1 µg/m^3 is the median PbA for the study; model also adjusted for soil Pb concentration, which may reduce estimated slope
[h]ln(PbB) = Ln(PbA) × 0.213 +1.615 for the 1987 cohort, see text in Section 4.5.1 for more study details.
[i]PbB = PbA × 8.6
[j]PbB =Pb A × 3.6
[k]ln(PbB) = ln(PbA) × 0.05 +2.12
[l]PbB = PbA × 9.63

GM, geometric mean; GSD, geometric standard deviation; PbB, blood Pb concentration (µg/dL); PbA, air-Pb concentration (µg/m^3)

2.9.3 Ecological Effects and Corresponding Lead Concentrations

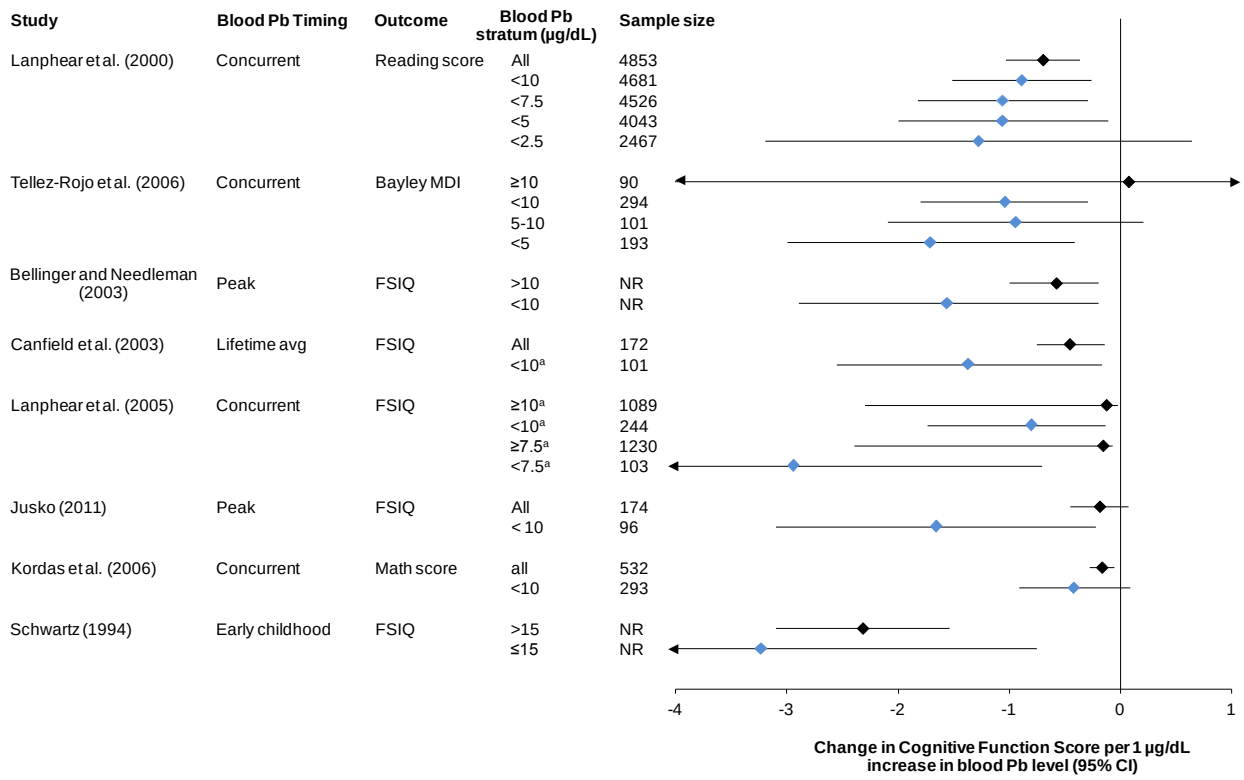
There is limited evidence to relate ambient air concentrations of Pb to levels of deposition onto terrestrial and aquatic ecosystems and to subsequent movement of atmospherically-deposited Pb through environmental compartments (e.g., soil, sediment, water, biota). The proportion of observed effects of Pb attributable to Pb from atmospheric sources is difficult to assess due to a lack of information not only on bioavailability, as affected by the specific characteristics of the receiving ecosystem, but also on deposition, and on kinetics of Pb distribution in ecosystems in long-term exposure scenarios. Therefore, the connection between air concentration and ecosystem exposure continues to be poorly characterized for Pb, and the contribution of atmospheric Pb to specific sites is not clear.

Furthermore, the level at which Pb elicits a specific effect is difficult to establish in terrestrial and aquatic systems, due to the influence of other environmental variables on both Pb bioavailability and toxicity, and also to substantial species differences in Pb susceptibility. Current evidence indicates that Pb is bioaccumulated in biota; however,

the sources of Pb in biota have only been identified in a few studies, and the relative contribution of Pb from all sources is usually not known. There are large differences in species sensitivity to Pb, and many environmental variables (e.g., pH, organic matter) determine the bioavailability and toxicity of Pb.

2.9.4 Concentration-Response Functions for Health Effects

With each successive assessment to-date, the epidemiologic and toxicological study findings show that progressively lower blood Pb levels or Pb exposures are associated with cognitive deficits and behavioral impairments (Section 5.3.9). C-R functions have been examined across different populations and the interpretation of these functions depends on several factors including lifestage and Pb biomarker used for the analysis. Compelling evidence for a steeper slope for the relationship between blood Pb level and children's IQ at lower blood Pb levels was presented in the 2006 Pb AQCD based on the international pooled analysis of seven prospective cohort studies by Lanphear et al. (2005), a subsequent reanalysis of these data focusing on the shape of the concentration response function (Rothenberg and Rothenberg, 2005), and several individual studies noted in Figure 2-2. The majority of the epidemiologic evidence from stratified analyses comparing the lower and the higher ends of the blood Pb distributions indicates larger negative slopes at lower blood Pb levels.



Note: Studies are presented in order of increasing mean blood Pb level.
[a]Strata refer to peak blood Pb level measured in child at any point during follow up.
FSIQ = full-scale IQ, MDI = mental development index. Effect estimates are standardized to a 1 µg/dL increase in blood Pb level.
Black symbols represent effect estimates among all subjects or in highest blood Pb stratum. Blue symbols represent effect estimates in lower blood Pb strata.

Figure 2-2 Comparison of associations between blood Pb and cognitive function among various blood Pb strata.

Relatively few studies examined the shape of the concentration-response relationship between Pb in blood or bone and effects in adults. There is uncertainty regarding the frequency, duration, timing and level of exposure contributing to the blood Pb or bone Pb levels in the adult population studied. Some of the populations examined (e.g., NHANES, NAS) are likely to have higher past than recent Pb exposure. Other populations (e.g., worker populations) studied have ongoing exposure to Pb. As described elsewhere in the document (Section 4.3, Section 5.3, Section 5.4, Section 5.5), the interpretation of the study findings depends on the exposure history and the choice of the biomarker in the context of what is known about that exposure history.

In NHANES analyses describing the C-R function for blood Pb level and neurocognitive effects in adults, only log-linear models were used to fit the data (Krieg et al., 2010; Krieg and Butler, 2009; Krieg et al., 2009). With regard to C-R relationships for cumulative exposure metrics, nonlinearity in the BMS and NAS cohorts of

community-dwelling older adults was examined with the use of quadratic terms, penalized splines, or visual inspection of bivariate plots (Bandeen-Roche et al., 2009; Weisskopf et al., 2007a; Shih et al., 2006). There was some evidence for nonlinearity for some but not all cognitive tests or subjects in the NAS cohort (Section 5.3.10). In analyses of the BMS cohort, observations of a statistically nonsignificant quadratic term (Shih et al., 2006) or spline (Bandeen-Roche et al., 2009) for tibia Pb indicated that a linear model adequately fit the relationship between tibia Pb level and various tests of cognitive performance.

Concentration-response relationships were examined in several epidemiologic studies of blood pressure and mortality (Section 5.4.5). With regard to the concentration-response relationship, meta-analysis of human studies found that each doubling of blood Pb level (between 1 and >40 μg/dL measured concurrently in most studies) was associated with a 1 mmHg increase in systolic BP and a 0.6 mmHg increase in diastolic BP (Nawrot et al., 2002). However, there is uncertainty in the concentration-response relationship to cardiovascular endpoints at lower blood Pb levels since most studies model a linear relationship. Weaver et al. (2010) provided the results of further analysis of this Korean worker cohort, with a focus on determining the functional form of the concentration-response relationships. The coefficient indicated that every doubling of blood Pb level was associated with a systolic BP increase of 1.76 mmHg. The J test, a statistical test for determining which, if either, of two functional forms of the same variable, provides superior fit to data in non-nested models. Davidson and MacKinnon (1981) returned a p-value of 0.013 in favor of the natural log blood Pb level, over the linear blood Pb level specification. This analysis indicates that systolic BP increase in this cohort is better described as a logarithmic function of blood Pb level within the blood Pb level range of the study than by a linear function. Animal toxicological studies provide support for this concentration response relationship. Few studies that focused on Pb-induced hypertension in experimental animals have included more than two exposure concentrations; however these few studies appear to have a supralinear (concave downward) dose response.

Studies investigating both all-cause and cardiovascular mortality report both linear and non-linear relationships (Section 5.4.5). Findings from NHANES analyses were mixed with Schober et al. (2006), reporting a linear association between the relative hazard for all cause mortality with blood Pb, and Menke et al. (2006), reporting a non-linear relationships between blood Pb level and the hazard ratio for all cause, MI, stroke, and cancer mortality. There is uncertainty regarding the frequency, duration, timing and magnitude of exposure contributing to the blood Pb levels among the NHANES population studied; individuals in this population are likely to have higher past than recent exposures. Weisskopf et al. (2009) examined the concentration-response

relationships of patella and tibia Pb with mortality. Concentration-response relationships were approximately linear for patella Pb on the log HR scale for all CVD, but appear nonlinear for IHD ($p < 0.10$). The peak HR is shown around 60 µg/g, beyond which the HR tends to decrease. It is important to note the wide confidence limits, which increase uncertainty at the lower and upper bounds of patella Pb levels. The strongest associations were observed between mortality and baseline patella Pb concentration. Baseline tibia Pb levels were more weakly associated with CVD mortality. Tibia bone Pb level is thought to reflect a longer cumulative exposure period than is patella bone Pb level because the residence time of Pb in trabecular bone is shorter than that in cortical bone.

Concentration response information was provided in a small number of studies of Pb-related nephrotoxicity in the occupational setting (Weaver et al., 2003b; Ehrlich et al., 1998). Data in 267 Korean Pb workers in the oldest age tertile (mean age = 52 years) revealed no threshold for a Pb effect (beta = 0.0011, $p = <0.05$; regression and lowess lines shown), however the mean blood Pb level in this population was 32 µg/dL (Weaver et al., 2003b).

Non-linear concentration/exposure response relationships or attenuation of these relationships at higher exposure levels is reported in the occupational literature for a variety of effects. Explanations for this phenomenon include greater exposure measurement error, competing risks, and saturation of biological mechanisms at higher exposure levels, and exposure-dependent variation in other risk factors (Stayner et al., 2003). With respect to Pb exposure, different biological mechanisms may operate at different exposure levels and/or there may be a lower incremental effect of Pb due to covarying risk factors such as low SES, poorer caregiving environment, and other higher environmental exposures. The 2006 Pb AQCD also considered the explanation for the supralinear concentration response function postulated by Bowers and Beck (2006), who stated that "a supralinear slope is a required outcome of correlations between a data distribution where one is lognormally distributed and the other is normally distributed." The 2006 Pb AQCD determined that, while the conclusions drawn by Bowers and Beck may be true under certain conditions, their assumptions (e.g., that IQ are scores forced into a normal distribution) were not generally the case in the epidemiologic analyses showing a supralinear concentration response function. To support this conclusion, the 2006 Pb AQCD cited Hornung et al. (2006), which provided evidence that the IQ data used in the pooled analysis of seven studies by Lanphear et al. (2005) were not normalized and a log-linear model (a linear relationship between IQ and the log of blood Pb) provided the best fit.

The factors contributing to the supralinear relationship between blood Pb levels and neurocognitive function in children has not been examined widely in epidemiologic

studies to date. However, in several populations, higher blood Pb levels have been measured in susceptible groups such as those with higher poverty, greater exposure to tobacco smoke, lower parental education, and lower birth weight (Lanphear et al., 2005; Lanphear et al., 2000). It has been suggested that in populations of low SES, poorer caregiving environment, and greater social stress, the incremental effect of Pb exposure may be attenuated due to the overwhelmingly larger effects of these other risk factors (Schwartz, 1994). Several studies found significant associations of these sociodemographic risk factors with neurocognitive deficits, and Miranda et al. (2009) found that indicators of SES (i.e., parental education and enrollment in a free/reduced fee lunch program) accounted for larger decrements in EOG scores than did blood Pb level (Figure 5-7). Few studies have compared Pb effect estimates among groups in different sociodemographic strata, and the limited data are mixed. Greater Pb-associated neurocognitive deficits were reported in low-SES groups by Bellinger et al. (1990). In a meta-analysis of eight studies, Schwartz (1994) found a smaller decrement in IQ per 1 µg/dL increase in blood Pb level for studies in disadvantaged populations (-2.7 points [95% CI: -5.3, -0.07]) than for studies in advantaged populations (-4.5 points [95% CI: -5.6, -2.8]). It is important to note that blood Pb level is associated with deficits in neurocognitive function in both higher and lower SES groups; however, it is unclear what differences there are between groups in the decrement per unit increase in blood Pb and whether these differences can explain the nonlinear concentration-response relationship.

In support of epidemiologic findings, toxicological studies provided some evidence that compared with control or higher Pb exposures (e.g., 150 ppm), lower Pb exposures (e.g., 50 ppm) during gestation and lactation (possibly with offspring stress co-exposure) impaired learning and memory as indicated by increased FI responses on schedule controlled behavior tests (Rossi-George et al., 2011; Cory-Slechta, 1994). The 2006 Pb AQCD did not identify a biological mechanism for a steeper slope at lower than at higher blood Pb levels but such a mechanism was not ruled out. In fact, several lines of toxicological evidence support the possibility of lower and higher Pb exposures acting through differentially activating mechanisms underlying cognition.

As detailed in Section 5.3.10, the shape of the C-R relationship for dopamine varied across studies. However, relative to higher Pb exposures, lower Pb exposures were found to reduce LTP (Gilbert et al., 1999) and glutamate release in the hippocampus (Lasley and Gilbert, 2002). LTP is one indication of synaptic plasticity (Section 5.3.8.4) and is considered to mediate learning and memory. Glutaminergic neurotransmission via its NMDA receptor has been implicated in learning and memory (Section 5.3.8.8). Thus, these differential responses to lower versus higher Pb exposures may provide mechanistic understanding and additional biological plausibility for the nonlinear associations of Pb

exposure or blood Pb levels with neurodevelopmental outcomes observed in animals and children.

While epidemiologic studies have not examined widely the shape of the concentration-response relationship for other nervous system effects, as detailed in Section 5.3.10, toxicological studies have found nonlinear C-R relationships for diverse outcomes such as rod and retinal effects in the visual system (Giddabasappa et al., 2011; Fox et al., 2010), motor function (Leasure et al., 2008), and hippocampal neurogenesis (Fox et al., 2008; Gilbert et al., 2005).

The supralinear concentration-response relationship widely documented for Pb is consistent with the lack of a threshold for Pb-associated nervous system effects in children because a smaller effect estimate would be expected at lower blood Pb levels if a threshold existed. However, an important limitation of previous studies in terms of identifying whether a threshold exists, is the limited examination of effects in populations or blood Pb strata with blood Pb levels more comparable to the current U.S. population mean. While Schwartz (1994) did not find evidence for a threshold in the Boston study data, the mean blood Pb in that population was 6.5 µg/dL, and 56% of subjects had a blood Pb level >5 µg/dL. Recent studies indicate a downward shift in the distribution of blood Pb levels (i.e., 50% of subjects in the 2001-2004 NHANES population had a blood Pb <1 µg/dL (Braun et al., 2008). Additionally, more sensitive quantification methods have improved the detection limits, for example, from 0.6 µg/dL in 1999-2002 NHANES to 0.025 µg/dL in 2003-2004 NHANES allowing categorization of children in multiple blood Pb quantiles below 1 µg/dL (Braun et al., 2008). Consequently, the examination of populations with large proportions of subjects at very low blood Pb levels has improved the ability to discern a threshold for Pb-associated nervous system effects. In the 2001-2004 NHANES population, Braun et al. (2008) found higher odds ratios for conduct disorder and ADHD among children with blood Pb levels 0.8-1.0 µg/dL (2nd quartile) compared with children with blood Pb levels 0.2-0.7 µg/dL (1st quartile). However. the large proportions of adolescents in NHANES analyses who were born the 1970s may have had higher past Pb exposures that contributed to associations observed with concurrent blood Pb levels. Nonetheless, several recent studies reported associations between blood Pb levels and deficits in cognitive and behavioral endpoints in children ages 8-11 years with mean or quantile blood Pb levels <2 µg/dL (Cho et al., 2010; Kim et al., 2009b; Miranda et al., 2009). In comparisons of various quantiles of blood Pb, Miranda et al. (2009) reported lower EOG scores in children in North Carolina with blood Pb levels of 2 µg/dL compared with children with blood Pb levels of 1 µg/dL. Collectively, these new findings in children, as summarized in this document, do not provide evidence for a threshold for the nervous system effects of Pb in the ranges of blood Pb levels examined to date.

2.9.5 Pb Exposure and Nervous System Effects in Children

As discussed in various sections across this document, there are uncertainties related to the frequency, timing, duration and level of Pb exposure contributing to the health effects observed in epidemiologic studies of adults and older children who are likely to have higher past than recent Pb exposure. Both blood Pb and bone Pb, which are the most common metrics of exposure/dose used in epidemiologic studies, are integrative measures and do not allow these aspects of exposure to be distinguished. Bone Pb is a measure of cumulative exposure in adults and is not typically used in studies of children. As discussed in Section 4.3.5, blood Pb may reflect both recent exposures and Pb released from the bone; the relative proportion of blood Pb from recent versus past exposure is uncertain in the absence of information on exposure timing and duration. Young children, however, do not have lengthy exposure histories and consequently the interpretation of associations with blood Pb levels for this age group may be less complicated compared to older age groups. Several lines of evidence, which are discussed below, inform the interpretation of study findings as they relate to aspects of exposure that can be attributed to the neurocognitive and behavioral effects of Pb observed in young children.

A common limitation of epidemiologic studies is the potentially high correlation between Pb exposure metrics at different ages in childhood and with maternal Pb exposure metrics. In longitudinal studies of the effect of Pb in children, blood Pb levels remained relatively stable over time. Thus, it is difficult to distinguish effects of past and concurrent exposures. Further, concurrent blood Pb levels in children, although highly affected by recent exposure, are also influenced by their past exposure (including prenatal exposure) due to the rapid growth-related bone turnover in children. Thus, concurrent blood Pb level in children also may reflect cumulative dose (Section 4.3.5.1). There is some evidence that the influence of maternal Pb levels on postnatal blood Pb level is substantially reduced soon after birth. Simon et al. (2007) followed a cohort of 13 children living near an Australian smelter from birth through 36 months. In general, immediately after birth, blood Pb levels fell for 1-2 months to approximately 47% of birth blood Pb level. After this initial fall, all infants' blood Pb levels rose with age until approximately 12 months old. There was a good correlation between child blood Pb level and child hand Pb loading ($R^2 = 0.70$) in this study, indicating the influence of concurrent Pb exposures on blood Pb during the early childhood years.

In epidemiologic studies, associations of cognitive function and behavior have been observed with prenatal, early-childhood, lifetime average, and concurrent blood Pb levels as well as with childhood tooth Pb levels and it is difficult to ascertain which lifestage within childhood is associated with the greatest risk of Pb-associated effects on cognition

(Section 5.3.9, Table 5-13, Table 5-14). Epidemiologic studies of Bayley MDI following children beginning in utero and through three years of age indicate that short-duration exposures in utero or during early childhood are associated with cognitive decrements in young children. Among studies with prenatal and concurrent blood Pb measurements, some found stronger associations for prenatal blood Pb levels (Hu et al., 2006; Bellinger et al., 1984), and other found stronger associations for concurrent blood Pb levels (Wasserman et al., 1998; Wasserman et al., 1992). Studies that found associations with concurrent blood Pb levels also tended to find associations with prenatal cord or maternal blood Pb levels. Thus, both postnatal child and maternal Pb exposures may contribute to lower cognitive function in young children. In addition, exposures that are reflected by concurrent blood Pb measured when children are older, by cumulative blood Pb levels or by tooth Pb levels have also been demonstrated to be associated with neurodevelopmental deficits throughout school-age and into adolescence. These findings are consistent with the understanding that the nervous system continues to develop throughout childhood. However, the weight of epidemiologic evidence supports associations of concurrent blood Pb level with neurodevelopmental effects (i.e., cognition and behavior) in children (Sections 5.3.2.1 and 5.3.3.1).

The persistence of neurodevelopmental effects from low-level Pb exposure was also considered in the 2006 Pb AQCD, with some evidence suggesting that the effects of Pb on neurodevelopmental outcomes persisted into adolescence and young adulthood. The toxicological evidence continues to support a range of effects with prenatal and early postnatal Pb exposures which persist to adulthood (Sections 5.3.2.1 and 5.3.2.4). A number of mechanisms, including changes in neurogenesis, synaptogenesis and synaptic pruning, long term potentiation, and neurotransmitter function have been identified that provide biological plausibility for epidemiologic and toxicological findings of persistent cognitive and behavioral effects that result from short-term Pb exposures during prenatal and early childhood periods. The persistence of effects appears to depend on the duration and window of exposure as well as other factors that may affect an individual's ability to recover from an insult.

Toxicological studies in the 2006 Pb AQCD highlighted the importance of Pb exposure during early life in promoting Alzheimer's like pathologies in the adult rodent brain, with Pb-induced neurodegeneration and formation of neurofibrillary tangles in aged animals in which blood Pb levels had returned to control levels after an earlier life Pb exposure (U.S. EPA, 2006b). Recent toxicological studies continue to point to an early life window in which Pb exposure can contribute to pathological brain changes consistent with Alzheimer's disease. The same Pb exposure (i.e., dose and duration equivalent to the early life exposure, to adult rodents) did not induce neurofibrillary tangles in the aged animals. However, blood Pb is not generally associated with Alzheimer's disease in

epidemiologic studies of adults. In other studies, recent evidence indicates associations between early life ALAD activity, a biomarker of Pb exposure, and schizophrenia later in adulthood when schizophrenia typically manifests. Consistent with these findings, toxicological studies have shown NMDA pathway disruption with Pb exposure; manipulation of this pathway is known to be associated with schizophrenia. There is also toxicological evidence for Pb-induced emotional changes in males and the occurrence of depression changes in females. Sensitive windows of early life Pb exposure have been associated with persistent changes in adulthood as demonstrated with animal models of neurodegeneration, i.e., neurofibrillary tangle formation, and with epidemiologic findings for the psychotic disorder schizophrenia. These effects are not reflective of concurrent blood-Pb levels at the age of manifestation of the pathology but instead are associated with an earlier life Pb exposure.

2.9.6 Populations Potentially At-Risk for Health Effects

The NAAQS are intended to provide an adequate margin of safety for both the population as a whole and those groups with unique factors that make them potentially at increased risk for health effects in response to ambient air pollutants. Interindividual variation in human responses to air pollution exposure suggests that some populations are at increased risk for detrimental effects of ambient exposure to an air pollutant. Epidemiologic studies reporting results from stratified analyses designed to identify effect measure modifiers comprise the overall weight of evidence for conclusions related to the increased risk of specific populations to the Pb-related health effects presented in Section 6.3. Supporting evidence from toxicological studies provide biological plausibility for conclusions and summarizes factors that potentially influence Pb levels within the body (Section 6.1) and factors related to differential Pb exposures (Section 6.2). The factors that were evaluated are listed in Table 2-8.

Table 2-8 Factors evaluated that may determine populations potentially at increased risk from lead

Physiological Factors that Influence the Internal Distribution of Lead	Population Characteristics Potentially Related to Differential Lead Exposure	Factors Potentially Related to Increased Risk of Lead Induced Health Effects
Age (Section 6.1 and Section 4.4)	Age (Section 6.2.1)	Age (Section 6.3.1, and Section 5.3.8)
	Sex (Section 6.2.2)	Sex (Section 6.3.2)
Genetics (Section 6.1, Section 4.1, Section 4.2)		Genetics (Section 6.3.3)
		Pre-existing Disease (Section 6.3.4)
	Race and Ethnicity (Section 6.2.3)	Race and Ethnicity (Section 6.3.6)
	Socioeconomic Status (Section 6.2.4)	Socioeconomic Status (Section 6.3.7)
	Proximity to Pb Sources (Section 6.2.5, Section 3.2, Section 3.3, Section 3.5, and Section 4.1)	
	Residential Factors (Section 6.2.6)	
		Lifestyle Factors
		Smoking (Section 6.3.5)
		Body Mass Index (Section 6.3.8)
		Alcohol Consumption (Section 6.3.9)
Nutrition (Section 6.1 and Section 4.2)		Nutrition (Section 6.3.10)
		Stress (Section 6.3.11)
		Cognitive Reserve (Section 6.3.12)
Co-exposure (Section 6.1 and Section 4.2)		Other metals (Section 6.3.13)

Studies are included in Section 6.3 only if analyses were conducted to identify the presence or absence of effect measure modification. By virtue of their design some cohort studies, including cohort studies of pregnant women or other populations or lifestages with no comparison group, are discussed in the endpoint-specific sections rather than in Chapter 6. This integrative summary, however, draws on evidence relating to potentially at-risk populations and lifestages appearing throughout this document. Also, physiological factors that influence the internal distribution of Pb, population characteristics potentially related to differential Pb exposure and factors potentially related to increased risk of Pb induced health effects are considered together in this integrative summary.

2.9.6.1 Age and/or Lifestage

Infancy and Early Childhood

It is recognized that Pb can cross the placenta to affect the developing nervous system of the fetus (Section 4.2.2.4). Further, elevated blood Pb levels among mothers present a potential exposure to their children through breast milk. This transfer of Pb from mother to fetus is observed to occur partly from the remobilization of the mother's bone stores (Section 4.2.2.4). Other biokinetic factors that vary by age, including bone turnover and absorption, also affect blood Pb levels. Typically, children have increased exposure to Pb compared with adults because children's behaviors and activities include increased hand-to-mouth contact, crawling, outdoor play, and poor hand-washing that typically result in increased ingestion compared with adults. Blood Pb among different age groups are shown in Table 6-1. Blood Pb levels are highest among the young children and decrease with increasing age of the child.

There is evidence of increased susceptibility to the neurocognitive effects of Pb exposure during several lifestages throughout childhood (Section 5.3.2.1 to Section 5.3.8, and Section 6.3.1.1). Exposure to environmental toxicants during prenatal and/or early postnatal development may alter the normal course of morphogenesis and maturation that occurs in utero and early in life, resulting in changes that affect structure or function of the central nervous system via altered neuronal growth and/or synaptogenesis/pruning structure (Section 5.3.9). Synaptic pruning, which is active throughout early childhood (ages 1-4 years), may underlie the elevated risk of young children to environmental exposures. Overall evidence indicates early childhood as a lifestage of increased risk for Pb-related health effects with epidemiologic studies report associations with cognition (Section 5.3.9) among the youngest age groups (6 months to 3 years). Toxicological studies provide support for the younger age groups being especially sensitive to Pb exposure. Toxicological studies have reported that younger animals, whose nervous systems are developing (i.e., laying down and pruning neuronal circuits) and whose junctional barrier systems in the brain (i.e., the blood brain barrier) and GI system (i.e., gut closure) are immature, are more at risk from the effects Pb exposure (Fullmer et al., 1985). Further, blood Pb level is associated with effects to the immune system (Section 5.6) of children. Findings of a recent study indicate that very young children may be at increased risk for Pb-associated activation of humoral immune responses and perturbations in cell-to-cell interactions that underlie allergic, asthma, and inflammatory responses (Section 5.6.2.1 and Section 5.6.3).

Adolescents

The 2007-2008 NHANES data suggest that sex-based differences in blood Pb levels are not substantial until adolescence at which time blood Pb levels of boys are higher than girls. Anatomical understanding of brain development in the typically or normally developing child also helps to inform findings with associated pathologies by providing grounds for comparison. Findings from MRI studies have been used to detail anatomical changes within separate brain segments in the normally developing child and adolescent, from age 3-30 (Section 5.3.9). Throughout adolescence, normal brain development remains dynamic. Volumes of specific regions vary largely by sex and age, but also include inter-individual variation. Studies have linked concurrent blood Pb level as well as other blood Pb metrics) in adolescents to decrements in cognitive function, delinquent or criminal behavior (Section 5.3.3.1). Delays in puberty onset (Section 5.8.1.3) and renal effects (Section 5.5.1.1) are also observed in association with concurrent blood Pb level in cross-sectional studies of adolescents. However, the populations of older children studied generally had higher past exposures, which may have influenced the findings of these studies.

Adulthood

There is uncertainty regarding the frequency, duration, timing and magnitude of exposure contributing to the blood Pb levels among the adult population studied. Associations of both blood Pb and/or bone Pb with blood pressure, hypertension and mortality, renal, immune, hematological, and reproductive effects. Blood Pb and bone Pb levels tend to be higher in older adults (>65 years) compared with the general population. Higher average and median bone and blood Pb levels among older adults could potentially be due to a shared experience of higher historical Pb exposures stored in bone in conjunction with remobilization of stored Pb during bone loss (Section 4.2). In recent studies, age was specifically examined as an effect modifier of the association of Pb with mortality (Section 5.4.5), cognition (Section 5.3.2.5) and blood pressure (Section 5.4.2) in adults. Results for age-related modification of the association between Pb and mortality were mixed and no difference by age was observed for the associations between Pb and cognitive function or blood pressure. Toxicological studies have shown increases in Pb-related health effects by age that may be relevant to nervous system effects in humans (Section 5.3.1).

2.9.6.2 Sex

Multiple associations between Pb and various health endpoints have been examined for effect measure modification by sex (Section 6.3.2). Some studies reported differences between the associations for males and females; overall, the findings were mixed. For example, studies on cognition from the Cincinnati Lead Study cohort and a study in Poland reported males to be an at-risk population, whereas studies from Australia pointed to females as an at-risk population. Toxicological studies continue to demonstrate increased susceptibility of males to Pb for specific endpoints such as sensory function, balance, liver hyperplasia, obesity, memory and gross motor skills. Males and females show differential susceptibility in other toxicological studies across a wide array of endpoints including of behavior, stress hormone homeostasis, and depression with some endpoints having greater effects in one sex versus the other based on the exposure paradigm.

2.9.6.3 Genes

The 2006 Pb AQCD observed that genetic polymorphisms s have been implicated as influencing the absorption, retention, and toxicokinetics of Pb in humans, with the majority of discussion focused on the aminolevulinate dehydratase (ALAD) and vitamin D receptor (VDR) polymorphisms (U.S. EPA, 2006b). Studies published since then continue to indicate that variants of the VDR and the ALAD polymorphism have been associated with varied internal Pb concentrations. Overall, studies of ALAD observed increased Pb-related health effects associated with certain gene variants. Other genes, such as VDR, MTHFR, APOE, HFE, DRD4, GSTM1, TNF-α, and eNOS, may also affect the risk of Pb-related health effects but conclusions are limited due to the small number of studies (Section 6.3.3).

2.9.6.4 Pre-existing Conditions

Studies have also been performed to examine whether certain morbidities increase an individual's risk of Pb-related effects on health. Recent studies have explored relationships for autism, atopy, diabetes, and hypertension; however, there were generally few studies available that evaluated conditions such as autism and atopy. The 2006 Pb AQCD concluded that diabetes and hypertension may result in increased risk of Pb-associated declines in renal function (U.S. EPA, 2006b). However, a recent study indicates that diabetes was not related to increased risk of Pb-related cardiovascular outcomes, and there were mixed results regarding the potential for hypertension to

increase the risk of Pb-related effects on renal function and cardiovascular effects (Section 6.3.4).

2.9.6.5 Race and Ethnicity

Higher blood Pb and bone Pb levels among African Americans has been well documented (U.S. EPA, 2006b). Recent studies are consistent with those previous findings (Section 6.2.3). Greater tibia Pb, but not patella Pb or blood Pb levels, was reported in the Baltimore population studied by Theppeang et al. (2008b). This finding may indicate greater historical exposure among African Americans compared to Caucasians. In addition, a higher proportion of blacks compared with other race-ethnicity groups has been reported in Census blocks where soil Pb concentration is higher, whereas the proportion of whites was higher in low soil Pb Census blocks for a study of New Orleans soil exposure (Campanella and Mielke, 2008). The results of recent epidemiologic studies suggest that there may be race/ethnicity-related increased risk for cardiovascular effects and delayed puberty, although the overall understanding of potential effect measure modification by race/ethnicity is limited by the small number of studies. Additionally, these results may be cofounded by other factors, such as socioeconomic status (Section 6.3.6).

2.9.6.6 Socioeconomic Status

Socioeconomic factors have sometimes been associated with Pb biomarkers, although these relationships have not always been consistent (U.S. EPA, 2006b). On a national level, the gap between income levels with respect to blood Pb has been decreasing. However, blood Pb level of children remains higher depending on income, enrollment in Medicaid and poverty income ratio (PIR), which is the ratio of family income to the poverty threshold appropriate for a given family size (Section 6.2.4). Although there are a limited number of studies, there is some evidence that Pb-associated neurocognitive effects may be larger in magnitude among lower SES populations (Section 6.3.7). There is also evidence that some cognitive effects of prenatal Pb exposure may be transient and that recovery is greater among children reared in households with more optimal caregiving characteristics and in children whose concurrent blood Pb levels were low (Bellinger et al., 1990). In a meta-analysis, Schwartz (1994) found that in studies in higher SES populations, blood Pb was associated with a greater decrement in IQ than in low SES populations

2.9.6.7 Proximity to Pb Sources and Residential Factors

Proximity to an industrial Pb source or Superfund site likely contributes to higher Pb exposures (U.S. EPA, 2006b). Recent studies show that soil Pb concentrations may be higher in some urban areas as a result of contemporaneous and/or historical Pb sources (Section 6.2.5). Consistent with findings of the 2006 Pb AQCD (U.S. EPA, 2006b), child blood Pb level was significantly associated with renovation activities in older homes as well as housing factors (e.g., year of construction, floor and windowsill condition). It has also been observed that windowsill dust Pb was significantly associated with the presence of deteriorated indoor paint. Other studies of renovation activities involving removal of Pb paint have included measurements of highly elevated blood Pb among children and adult workers. Living in a home built prior to 1950, where old home age is a surrogate for presence of Pb paint, has also been shown to be a significant predictor of blood Pb. (Sections 4.1.3.2 and 6.2.6).

2.9.6.8 Lifestyle Factors

Body mass index (BMI), obesity and alcohol consumption have been examined in epidemiologic and toxicological studies. Modification of associations between Pb with mortality and HRV was not observed by BMI or obesity (Section 6.3.8). There is limited evidence on the potential for alcohol consumption as a modifier of Pb-related effects (Section 6.3.9) and mixed findings on whether smoking modifies the relationship between Pb and health effects (Section 6.3.5).

2.9.6.9 Nutritional Factors

It is well established that diets sufficient in minerals such as calcium, iron, and zinc offer some protection from Pb exposure by preventing or competing with Pb for absorption in the GI tract (Section 6.1). The 2006 Pb AQCD included studies that indicated individuals with iron-deficiency and malnourishment had greater inverse associations between Pb and cognition/intellect (U.S. EPA, 2006b), and recent epidemiologic and toxicological studies continue to observe greater Pb-related health effects among individuals with low levels of iron (Section 6.3.10). Calcium intake from diet and vitamin D supplement can modify blood Pb levels in women of various ages. Calcium supplementation during pregnancy and lactation may decrease the amount of Pb to which the developing fetus of infant is exposed. The evidence for this seems especially strong for protection during pregnancy and more mixed for protective effects of calcium during lactation. There is little recent evidence available on the potential for zinc or other as modifiers of Pb-related

health effects associations. A recent study in China reported that children who regularly consumed breakfast had lower blood Pb levels than those children that did not eat breakfast (Liu et al., 2011b). Recent toxicological studies r indicate that diets designed to limit or reduce caloric intake and induce weight loss have been associated with increased blood Pb levels and an epidemiologic analysis reported that regular consumption of breakfast reduced blood Pb levels in children, compared with children who did not eat breakfast (Section 6.1).

2.9.6.10 Stress and Cognitive Reserve

Animal toxicology findings described in the 2006 Pb AQCD demonstrated interactions between Pb exposure and stress. Pb-exposed animals reared in cages with enriched environments (toys) perform better in the Morris water maze than their Pb-exposed littermates who were reared in isolation. New findings indicate a potentiating effect of stress on behavior and memory at low-dose Pb exposures. Although examined in a limited number of studies, recent epidemiologic studies observed modification of the association between Pb and various nervous system and cardiovascular effects by stress-level and also indicated that maternal self-esteem may attenuate the negative effects observed of Pb on MDI and PDI scores. Toxicological studies have demonstrated that early life exposure to Pb and maternal stress can result in altered responses in multiple systems, including altered corticosterone and neurotransmitter levels. Additionally, toxicological studies have demonstrated that immune stress also affects associations with Pb (Section 6.3.11).

2.9.6.11 Co-exposure of Lead with Metals and Chemicals

Other exposures have also been studied to assess how they affected the uptake and absorption of Pb. Recent toxicological studies that have examined the addition of arsenic (As) to Pb and Cd mixtures report increases in bioavailability of Pb (Section 6.1). The 2006 Pb AQCD reported that the majority of studies examined other metals as potential confounders rather than effect measure modifiers (U.S. EPA, 2006b). Recent epidemiologic studies have, however, begun to explore the possible interaction between Pb and other metals. These studies report some stronger associations between Pb and various health endpoints with co-exposure to Cd, As and Mn (Section 6.3.13); some studies indicate that coexposures may increase bioavailability of Pb (Section 6.1). Since Pb is acid soluble, fluoridation may increase Pb concentration in water through leaching from pipes and Pb solder (Section 4.1.3.3)

2.9.6.12 Summary of At-Risk Populations

As shown in Table 2-9 (Table 6-4) the most well-substantiated at risk population for the effects of Pb exposure is children. Evidence for all other factors was limited. Among children, the youngest age groups were observed to be most at risk of elevated blood Pb levels, with levels decreasing with increasing age of the children. Recent epidemiologic studies of infants/children detected increased risk of Pb-related health effects, and this was supported by toxicological studies. Synaptic pruning, which is active throughout early childhood (ages 1-4 years), may underlie the elevated risk of neurodevelopmental effects in young children to environmental exposures. Other factors that have been studied with regard to the influence on Pb-related risk are listed in Table 2-9 below.

Table 2-9 Summary of evidence for factors that potentially increase the risk of lead-related health effects

Factor Evaluated	Potentially Related to Increased Risk
Age (Section 6.3.1)	Children
Sex (Section 6.3.2)	Males,[a] Females[a]
Genetics (Section 6.3.3)	ALAD[a], VDR[a]*, DRD4[a]*, GSTM1[a], TNF-α[a], eNOS[a], APOE[a], HFE[a]
Pre-existing Disease (Section 6.3.4)	Autism[a], Atopy[ab], Hypertension[b]
Smoking (Section 6.3.5)	Smokers[a]
Race/Ethnicity (Section 6.3.6)	Non-Hispanic Blacks[a], Hispanics[a]
Socioeconomic Status (SES) (Section 6.3.7)	Low SES[a]
Nutrition (Section 6.3.10)	Iron deficiency[a]
Stress (Section 6.3.11)	High stress[a]
Cognitive Reserve (Section 6.3.12)	Low cognitive reserve[ab]
Other Metals (Section 6.3.13)	High/co-exposure to Cd[a], As[a], Mn[a]

[a] Evidence for this factor was limited.
[b]Possible mediator

2.10 Summary

Table 2-10 summarizes the main conclusions from the 2006 Pb AQCD and from this assessment, including causality determinations, regarding the health and ecological effects of Pb.

Table 2-10 Summary of evidence from epidemiologic, animal toxicological and ecological studies on the effects associated with exposure to Pb

Outcome/Effect	Conclusions from the 2006 Pb AQCD	Conclusions from the (2012-2nd Draft) Pb ISA
Health Outcomes:		
Nervous System Effects	The 2006 Pb AQCD did not integrate the evidence across specific endpoints within the nervous system to make conclusions regarding role of Pb in causing effects for the organ system as a whole.	Based most heavily on cognitive function decrements and behavioral problems in children, the collective body of evidence is sufficient to conclude that there is a causal relationship between Pb exposures and nervous system effects.
Neurocognitive Function and Learning	**Children:**	
	The overall weight of the available evidence provides clear substantiation of neurocognitive decrements being associated in young children with blood-Pb concentrations in the range of 5-10 µg/dL, and possibly lower. Prenatal, early childhood, lifetime average, and concurrent blood Pb levels were associated with decrements in IQ and specific indices of learning and memory; however, concurrent blood Pb level was the strongest predictor.	Recent epidemiologic studies in children continue to demonstrate associations of concurrent blood Pb level with IQ decrements; most new evidence emphasizes associations of concurrent blood Pb levels with specific indices of neurocognitive function (e.g., verbal skills, memory, learning visuospatial processing). The weight of evidence supports associations in populations with mean blood Pb levels 2-7 µg/dL.
	Adults**:**	
	Among environmentally-exposed adults, bone Pb levels but not blood Pb levels were associated with poorer cognitive performance. These findings point to an effect of long-term cumulative Pb exposure.	Consistent with previous studies, the weight of evidence in new studies indicates associations of cumulative Pb exposure metrics with cognitive performance in environmentally-exposed adults. However, as these outcomes are observed in adults with likely higher past Pb exposures, uncertainty exists as to the Pb exposure level, frequency, duration, and timing contributing to the observed associations
Neurobehavioral Effects	Children:	
	Several epidemiologic studies reported associations between Pb exposure and effects that ranged from inattention and aggression in children to delinquent behaviors and criminal activities in adolescents and young adults. Most studies examined blood Pb levels measured earlier in childhood (means ~ 10 µg/dL), tooth Pb, or bone Pb. There was little examination of concurrent blood Pb levels. Uncertainty remained regarding whether Pb exposure was an independent predictor of neurobehavioral effects. Results from studies of ADHD were inconclusive. Suggestive relationship for both blood and bone Pb with withdrawn behavior and anxiety symptoms in children.	Recent studies in children continue to support associations of Pb exposure with a range of effects, largely inattention and hyperactivity, and also misconduct delinquent behavior. In new studies, the weight of evidence supports associations with concurrent blood Pb in populations with lower mean blood Pb levels (2–5 µg/dL) than those in previous studies. New evidence indicates associations of concurrent blood Pb levels with ADHD diagnosis and contributing diagnostic indices in populations with mean blood Pb levels 2-4 µg/dL.

Outcome/Effect	Conclusions from the 2006 Pb AQCD	Conclusions from the (2012-2nd Draft) Pb ISA
Neurobehavioral, Mood and Psychiatric Effects	Adults:	
	Associations of Pb exposure with behavioral outcomes were not widely examined in environmentally-exposed adults.	In the few available new studies of environmentally-exposed adults, blood and bone Pb levels are associated with symptoms of depression and anxiety.
Sensory Organ Function	The selective action of Pb on retinal rod cells and bipolar cells is well documented in earlier AQCDs. There was coherence between the extensive animal and the limited available human literature reporting associations between concurrent blood Pb levels (population means 7-12 µg/dL) and decreased auditory function in children.	The limited available new epidemiologic studies on sensory organ function in children examined children with high blood Pb levels ((means > 30 µg/dL. A recent toxicological study found retinal effects in male rodents who had been exposed at gestation through 10 days of age at exposures resulting in lower blood Pb levels (~12 µg/dL) than those at which effects had been previously reported.
Neurodegenerative Diseases	In the limited body of epidemiologic studies, blood and bone Pb levels were not associated with Alzheimer's disease or Amyotrophic Lateral Sclerosis among environmentally-exposed adults. Each study had sufficient limitations.	A few case-control studies report associations between bone Pb levels and PD in environmentally-exposed adults. Recent toxicological evidence suggests that early life Pb exposure may be associated with neurodegeneration in adult animals.
Cardiovascular Effects	The 2006 Pb AQCD did not integrate the evidence across specific endpoints within the cardiovascular system to make conclusions regarding role of Pb in causing effects for the organ system as a whole.	The weight of the evidence continues to support and expand upon the strong body of evidence that Pb exposure is associated with increased blood pressure and hypertension in adults. The evidence is sufficient to conclude that there is a causal relationship between Pb exposures and cardiovascular effects; however, as these outcomes are observed in adults with likely higher past Pb exposures, uncertainty exists as to the Pb exposure level, frequency, duration, and timing contributing to the observed associations.
Blood Pressure	A meta-analysis of numerous epidemiologic studies estimated that a doubling of blood Pb level (e.g., from 5 to 10 µg/dL) was associated with a 1 mmHg increase in systolic BP and a 0.6 mmHg increase in diastolic BP."	Recent epidemiologic and toxicological studies continue to support associations between long-term Pb exposure and increased BP. Associations of increased BP with blood and bone Pb concentrations are observed in populations with lower mean blood Pb levels.
Hypertension	Epidemiologic studies consistently demonstrated associations between Pb and incidence of hypertension with suggestive evidence that bone Pb may be associated with hypertension. Animal studies demonstrated that long-term exposure to Pb resulted in hypertension that persisted after cessation of exposure.	Recent studies, including those using bone Pb as a metric of cumulative exposure, continue to demonstrate associations of hypertension with Pb levels in adults at lower population Pb concentrations. Recent studies have emphasized the interaction of cumulative exposure to Pb with other factors including stress.
Cardiovascular Mortality	The evidence for an association of Pb with cardiovascular mortality is limited but supportive.	Recent studies address limitations of previous studies and provide additional evidence for an association of Pb with cardiovascular mortality in adults. Specific causes of mortality that were associated with Pb could be related to increased BP and hypertension.
Renal Effects	The 2006 Pb AQCD did not integrate the evidence across specific endpoints within the renal system to make conclusions regarding role of Pb in causing effects for the organ system as a whole. Circulating and cumulative Pb was associated with longitudinal decline in renal function in adults. Toxicological studies demonstrated that initial accumulation of absorbed Pb occurred primarily in the kidneys and noted a hyperfiltration phenomenon during the first 3 months of exposure, followed by decrements in kidney function.	Recent epidemiologic and toxicological studies evaluated in the current review support or expand upon the strong body of evidence indicating that Pb exposure is associated with kidney dysfunction (e.g., lower creatinine clearance, higher serum creatinine, and lower GFR) in nonoccupationally-exposed adults. The evidence is sufficient to conclude that there is a causal relationship between Pb exposures and renal health effects; however, as these outcomes are most often observed in adults with likely higher past Pb exposures, uncertainty exists as to the Pb exposure level, frequency, duration, and timing contributing to the observed associations.

Outcome/Effect	Conclusions from the 2006 Pb AQCD	Conclusions from the (2012-2nd Draft) Pb ISA
Immune System Effects	The 2006 Pb AQCD did not integrate the evidence across specific endpoints within the immune system to make conclusions regarding role of Pb in causing effects for the organ system as a whole.	The consistency and coherence of findings across the continuum of related immune parameters that demonstrate a stimulation of Th2 responses in toxicological studies combined with the supporting epidemiologic evidence in children are sufficient to conclude that there is a causal relationship between Pb exposures and immune system effects.
	Children:	
	Several epidemiologic studies suggested that Pb exposure may be associated with effects on cellular and humoral immunity in children. The principal effects demonstrated were decreases in T cell abundance and increases in serum immunoglobulin E levels with concurrent blood Pb levels > 10 µg/dL. Toxicological evidence supported these findings with extensive evidence for prenatal and early postnatal Pb exposures skewing toward Th2 cytokine production and affecting downstream events such as inflammation and decreased responses to antigens (e.g., delayed type hypersensitivity, bacterial resistance).	A small body of new studies supports the previous evidence that Pb exposure is associated with immune effects in children. New studies in children added to the evidence for associations of blood Pb levels with asthma, allergy, and IgE. The consistency and coherence of findings among related immune effects that support a shift from a Th1 to a Th2 phenotype establishes the biological plausibility for epidemiologic observations of associations with asthma, allergy and inflammation-related effects in other organ systems.
	Adults:	
	In the large body of studies in occupationally-exposed adults, the most consistent findings were reduced neutrophil functionality in workers with blood Pb levels > 30 µg/dL. Pb exposure-associated immune effects were not widely examined in environmentally-exposed adults. Several toxicological studies found a Pb-induced shift to Th2 cytokine production and a hyperinflammatory phenotype of macrophages in adult animals with long-term (> weeks) exposure.	A small body of available studies provides new evidence for immune effects in environmentally-exposed adults. Specific endpoints varied among studies but were consistent with increased inflammation. Associations were observed in populations with a wide range of mean concurrent blood Pb levels (3-22 µg/dL). However, as these outcomes are observed in adults with likely higher past Pb exposures, uncertainty exists as to the Pb exposure level, frequency, duration, and timing contributing to the observed associations. A few available toxicological studies find Pb-associated immune effects in adult mice.
Heme Synthesis and RBC Function	Children:	
	Pb exposure was associated with disruption in heme synthesis with increases in blood Pb levels of approximately 20 µg/dL sufficient to halve ALAD activity and inhibit ferrochelatase. Risk of clinical anemia in children becomes apparent at high blood Pb levels: 10% probability of anemia was estimated to be associated with ~ 20 µg/dL Pb at 1 year of age, 50 µg/dL at 3 years of age, and 75 µg/dL at 5 years of age.	Recent epidemiologic studies provide strong evidence that exposure to Pb is associated with numerous deleterious effects on the hematological system in children, including altered hematological parameters (Hb, MCV, MCH, RBC count), perturbed heme synthesis mediated through decreased ALAD and ferrochelatase activities, and oxidative stress. Associations were observed in populations with mean (or median) blood Pb concentrations as low as approximately 5 µg/dL.
	Adults:	
	Pb exposure was associated with disruption in heme synthesis with increases in blood Pb levels of approximately 20 µg/dL sufficient to halve ALAD activity and inhibit ferrochelatase. Exposures to Pb resulting in blood concentrations < 40 µg/dL appear to be tolerated without decreases in blood hemoglobin or hematocrit, however changes in erythropoiesis do occur at these blood levels.	Recent epidemiologic studies provide strong evidence exposure to Pb is associated with numerous deleterious effects on the hematological system, including altered hematological parameters (Hb, MCV, MCH, RBC count), perturbed heme synthesis mediated through decreased ALAD and ferrochelatase activities, decreased erythropoiesis, and oxidative stress.
Reproductive Effects and Birth Outcomes	The 2006 Pb AQCD did not integrate the evidence across specific endpoints within the reproductive system to make conclusions regarding role of Pb in causing effects for the organ system as a whole.	The collective body of evidence integrated across epidemiologic and toxicological studies with a focus on the strong relationship observed with negative effects on sperm and delayed pubertal onset is sufficient to conclude that there is a causal relationship between Pb exposures and reproductive and developmental effects.
	Children:	

Outcome/Effect	Conclusions from the 2006 Pb AQCD	Conclusions from the (2012-2nd Draft) Pb ISA
	No epidemiologic studies of delayed onset of puberty were reviewed.	Recent toxicological and epidemiologic studies provide strong evidence for delayed onset of puberty in males and females. The weight of evidence for delayed onset of puberty was among children ages 6-18 years with mean/median blood Pb levels less than 5 µg/dL.
	Adults:	
	Epidemiologic evidence suggested small associations between Pb exposure and male reproductive outcomes including perturbed semen quality and increased time to pregnancy. Associations between Pb exposure and male reproductive endocrine status were not observed in the occupational populations studied. Toxicological studies provided evidence that Pb produced effects on male and female reproductive junction and development and disrupts endocrine function.	Recent toxicological and epidemiologic studies provide strong evidence for effects on sperm. Evidence on pregnancy outcomes was inconsistent and less coherent across disciplines for preterm birth, spontaneous abortion, low birth weight, birth defects, hormonal influence and fecundity.
Cancer	Epidemiologic studies of highly exposed occupational populations suggest a relationship between Pb and cancers of the lung and the stomach; however the evidence is limited by the presence of various potential confounders, including metal coexposures (e.g., to arsenic, cadmium), smoking, and dietary habits. The 2003 NTP and 2004 IARC reviews concluded that Pb and Pb compounds were probable carcinogens, based on limited evidence in humans and sufficient evidence in animals. Based on animal data and inadequate human data Pb and Pb compounds would be classified as likely carcinogens according to the EPA Cancer Assessment Guidelines for Carcinogen Risk Assessment.	The toxicological literature continues to provide the strongest evidence for Pb exposure and cancer with supporting evidence provided by the epidemiologic literature. Epidemiologic studies of cancer incidence and mortality reported inconsistent results.The evidence i is sufficient to conclude that there is a likely causal relationship between Pb exposure and cancer.
Ecological/Welfare Effects:		
	Terrestrial Organisms:	
Physiological Stress	Pb exposure may cause lipid peroxidation and changes in glutathione concentrations. There are species differences in resistance to oxidative stress.	Recent studies continue to support previous associations of Pb exposure with physiological stress. New evidence includes upregulation of antioxidant enzymes, production of reactive oxygen species and increased lipid peroxidation associated with Pb exposure in additional species of terrestrial plants, invertebrates and vertebrates. Experimental exposures increasing from background concentrations to concentrations higher than near point sources result in increasing effects. The evidence is sufficient to conclude a causal relationship between Pb exposure and physiological stress in terrestrial plants, invertebrates and vertebrates.
	Aquatic Organisms:	
	Pb exposure associated with alterations in enzymes involved in physiological stress responses.	Recent studies continue to support previous associations of Pb exposure with physiological stress. New evidence includes upregulation of antioxidant enzymes, production of reactive oxygen species and increased lipid peroxidation associated with Pb exposure in additional species of aquatic plants, invertebrates and vertebrates and decreased glycogen levels in freshwater snails. Observed effects generally occurred at concentrations that typically exceed Pb levels in U.S. waters with limited evidence for effects associated with Pb at polluted sites. The evidence is sufficient to conclude a causal relationship between Pb exposure and physiological stress in aquatic plants.

Outcome/Effect	Conclusions from the 2006 Pb AQCD	Conclusions from the (2012-2nd Draft) Pb ISA
Hematological Effects	Terrestrial Organismps:	
	Pb effects on heme synthesis were documented in the 1986 Pb AQCD and continue to be studied in terrestrial biota. Changes in ALAD are not always related to adverse effects but may simply indicate exposure. The linkage between effects of Pb on blood parameters is well documented, however, the linkage between hematological indicators and ecologically relevant effects is less well understood.	Consistent with previous studies, the weight of the evidence in new studies continues to support findings of Pb effects on heme synthesis and ALAD enzyme activity. New studies in birds near historical mining areas and altered serum profiles and blood cell counts in vertebrates provide evidence for additional species and hematological endpoints potentially effected by Pb. The evidence is sufficient to conclude a causal relationship between Pb exposure and hematological effects in invertebrates and vertebrates in terrestrial ecosystems.
	Aquatic Organisms:	
	In metal impacted habitats, ALAD is a recognized biomarker of Pb exposure. Changes in ALAD are not always related to adverse effects but may simply indicate exposure. In fish, Pb effects on blood chemistry have been documented with Pb concentrations ranging from 100 to 10,000 µg Pb/L.	Consistent with previous studies, the weight of the evidence in new studies continues to support findings of Pb effects on ALAD and expands this evidence to additional species of bacteria, invertebrates, and vertebrates as well as new studies on altered blood cell counts in vertebrates. The evidence is sufficient to conclude a causal relationship between Pb exposure and hematological effects in invertebrates and vertebrates in aquatic ecosystems.
Neurobehavioral Effects	Terrestrial Organisms:	
	Exposure to Pb in laboratory studies and simulated ecosystems may alter species competitive behaviors, predator-prey interactions and contaminant avoidance behaviors.	Recent studies continue to support previous evidence that Pb exposure is associated with behavioral alterations. New studies identify possible molecular targets for Pb neurotoxicity in invertebrates and there is new evidence in a few invertebrate and vertebrate species for behavioral effects associated with Pb exposure (i.e., feeding and escape behaviors). The evidence is sufficient to conclude that there is a likely causal relationship between Pb exposure and neurobehavioral effects in terrestrial invertebrates and vertebrates.
	Aquatic Organisms:	
	Exposure to Pb has been shown to affect brain receptors in fish and may alter avoidance behaviors and predator-prey interactions.	Recent studies continue to support previous evidence that Pb exposure is associated with behavioral alterations. New studies identify possible molecular targets for Pb neurotoxicity in fish and provide additional evidence for Pb effects on behaviors in aquatic organisms that may impact predator avoidance (swimming). The evidence is sufficient to conclude that there is a likely causal relationship between neurobehavioral effects in aquatic invertebrates and vertebrates.

Outcome/Effect	Conclusions from the 2006 Pb AQCD	Conclusions from the (2012-2nd Draft) Pb ISA
Developmental and Reproductive Effects	Terrestrial Organisms:	
	No information on reproduction in plants.	There are an insufficient number of studies that consider Pb effects on plant reproduction. Thus the evidence is inadequate to infer a causal relationship for terrestrial plants
	Limited evidence in invertebrates and vertebrates.	Recent studies in a few taxa expand the evidence for Pb effects on developmental and reproductive endpoints for invertebrates and vertebrates at concentrations that generally exceed Pb levels in U.S. soils. In some organisms, exposure-dependent responses in development and reproductive outcomes are observed in experiments where exposure increases from background level to levels greater than near point sources. Data on terrestrial species is supported by toxicological data from mammals in the context of human health research. The evidence is sufficient to conclude a causal relationship in terrestrial invertebrates and vertebrates.
	Aquatic Organisms:	
	No reviewed studies on reproductive effects in aquatic plants. Reproductive and developmental effects reported in a few species of invertebrates at <50 µg Pb/L and in fish at <150 µg Pb/L	Recent evidence supports previous findings of reproductive and developmental effects of Pb in aquatic biota and differential lifestage response at near ambient concentrations of Pb in some organisms. The evidence is inadequate to conclude a causal relationship for plants, and sufficient to conclude a causal relationship in invertebrates and vertebrates.
Growth	Terrestrial Organisms:	
	Pb inhibits photosynthesis and respiration in plants. Limited evidence for growth effects in soil invertebrates, avian and mammalian consumers.	Recent studies support previous findings of Pb effects on plant growth with some evidence for exposure-dependent decreases in some plant species' biomass in soil amended with 30 mg Pb/kg soil. The evidence is adequate to conclude a causal relationship in plants. Limited studies considered effects on growth in invertebrates and vertebrates. The evidence is inadequate to conclude a causal relationship for terrestrial invertebrates and vertebrates.
	Aquatic Organisms:	
	Evidence for growth effects in algae, aquatic plants and aquatic invertebrates Most primary producers experience EC_{50}s for growth in the range of 1,000 to 100,000 µg Pb/L	The weight of the evidence continues to support growth effects of Pb in aquatic plants and invertebrates.Recent studies on growth in invertebrates find effects of Pb at lower concentrations than previously reported. The evidence is sufficient to conclude a causal relationship between Pb exposure and growth in aquatic plants and invertebrates. Growth inhibition in one species of freshwater snail was observed at <4 µg Pb/L in juveniles. Lowest genus mean chronic value for Pb reported at 10 µg Pb/L in a freshwater mussel. The evidence is inadequate to conclude a causal relationship between Pb exposure growth effects in aquatic vertebrates.

Outcome/Effect	Conclusions from the 2006 Pb AQCD	Conclusions from the (2012-2nd Draft) Pb ISA
Survival	Terrestrial Organisms:	
	No information on mortality in plants. Effects of Pb on invertebrates and vertebrates include decreased survival. In terrestrial and avian species toxicity was observed in laboratory studies over a wide range of doses (<1 to >1,000 mg Pb/kg body weight•day) (U.S. EPA, 2005b).	Recent studies in invertebrates and vertebrates support previous associations between Pb exposure and mortality. The evidence is inadequate to conclude a causal relationship between Pb exposure and survival for terrestrial plants. The evidence is sufficient to conclude a causal relationship in terrestrial vertebrates and invertebrates.
	Aquatic Organisms:	
	No studies reviewed on mortality in plants at current concentrations of Pb in the environment. Pb impacted survival of some aquatic invertebrates at <20 µg Pb/L dependent upon water quality variables (i.e., DOC, hardness, pH). Range of 96-hour LC_{50} values in fathead minnow: 810->5,400 µg Pb/L	The weight of evidence continues to support Pb effects on survival of aquatic invertebrates and vertebrates and indicates that there are effects in a few species at lower concentrations than previously reported. New evidence for effects in a few invertebrates: at <20 µg Pb/L New evidence in fish for impacts to survival at <100 µg Pb/L dependent upon water quality parameters and lifestage 96- hour LC_{50} values as low as 41 µg Pb/L in fathead minnows tested in natural waters from across the U.S. The evidence is inadequate to conclude a causal relationship between Pb exposure and survival for aquatic plants. The evidence is sufficient to conclude a causal relationship between Pb exposure and survival for aquatic invertebrates and vertebrates.
Community and Ecosystem Level Effects	Terrestrial Ecosystems:	
	Effects of Pb difficult to interpret because of the presence of other stressors including metals. The 1986 Pb AQCD reported shifts toward Pb-tolerant communities at 500 to 1,000 mg Pb/kg soil. In the 2006 Pb AQCD, decreased species diversity and changes in community composition were observed in ecosystems surrounding former smelters.	New evidence for effects of Pb in soil microbial communities add to the body of evidence for effects at higher levels of biological organization. However, most evidence for Pb toxicity to terrestrial biota is from single-species assays. Uncertainties exist in generalizing effects observed under small-scale, predicted conditions up to effects at the ecosystem level however, uptake of Pb into terrestrial organisms and subsequent effects on reproduction, growth and survival at the species level is likely to lead to effects at the population, community and ecosystem level. The evidence is sufficient to conclude that there is a likely causal relationship between Pb exposure and the alteration of species richness, species composition and biodiversity in terrestrial ecosystems.
	Aquatic Ecosystems:	
	Most evidence of community and ecosystem level effects is from near point sources, usually mining effluents. Effects of Pb difficult to interpret because of the presence of other stressors including metals. Generally, there is insufficient information available for single materials in controlled studies to permit evaluation of specific impacts on higher levels of organization (beyond the individual organism).	New evidence for Pb effects on sediment-associated and aquatic plant communities add to the body of evidence of effects at higher levels of biological organization. However, most evidence for Pb toxicity to aquatic biota is from single-species assays. Uncertainties exist in generalizing effects observed under small-scale, predicted conditions up to effects at the ecosystem-level however, uptake of Pb into aquatic organisms and subsequent effects on reproduction, growth and survival at the species level is likely to lead to effects at the population, community and ecosystem level. The evidence is sufficient to conclude that there is likely to be a causal relationship between Pb exposure and the alteration of species richness, species composition and biodiversity in aquatic ecosystems.

CHAPTER 3 AMBIENT LEAD: SOURCE TO CONCENTRATION

3.1 Introduction

This chapter reviews concepts and findings in atmospheric sciences that provide a foundation for the detailed presentation of evidence of Pb exposure and Pb-related health and ecological effects in subsequent chapters. Information in this chapter builds on previous Pb AQCDs using new data and studies. This includes new knowledge of Pb fate and transport, the latest developments in monitoring and analysis methodologies, and recent data describing Pb concentrations as a function of size range. The chapter focuses on Pb concentrations in the U.S. but includes non-U.S. studies to the extent that they are informative regarding current conditions in the U.S. Description of the chemical forms of Pb is not provided here, however, because this information is well established. The reader is referred to the 2006 Pb AQCD for a description of the chemical forms of Pb (U.S. EPA, 2006b).

Section 3.2 provides an overview of the sources of ambient air Pb. Section 3.3 provides a description of the fate and transport of Pb in air, soil, and aqueous media. Descriptions of Pb measurement methods, monitor siting requirements, and monitor locations are presented in Section 3.4. Ambient Pb concentrations, their spatial and temporal variability, size distributions of Pb-bearing particulate matter (PM), associations with copollutants and background Pb concentrations are characterized in Section 3.5. Concentrations of Pb in non-air media and biota are described in Section 3.6.

3.2 Sources of Atmospheric Lead

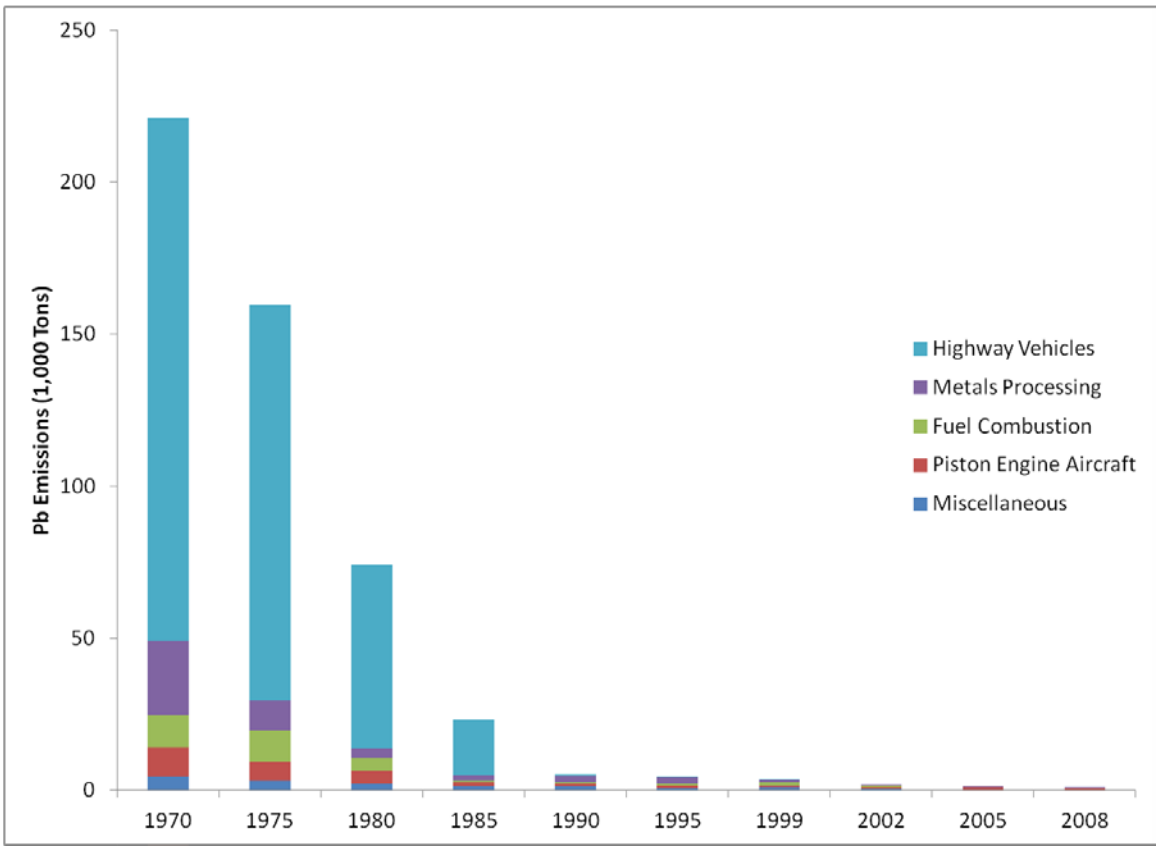
The following section reviews updated National Emissions Inventory (NEI) data from 2008 (U.S. EPA, 2011a), which is the most recently available quality-assured Pb emissions data and compares these emissions data with those from previous years. This section also reviews updated information from the peer-reviewed literature regarding sources of ambient Pb. Detailed information about processes for anthropogenic emissions and naturally-occurring emissions can be found in the 2006 Pb AQCD (U.S. EPA, 2006b). The papers cited herein generally utilized PM sampling data, because ambient airborne Pb readily condenses to PM. The mobile source category included combustion products from organic Pb antiknock additives used in piston-engine aircraft (hereafter referred to piston-engine aircraft emissions).

3.2.1 National Emissions Inventory

The 2006 Pb AQCD (U.S. EPA, 2006b) listed the largest sources to be (in order): industrial-commercial-institutional boilers and process heaters (17%), coal utilities boilers (12%), mobile sources (10%), iron and steel foundries (8%), and miscellaneous sources from industrial processes, incineration, and utilities, each contributing less than 5% (53%). The sources listed in the 2006 Pb AQCD were based on the 2002 NEI (U.S. EPA, 2006a). Subsequent correction of computational errors prior to completion of the 2008 NAAQS review provided corrected estimates for the 2002 inventory which indicated the largest sources to be (in order): mobile sources from the use of leaded aviation gas usage in piston-engine aircraft (45%), metallurgical industries (23%), manufacturing (14%), incineration (8%), boilers (6%), and miscellaneous sources contributing less than 5% (U.S. EPA, 2007h). The 2002 and prior year inventories discussed in this document reflect the corrected information.

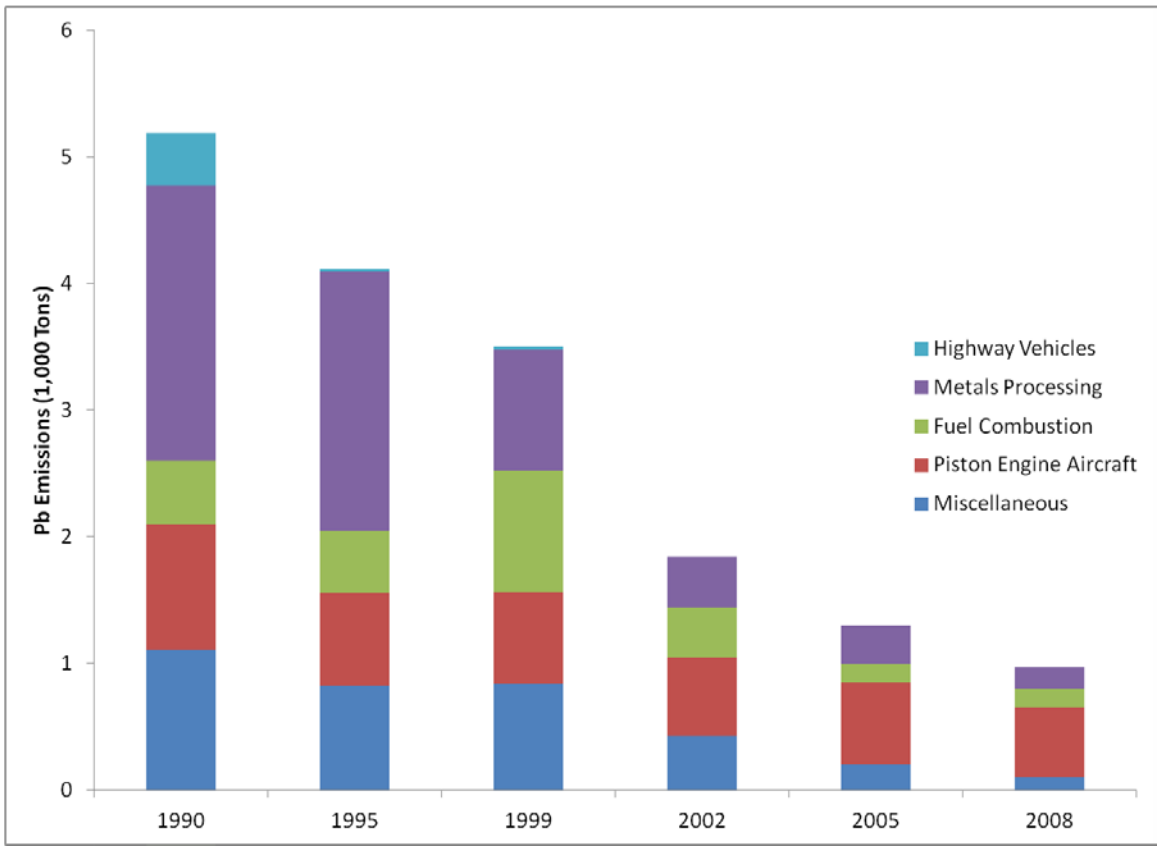
Emissions of Pb have dropped substantially over the past forty years, as shown in Figure 3-1 and Figure 3-2. The reduction before 1990 is largely due to the phase-out of Pb as an anti-knock agent in gasoline for on-road automobiles, as discussed in the 2006 Pb AQCD (U.S. EPA, 2006b). This action resulted in a 98% reduction in Pb emissions from 1970-1995. Total Pb emissions over the period 1995-2008 decreased an additional 76%, from 4,100 tons in 1995 to 970 tons in 2008. Additional emissions reductions are related to enhanced control of the metals processing industry. In 1995, metals processing accounted for 42% (2,200 tons) of total Pb emissions. By 2008, metals processing accounted for 18% (170 tons) of total emissions. This represented more than an order of magnitude decrease in Pb emissions from metals processing. Emissions from piston-engine aircraft decreased 34% over this time period. In 1990, nonroad Pb emissions were 990 tons, 830 tons of which were generated from piston-engine aircraft, and represented 19% of total Pb emissions. In 2008, nonroad Pb emissions from piston-engine aircraft were slightly lower at 550 tons,[1] which represented 56% of all Pb emissions. 2008 piston-engine aircraft emissions were comprised of 254 tons of Pb from emissions at or near airports and 296 tons of Pb emitted in flight (i.e., outside the landing and take-off cycles). "Miscellaneous" emissions from other industrial processes, solvent utilization, agriculture, and construction constituted 10% of emissions (100 tons) in 2008 (U.S. EPA, 2011a, 2008a).

[1] This is the most recent version of the 2008 National Emissions Inventory and is posted separately from version 1 and version 1.5. The piston-engine aircraft emissions inventory can be obtained from the following site: http://www.epa.gov/ttnchie1/net/2008inventory.html under the link for Aircraft, Locomotive, and Commercial marine Vessel sources.



Source: U. S. EPA (2011a, 2008a)

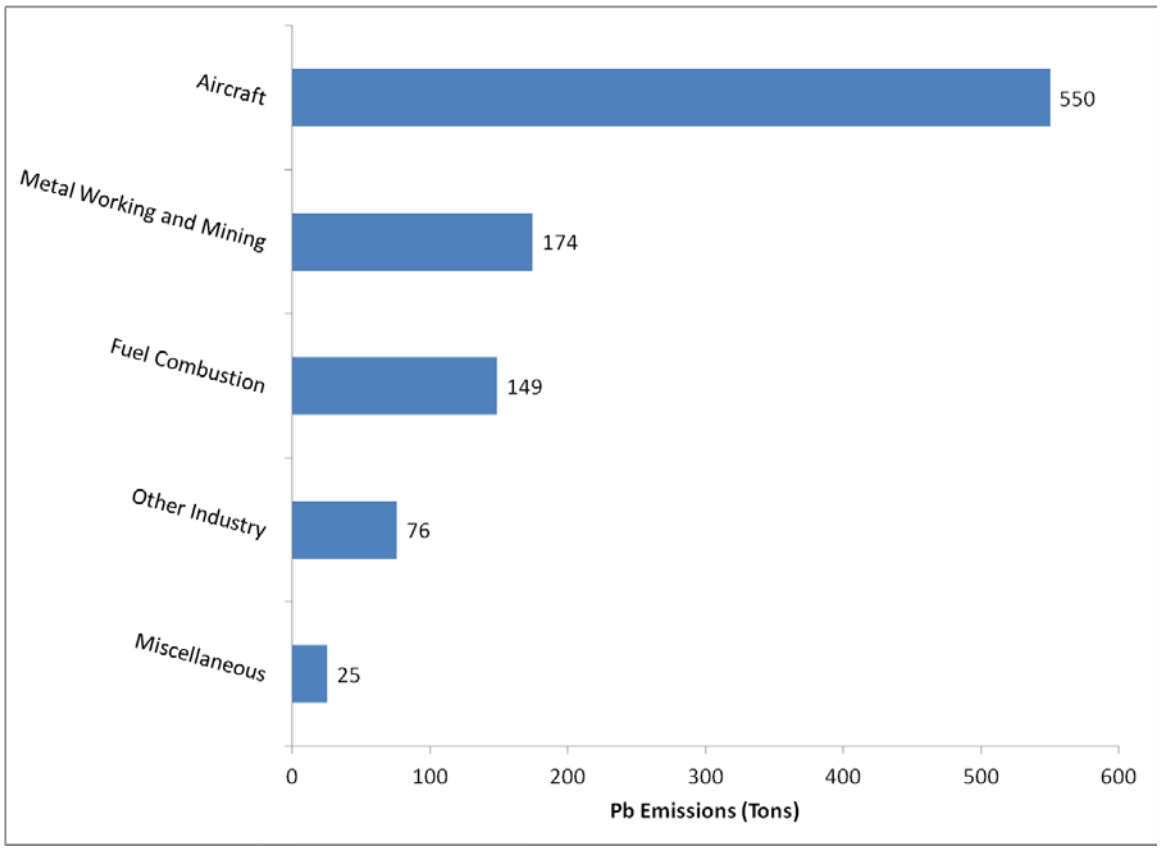
Figure 3-1 Trends in Pb emissions (thousand tons) from stationary and mobile sources in the U.S., 1970-2008.



Source: U. S. EPA (2011a, 2008a)

Figure 3-2 Trends in Pb emissions (thousand tons) from stationary and mobile sources in the U.S., 1990-2008.

Direct emissions of Pb into the atmosphere primarily come from piston-engine aircraft, fuel combustion, and industrial activities. Direct Pb emissions estimated by the 2008 NEI are shown in Figure 3-3. Piston-engine aircraft produced more than half of all emissions (550 tons). Metal working and mining contributed 170 tons (18%) of Pb emissions in 2008, followed by industrial fuel combustion (15%), other industry (8%), and miscellaneous contributions from agriculture, solvent utilization, and operation of commercial marine vessels and locomotives (3%) (U.S. EPA, 2011a). Pb emissions from the "metal working and mining" category include the single primary Pb smelter in the U.S., the Doe Run facility in Herculaneum, MO; secondary Pb smelters, mostly designed to reclaim Pb for use in Pb-acid batteries; and smelters for other metals.



Source: U. S. EPA (2011a)

Figure 3-3 Nationwide stationary and mobile source Pb emissions (tons) in the U.S. by source sector in 2008.

There is substantial variability in Pb emissions across U.S. counties, as shown in Figure 3-4 for the continental U.S. The emissions levels, shown in units of tons, vary over several orders of magnitude. Ninety-four percent of U.S. counties had 2008 emissions below 1 ton, and 50% of counties had 2008 emissions below 0.044 tons. This category included all counties emitting more than 20 tons of Pb in 2008. Jefferson County, MO was the highest emitting county, with over 34 tons of airborne Pb emissions in 2008. Jefferson County is home to the Doe Run primary Pb smelting facility, which is the only remaining operational primary Pb smelter in the U.S. and is planning to cease the existing smelter operations at this site by April, 2014 (DRRC, 2010). Pb emissions from piston-engine aircraft operating on leaded fuel occur at approximately 20,000 airports across the U.S. Airports tend to be more numerous around highly populated metropolitan regions, which suggests that emissions from piston-engine aircraft may be higher in these locations compared with rural areas. In twenty-five counties, piston-engine aircraft are estimated to emit cumulatively greater than one ton of Pb in 2008 U.S. EPA (2011a).

3.2.2 Anthropogenic Sources

Anthropogenic Pb source categories are organized below in order of magnitude with regard to the sum of emissions nationally reported on the 2008 NEI (U.S. EPA, 2011a). Pb sources were reviewed in the 2006 Pb AQCD (U.S. EPA, 2006b) by species. Forms of Pb commonly observed in the environment are carried forward from the 2006 Pb AQCD (U.S. EPA, 2006b) and are presented in Table 3-1 to serve as a reference for the categories of Pb sources described in Sections 3.2.1 and 3.2.2.

Table 3-1 Pb compounds observed in the environment

Emission Source	Observed Pb Compounds
Minerals	PbS (Galena)
	PbO (Litharge, Massicot)
	Pb_3O_4 ("Red Pb")
	$PbSO_4$ (Anglesite)
Smelting aerosols	Pb^0, PbS
	$PbSO_4$, PbO
	$PbCO_3$
	Pb silicates
Coal combustion aerosols	PbS
	PbSe
Coal combustion flue gases	Pb^0, PbO, PbO_2 (Above 1,150 K)
	$PbCl_2$ (Low rank coals, above 1,150 K)
	$PbSO_4$ (Below 1,150 K)
Wood combustion	$PbCO_3$
Waste incineration aerosols	$PbCl_2$, PbO
Soils near mining operations	$PbCO_3$
	$PbSO_4$
	$[PbFe_6(SO_4)_4(OH)_{12}]$
	$[Pb_5(PO_4)_3Cl]$
	$[Pb_4SO_4(CO_3)_2(OH)_3]$
	$PbS\text{-}Bi_2S_3$
	Pb oxides, silicates
Piston-engine aircraft emissions, racing vehicle exhaust (combustion of leaded fuel)	$PbBr_2$
	Alkyl Pb
	$PbBrCl\text{-}NH_4Cl$, $PbBrCl\text{-}_2NH_4Cl$
Roadside dust	$PbSO_4$, Pb^0, $PbSO_4(NH_4)SO_4$, Pb_3O_4, $PbO\text{-}PbSO_4$ and $_2PbCO_3\text{-}Pb(OH)_2$
Brake wear, wheel weights	Pb^0
Aircraft engine wear	Pb^0

3.2.2.1 Lead Emissions from Piston-engine Aircraft Operating on Leaded Aviation Gasoline and Other Non-Road Sources

The largest source of Pb in the NEI, in terms of total emissions nationally, is emissions from piston-engine aircraft operating on leaded aviation gasoline (U.S. EPA, 2011a). Levin et al. (2008) point out that emissions from piston-engine aircraft are exempt from reporting to the EPA Toxic Release Inventory. As outlined in Table 3-1, there are several forms of Pb emitted from engines operating on leaded fuel. Dynamometer testing has indicated that Pb emissions from piston engines operating on leaded fuel can occur in the particulate and gaseous forms. For example, Gidney et al. (2010) performed dynamometer testing on automobiles operating on standard gasoline and on gasoline with low levels of organometallic additives. Tetraethyl Pb was included since it is still used in

piston-engine aircraft fuel. Gidney et al. (2010) point out that, where tetraethyl Pb is used as an additive in piston-engine aircraft fuel, the fuel also contains ethylene dibromide, which reacts with Pb to form Pb bromide and Pb oxybromides. Pb bromides and Pb oxybromides are more volatile than elemental Pb at combustion temperatures and are therefore exhausted from the engine. After being exhausted, the brominated Pb compounds cool to ambient temperatures and condense to form solid particles. In contrast, emissions of organic Pb would remain largely in the vapor phase at ambient temperatures. Studies of Pb emissions within enclosed microenvironments where automobiles were the dominant Pb source cited within the 1986 Pb AQCD (U.S. EPA, 1986a), reported that organic Pb vapors contributed less than 20% of total vehicular Pb emissions. A more recent study supports this (Shotyk et al., 2002). The 20% estimate of organic Pb emissions from the previous studies of on-road Pb emissions may potentially provide an upper bound for organic Pb emissions from current piston-engine aircraft.

Pb emission rates from piston aircraft vary with fuel consumption rates, which depend on the engine/airframe combination and the mode of operation of the aircraft. The ASTM specification for the maximum Pb content in "100 Low Lead", the most commonly used leaded piston-engine aircraft fuel, is 2.12 g of elemental Pb/gallon (ASTM, 2007). Fuel consumption rates can be obtained for some engine/aircraft combinations by running FAA's Emissions and Dispersion Modeling System (FAA, 2011). Fuel consumption for piston-engine aircraft operating at one airport in the U.S. were estimated to range from 1.6 g/sec of fuel during taxi-out to 15.3 g/sec of fuel during run-up preflight check for single-engine aircraft and 5.1 g/sec during taxi and 50 g/sec during preflight run-up check for twin-engine aircraft (Carr et al., 2011). Fuel consumption rates for aircraft listed in FAA's Emissions and Dispersion Modeling System were used to develop the Pb emissions inventory for piston aircraft that are discussed in Section 3.2.1. EPA estimates that on average, 7.34 g of Pb is emitted during a landing and take-off cycle conducted by piston-engine aircraft (ERG, 2011).

3.2.2.2 Emissions from Metals Processing and Mining

High Pb emissions were observed in the 2008 NEI (U.S. EPA, 2011a) in Herculaneum, MO, where the Doe Run Pb smelter is operated. Although it is set to cease smelting operations in 2014 (2010), it is of interest to consider studies of primary smelter emissions in the context of the data analyzed in this ISA. Batonneau et al. (2004) and Sobanska et al. (1999) found that the Pb content in PM emitted from a primary Pb smelter was 56.6% by weight, and the Pb content in PM from a Pb/Zn smelter was 19.0% by weight. Choel et al. (2006) confirmed that Pb was strongly associated with sulfur in Pb-Zn smelter emission PM, and that Pb sulfates and Pb oxy-sulfates were the most

abundant species, with important contributions from Pb oxides. Pb concentrations downwind of the smelter were roughly thirty-five times higher than upwind in this study (0.625-0.880 µg/m^3).

Fugitive emissions from secondary Pb processing can be substantial over the course of a year, but they are difficult to estimate. Thurston et al. (2011) performed source apportionment of $PM_{2.5}$ found that Pb-$PM_{2.5}$ concentrations from the Chemical Speciation Network (CSN) were associated with the metals industry along with Zn-$PM_{2.5}$. Goyal et al. (2005) estimated fugitive emissions using concentration data obtained from samplers sited in close vicinity of secondary Pb recovery facilities and meteorological data from nearby weather monitoring stations. Regression modeling and Bayesian hierarchical modeling were both used to estimate fugitive and stack emissions from facilities in Florida, Texas, and New York. Depending on the model used, median fugitive emissions were estimated to be 1.0×10^{-6} to 4.4×10^{-5} g Pb/m^2·sec at the Florida site, 9.4×10^{-7} to 2.0×10^{-6} g/m^2·sec for the Texas site, and 8.8×10^{-7} to 1.1×10^{-6} g/m^2·sec at the New York site. Median stack emissions estimates varied widely among the models, with the Florida site median ranging from 1.4×10^{-6} to 1.4×10^{-1} g Pb/sec, the Texas site median ranging from 8.4×10^{-2} to 8.6×10^{-2} g/sec, and the New York site ranging from 8.4×10^{-3} to 1.0×10^{-2} g/sec. Additionally, the Bayesian hierarchical model was used to estimate fugitive Pb emissions nationwide using concentration data as prior information. Nationwide median fugitive emissions were estimated to be 9.4×10^{-7} to 3.3×10^{-6} g/m^2·sec. Recently, speciation of emissions from a battery recycling facility indicated that PbS was most abundant, followed by Pb sulfates ($PbSO_4$ and $PbSO_4$-PbO), PbO and Pb^0 (Uzu et al., 2009).

In addition to secondary Pb smelting, Pb emissions occur from processing of other metals. For example, a recent study examined Pb emissions from a sintering plant, a major component of the steel making process in southern France (Sammut et al., 2010). Cerussite, a Pb carbonate ($PbCO_3$-$_2H_{2O}$), was observed to be the most abundant species and contributed 20 g Pb/kg measured PM. In another example, Reinard et al. (2007) used a real-time single particle mass spectrometer to characterize the composition of PM_1 collected in Wilmington, Delaware in 2005 and 2006. Strong Pb-Zn-K-Na associations were observed within 13% of PM samples. Comparison with stack emissions revealed that a nearby steel manufacturing facility was an important source of Pb. Ambient PM classes containing only a subset of such elements, e.g., Zn only, Pb-K only were non-specific and so could not be mapped to individual sources. Ogulei et al. (2006) observed that 6% of Pb in $PM_{2.5}$, along with some O_3, Cu, and Fe, was attributed to steel processing in Baltimore, MD. Murphy et al. (2007) conducted a detailed study of the distribution of Pb in single atmospheric particles during the fifth Cloud and Aerosol Characterization Experiment in the Free Troposphere campaign at the Jungfraujoch

research station in Switzerland and found that the predominant type of urban Pb-bearing aerosols contained Pb together with K and Zn. The mode of the size distribution for this type was around 200 nm.

Waste from current or defunct mines has been shown to present an additional fugitive source of Pb. For example, Zheng et al. (2009) applied source apportionment in three northeastern Oklahoma towns to identify the influence of "chat", or waste piles from formerly operational Pb-Zn mines, on $PM_{10-2.5}$ and $PM_{2.5}$. They estimated that mine waste was responsible for 88% of Pb in $PM_{10-2.5}$ samples and 40% of Pb in $PM_{2.5}$ samples.

3.2.2.3 Fossil Fuel Combustion

Murphy et al. (2007) found that the volatility of Pb and its compounds such as PbO may result in its presence at high concentration in the submicron fraction of PM emitted from coal emissions. $PbSO_4$, also derived from coal combustion, has low water solubility (Barrett et al., 2010). Murphy et al. (2007) presented an estimated U.S. mass budget for Pb emitted from consumption of select fuels and crude oil. Fuel consumption estimates for 2005 were employed (Freme, 2004). Based on an annual consumption of 1.0×10^9 tons coal with an average Pb concentration of 20 mg/kg (range: 5 to 35 mg/kg) and using an emission factor (airborne fraction) of approximately 0.01, coal contributed approximately 200 tons Pb/yr to the atmosphere. At the time of the Murphy et al. (2007) study, there were no emission factors for crude oil or residual oil but these represent potentially large sources (up to 100-500 tons/year and up to 25-700 tons/year, respectively). As part of recent rulemaking, EPA has developed a draft Pb emission factor of 1.3×10^{-5} lb/MMBtu for boilers larger than 25 MW that use #2 or #6 fuel oil (U.S. EPA, 2011b).The amounts of Pb emitted from these U.S. sources, however, are several orders magnitude smaller than those estimated to arise from coal combustion in China.

Coal combustion is considered to be a major source of Pb in the atmosphere now that leaded gasoline has been phased out for use in on-road vehicles (Diaz-Somoano et al., 2009). Global Pb estimates are considered here to inform understanding of U.S. Pb emissions from coal combustion. Rauch and Pacyna (2009) constructed global metal cycles using anthropogenic data from 2000. They confirmed that the largest anthropogenic airborne Pb emissions arise from fossil fuel combustion, and they quantified Pb emissions at 85,000 tons/year worldwide. Globally, Pb emissions from stationary sources have been increasing and the north-south gradient in aerosol Pb concentrations over the Atlantic Ocean has disappeared as a result of industrialization of the southern hemisphere (Witt et al., 2006; Pacyna and Pacyna, 2001). The Pb isotope

ratio values (mainly $^{206}Pb/^{207}Pb$) for coal from around the world have been compared with those for atmospheric aerosols. In most parts of the world, there has been a difference between the signature for aerosols and that for coal, where the atmospheric $^{206}Pb/^{207}Pb$ ratio values are lower, indicative of additional contributions from other sources. Zhang et al. (2009a) used single particle aerosol mass spectrometry (ATOFMS) to find that PM containing Pb along with OC and/or EC was attributed to coal combustion processes in Shanghai, China; this accounted for roughly 45% of Pb-bearing PM.

Seasonal effects of the contributions of Pb emissions from coal combustion have been observed. For example, in Tianjin, northern China, the winter heating period starts in November, and the contribution from coal combustion to the Pb aerosol becomes high during the winter. This leads to both a high Pb content and a high $^{206}Pb/^{207}Pb$ ratio. Coal consumption and Pb-bearing PM concentrations declined during the summer months, and Pb from other sources, mainly vehicle exhaust emissions, became relatively more pronounced (Wang et al., 2006c). This seasonal relationship contrasts with observations for the U.S. described in the 2006 Pb AQCD (U.S. EPA, 2006b) which indicated that for West Virginia, higher emissions from power stations occurred in summer months. The increased energy use in summer periods in the U.S. may be attributable to increased requirements for air-conditioning.

3.2.2.4 Waste Incineration

Waste incineration studies suggest that the Pb content vary by industrial or municipal waste stream. For example, Ogulei et al. (2006) performed positive matrix factorization of $PM_{2.5}$ and gaseous copollutants for Baltimore, MD and observed that 63% of Pb in $PM_{2.5}$ was attributed to waste incineration. Other prevalent compounds associated with incineration included NO_3^-, EC, Cd, Cu, Fe, Mn, Se, Zn, O_3, and NO_2 (note that Cl was not observed in this study). A study by Moffet et al. (2008a) found that Pb-Zn-Cl-containing particles in $PM_{2.5}$ samples collected from an industrial area in Mexico City represented as much as 73% of fine PM. These were mainly in the submicron size range and were typically mixed with elemental carbon (EC), suggesting a combustion source. Zhang et al. (2009a) also observed high correlation between Pb and Cl associated with waste incineration in Shanghai, China. Several Pb isotope studies have also been used to distinguish contributions to incineration from industrial sources. Isotope analysis is discussed in more detail in Section 3.4.1.5. Novak et al. (2008) evaluated changes in the amounts and sources of Pb emissions in the U.K. and Czech Republic during the 19th and 20th centuries and found uncertainty in the amount and the isotope composition of Pb emanating from incineration plants. The isotopic signature of Pb recycled into the atmosphere by incineration of various industrial wastes could have shifted from relatively

high $^{206}Pb/^{207}Pb$ ratios consistent with local Variscan ores to lower values reflecting imported Precambrian ores. However, other environmental studies concerning incineration have given highly consistent values for the Pb isotope ratio for European incineration sources. For example, Cloquet et al. (2006) showed that the Pb isotopic composition of urban waste incineration flue gases in northeastern France was ~1.16. de la Cruz et al. (2009) reported that waste incineration was an important source of Pb and showed that the $^{206}Pb/^{207}Pb$ and $^{208}Pb/^{207}Pb$ ratios for waste incineration Pb emitted in European countries were 1.14-1.16 and 2.43 respectively (de la Cruz et al., 2009).

3.2.2.5 Wood Burning

Another potentially uncontrollable source is Pb deposited historically in forests and remobilized during forest fires. The 2006 Pb AQCD (U.S. EPA, 2006b) presented data by Nriagu (1989) estimating that 1,900 metric tons of Pb were emitted globally each year from wildfires. Wildfire Pb emissions were not included in the NEI. Murphy et al. (2007) observed that a fraction of particles contained small quantities of Pb on biomass particles measured using ATOFMS to sample directly from forest fire plumes in northwest Canada and eastern Alaska in July, 2004; these particles also typically contained SO_4^{-2}. Several studies illustrate moderate-to-long range transport of biomass burning plumes containing Pb. Using positive matrix factorization, Ogulei et al. (2006) estimated that 20% of Pb in $PM_{2.5}$ measured in Baltimore, MD was attributed to a July, 2002 episode of wildfires in Quebec, Canada. Other components strongly associated with the Quebec wildfires included NO_3^-, OC, EC, Cd, Mn, Zn, O_3, and CO. Qureshi et al. (2006) also observed a spike up to 42 ng/m^3 in Pb-$PM_{2.5}$ concentration in Queens, NY coinciding with the Quebec wildfires; for comparison, the authors provide the 3-month average from July to September of 5.1 ng/m^3 for Pb-$PM_{2.5}$ in Queens. Similarly, Anttilla et al. (2008) measured PM_{10} in Virolahti, Finland during a wildfire in Russia and observed average Pb-PM_{10} concentrations during the forest fire episodes to be 1.7-3.0 times higher than the reference concentration of 3.5 ng/m^3. Hsu et al. (2009c) observed Pb concentrations in Taiwan attributed to biomass burning in Northeastern China; Pb was highly correlated with K attributed to biomass burning during these episodes. Odigie and Flegal (2011) studied remobilization of Pb during the 2009 wildfires in Santa Barbara, CA. Pb concentrations in ash samples obtained after the wildfire ranged from 4.3 to 51 mg/kg. Isotopic analysis of the ash suggested that the remobilized Pb was initially emitted by a mix of contemporary and previous industrial sources and historic combustion of leaded gasoline. Grouped with "miscellaneous" Pb emissions, fires from agricultural field burning and prescribed fires accounted for 2.4 tons of U.S. Pb emissions in 2008 (U.S. EPA, 2011a).

Several studies have explored the chemical properties of biomass emissions. Obernberger et al. (2006) simualated biomass combustion in a laboratory setting to assess emissions. They reported pre-combustion mean Pb content in wood, bark, and logging residues to range from 2-5 mg/kg dry basis. They reported volatilization and subsequent condensation of Pb emissions from combustion. van Lith et al. (2008; 2006) studied the inorganic element content of wood chips and particle board and the release of inorganic elements during combustion of those materials in laboratory experiments. They measured a Pb content of 16 mg/kg dry basis in particle board and of 0.44 mg/kg dry basis in spruce wood chips. Using three different types of combustion for different materials, they found that up to 10% of Pb was released at a combustion temperature of 500 °C and up to 85% was released at a temperature of 850 °C. At temperatures greater than 650 °C, PbO gas was released under oxidizing conditions; under reducing conditions, Pb gas, PbCl gas, and PbS gases were released at temperatures above 500 °C. Jimenez et al. (2008) performed laboratory experiments of olive tree combustion and concluded that Pb vaporizes upon combustion and then condenses between 900 °C and 560 °C. Jimenez et al. (2008) also observed that Pb concentration in PM changes with oxygen content and temperature, with concentrations converging toward 2,000 mg/kg for increasing percent available oxygen and increasing temperature.

Pb deposition on trees has been documented in Acadia National Park in Maine with mean foliar concentrations ranging from <0.5 to 3.1 mg/kg (Wiersma et al., 2007). Tree ring core samples obtained in the Czech Republic illustrate that the amount of Pb deposited on trees from coal and leaded gasoline combustion sources tended to increase over the depth of the core, with maximum concentrations corresponding to time periods of 1969-1972, 1957-1960, and 1963-1966 in three samples (Zuna et al., 2011).

3.2.2.6 Roadway-Related Sources

Contemporary Emissions from Vehicle Parts

Contemporary Pb emissions from motor vehicles may occur because several vehicle parts still contain Pb. Wheel weights, used to balance tires, are clipped to the rims of tire wheels in order to balance the tires, and may become loose and fall off. Pb wheel weights have been banned in several states including Washington, Maine, and Vermont with legislation considered in Iowa, California, and Maryland. However, Pb wheel weights are a source in most states for the period of time covered in this assessment. Ambient air Pb concentrations near heavily trafficked areas may be related to use of Pb-based wheel weights that are prone to dislodgement. On pavement they may be ground into dust by the pounding forces of traffic (Root, 2000). For example, Schauer et al. (2006) measured

Pb emissions in two traffic tunnels and found that the Pb-$PM_{2.5}$ concentration did not exceed 17% of the Pb-PM_{10} concentration in any of the runs. Schauer et al. (2006) suggested that enrichment in the coarse fraction may have been related to wheel weights. Additionally, Schauer et al. (2006) measured PM_{10} and $PM_{2.5}$ composition from brake dust and found concentrations that were low but statistically significantly greater than zero for Pb in PM_{10} (0.02 ± 0.01 mg/g) and Pb in $PM_{2.5}$ (0.01 ± 0.00 mg/g) for semi-metallic brake pads and for Pb in PM_{10} (0.01 ± 0.00 mg/g) for low-metallic brake pads. Song et al. (2011) speciated coarse and fine PM samples obtained next to the New Jersey Turnpike in winter and summer of 2007-2008. Using principal component analysis, they found that Pb was prevalent in the factor including automobile exhaust and brake wear. Pb was observed to have a similar size distribution as Zn in the winter and Zn and Cd in the summer, with higher concentrations in the fine fraction at a mode of 0.18-0.32 µm. Additionally, Hjortenkrans et al. (2007) used material metal concentrations, traffic volume, emissions factors, and sales data to estimate the quantity of Pb emitted from brake wear and tires in Stockholm, Sweden in 2005. They observed that 24 kg Pb were emitted from brake wear each year, compared with 2.6 kg of Pb from tire tread wear; an estimated 549 kg was estimated to have been emitted from brake wear in 1998. McKenzie et al. (2009) determined the composition of various vehicle components including tires and brakes and found that tires were a possible source of Pb in stormwater, but no identification of Pb-containing PM in stormwater was carried out. However, PM from tire abrasion is usually found in coarser size ranges (Chon et al., 2010), while those in the submicron range are more typically associated with combustion and incineration sources.

Unleaded Fuel

Unleaded fuel contains Pb as an impurity within crude oil (Pacyna et al., 2007). Schauer et al. (2006) measured Pb in $PM_{2.5}$ from tailpipe emissions and observed quantities in on-road gasoline emissions that were statistically significantly different from zero (83.5 ± 12.80 mg/kg), whereas emissions of Pb from diesel engines were not statistically significantly different from zero. Hu et al. (2009a) investigated the heavy metal content of diesel fuel and lubricating oil. They found <1-3 mg/kg Pb in samples of lubricating oil. Hu et al. (2009a) also measured the size distribution of Pb emissions during dynamometer testing of heavy duty diesel vehicles with different driving patterns and control technologies. An urban dynamic driving schedule (UDDS) designed to mimic urban stop-go driving conditions, was simulated in two cases to produce 80 and 241 ng Pb/km driven, depending on the control technology used. Respectively, 54% and 33% of those emissions were smaller than 0.25 µm in MMAD.

3.2.2.7 Deposited Lead

Soil Pb can serve as a reservoir for deposited Pb. The following subsections describe studies of previously deposited Pb that originated from industrial activities, historical use of leaded on-road gasoline, and urban sources such as paint and building materials. The 2006 Pb AQCD (U.S. EPA, 2006b) cited an estimate by Harris and Davidson (2005) that more than 90% of airborne Pb emissions in the South Coast Basin of California were from soil resuspension. This value was obtained by constructing mass balances rather than from direct measurements of Pb along roads, and hence it is an estimate. Currently, measured data are not available with sufficient spatial resolution to discern the specific contribution of soil Pb resuspension to air Pb concentration, but resuspended soil Pb cannot be eliminated as a potential notable source of airborne Pb. The concentration of historically deposited Pb in soil is expected to be the greatest in soil next to roads. Section 3.5.1.2 includes recent information on ambient air concentrations of Pb-TSP, sampled at 6 m AGL at a distance of 500 m from the heavily trafficked I-405 and 10 m from a busy arterial road in Los Angeles. From this monitor, average concentrations were not substantially higher than the local urban background concentration (Sabin et al., 2006b). Insufficient data are available to ascertain if the near road Pb-TSP concentrations would be higher at lower monitor heights. The 2006 Pb AQCD (U.S. EPA, 2006b) also noted a smaller estimate of 40% for the Southern California Air Basin (Lankey et al., 1998).

In a recent paper, Laidlaw and Filipelli (2008) analyzed Interagency Monitoring of Protected Visual Environments (IMPROVE) data to explore conditions under which $PM_{2.5}$ particles estimated to be of crustal origins that may contain Pb may become airborne. They observed a seasonal pattern in the concentration of $PM_{2.5}$ of crustal origins in the atmosphere, and they also found that at one IMPROVE site in central Illinois, 83% of the variability in concentrations of crustal $PM_{2.5}$ was predicted by variability in meteorology and soil moisture content. The authors concluded that seasonality and climate parameters could not be eliminated in relation to ambient Pb concentrations. Such mechanisms are described in more detail in Section 3.3. As described in Sections 3.2.2.6 and 3.6.1, there are many contemporary contributions of Pb to soil in urban areas, and studies summarized here have not quantitatively differentiated the contributions of these various sources to Pb concentrations in urban areas.

Lead from Industrial Activities

Several studies have indicated elevated levels of Pb are found in soil exposed to industrial emissions, including brownfield sites (Dermont et al., 2010; Verstraete and Van Meirvenne, 2008; Jennings and Ma, 2007; Van Herwijnen et al., 2007; Deng and

Jennings, 2006). Pb in industrial soils is described in Section 3.6.1. Recent Pb speciation results also indicate a contribution from resuspended soils in areas with previous major emission sources, but without current major sources. Data from airborne PM in the vicinity of an inactive smelter in El Paso, TX were consistent with Pb-humate as the major form of Pb in airborne PM, suggestive of soil resuspension since the local near-surface soils had high humic content (Pingitore et al., 2009).

Lead from Paint and Building Materials

Exterior structures painted with Pb-based paint have long been known to be a source of Pb in outdoor dust or grit (U.S. EPA, 2006b). Recent studies support older findings. Mielke and Gonzales (2008) sampled exterior paint chips from 25 homes in New Orleans, LA, and they found elevated Pb levels in 24 of the 25 tested exterior paints (median: 36,000 mg/kg). Weiss et al. (2006) studied the distribution of Pb concentration in roadway grit in the vicinity of steel structures in New York City and contrasted those data with roadway grit concentration data where no steel structure was nearby. In each case, the comparison was significant ($p < 0.006$ at one site and $p < 0.0001$ at 4 other sites), with median Pb concentrations in the grit under the steel structures (median: 1,480 mg/kg) collectively being 4.4 times higher than median Pb concentrations in the roadway grit not near a structure (median: 340 mg/kg).

The studies described above considered paint as a source of Pb in outdoor dust through gradual abrasion of the painted surfaces. However, atmospheric conditions may also affect the availability of Pb in paints. Edwards et al. (2009) performed experiments to simulate one week of exposure of Pb-based paints to highly elevated levels of O_3 (11.3 ± 0.8 mg/kg or 150 times the level of the 8-hour NAAQS) and NO_2 (11.6 ± 0.9 mg/kg, or 220 times the level of the annual NAAQS). Following NO_2 exposure, the Pb availability in wipe samples increased by a median of 260% ($p < 0.001$), and following O_3 exposure, the Pb availability increased by a median of 32% ($p = 0.004$).

Building demolition was listed as a source of Pb in urban dust in the 2006 Pb AQCD (U.S. EPA, 2006b). In a follow-up study to previous work cited therein, Farfel et al. (2005) observed that surface loadings of dust containing Pb increased by 200% in streets, by 138% in alleys, and by 26% in sidewalks immediately following demolition of an old building. One month later, Pb dust loadings were still elevated in alleys (18%) and sidewalks (18%), although they had decreased in streets by 29%. However, Farfel et al. (2005) did not provide detailed time series samples from before or after demolition to judge whether the observations made one month following demolition were within the normal conditions of the urban area. These results suggest that building demolition may

be a short-term source of Pb in the environment, but it is unclear if demolition is related to long-term Pb persistence in the environment.

Lead from Historic Automobile Emissions

Historic Pb emissions, or Pb emitted from on-road vehicles prior to the ban on use of leaded automobile gasoline, deposited onto soil and in some areas may serve as a potential source of airborne Pb. The historical use of leaded on-road gasoline has been estimated from documents submitted by Ethyl Corporation to the U.S. Senate (1984) and a report by the U.S. Geological Survey (USGS, 2005); see Mielke et al. (2010a). These estimates are presented in Figure 3-5. The peak U.S. use of Pb additives occurred between 1968 and 1972 with an annual amount of over 200,000 metric tons. According to Ethyl Corporation, the 1970 use of Pb additives was 211,000 metric tons. By 1980, the annual use of Pb additives to on-road gasoline decreased to about 91,000 metric tons or a 57% reduction from its 1970 peak. From 1970 to 1990 there was a 92% decline in Pb additive use. In 1990, the annual U.S. use of Pb additives decreased to 16,000 metric tons, a further 82% decline in Pb additive use from 1980. The final U.S. ban on the use of Pb additives for highway use in on-road gasoline occurred in 1996. After that time, Pb additives were only allowed in nonroad applications, including piston-engine aircraft fuel, racing fuels, farm tractors, snowmobiles, and boats.

Note: Estimates were derived from the proceedings of the U.S. Senate hearings on the Airborne Pb Reduction Act of 1984, S. 2609 (1984) and the U.S. Geological Survey Pb end use statistics (USGS, 2005).

Figure 3-5 Total U.S. Pb additives in on-road gasoline used in on-road vehicles, 1927-1995.

Pb emissions from on-road sources were estimated by the U.S. EPA (1986a), which indicated that 75% of Pb additives were emitted as exhaust, while the remainder were retained within the engine. The tonnages of relatively large >10 µm mass median aerodynamic diameter (MMAD) Pb-PM probably settled locally. EPA (1986a) indicated that 35% of the Pb-PM at that time were < 0.25 µm in MMAD. In high traffic urbanized areas, soil Pb from historic emissions as well as contemporary sources, are elevated adjacent to roadways and decrease with distance away from roadways (Laidlaw and Filippelli, 2008).

The use of Pb additives resulted in a national scale of influence. For example, variously sized urbanized areas of the U.S. have different amounts of vehicle traffic associated with Pb (Mielke et al., 2010b). Figure 3-6 illustrates the national scale of the estimated vehicle-derived Pb aerosol emissions. Note that the estimated 1950-1982 Pb aerosol emissions in the 90 cities below vary from 606 metric tons for Laredo, Texas, to nearly 150,000 metric tons for the Los Angeles-Long Beach-Santa Anna urbanized area. The implication of this figure is that the soil Pb concentration in these areas will be proportional to the magnitude of historic on-road emissions in each city. It is recognized that the amount of soil turnover since 1982 may have varied substantially among the

cities illustrated in Figure 3-6, depending on the amount of highway construction in those cities. As noted in Section 3.2.2.6 , there have historically been, and are currently, many additional sources of Pb contributing to near-roadway soil Pb concentrations. Data are lacking that quantify the range of airborne Pb concentrations originating from historic Pb in resuspended soil particles, but data on airborne concentrations near roadways indicate measured air Pb concentrations (from all contributing sources) to be generally less than 0.02 µg/m^3 (Section 3.5.3.2).

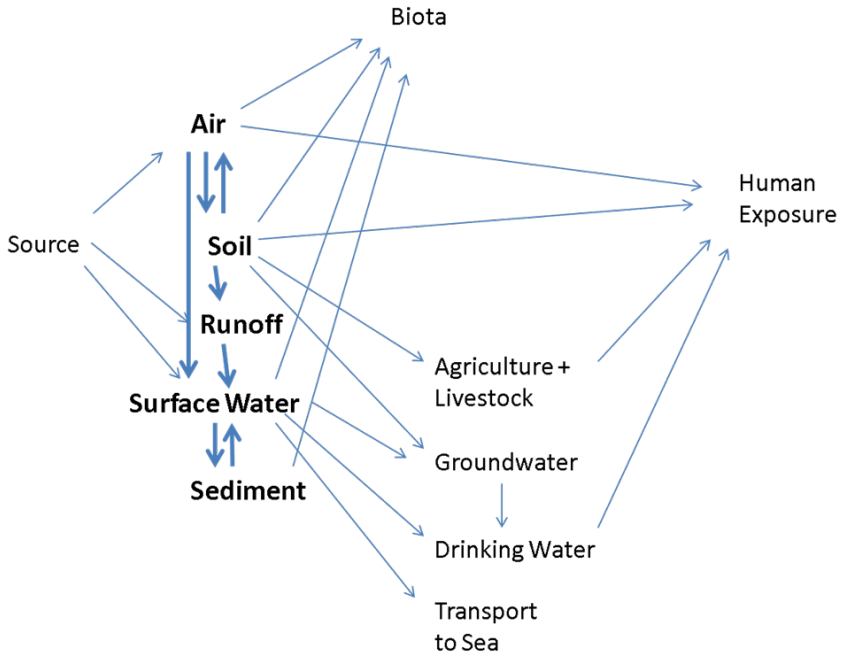
3.3 Fate and Transport of Lead

There are multiple routes of exposure to Pb, including direct exposure to atmospheric Pb, exposure to Pb deposited in other media after atmospheric transport, and exposure to Pb in other media that does not originate from atmospheric deposition. As a result, an

understanding of transport within and between media such as air, surface water, soil, and sediment is necessary for understanding direct and indirect impacts of atmospheric Pb as well as the contribution of atmospheric Pb to total Pb exposure. Figure 3-7 describes relevant Pb transport pathways through environmental media discussed in this chapter and their relationship to key environmental exposure pathways for which some or all of the Pb is processed through the atmosphere. This discussion includes new research on atmospheric transport of Pb, atmospheric deposition and resuspension of Pb, Pb transport in surface waters and sediments, and Pb transport in soil.



Note: Media through which Pb is transported and deposited are shown in bold.

Figure 3-7 Fate of atmospheric lead.

3.3.1 Air

The 2006 Pb AQCD (U.S. EPA, 2006b) concluded that Pb was primarily present in submicron aerosols, but that bimodal size distributions were frequently observed. Pb-PM in the fine fraction is transported long distances, found in remote areas, and can be modeled using Gaussian plume models and Lagrangian or Eulerian continental transport models as reported by several studies. Good agreement between measurements and these models have been reported. Historical records of atmospheric deposition to soil, sediments, peat, plants, snowpacks, and ice cores have provided valuable information on

trends and characteristics of atmospheric Pb transport. Numerous studies using a variety of environmental media indicated a consistent pattern of Pb deposition peaking in the 1970s, followed by a more recent decline. These findings indicated that the elimination of leaded gasoline for motor vehicles has not only led to lower atmospheric concentrations in areas impacted by vehicles (Section 3.5), but a pervasive pattern of decreasing atmospheric Pb deposition and decreasing concentrations in other environmental media even at great distances from sources.

The 2006 Pb AQCD (U.S. EPA, 2006b) documented that soluble Pb was mostly removed by wet deposition, and most of the insoluble Pb was mostly removed by dry deposition. As a result, dry deposition was the major removal mechanism for Pb in coarse PM (which is mainly insoluble) and wet deposition as the most important removal mechanism for fine PM and Pb halides (which were more soluble). Numerous studies reported that Pb dry deposition velocities in the U.S. were mostly within a range of 0.05 to 1.0 cm/sec and dry deposition fluxes ranging from 0.04 to 4 $mg/m^2 \cdot yr$. Precipitation concentrations ranged mostly from 0.5 to 60 μg/L, but with considerably lower concentrations in remote areas, and wet deposition fluxes in the U.S. ranged from 0.3 to 1.0 $mg/m^2 \cdot yr$. Wet deposition was linked to precipitation intensity, with slow even rainfalls usually depositing more Pb than intense rain showers. Rain concentrations decreased dramatically between the early 1980s and the 1990s, reflecting the overall decreasing trend in Pb emissions due to elimination of leaded motor vehicle gasoline. A summary of studies investigating total deposition including both wet and dry deposition indicated typical deposition fluxes of 2-3 $mg/m^2 \cdot yr$ and dry to wet deposition ratios ranging from 0.25 to 2.5. Seasonal deposition patterns can be affected by both variations in local source emissions and vegetation cover, and as a result a consistent seasonal pattern across studies has not been observed, although there have been only a few investigations. The 2006 Pb AQCD (U.S. EPA, 2006b) concluded that resuspension by wind and traffic contribute to airborne Pb near sources.

3.3.1.1 Transport

New research on long range transport as well as transport of Pb in urban areas has advanced the understanding of Pb transport in the atmosphere. While the 2006 Pb AQCD described long range Pb transport as essentially a process of submicron PM transport (U.S. EPA, 2006b), much of the recent research on Pb transport has focused on interactions between anthropogenic and coarser geogenic PM that leads to incorporation of Pb into coarse PM as well as subsequent transformation on exposure to mineral components of coarse PM. Using scanning electron microscopy (SEM), Schleicher et al. (2010) observed interactions of anthropogenic soot and fly ash particles on the surfaces

of coarse geogenic mineral particles and concluded that toxic metals were often associated with coarse PM. Murphy et al. (2007) found that PM released from wild fires and transported over long distances scavenged and accumulated Pb and sulfate through coagulation with small Pb rich PM during transport and that Pb was associated with PM over a wide size range. Erel et al. (2006) also found that Pb enrichment factors calculated for PM from dust storms collected in Israel were much greater than those sampled at their north African source, suggesting that the dust samples had picked up pollutant Pb in transit between the Saharan desert and Israel. Marx et al. (2008) characterized dust samples collected from the surface of glaciers and in dust traps on the remote west coast of New Zealand's South Island and observed that most of the dust samples were enriched in metals, including Pb, compared with their source area sediments.

Pb accumulated on mineral dusts is also subject to atmospheric transformations. $PbSO_4$ is one of the main constituents of Pb-containing aerosols resulting from coal combustion (Gieré et al., 2006) and it has been shown to react with calcite, $CaCO_3$, a PM mineral component, to form $Pb_3(CO_3)_2(OH)_2$, $Pb(CO_3)$ and $Ca(SO_{4)2}{\cdot}H_2O$ on the surface of the calcite (Falgayrac et al., 2006). In laboratory experiments, (Ishizaka et al., 2009) also showed that $PbSO_4$ could be converted to $PbCO_3$ in the presence of water. Approximately 60-80% was converted after only 24 hours for test samples immersed in a water droplet. This compared with only 4% conversion for particles that had not been immersed. As a result of recent research, there is considerable evidence that appreciable amounts of Pb can accumulate on coarse PM during transport, and that the physical and chemical characteristics of Pb can be altered by this process due to accompanying transformations.

3.3.1.2 Deposition

Wet Deposition

The 2006 Pb AQCD (U.S. EPA, 2006b) documented that dry deposition was the major removal mechanism for Pb in coarse PM and wet deposition as the most important removal mechanism for fine PM. Which process is most important for atmospheric removal of metals by deposition is largely controlled by solubility in rain water. Metal solubility in natural waters is determined by a complex multicomponent equilibrium between metals and their soluble complexes and insoluble ionic solids formed with hydroxide, oxide, and carbonate ions. This equilibrium is strongly dependent on pH and ionic composition of the rain water. As pH increases, Pb solubility is reduced. As a consequence, it is possible that efforts to reduce acidity of precipitation could also reduce wet deposition of Pb. Recent research confirms the general trend described in the 2006 Pb AQCD (U.S. EPA, 2006b) that Pb associated with fine PM is usually more soluble in

rain water than Pb associated with coarse PM, leading to a relatively greater importance of wet deposition for fine Pb and of dry deposition for coarse Pb. This could also explain the greater importance of dry deposition near sources because coarse mode PM makes a greater contribution to PM mass. Although recent observations are consistent with these trends they also indicate considerable spatial and seasonal variability. Birmili et al. (2006) found that Pb solubility varied between the two main Pb-containing size fractions, <0.5 µm (~40%) and 1.5-3.0 µm (~10%), indicative of a different chemical speciation. However, the observation that the amount of soluble Pb was higher in their U.K. samples than in an analytically identical study carried out in Seville, Spain (Fernandez Espinosa et al., 2004), led them to conclude that Pb solubility in fine PM may vary on a regional basis (Birmili et al., 2006). For PM_{10} from Antarctica, 90 to 100% of the Pb was insoluble at the beginning of the summer season (November), but by the end of the summer (January), approximately 50% was soluble. Most of the Pb was from long range transport (Annibaldi et al., 2007). These studies illustrate the variable nature of atmospheric Pb solubility.

Dry Deposition

Recent research on dry deposition has focused differences between urban or industrial sites and rural or less industrial areas. For locations outside of industrial areas, new measurements of Pb dry deposition fluxes are similar to those reported in the 2006 Pb AQCD (U.S. EPA, 2006b), but in industrialized urban areas, they are considerably greater. The following studies presented measurements of dry deposition flux obtained by capturing deposited particles onto a sampling substrate. Hence, these measurements did not provide information on net deposition following resuspension of deposited material. Resuspension processes and measurements thereof are described in Section 3.3.1.3. For example, Yi et al. (2006) calculated dry deposition fluxes for trace elements including Pb in New York-New Jersey harbor and observed much greater dry deposition fluxes for this urban industrial site in Jersey City (mean: 50 $\mu g/m^2 \cdot d$) than for suburban New Brunswick (mean: 8 $\mu g/m^2 \cdot d$). Sabin and Schiff (2008) (2008) measured dry Pb deposition flux along a transect from Santa Barbara to San Diego, CA in 2006 and observed and observed a range of 0.52-14 $\mu g/m^2 \cdot d$ for the median values across the eight sites. The highest median Pb flux was observed at Los Angeles Harbor, which is downwind of a harbor with a mix of industrial (harbor-related) and urban activities (14 $\mu g/m^2 \cdot d$). The second highest median Pb flux was observed at San Diego Bay, a military port (3.3 $\mu g/m^2 \cdot d$). This is consistent with similar observations of dry deposition fluxes that were more than ten times greater in urban Chicago than in rural South Haven, Michigan (Paode et al., 1998). These results illustrate the strongly localized nature of atmospheric Pb deposition in source rich areas.

Elements from anthropogenic sources, including Pb, were generally associated with fine PM. In a study of Tokyo Bay (Sakata and Asakura, 2008), reported an average dry deposition velocity of 1.06 cm/sec, which is at the upper end of dry deposition velocities reported in the 2006 Pb AQCD (U.S. EPA, 2006b). They also reported that dry deposition fluxes were greater in industrially impacted urban areas, ranging from 12-17 mg/m^2·yr, more than 10 times the upper bound of the range reported in the 2006 Pb AQCD (U.S. EPA, 2006b).

Recent results also confirmed the trend of decreasing overall deposition fluxes after removal of Pb from on-road gasoline, as described in the 2006 Pb AQCD (U.S. EPA, 2006b). Watmough and Dillon (2007) found that the bulk annual deposition of Pb in a central Ontario forested watershed during 2002-2003 was 0.49 mg/m^2·yr; this was lower than the value of 1.30-1.90 mg/m^2·yr for 1989-91 and represented a 75% decline in Pb deposition. It was consistent with the decline more generally observed for the Northeastern U.S. as a consequence of the restrictions to alkyl-Pb additives in on-road gasoline. From previously published work, and in agreement with the precipitation data described above, most of the decline took place before the start of the Watmough and Dillon (2007) study.

Several important observations can be highlighted from the few studies of atmospheric Pb deposition carried out in the past several years. Deposition fluxes have greatly declined since the removal of Pb additives from on-road gasoline. However, new results in industrial areas indicate that local deposition fluxes there are much higher than under more typical conditions. In general, wet deposition appears to be more important for Pb in fine PM, which is relatively soluble; and dry deposition appears to be generally more important for Pb in coarse PM, which is relatively insoluble. However, the relative importance of wet and dry deposition is highly variable with respect to location and season, probably reflecting both variations in Pb speciation and variations in external factors such as pH and rain water composition. Although industrial Pb emissions are mainly associated with fine PM, and wet deposition is likely to be more important for this size range, a substantial amount of Pb is apparently removed near industrial sources.

3.3.1.3 Resuspension of Lead from Surface Soil to Air after Deposition

The following information focuses on issues regarding the transport processes affecting resuspended soil Pb and dust Pb in urban environments. As described in Section 3.2.1, the greatest point source Pb emissions in the U.S. occur in locations near specific major facilities, such as secondary smelters, and other industrial operations involving large

scale metal processing or fuel combustion. However, in the absence of such sources and in the vicinity of previous major sources, the 2006 Pb AQCD (U.S. EPA, 2006b) concluded that resuspension by mechanical stressors such as traffic, construction, and wind can be a source of airborne Pb above background levels near sources, with Pb accounting for between 0.002 to 0.3% of the mass of resuspended PM_{10}.

Results from several studies have suggested a minor contribution from resuspension to airborne Pb concentration is indicated by a smoothed soil Pb concentration profile that decreases with distance from various sources, including city centers (Laidlaw and Filippelli, 2008), major freeways (Sabin et al., 2006b), and steel structures with abrading paint (Weiss et al., 2006). The smoothed profile is suggested to be consistent with continual Pb resuspension and deposition due to atmospheric turbulence. As noted in the 2006 Pb AQCD (U.S. EPA, 2006b), the contribution of resuspended soil and dust to the airborne burden may be significant from highly contaminated sites (e.g., active or abandoned industrial facilities and Superfund sites). In contrast, as summarized in Section 3.5.3, Pb concentrations near roads in urban areas are one to two orders of magnitude below the current Pb NAAQS.

The urban environment can be considered quite different from natural landscapes because it has been highly modified by human activity, including above- and below-ground infrastructure, buildings, and pavement, and a high density of motorized transportation. These factors may influence the distribution and redistribution of Pb-bearing PM. As shown in Figure 3-8, urban turbulence occurs on several scales. Transport and dispersion of urban grit is subject to air movement within the urban canopy layer, where air movement is driven by air velocity within the urban boundary layer and urban topographical conditions such as building shape, building façade, and street canyon aspect ratio (Fernando, 2010). Within a street canyon, air circulates and tends to form counter-rotating eddies along the height of the canyon (Figure 3-8), which result in lower mean components of air movement, higher turbulence components, and higher shear stress within the canyon compared with open field conditions (Kastner-Klein and Rotach, 2004; Britter and Hanna, 2003). Recirculation around intersection corners and two-way traffic conditions can also enhance turbulence levels, while one-way traffic conditions increase air velocity along the street (Soulhac et al., 2009; Kastner-Klein et al., 2003; Kastner-Klein et al., 2001). Sedefian et al. (1981) measured the length scales of turbulent eddies resulting from passing 50 mph (22.2 m/s) traffic on a test road and observed scales of 0.6-2.7 m when winds were perpendicular to the test road and scales of 1.8-2.7 m when winds were parallel to the road.

Note: Top: multiple scales within the atmospheric boundary layer. Bottom: illustration of airflow recirculation within a single street canyon located in the urban canopy layer.

Figure 3-8 Scales of turbulence within an urban environment.

Recent research on urban PM transport is highly relevant to Pb transport and dispersion because Pb is most prevalently particle-bound. Relevant results for Pb exposure in these areas include observations that PM concentration peaks dissipate more rapidly on wider streets than in narrow street canyons (Buonanno et al., 2011); concentrations are typically

low next to a building because either less source material is available or less material penetrates the boundary layer of the building (Buonanno et al., 2011); and there are stronger inverse relationship between mean wind speed and PM concentration fluctuation intensities at middle sections of urban street blocks compared with intersections (Hahn et al., 2009). Patra et al. (2008) conducted experiments in London, U.K. in which a "tracer" grit (i.e., rock salt) was applied to a road and then the grit's dispersion by traffic was measured over time to simulate resuspension and transport of road dust. During the experiments, 0.039% of the tracer grit was measured to move down the road with each passing vehicle, 0.0050% was estimated to be swept across the road with each passing vehicle, and 0.031% was estimated to become airborne when a vehicle passed.

Harris and Davidson (2008) developed a model of resuspension of single particles initially at rest on a solid surface based on the balance of lift, drag, gravity, torque, and adhesion forces on the particle in addition to turbulent wind fluctuations within a simulated urban boundary layer. In their model simulations showed that 2.5 µm and 10 µm particles reached a maximum height of 0.04-0.06 m above ground level (AGL), while 50 µm particles reached a maximum of 0.2 m AGL and 75 µm particles reached at least 0.4 m AGL. Empirical analysis has shown that lift force is proportional to particle diameter to the power of approximately 1.5, so that large particles actually have larger initial displacement than smaller particles. At the same time, lateral travel distance following resuspension tended to decrease linearly with increasing particle size (0.5 µm particle: median lateral distance estimated at 3.75 m; 100 µm particle: median lateral distance estimated at 0.5 m), reflecting the counteracting force of gravity. Harris and Davidson (2008) estimated that the combination of forces caused a maximum height of 0.05 m to occur for particles with diameters around 75-100 µm, depending on turbulent wind conditions. For all cases simulated, the resuspension and deposition were estimated to occur over time frames on the order of seconds.

Early work described resuspension as an important process for wind erosion for particles up to 100 µm, but indicated that particles larger than this rarely became suspended, and that the tendency of particles to remain airborne long enough for appreciable transport decreases sharply beyond a size of 10 to 20 µm (Nicholson, 1988; Gillette et al., 1974). As a result, long range transport of dust is usually limited to particles smaller than 10 µm (Prospero, 1999).

In urban environments the transport distance that must be traversed to penetrate indoors can be very short, and at the same time resuspension and dispersion of larger particles may be caused by motor vehicles. Resuspension of road dust by traffic becomes more difficult with decreasing particle size because adhesive forces are stronger than shear force that is imparted by traffic-induced turbulent air movement (Harris and Davidson,

2008). The critical diameter at which resuspension occurs when a particle's settling velocity becomes lower than the friction velocity of air needed to move the particle from rest. The work of Gillette et al. (1974), in which a critical diameter of roughly 20 µm was estimated, is based on wind in an open landscape. It would be reasonable to expect that friction velocity would be higher for urban environments with traffic-induced turbulence (Britter and Hanna, 2003). Hence, it is possible that larger particles are resuspended in a heavily-trafficked urban setting (Nicholson and Branson, 1990).

Particle size determines the distance particles can travel and the height which they can achieve before they are removed by gravitational settling. Song et al. (2011) observed that coarse mode Pb concentration was negatively correlated with wind speed (D_p = 14: ρ = -0.62; D_p = 7.8; ρ = -0.76), which suggests that coarse Pb may be dispersed by wind. Observations in near road environments indicate that roughly 15% of Pb in airborne dust in areas impacted by heavy traffic is greater than 10 µm (Cho et al., 2011; Lough et al., 2005; Zereini et al., 2005). Sabin et al. (2006b) also collected three size fractions greater than 11 µm and found that approximately 25% of all Pb mass was associated with particles larger than 29 µm at a site 10 m from a freeway, but only a very small percentage of Pb mass was in this size fraction at an urban background site. These results suggest that both size distribution and concentrations in the immediate vicinity of roadways might differ from estimates based on concentrations from monitoring sites at some distance from roads or on elevated rooftops. In these studies, only one size fraction slightly greater than 10 µm was collected, but another study of road dust (not specific to Pb) reported size fractions extending up to 100 µm with a mass median diameter of greater than 60 µm (Yang et al., 1999). Although the Yang et al. (1999) study did not include Pb, the results suggest that resuspended dust can be larger than PM_{10}. Collectively, the size distribution of Pb-containing resuspended dust is uncertain.

New resuspension studies complement previous research indicating street dust half-lives on the order of one-hundred days (Allott et al., 1989), with resuspension and street run-off as major sinks (Vermette et al., 1991) as well as observations of a strong influence of street surface pollution on resuspension (Bukowiecki et al., 2010), observations of greater resuspension of smaller PM than coarser PM (Lara-Cazenave et al., 1994), leading to enrichment of metal concentrations in resuspended PM relative to street dust (Wong et al., 2006) and observations of wind speed, wind direction, vehicular traffic, pedestrian traffic, agricultural activities, street sweeping and construction operations as important factors determining resuspension.

3.3.2 Water

As described in the 2006 Pb AQCD (U.S. EPA, 2006b), atmospheric deposition has been identified as the largest source of Pb in surface waters, but urban runoff and industrial discharge are also important. Water columns have been described as transient reservoirs with Pb residence times in lakes typically several months long, and shorter residence times expected in turbulent waterways. Because dispersal in waterways is a relatively rapid process, concentrations in surface waters are highest near sources of pollution before substantial Pb removal by flushing, evaporation, and sedimentation occurs. Transport in surface water is largely controlled by exchange with sediments, and the cycling of Pb between water and sediments is governed by chemical, biological, and mechanical processes that are affected by many factors, including salinity, organic complexation, oxidation-reduction potential, and pH. As described in the 2006 Pb AQCD (U.S. EPA, 2006b), metals in waterways are transported primarily as soluble chelates and ions, or adsorbed on colloidal surfaces, including secondary clay minerals, iron and manganese oxides or hydroxides, and organic matter, and adsorption on organic or inorganic colloids is particularly important for Pb. The extent of sorption strongly depends on particle size as smaller particles have larger collective surface areas. Aqueous Pb concentrations also increase with increasing salinity. Pb is found predominantly as PbO or $PbCO_3$ in aqueous ecosystems. Pb is relatively stable in sediments, with long residence times and limited mobility. However, Pb-containing sediment particles can be remobilized into the water column. As a result trends in sediment concentration tend to follow those in overlying waters. Fe and Mn oxides are especially susceptible to recycling with the overlying water column. Although resuspension of sediments into overlying waters is generally small compared to sedimentation, resuspension of contaminated sediments is often a more important source than atmospheric deposition. Organic matter (OM) in sediments has a high capacity for accumulating trace elements. In an anoxic environmental removal by sulfides is particularly important.

Although atmospheric deposition was identified as the largest source of Pb in surface waters in the 2006 Pb AQCD (U.S. EPA, 2006b), runoff from storms was also identified as an important source. A substantial portion of Pb susceptible to runoff originates from atmospheric deposition. Runoff from buildings due to paint, gutters, roofing materials and other housing materials were also identified as major contributors to Pb in runoff waters. Investigations of building material contributions indicated runoff concentrations ranging from 2 to 88 mg/L, with the highest concentrations observed from more than 10-year-old paint and the lowest concentrations from residential roofs. There was some indication that Pb from roofing materials, siding, and piping could be due to dissolution of Pb carbonate (cerussite) or related compounds. In several studies Pb in runoff was consistently mostly PM, with a relatively small dissolved fraction. Runoff release was

dependent on storm intensity and length of dry periods between rain events, with greater runoff of Pb associated with more intense storms and with longer periods between rain events. Several studies indicated a "first flush effect," with highest runoff concentrations observed at the beginning of a rain event.

3.3.2.1 Lead Transport in Water and Sediment

Recent publications provide additional detail regarding Pb adsorption on iron rich and organic rich colloids. Correlation between Pb concentration in unfiltered water with total Fe was observed (Hassellov and von der Kammer, 2008), which is consistent with previous research using cross flow filtration (Pokrovsky and Schott, 2002; Ross and Sherrell, 1999) and SEM examination of single particles (Taillefert et al., 2000).

Two distinct colloidal phases, one organic-rich (0.5-3 nm in diameter) and the other Fe-rich (>3 nm in diameter), have been observed to coexist in both soil isolates and river water (Stolpe and Hassellov, 2007). Pb was observed to be predominantly associated with Fe-oxide PM in river water but also associated with the organic colloids in the soil isolates (Hassellov and von der Kammer, 2008). Investigation of Pb binding onto ferrihydrite showed Pb binding data were consistent with Pb being held at the surface by sorption processes, rather than enclosed within the particle structure (Hassellov and von der Kammer, 2008).

Observations in boreal rivers and soil pore waters in permafrost dominated areas of Central Siberia indicated that Pb was transported with colloids in Fe-rich waters. Trace elements that normally exhibited limited mobility (including Pb) had 40-80% of their annual flux in the nominal dissolved phase, operationally defined as material that passes through a 0.45 µm pore-size filter, and that these metals had a higher affinity for organo-mineral Fe-Al colloids (Pokrovsky et al., 2006). Pokrovsky et al. (2006) postulated that during the summer, rainwater interacts with degrading plant litter in the top soil leading to the formation of Fe-Al-organic colloids with incorporated trace elements. Migration of trace element-Fe-Al-OM colloids may result in export of Pb and other elements to riverine systems. Most of the transport occurred after thawing had commenced. This contrasts with permafrost free areas where trace elements such as Pb are incorporated into iron colloids during OM-stabilized Fe-oxyhydroxide formation at the redox boundary of Fe(II)-rich waters and surficial DOC-rich horizons. Similarly, during a spring flood (May) that exported 30-60% of total annual dissolved and suspended flux of elements including Pb, Pb was mainly in the nominal dissolved phase, operationally defined as material that passes through a 0.45 µm pore-size filter (Pokrovsky et al., 2010). Pb adsorbed on colloidal surfaces rather than incorporated into particle structure is

likely to be more readily dissolved because dissolution of the entire particle is not required.

Recent research on retention of Pb in water bodies and sediments has focused on the estuarine and marine environment, where considerable retention of Pb was observed in estuarine sediments. For a large riparian system, the Trinity River, Texas, Warnken and Santschi (2009) found that 80% of riverine Pb was retained in Lake Livingston, an estuarine region, while an additional 16% was removed to estuarine sediments, and only about 4% eventually reached the ocean. Geochemical (sorption by Fe oxyhydroxides), biological (seasonal uptake by sinking algae in Lake Livingston) and hydrological (dilution effects by increasing flow rates) processes were mainly responsible for controlling dissolved trace metal concentrations rather than pollution sources.

Overall, recent research on Pb transport in aquatic systems has provided a large body of observations confirming that Pb transport is dominated by iron and organic rich colloids. In addition, new results indicated that although the 2006 Pb AQCD (U.S. EPA, 2006b) described rivers and lakes as temporary reservoirs with Pb lifetimes of months or less, estuaries can present a substantial barrier to transport into the open ocean.

3.3.2.2 Deposition of Lead within Bodies of Water and in Sediment

As described in the 2006 Pb AQCD (U.S. EPA, 2006b), in general Pb is relatively stable in sediments, with long residence times and limited mobility. As described in previous sections, Pb enters and is distributed in bodies of water largely in PM form. In rivers, particle-bound metals can often account for ≥ 75% of the total load, e.g. (Horowitz and Stephens, 2008). Urbanized areas tend to have greater aquatic Pb loads, as several studies have shown the strong positive correlation between population density and river or lake sediment Pb concentrations (Horowitz et al., 2008; Chalmers et al., 2007). Indeed, Chalmers et al. (2007) revealed that in river and lake sediments in New England, there was an order of magnitude difference between Pb sediment concentrations in rural versus urbanized areas.

The fate of Pb in the water column is determined by the chemical and physical properties of the water (pH, salinity, oxidation status, flow rate and the suspended sediment load and its constituents, etc). Desorption, dissolution, precipitation, sorption and complexation processes can all occur concurrently and continuously, leading to transformations and redistribution of Pb. The pH of water is of primary importance in determining the likely chemical fate of Pb in terms of solubility, precipitation or organic complexation. In peatland areas, such as those in upland areas of the U.K., organic acids

draining from the surrounding peatlands can lower stream water pH to below 4. Under these conditions, Pb-PM can be desorbed and released into solution, leading to elevated dissolved Pb concentrations (Rothwell et al., 2008). At the other end of the pH scale, Pb tends to remain or become complexed, precipitated or sorbed to suspended sediments in water, as observed by Das et al. (2008) who studied trace metal geochemistry in a South African lake with water pH of 9. They also found marked differences in Pb concentrations associated with increasing depth in the water column [e.g., the surface Pb-PM concentration of 2 µg/L increased to 60 µg/L at depth and the Pb concentration in the <0.45 µm fraction increased from 2 µg/L at the surface to 19 µg/L at depth (Das et al., 2008)]. This is suggestive of a settlement process in action.

In estuarine and wider marine environments the processes may be more complex because of the additional perturbation caused by tidal action and the strong effects of salinity. Again, PM forms of Pb are important in determining Pb distribution and behavior. Li et al. (2010a) reported that PM Pb accounted for 85 ± 15% and 50 ± 22% in Boston Harbor and Massachusetts Bay, respectively, while Lai et al. (2008b) reported a solid (acid soluble):dissolved Pb ratio of 2.6 for areas of the Australian sector of the Southern Ocean.

The accurate modeling of Pb behavior in marine waters (including estuaries) requires consideration of many parameters such as hydrodynamics, salinity, pH, suspended PM, fluxes between PM and dissolved phases (Hartnett and Berry, 2010). Several new advances in the study of Pb cycling in these complex environments have been described in recent publications. Li et al. (2010a) used particle organic carbon (POC) as a surrogate for the primary sorption phase in the water column to describe and model the partitioning of Pb between PM and dissolved forms. Huang and Conte (2009) observed that considerable change in the composition of PM occurs as they sink in the marine environment of the Sargasso Sea, with mineralization of OM resulting in increased Pb-PM concentration with increased depth. As a result of this depletion of OM in sinking particles, geochemical behavior at depth was dominated by inorganic processes, e.g. adsorption onto surfaces, which were largely independent of Pb source. Sinking rates in marine environments can vary, but a rate approximating 1 m/day has been used in some models of Pb transport and distribution in aquatic-sediment systems (Li et al., 2010a). Surface sediment Pb concentrations for various continental shelves were collated and compared by Fang et al. (2009); (Table 3-2).

Table 3-2 Surface sediment Pb concentrations for various continental shelves

Location	Digestion solution	Pb[a] (mg/kg)
East China Sea	$HCl/HNO_3/HF$	10-49 (27)[a]
Mediterranean, Israel coast	HNO_3	9.9-20
Aegean Sea	$HCl/HNO_3/HF$	21-44 (34)
Banc d'Arguin, Mauritania	$HCl/HNO_3/HF$	2.8-8.9
Campeche shelf, Gulf of Mexico	HCl/HNO_3	0.22-20 (4.3)
Laptev Sea, Siberia	$HCl/HNO_3/HF$	12-22
Pechora Sea, Russia	Not reported	9.0-22 (14)

[a]Values in parentheses are the average, where calculable

3.3.2.3 Flux of Lead from Sediments

Sediments can be either a source or a sink for metals in the aquatic environment. Release can be via re-suspension of the sediment bed via wind, wave and tidal action or by dissolution from sediment to the water column. When external Pb inputs to bodies of water are decreased by environmental improvement actions or regulations, contributions of Pb to the water column from the existing sediments can become an increasingly important source. (Roulier et al., 2010) determined that Pb flux from sediments originated mostly from organic fractions, but also partially from Mn and Fe components undergoing reductive dissolution. The rate of release was controlled by OM content, particle size, clay type and content, and silt fraction (Roulier et al., 2010). The importance of sediment particle size, OM content and acid volatile sulfide concentration in relation to metal release was similarly identified (Cantwell et al., 2008). The effect of pH change on Pb release from lake sediments has also been examined, revealing that 1.8 protons (H^+) were exchanged per divalent metal cation released (Lee et al., 2008a). Processes governing Pb release from lake sediments, including microbial reductive dissolution of Fe, biogenic sulfide production and metal sorption-desorption, have been investigated and results indicated that release of Pb from suboxic and anoxic zones of the sediment act as a Pb source to the overlying water of the lake (Sengor et al., 2007). Bacardit et al. (2010a, b) performed a mass balance of Pb, Zn, and As for three lakes in the Central Pyrenees in France to identify dominant metals distribution processes. They estimated that flux from the catchment accounted for 91-99% of the lakes' Pb inputs, while sediment flux accounted for 98-99% of Pb outputs. In this paper, sediment was only modeled as an output.

Sediment resuspension from marine environments is similarly important, with disturbance of bed sediments by tidal action in estuarine areas resulting in a general

greater capacity for re-suspension of PM. Benthic fluxes of dissolved metals released from sediments measured in Boston Bay were calculated as strong enough that in the absence of Pb inputs such benthic flux would reduce sediment Pb concentrations in Boston Bay to background levels in 30-60 years (Li et al., 2010a). In a related way, a half-life for sediment Pb (considering benthic flux alone as the loss mechanism) of 5.3 years was estimated for marine sediments off the Belgian coast (Gao et al., 2009). Atkinson et al. (2007) conducted experiments in an area contaminated by metal smelters, Lake Macquarie, Australia, to assess the factors that influence flux of metals from marine sediment. Low pH (pH = 6 ± 1), bioturbation, and other mixing processes were found to have stronger influence over flux than binding to sulfides, which were thought to be sequestered in deeper sediments.

Radakovitch et al. (2008) investigated the riverine transport of PM including Pb to the Gulf of Lion, France, and also concluded that a major part of annual fluxes could be delivered over a short time period. From budget calculations, riverine inputs were more important than atmospheric deposition and Pb concentrations in the prodelta sediments showed a strong correlation with OM content. These sediments, however, were not considered to be a permanent sink, as resuspension in these shallow areas was an important process. OM, Pb and other metals were enriched in resuspended PM compared with the sediment.

Birch and O'Hea (2007) reported higher total suspended solids, turbidity and total water metal concentration in surface compared with bottom water as well as a difference in suspended PM metal concentrations between surface water and bottom sediments, demonstrating that stormwater discharge was the dominant process of metal transfer during high rainfall events. Total suspended sediments (and total water metals) in bottom water were higher than in the surface water plume, indicating that resuspension of bottom sediment is a greater contributor of total suspended sediments than stormwater during such events, especially in shallower regions of the bay. Soto-Jimenez and Páez-Osuna (2010) determined diffusive and advective fluxes, geochemical partitioning of Pb and Pb-isotopic signatures in a study of mobility and behavior of Pb in hypersaline salt marsh sediments. They determined that sulfides were the main scavengers for Pb that was diagenetically released Pb.

Overall, recent research on Pb flux from sediments in natural waters provided greater detail on resuspension processes than was available in the 2006 Pb AQCD (U.S. EPA, 2006b), and has demonstrated that resuspended Pb is largely associated with OM or Fe and Mn particles, but that anoxic or depleted oxygen environments in sediments play an important role in Pb cycling. This newer research indicated that resuspension and release from sediments largely occurs during discrete events related to storms. It has also

confirmed that resuspension is an important process that strongly influences the lifetime of Pb in bodies of water. Finally, there have been important advances in understanding and modeling of Pb partitioning in complex aquatic environments.

3.3.2.4 Lead in Runoff

Runoff is a major source of Pb in surface waters. This complicates any evaluation of the contribution of atmospheric Pb to watersheds, which must take into account direct atmospheric deposition, runoff of atmospherically deposited Pb, and runoff of Pb from sources such as mine tailings or paint chips that are shed from outdoor structures. The 2006 Pb AQCD (U.S. EPA, 2006b) concluded that runoff was consistently mostly PM, with a relatively small dissolved fraction, and that dissolution of carbonate and related compounds were important contributors to Pb pollution in runoff waters. It also described runoff Pb release into runoff as dependent on storm intensity and length of dry periods between rain events, and a "first flush effect," with highest runoff concentrations observed at the beginning of a rain event. Subsequent research has provided considerable new information about the flux of Pb from roadway and urban runoff and snow melt to watersheds.

Severe contamination due to export of anthropogenic Pb to adjacent ecosystems via sewage systems (urban runoff and domestic wastewater) and to a lesser extent by direct atmospheric deposition has been documented (Soto-Jiménez and Flegal, 2009). Recent investigations also confirm roof runoff as an important contributor to Pb pollution. Huston et al. (2009) measured Pb concentrations in water from urban rainwater tanks and found Pb concentrations in bulk deposition were consistently lower than in water in the rainwater tanks, but that sludge in the tanks had a high Pb content, indicating that not all major sources of Pb are from atmospheric deposition. Pb levels frequently exceeded drinking water standards. Pb flashing on the roofs was implicated as the source of Pb in the rainwater tanks although other possible sources include old paint and Pb stabilized PVC drain pipes (Lasheen et al., 2008; Weiss et al., 2006; Al-Malack, 2001).

New research has improved the understanding of suspended PM size ranges, speciation, and impacts of Pb runoff from urban soil and road dust. Soil and road dust have been identified as major sources of Pb pollution to near-coastal waters, leading to high Pb concentrations in stormwater runoff that became associated with dissolved and suspended PM phases as well as bedload, material moved by rolling, sliding, and saltating along the bottom of a stream (Birch and McCready, 2009).

Several new studies reported that the size distribution of PM transported in runoff is relatively uniform. Characterization of the roadside dust in Australia showed that Pb in

PM was approximately uniformly distributed among PM size fractions of up to 250 µm. The Pb-containing particles had the potential to be dispersed to some distance into sensitive ecosystems (Pratt and Lottermoser, 2007). Pb in roadside dusts in Thessaloniki, Greece was characterized by Ewen et al. (2009) and no difference in Pb concentration was found between <75 µm and 75-125 µm PM size ranges, although a difference in the chemical form of Pb between slightly versus highly contaminated areas was observed.

Ewen et al. (2009) reported that Pb was mainly in a more exchangeable form (similar to that in an old auto-catalyst reference material) in small particles, but in the residual, or least mobile fraction in larger particles. In urban road dust from Manchester U.K., Pb-bearing Fe-oxides were observed to be dominant in most of the size fractions, and $PbCrO_4$ comprised 8-34% of total Pb with the highest concentrations being found in the largest and smallest size fractions. $Pb(CO_3)_2$ and $Pb(OH)_2$ were measured in the two middle size fractions, while PbO and $PbSO_4$ were present in the largest and smallest size fractions (Barrett et al., 2010).

Murakami et al. (2007) also emphasized the importance of $PbCrO_4$ as an important species of Pb from road surfaces. That study identified individual particles containing high levels of Pb and Cr ($\geq$ 0.2%), most likely from the yellow road line markings. The identified PM constituted 46% of Cr and Pb in heavy traffic dust and 7-28% in dust from residential areas and soakaway sediments. The presence of such particles in soakaway sediments is consistent with their low environmental solubility.

Recent research also continues to document the first flush effect described in the 2006 Pb AQCD. Flint and Davis (2007) reported that in 13% of runoff events, more than 50% of Pb was flushed in the first 25% of event water. A second flush occurred less frequently (4% of runoff events for Pb). In agreement with the 2006 Pb AQCD (U.S. EPA, 2006b), most recent studies have concluded that, during storm events, Pb is transported together with large PM. Some studies, however, found that Pb was concentrated in the fine PM fraction and, occasionally, Pb was found predominantly in the dissolved fraction. Tuccillo (2006) found that Pb was almost entirely in the >5 µm size range and, indeed, may be associated with PM larger than 20 µm. (Sansalone et al., 2010) compared Pb-containing PM size distributions from New Orleans, LA; Little Rock, AR; North Little Rock, AR; and Cincinnati, OH and found no common distribution pattern. Pb was associated with Cincinnati PM mainly in the <75 µm fractions, at Baton Rouge and Little Rock Pb mainly in the 75-425 µm PM fractions, and at North Little Rock Pb predominantly in the >425 µm PM fractions. New Orleans Pb was almost uniformly distributed among the smaller size PM fractions. McKenzie et al. (2008) found that Pb was enriched in the finest PM (0.1-0.3 µm) in stormwater samples collected in California, particularly for storms that occurred during and after an extended dry period.

Guo et al. (2006a) investigated the effect of engineered partial exfiltration reactor (PER) systems on the partitioning and speciation of Pb in rainfall-runoff at the upstream end of an urban source area catchment that is part of the much larger urbanized and industrial Mill Creek watershed in Hamilton County, Ohio. The catchment is paved to a large extent with asphalt and is used for transportation. Guo et al. (2006a) investigated a catchment that drained toward a wide grassy area and found that Pb was mainly associated with dissolved organic matter (DOM). The study suggested that interaction of the rainfall-runoff with the grassy area may have resulted in removal of PM-bound Pb and hence in the association of Pb with DOM. PM amount and size can also be influenced by the runoff surface. Guo et al. (2006a) found that Pb entering the engineered PER system was mainly in the dissolved fraction with ~76%.

There were several recent observations of a relationship between road traffic volume and runoff Pb concentration, although a clear relationship was not always observed. At a relatively clean location, Desta et al. (2007) studied highway runoff characteristics in Ireland and found that although as expected, Pb was strongly correlated with TSP, no relationship between total suspended solids and rainfall, rain intensity, antecedent dry days or runoff event duration were observed, and traffic volume also did not appear to have an effect They concluded that runoff composition from site to site could be highly variable. Most other studies, however, did find a relationship between traffic volume and Pb concentration. A California study of highway runoff by Kayhanian et al. (2007) reported that 70-80% Pb was in PM form for both non-urban and urban highways, and that the concentration of Pb in runoff from low traffic flow (30,000-100,000 vehicles/day) urban highways was 50% higher than that from non-urban highways (mean = 16.6 µg/L). Additionally, the concentrations in runoff from high traffic flow (>100,000 vehicles/day) urban areas were five times higher than those from non-urban highways. Helmreich et al. (2010) characterized road runoff in Munich, Germany, with an average daily traffic load of 57,000 vehicles. The mean Pb concentration, 56 µg/L (maximum value = 405 µg/L), lay in between the values for low traffic flow and high traffic flow runoff from urban areas in California, i.e., there was good agreement with Kayhanian et al. (2007). There was no detectable dissolved Pb, i.e. 100% in PM form. Seasonal effects of highway runoff have also been observed recently. Hallberg et al. (2007) found that summer Pb concentrations in runoff water in Stockholm ranged from 1.37-47.5 µg/L while, in winter, the range was 1.06-~296 µg/L. There was a strong correlation between Pb (and most other elements) and total suspended solids (R^2 = 0.89). Helmreich et al. (2010) also found higher metal concentrations during cold seasons in Stockholm but Pb concentrations increased only slightly during the snowmelt season. There was no change in the distribution of Pb between dissolved and PM forms for the rain and snowmelt periods. Runoff from urban snowmelt has been intensively investigated since the 2006 Pb AQCD was published (U.S. EPA, 2006b). The relocation of snow means that the area

receiving the snowmelt is not necessarily the same area that which received the snowfall. Magill and Sansalone (2010) also noted that plowed snowbanks alongside roadways form a temporary linear reservoir for traffic generated constituents such as metals and PM. Snowmelt concentrations of metals such as Pb can therefore be several orders of magnitude higher than those in rainfall runoff (Sansalone and Buchberger, 1996). The melt process usually occurs in a sequence: pavement melt, followed by roadside (impervious) and finally pervious area melt. As part of this sequence, rain-on-snow can transport high loads of PM-associated pollutants (Oberts, 2000). Westerlund and Viklander (2006) investigated differences in PM and Pb concentrations between rainfall events occurring during snowmelt and rain periods. Runoff events occurring during the snowmelt period (i.e. rain-on-snow) had about five times higher numbers of particles (in the size range 4 to 120 µm)/liter of runoff. The first rain-on-snow event was characterized by an increase in the number of particles in the 4 to 25 µm size range. The rain-on-snow gave a "flush" through the snow but this was still not sufficient to transport the larger sized particles. Only the highest energy rain-on-snow events increased transport of PM across the entire size spectrum. There was no difference in particle size distributions between snowmelt and rain on snow events, although more was transported during snowmelt. Pb concentrations were most strongly associated with the smaller PM size fractions.

Overall, there was a significant difference between the melt period and the rain period in terms of concentrations, loads, transportation and association of heavy metals with particles in different size fractions (Westerlund and Viklander, 2006). Over a 4-year period, Magill and Sansalone (2010) analyzed the distribution of metal in snow plowed to the edge of roads in the Lake Tahoe catchment in Nevada, and concluded that metals including Pb were mainly associated with coarser PM (179-542 µm). The PM-associated metal could be readily separated from runoff water (e.g., in urban drainage systems), but there is potential for leaching of metals from the PM within storage basins (Ying and Sansalone, 2008). For adsorbed species that form outer sphere complexes, a decrease in adsorption and an increase in aqueous complexes for pollutant metals is a likely consequence of higher deicing salt concentrations. If metals form inner-sphere complexes directly coordinated to adsorbent surfaces, background deicing salt ions would have less impact. It is thought that physical and outer-sphere complexes predominate for coarse PM, as was the case in Nevada, and so leaching would be likely to cause an increase in dissolved phase Pb concentrations.

Rural runoff has also been extensively studied since publication of the 2006 Pb AQCD (U.S. EPA, 2006b), including several recent publications on a forested watershed (Lake Plastic) in central Ontario (Landre et al., 2010, 2009; Watmough and Dillon, 2007) and nearby Kawagama Lake, Canada (Shotyk and Krachler, 2010). Results indicated that

bulk deposition substantially decreased to 0.49 mg/m^2 in 2002 from 1.30-1.90 mg/m^2 in 1989-91. The upland soils retained >95% of the Pb in bulk deposition, i.e. leaching losses to stream water were small. The wetland area was, however, a net source of Pb with annual Pb concentrations in stream water ranging from 0.38 to 0.77 µg/L. Lake sediments were efficient sinks for atmospherically deposited Pb with 80-91% of the Pb input being retained. Up to 68% of the Pb entering the lake was derived from the terrestrial catchment. Overall, the watershed effectively retained atmospherically deposited Pb, but some Pb was then redistributed from the catchment to the lake sediments; and the Pb in the near-surface lake sediments reflected terrestrially transported soil material, rather Pb being deposited from the atmosphere. The highest concentrations of dissolved organic carbon (DOC), Fe and Pb in the wetland draining stream occurred in summer when it frequently exceeded 1 µg/L (Landre et al., 2009).

Graham et al. (2006) observed two temporally separated mechanisms occurring during storm events in a rural organic rich upland catchment. At the beginning of an event, Pb was transported together with large particles in the >25 µm size range, but after several hours Pb was mainly transported with colloidal or DOM (<0.45 µm), and the remaining 30-40% of storm related Pb was transported in this form. This indicated that rapid overland flow rapidly transported Pb-PM into the receiving streams at the very beginning of the event, and this was followed within a few hours by transport of organic-colloidal Pb via near-surface throughflow. The authors used a conservative estimate of Pb removal, based on their observations that the catchment was continuing to act as a sink for Pb. These observations about the transport and fate of Pb agree well with those of Watmough and Dillon (2007) and Shotyk et al. (2010).

Soil type was also found to have a strong influence on runoff contributions. Dawson et al. (2010) found that for organic-rich soils, Pb was mobilized from near-surface soils together with DOC but for more minerogenic soils, percolation of water allowed Pb, bound to DOC, to be retained in mineral horizons and combine with other groundwater sources. The resulting Pb in stream water that had been transported from throughout the soil profile and had a more geogenic signature (Dawson et al., 2010). The findings of both Graham et al. (2006) and Dawson et al. (2010) were important because the provenance and transport mechanisms of Pb may greatly affect the net export to receiving waters, particularly since higher concentrations of previously deposited anthropogenic Pb are usually found in the near-surface sections of upland U.K. soils [e.g., (Farmer et al., 2005)].

In another study Rothwell et al. (2007a) observed stormflow Pb concentrations almost three times higher than those reported by Graham et al. (2006) for northeastern Scotland. The generally high dissolved Pb were due to high soil Pb pools and high stream water

DOC concentrations (Rothwell et al., 2007a). In a separate study, Rothwell et al. (2007b) showed that OM was the main vector for Pb transport in the fluvial system. Some seasonal variability was observed: declining Pb concentrations in autumn stormflow may indicate the exhaustion of DOC from the acrotelm (the hydrologically active upper layer of peat which is subject to a fluctuating water table and is generally aerobic) or a dilution effect from an increasing importance of overland flow.

Erosion of agricultural soils and the effects of different types of storm events on soil particle and Pb losses from these soils was characterized by Quinton and Catt (2007). A close link between metal concentration and the silt, or clay and organic content of stream sediments was consistent with enrichment of metals as a consequence of small erosion events. They also noted that short intense events could produce the same amount of sediment as longer low-intensity events. More intense events, however, could mobilize a wider range of particle sizes whereas low intensity events mobilized finer but more metal-rich material. Smaller events accounted for 52% of Pb losses from the agricultural soil.

The Tinto River in Spain drains one of the largest polymetallic massive sulfide regions in the world: the Iberian Pyrite Belt. Evaporitic sulfate salts, formed as a result of acid mine drainage processes, are considered to be a temporary sink for many heavy metals. Upon the arrival of rainfall, however, they rapidly dissolve, releasing acidity and contaminant metals into receiving waters. Thus rivers in semi-arid climate regions such as the Tinto River which alternate between long periods of drought and short but intense rainfall events, can experience quick acidification and increases in metal concentration. In a study of such events, Cánovas et al. (2010) found that while many element concentrations decreased during events, the concentrations of Fe, Cr, Pb and As increased. This was attributed to the redissolution and transformation of Fe oxyhydroxysulfates and/or desorption processes.

Dunlap et al. (2008) studied a large (>160,000 km^2) riparian system (the Sacramento River, CA) and showed that the present day flux of Pb was dominated by Pb from historical anthropogenic sources, which included a mixture of high-ratio hydraulic Au mining-derived Pb and persistent historically-derived Pb from leaded on-road gasoline. Outside of the mining region, 57-67% Pb was derived from past on-road gasoline emissions and 33-43% was from hydraulic Au mining sediment. The flow into the Sacramento River from these sources is an ongoing process. Periods of high surface runoff, however, mobilize additional fluxes of Pb from these two sources and carry them into the river. These pulses of Pb, driven by rainfall events, suggest a direct link between local climate change and transport of toxic metals in surface waters (Dunlap et al., 2008).

Rothwell et al. (2007a) commented that although there have been substantial reductions in sulfur deposition to U.K. uplands over the last few decades (Fowler et al., 2005), anthropogenic acidification of upland waters is still possible if there is nitrogen leaching from the surrounding catchment and this may increase with nitrogen saturation (Curtis et al., 2005). Rothwell et al. (2007a) predicted that if an increase in surface water acidification is coupled with further increases in DOC export from organic-rich catchments, metal export from peatland systems will increase. The deterioration of peat soils by erosion is considered to be exacerbated by climatic change. Rothwell et al. (2010) used digital terrain analysis to model suspended Pb concentrations in contaminated peatland catchments. The peat soils of the Peak District are characterized by extensive eroding gullies and so they were combined in an empirical relationship between sediment-associated Pb concentrations and mean upslope gully depth with fine-resolution mapping of the gully areas. This model will enable prediction of metal contamination in receiving waters.

Klaminder et al. (2010) investigated the environmental recovery of sub-arctic lakes in response to reduced atmospheric deposition over the last few decades. They found that there had been no improvement in surface sediments and indeed the reduction in Pb contamination had been much less than the 90% reduction in emissions over the last four decades. The weak improvement in the $^{206}Pb/^{207}Pb$ ratio together with the Pb contaminant concentrations suggests that catchment export processes of previously-deposited atmospheric contaminants have had a considerable impact on the recent contaminant burden of sub-arctic lakes. In Arctic regions, soil export of contaminants to surface waters may dramatically increase in response to climate change if it triggers thawing of frozen soil layers. It is thought that thawing may generate accelerated soil erosion, altered hydrological flow paths, increased runoff and exposure of soluble compounds that had previously been in the frozen layers. At this stage, however, the links between catchment export and climate change have not yet been clearly established.

Coynel et al. (2007) also considered the effects of climate change on heavy metal transport. In this case, the scenario of flood-related transport of PM in the Garonne-Gironde fluvial-estuarine system was investigated. Export of suspended PM during a five-day flood in December 2003 was estimated at ~440,000 tons, accounting for ~75% of the annual suspended PM fluxes. Sediment remobilization accounted for ~42% of the total suspended particulate matter (SPM) flux during the flood event (~185,000 tons suspended PM) and accounted for 61% of the 51 tons Pb that was exported. Coynel et al. (2007) postulate that flood hazards and transport of highly polluted sediment may increase as a result of climate change and/or other anthropogenic impacts (flood management, reservoir removal).

In heavily contaminated catchments [e.g., that of the Litavka River, Czech Republic (Zak et al., 2009)], the flux of heavy metals to the river during storm events can be substantial. Even during a minor 4-day event, 2,954 kg of Pb was transported, and the majority was associated with suspended PM. For the Adour River in a mountainous area of France, Pb pollution predominantly originated from mining activities, and Point et al. (2007) showed that 75% of annual soil fluxes into the river were transported in 30-40 days.

The consequences of flood management (dam flushing) practices on suspended PM and heavy metal fluxes in a fluvial-estuarine system (Garonne-Gironde, France) were considered by Coynel et al. (2007). Dam flushing enhanced mobilization of up to 30-year-old polluted sediment from reservoir lakes. Sediment remobilization accounted for ~42% of the total suspended PM fluxes during the flood and strongly contributed to PM-bound metal transport (61% for Pb). They concluded that flood management will need to be taken into consideration in future models for erosion and pollutant transport.

Bur et al. (2009) investigated the associations of Pb in stream-bed sediments of the French Gascony region. They found that Pb enrichment in stream sediments was positively correlated with catchment cover and increasing organic content whereas Pb concentration was strongly linked with Fe-oxide content in cultivated catchments. For the low-OM, anthropogenic Pb was associated with carbonates and Fe-oxides (preferentially, the amorphous fraction). Fe-oxides became the most efficient anthropogenic Pb trapping component as soon as the carbonate content is reduced. They noted, however, that OM was always weakly involved. N'Guessan et al. (2009) also studied trace elements in stream-bed sediments of the French Gascony region. They used enrichment factors to show that only ~20-22% of Pb was from anthropogenic sources with the remainder originating from natural weathering processes.

Overall, research results from the last several years have greatly expanded the extent of the knowledge concerning Pb from runoff. Substantial Pb input to estuarine and marine ecosystems has been well documented. More detail concerning the origin of Pb from roof runoff has led to the conclusion that roof flashing could be especially important. Research on road runoff has provided valuable insight into PM size and composition, indicating that size distributions for Pb-containing PM in runoff water varies from study to study and from location to location. Recent studies confirmed the "first flush" effect, releasing more Pb at the beginning of rainfall than subsequently, and documented size distributions of Pb-containing PM also vary considerably when water from the first flush is isolated. Influence of road traffic volume on runoff has also been more fully documented in recent years. The role of urban snowmelt and rain-on-snow events is also better understood, and it has been observed that greater runoff occurs from snowmelt and in rain on snow events than when snow is not present, and that metals, including Pb, are often associated with

coarse PM under these circumstances. Runoff in rural areas is strongly controlled by soil type and the presence of vegetation, with less runoff and greater retention in mineral soils or when grass is present, and more runoff for soils high in OM. Runoff also follows a two-step process of transport of larger particles at the beginning of an event, followed within hours by transport of finer colloidal material. Some initial research on the effects of climate change on runoff has focused on documenting the association between increased runoff and more intense rain events and greater thawing. Overall, recent research has provided greater detail on amounts, particle size distributions, composition, and important processes involving Pb transport, and the understanding of Pb runoff has become more complete since publication of the 2006 Pb AQCD (U.S. EPA, 2006b).

3.3.3 Soil

The 2006 Pb AQCD (U.S. EPA, 2006b) summarized that Pb has a relatively long retention time in the organic soil horizon, although its movement through the soil column also suggests potential for contamination of groundwater. Leaching was consistently observed to be a slower process for Pb than for other contaminants because Pb was only weakly soluble in pore water, but anthropogenic Pb is more available for leaching than natural Pb in soil. Pb can bind to many different surfaces and Pb sorption capacity is influenced by hydraulic conductivity, solid composition, OM content, clay mineral content, microbial activity, plant root channels, animal holes, and geochemical reactions. As a result of Pb binding to soil components, leaching is retarded by partitioning to soils, which is not only influenced by sorption capacity, but leaching also increases with proximity to source, increasing pH, and increasing metal concentrations. Leaching is also strongly influenced by pore water flow rates, with more complete sorption contributing to slower leaching at lighter flows. Leaching rates are especially high in soils with a high Cl content, but typically the most labile Pb fraction is adsorbed to colloidal particles that include OM, clay, and carbonates. Transport through soils is enhanced by increasing amount of colloidal suspensions, increasing colloidal surface charge, increasing organic content of colloids, increasing colloidal macroporosity, and decreasing colloidal size. Acidity and alkalinity have a more complex influence, with sorption maximized at neutral pH between pH = 5 and pH = 8.2, and greater mobility at higher and lower pH. High Pb levels have been observed in leachates from some contaminated soils, but this effect appears to be pH dependent. In several studies of contaminated soils a substantial fraction of Pb was associated with Mn and Fe oxides or carbonate.

3.3.3.1 Deposition of Lead onto Soil from Air

As described in the 2006 Pb AQCD (U.S. EPA, 2006b), a considerable amount of Pb has been deposited from air onto soils in urban areas and near stationary sources and mines, and soil Pb concentrations are typically on the order of 100 mg/kg (Mielke et al., 2010a). Removal and translocation of Pb in soil is an ongoing process.

High Pb soil concentrations were observed near stationary sources such as smelters and battery disposal operations, and soil Pb concentrations decreased rapidly with distance from the source. Several recent studies continue to document high concentrations of Pb in soil. A study of soil Pb concentrations in Queensland, Australia described atmospheric transport and deposition of Pb in urban soils due to ongoing emissions from nearby mining and smelting activities are continuing to impact on the urban environment (Taylor et al., 2010). Similarly, sediment cores from four remote Canadian Shield headwater lakes located along a transect extending 300 km from a non-ferrous metal smelter generated useful information about distance of Pb transport from the smelter prior to deposition (Gallon et al., 2006). Shotyk and Krachler (2010) postulated that long-range transport of Pb from a smelter at Rouyn-Noranda may still contribute to deposition on these lakes. Recent measurements of deposition fluxes to soil in rural and remote areas have ranged from approximately 0.5 $mg/m^2 \cdot yr$ to about 3 $mg/m^2 \cdot yr$ with fair agreement between locations in Canada, Scandinavia, and Scotland and showed a substantial decrease compared to when leaded on-road gasoline was in widespread use (Shotbolt et al., 2008; Watmough and Dillon, 2007; Fowler et al., 2006; Graham et al., 2006).

There has been considerable interest in the response of soils to the decreasing aerosol Pb concentrations and Pb deposition rates that have been recorded in recent years. Kaste et al. (2006) resampled soils at 26 locations in the Northeast U.S. (during a 2001-2002 survey of soil sites originally sampled in 1980), and found no significant change in the amount of Pb in the O-horizon at high altitude sites. However, the amount of Pb in the O-horizon had decreased at some locations in the southern part of the survey region (Connecticut, New York, Pennsylvania), where the forest soils have typically thinner O-horizons, the reasons for which are discussed further in Section 3.3.3.2. High Pb concentrations at greater altitudes were also found in Japan, especially above 600 m (Takamatsu et al., 2010).

Further support for the use of mosses as bioindicators or monitors for atmospheric Pb inputs to peat bogs have recently been published by Kempter et al. (2010) who found that high moss productivity did not cause a dilution of Pb concentrations in peat bogs. They also found that productive plants were able to accumulate particles from the air and that rates of net Pb accumulation by the mosses were in excellent agreement with the atmospheric fluxes obtained by direct atmospheric measurements at nearby monitoring

stations. In addition, Bindler et al. (2008) used Pb isotopes to compare the distribution of Pb in the forest soils with that of lake sediments where no "plant pumping" processes could be invoked, and used Pb isotope ratios to demonstrate that observations were consistent with anthropogenic Pb deposition to the soils rather than intermixing of natural Pb from underlying mineral soil horizons.

Overall, recent studies provided deposition data that was consistent with deposition fluxes reported in the 2006 Pb AQCD (U.S. EPA, 2006b), and demonstrated consistently that Pb deposition to soils has decreased since the phase-out of leaded on-road gasoline. Follow-up studies in several locations indicated little change in soil Pb concentrations since the phase-out of leaded on-road gasoline, consistent with the high retention reported for Pb in soils.

3.3.3.2 Sequestration of Lead from Water to Soil

The 2006 Pb AQCD described Pb as being more strongly retained in soil than other metals because of its weak solubility in pore water, but that anthropogenic Pb was more available for leaching than natural Pb (U.S. EPA, 2006b). It also described a complex variety of factors that influence Pb retention, including hydraulic conductivity, solid composition, OM content, clay mineral content, microbial activity, plant root channels, geochemical reactions, colloid amounts, colloidal surface charge, and pH.

Recent research in this area has provided more insight into the details of the Pb sequestration process. Importance of leaf litter was further investigated, and it was observed that the absolute Pb content can be substantial because rain events cause splashing of the leaf litter with soil thus placing the litter in direct contact with soil metals. The resulting increase in leaf litter metal concentrations suggests that the litter can act as a temporary sink for metals from the soil around and below leaves on the ground. The low solubility of Pb in the leaf litter indicates that the Pb is tightly bound to the decomposing litter, making the decomposing leaves act as an efficient metal storage pool (Scheid et al., 2009). Differences between throughfall (i.e., water depositing onto the soil following collection on leaves) and litterfall (i.e., deposition of leaves, bark, and other vegetative debris onto soil) in forested areas have been investigated in forested areas, and the combined input of Pb to the forest floor from throughfall and litterfall was approximately twice that measured in bulk deposition (Landre et al., 2010). The difference was attributed to a substantial contribution from internal forest cycling and indicates that bulk deposition collectors may underestimate the amount of Pb reaching the forest floor by about 50% (Landre et al., 2010).

New research has also provided details about the complexity of Pb sequestration during soil OM decomposition. Schroth et al. (2008) investigated Pb sequestration in the surface layer of forest soils and the transformation of Pb speciation during soil OM decomposition. The pH range for forest floor soils in the Northeast U.S. is typically 3.5-5 and, under these conditions, dissolved Pb would adsorb strongly to soluble OM and to Fe/Al/Mn oxides and oxyhydroxides. It had been thought that the high affinity of Pb for organic ligands meant that sequestered atmospheric Pb would be preferentially bound to soluble OM. As a consequence, decomposition of OM would lead to Pb migration to the underlying mineral layers where it would be precipitated with the dissolved OC or adsorbed to pedogenic mineral phases. However, recent research has revealed a more complicated picture of gasoline-derived Pb associations in the forest floor. More recent research indicates that, as decomposition progresses, Pb and Fe become more concentrated in "hotspots" and Pb likely becomes increasingly distributed on surfaces associated with Fe and Mn (and to some extent Ca). It was postulated that Pb was initially bound to labile organic but, following decomposition, the Pb was adsorbed at reactive sites on pedogenic mineral phases (Schroth et al., 2008). Differences in litter types were also reported, with more rapid decomposition of OM in high quality deciduous litter mobilizing more Pb initially bound to labile OM than coniferous litter, and producing more pedogenic minerals that could readily sequester the released Pb (Schroth et al., 2008). In the next stage of the study, the speciation of Pb in the O-horizon soils of Northern Hardwood, Norway spruce and red pine forest soils were compared. In general there was good agreement between the Pb speciation results for the soils and those for the laboratory decomposition experiments. Specifically, for the Northern Hardwood forest soil, a little more than 60% of the Pb was bound to SOM and this percentage increased to ~70% and ~80% for the Norway spruce and red pine soils, respectively. In all three cases, however, most of the remainder of the Pb was bound to ferrihydrite rather than to birnessite. This was not considered to be surprising because of the well-known leaching and cycling behavior of Mn that would be expected in the natural system. Thus the prevalence of Mn phases in the field based samples would be lessened (Schroth et al., 2008).

More generally, other studies have observed Pb sorption to Mn and Fe phases in soils. For example, Boonfueng et al. (2006) investigated Pb sequestration on Mn oxide-coated montmorillonite. Pb formed bidentate corner-sharing complexes. It was found that Pb sorption to MnO_2 occurred even when MnO_2 was present as a coating on other minerals, e.g., montmorillonite. Although their importance in the near-surface phases has clearly been demonstrated by Schroth et al. (2008), ferrihydrite surfaces may not be a long-term sink for Pb since reductive dissolution of this Fe(III) phase may release the surface-bound Pb into the soil solution. Sturm et al. (2008) explored the fate of Pb during dissimilatory Fe reduction. Pb was indeed released but was then incorporated into less reactive phases.

These phases could not, however, be identified. Even so, it was asserted that Pb should be largely immobile under Fe-reducing conditions due to its incorporation into refractory secondary minerals.

Kaste et al. (2006) found that Pb species currently in the soil O-horizons of the Northeast U.S. differed considerably from those that were originally deposited from fossil fuel combustion (including on-road gasoline). $PbSO_4$ was considered to be the main form of Pb that had been delivered from the atmosphere to the surface of the Earth and it was postulated that the presence of sulfate may have facilitated the adsorption of Pb to colloidal Fe phases within the organic-rich horizons.

Altogether, these new results enhance the understanding of Pb sequestration in forest soils. First, the role of leaf litter as a major Pb reservoir is better understood. Second, the effect of decomposition on Pb distribution and sequestration on minerals during OM decomposition has been further characterized, and finally, the relative importance of Mn and Fe in sequestration is better understood.

Recent research also addressed roadsides soils. Jensen et al. (2006) found that Pb was retained by an organic-rich blackish deposit with a high OM content and elevated soil Pb concentrations, originating from total suspended solids in road runoff and from aerial deposition. Hossain et al. (2007) observed that after long dry periods, OM oxidation may potentially result in the release of Pb. Microbial activity may also breakdown OM and have similar consequences (i.e., Pb release). Bouvet et al. (2007) investigated the effect of pH on retention of Pb by roadside soils where municipal solid waste incineration (MSWI) bottom ash had been used for road construction. They found that the Pb that had leached from the road construction materials was retained by the proximal soils under the prevailing environmental conditions (at pH = 7, <2% was released, but at pH = 4, slightly more Pb (4-47%) was released) and the authors speculated that the phase from which Pb had been released may have been $Pb(CO_3)_2(OH)_2$, indicating that sequestration of Pb via formation of oxycarbonate minerals is only effective at near-neutral to alkaline pH values (Figure 3-9 in Section 3.3.3.3).

Other recent research on Pb sequestration focused on microbial impacts and soil amendments. There have been few if any previous observations of microbial sequestration of Pb in soil. Perdrial et al. (2008) observed bacterial Pb sequestration and proposed a mechanism of Pb complexation by polyphosphate. They also postulated that bacterial transport of Pb could be important in sub-surface soil environments. Wu et al. (2006) also and concluded that Pb adsorption to the bacterial cell walls may be important with respect to Pb transport in soils. This new area of research provides important evidence that bacteria can play an important role in both sequestration and transport of Pb. Phosphate addition to immobilize Pb-contaminated soils has often been used to

immobilize Pb in situ through the formation of Pb phosphate minerals such as chloropyromorphite. Recent research investigated factors affecting the long-term stability of such products, which depends on the equilibrium solubility and the dissolution rate of the mineral, trace impurities, such as $Pb(OH)_2$, the presence of complexing agents, and pH (Xie and Giammar, 2007). Overall, in agreement with the 2006 Pb AQCD (U.S. EPA, 2006b), the addition of phosphate can enhance immobilization of Pb under certain conditions in the field but may cause desorption and mobilization of anionic species of As, Cr and Se.

3.3.3.3 Movement of Lead within the Soil Column

The 2006 Pb AQCD summarized studies that demonstrated that Pb has a long retention time in the organic soil horizon, it also has some capacity to leach through the soil column and contaminate groundwater more than other contaminants do, because Pb is only weakly soluble in pore water (U.S. EPA, 2006b). The fate of any metal transport in soil is in response to a complex set of parameters including soil texture, mineralogy, pH and redox potential, hydraulic conductivity, abundance of OM and oxyhydroxides of Al, Fe, and Mn, in addition to climate, situation and nature of the parent material. As a consequence, it is impossible to make general conclusions about the final fate of anthropogenic Pb in soils. Indeed, Shotyk and LeRoux (2005) contend that the fate of Pb in soils may have to be evaluated on the basis of soil type. Some generalizations are, however, possible: Pb migration is likely to be greater under acidic soil conditions (Shotyk and Le Roux, 2005). In this respect, it would be expected that there should be considerable mobility of Pb in the surface layers of certain types of forest soils. This section reviews recent research on movement of Pb through soil types by first focusing on forest soils, followed by a broader treatment of a more diverse range of soils.

Forest Soils and Wetlands

Several studies confirmed the slow downward movement of Pb within the soil column. Kaste et al. (2006) found that the amount of Pb in O-horizon soils had remained constant at 15 of 26 sites in remote forested areas of the Northeast U.S. that had been re-sampled after a 21-year time period had elapsed, but that measured soil Pb concentrations were lower than predicted concentrations from total deposition, strongly suggesting that the O-horizon had not retained all of the atmospheric Pb, and that a proportion of the atmospheric deposition must have leached into the underlying mineral layers. At some sites, mainly those at the southern latitudes and lower altitude sites, the proportion of Pb that had been leached downward from the O-horizon was quite considerable. Relative

retention of Pb was influenced by the rate of OM decomposition, depth of soil O-horizon, and pH. For soils where Pb was strongly retained by the O-horizon, a relationship between Pb and Fe-rich phase was observed, but Pb was also significantly correlated with other metals. XANES data suggested a possible interaction with an amorphous Fe oxide, but spectra were not entirely explained by Fe and oxygen and an additional spectral feature suggested the presence of a S or P atom, which could result if OM functional groups were binding to Pb. Kaste et al. (2006) concluded that a substantial fraction of Pb was associated with amorphous Fe-hydroxides. The strong binding of Pb coupled with the low solubility of Fe phases under oxic conditions, helped to explain the relatively long residence time of gasoline-derived Pb in forest floors which had thick O-horizons and were well-drained. In the situations where Pb was leached downward to a large extent, mobility was likely governed by OM decomposition and colloidal transport of Pb associated with colloidal Fe and OM.

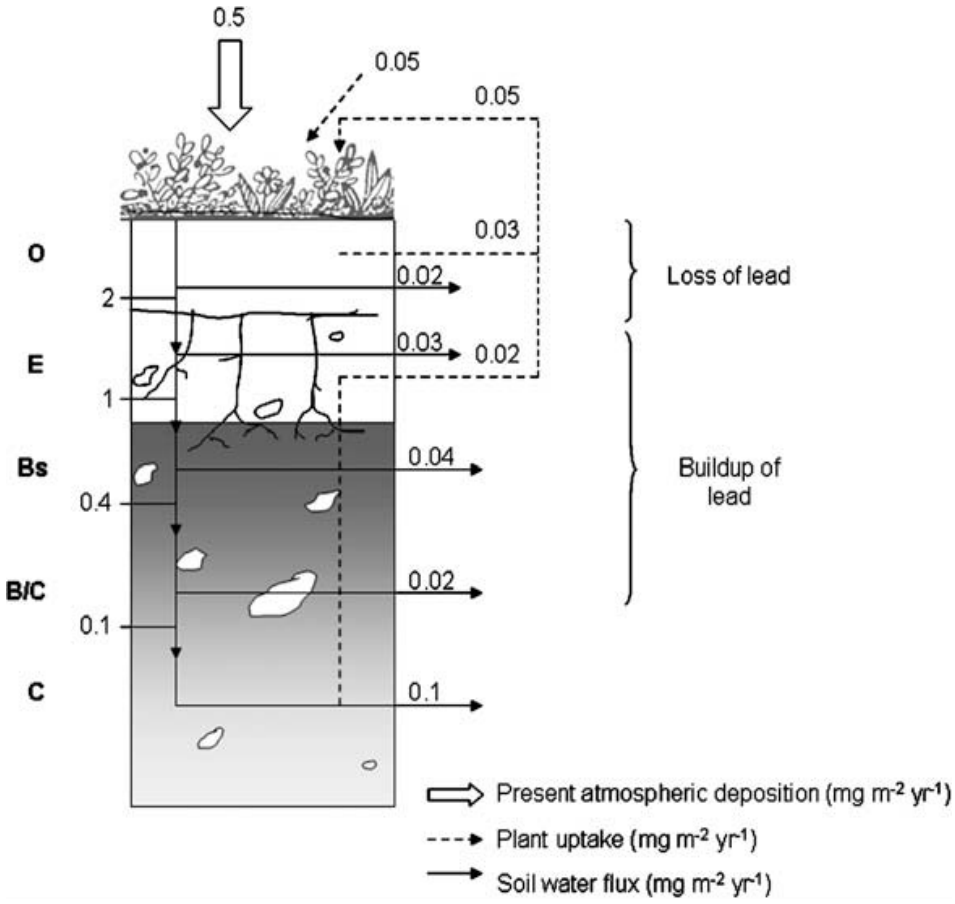
Klaminder et al. (2006b) also considered the transfer of Pb from the O-horizon to the underlying mineral horizons (including the C-horizon). They concluded that atmospheric pollution-derived Pb migrated at a rate about 10-1,000 times slower than water. They assumed that Pb was mainly transported by dissolved OM and so the mean residence time of Pb in the O-horizon depended on OM transport and turnover. The retardation rate was a reflection of the slow mineralization and slow downward transport rates of organic-Pb complexes, due to sorption and desorption reactions involving mineral surfaces.

In a study involving stable Pb isotopes, Bindler et al. (2008) showed that Pb with a different isotopic composition could be detected in the soil down to a depth of at least 30 cm and sometimes down to 80 cm in Swedish soils. In comparison, in North American podzols, pollution Pb is typically only identified to a depth of 10-20 cm (even with the aid of isotopes). This difference is attributed to the longer history of metal pollution in Europe (as has been traced using lake sediments).

Several research groups have attempted to determine the mean residence time of Pb in the O-horizon of forest soils. Klaminder et al. (2006a) used three independent methods to estimate a mean residence time of about 250 years for Pb in the O-horizon of boreal forests in Sweden, indicating that deposited atmospheric Pb pollution is stored in the near-surface layers for a considerable period and, consequently, will respond only slowly to the reduction in atmospheric inputs. It should be noted, however, the OM in the upper parts of the O-horizon is continually being replaced by fresh litter and the mean residence time of Pb in these horizons is only 1-2 years. Thus, the uppermost layer will respond more quickly than the rest of the O-horizon to the decreases in Pb inputs.

Klaminder et al. (2008a) considered the biogeochemical behavior of atmospherically derived Pb in boreal forest soils in Sweden (Figure 3-9). The estimated annual losses via

percolating soil water were ~2 mg/m^2·yr (Klaminder et al., 2008a) and so the annual loss, assumed to be from the mor layer, was greater than the atmospheric input of ~0.5 mg/m^2·yr. The upward transport of Pb did not compensate for the losses either. In contrast, the amount of Pb being stored in the mineral soil layers was increasing. The mean residence time of Pb in the mor layer was estimated to be ~300 years, in reasonable agreement with their earlier work (Klaminder et al., 2006a). These values were greater than the values of 2-150 years determined for U.S. forest soils, e.g. (Watmough et al., 2004; Kaste et al., 2003) but the difference was attributed to the lower decomposition rates of OM within the northern boreal forests of Sweden. They concluded that more research was needed to determine the processes occurring within the mor layer that control the release of Pb from this horizon.



Notes The atmospheric deposition rate is from (Klaminder et al., 2006a), the plant uptake rates from (Klaminder et al., 2005) and estimated soil-water fluxes from (Klaminder et al., 2006b).

Figure 3-9 Schematic model summarizing the estimated flux of Pb within a typical podzol profile from northern Sweden using data from Klaminder et al. (2006a).

Klaminder et al. (2008b) investigated in more detail the distribution and isotopic signature of Pb persisted within the O-horizon (mor layer) of boreal forest soils. They found that the mor layer preserved a record of past Pb emissions from a nearby smelter. Minimal animal burrowing activity and low leaching rates observed at the sampling location were important factors contributing to the preservation of this record. They concluded that temporal changes in atmospheric fallout in addition to adsorption processes need to be considered when interpreting Pb concentrations changes within the mor layer.

Significantly higher O-horizon Pb concentrations have been observed in coniferous than deciduous forest soils (McGee et al., 2007). Steinnes et al. (2005) noted evidence for downward migration of Pb from the O-horizon to the E-horizon of most soils and in some cases the upper B-horizon. They found that the downward transport of Pb differed considerably between the sites, e.g., from almost no anthropogenic Pb in the B-horizon at some sites to ~70% at other sites. The greater downwards transport in some locations was attributed to climatic variations, with more extensive leaching and possibly a greater turnover of OM at sites where higher mean annual temperatures were experienced. Higher atmospheric deposition of acidifying substances in these locations was considered the most important factor in Pb transport, causing release of Pb from exchange sites in the humus layer and promoting downward leaching.

Seasonal variation in Pb mobility has also been observed in forest soil. Other research indicated that Pb concentrations correlated with DOC concentrations in the soil solution from the O-horizon, and were lower during late winter and spring compared with summer months (Landre et al., 2009). The degradation of OM in the O-horizon produced high DOC concentrations in the soil solution. It was also shown that Pb was associated with the DOC, and concluded that DOC production is a primary factor enhancing metal mobility in this horizon. In the underlying mineral horizons, DOC concentrations declined due to adsorption and cation exchange processes. The B-horizon retained most of the DOC leached from the O-horizon and it has also been observed that Pb is similarly retained.

Non-forested Soils

In contrast with forest soils, most non-forested soils are less acidic and so most studies of Pb behavior in non-forested soils have focused on Pb immobility. However, there are acid soils in some locations that are not forested. For these soils, as for forest soils, Pb mobility is weak but correlated with OM. For example, Schwab et al. (2008) observed that low molecular weight organic acids added to soil enhanced Pb movement only slightly. Citric acid and tartaric acid enhanced Pb transport to the greatest degree but the

extent of mobilization was only slightly higher than that attained using deionized water even at high concentrations. While the formation of stable solution complexes and more acidic conditions favored mobilization of Zn and Cd, Pb remained strongly sorbed to soil particles and so the presence of complexing agents and low pH (2.8-3.8) did not substantially enhance Pb mobility. Similarly, limited penetration and leaching was observed in an extremely complex temperate soil profile, with highest concentrations of Pb (~80 mg/kg) found in the top 0-5 cm section of soil. For this uppermost soil section, there was a strong correlation between Pb concentration and OC content, both for the total soil fraction and the acid-extractable fraction. The Pb migration rate was calculated to be 0.01 cm/yr and it was estimated that Pb would be retained in the soil column for 20,000 years, with no evidence of rapid movement of anthropogenic Pb from the top 0-5 cm soil section into the soil profile Kylander et al. (2008).

Other recent studies also reported strong retention on non-forest soils and enhanced mobility on Fe and OM colloids. Pb was strongly retained on acidic Mediterranean soil columns, with association of Pb with the exchangeable, OM and crystalline Fe oxide fractions appearing to favor mobility while association with Mn oxides and amorphous Fe oxides was linked with semi-irreversible retention of Pb in the solid phase (Garrido et al., 2008). In another study of Pb mobility within Mediterranean soils, Pb infiltration velocity was measured to be 0.005 m/yr (Erel, 1998). The authors attributed Pb movement within the soil column to advection and concluded that the soil profile of Pb is similar to the anthropogenic air Pb emissions trend. Pedrot et al. (2008) studied colloid-mediated trace element release at the soil/water interface and showed that Pb was mobilized by Fe nanoparticles that were bound to humic acids.

Soil pH value is probably the single most important factor affecting solubility, mobility and phytoavailability but reducing conditions also results in increased Pb mobility, with the release of Pb into an anoxic soil solution due to the combined effect of Fe(III) reductive dissolution and dissolved OM release. Dissolved OM is more important than Fe oxyhydroxides in determining Pb mobility. Under oxic conditions, Fe-Mn-hydroxides often play an important role in the sorption of Pb to the solid phase soil (Schulz-Zunkel and Krueger, 2009). In an agricultural soil, fate of Pb in soils is related to agricultural management. Although Pb was found to be strongly sorbed to the soil, downward migration was observed and the movement of Pb to deeper soils was due to the soil mixing activities of earthworms (Fernandez et al., 2007). Thus in relatively unpolluted non-forested soils, as in forested soils, colloidal Fe and OM, pH, and biophysical transport all enhance Pb mobility in soil. Pb transport in more highly contaminated soils has also been the subject of recent research. In a vegetated roadside soil, Pb was leached from the upper 50 cm of the soil even though the pH was 7.2. Pb was transported on mobile particles and colloids in the soil solution. Some of the colloids may have formed

from OM produced by roots and decaying shoots. The transport process was enhanced by preferential flow triggered by intense rainfall events. This study suggested that the value of the effective sorption coefficient estimated under dynamic conditions was unrelated to values measured in conventional batch studies. This indicates that the use of batch studies to derive input values for sorption coefficients in transport models requires caution. It was concluded that the primary control of Pb transport in the long term was the degree of preferential flow in the system (Roulier et al., 2008b).

Other studies also noted similarly low Pb mobility, but with substantial variation between soil types and locations. A decline in O-horizon Pb concentrations and Pb accumulation in mineral horizons was also observed for forest soils by Watmough and Dillon (2007), but did not hold for nearby wetland areas from which a large amount of DOC is exported, with approximately 10 times more Pb being associated with a given amount of DOC in the leachate from the LFH-horizon of the wetland soil than with the DOC in the stream water draining the wetland. This may reflect greater retention of Pb by the wetland and/or a change in structure of DOC leading to a change in complexing capacity possibly because of changes in pH or competition with Al and Fe.

Williams et al. (2006) characterized Pb speciation in a mine waste-derived fertilizer, ironite. It was thought that PbS would be the main form of Pb, but instead was the predominant form was $PbSO_4$, which may move more easily through soil and enter proximal waters. In contrast, Courtin-Nomade et al. (2008) showed that Pb was incorporated into barite rather than goethite in waste rock pile materials. The high-stability phase formed was an anglesite-barite solid solution.

In weathering flotation residues of a Zn-Pb sulfide mine were more Pb was mobile in weathered topsoil than in the unweathered subsoil. The topsoil had a very high OM content and the Pb enrichment was attributed to an interaction with soil OM. Overall, the results contrast strongly with most other studies but the interpretation was supported by the sequential extraction results which showed that there was a very large exchangeable Pb component in these surface soils (Schuwirth et al., 2007). Scheetz and Rimstidt (2009) characterized shooting range soils in Jefferson National Forest, VA, in which the metallic Pb shot rapidly became corroded and developed a coating of hydrocerussite, which dissolved at the pH values of 8-9; see Figure 3-10, which shows an Eh-pH diagram indicating the solubility, equilibrium, and stability of these corroded Pb molecules in terms of the activity of hydrogen ions (pH) versus the activity of electrons (Eh [in volts]). The solubilized Pb was largely re-adsorbed by the Fe and Mn oxides and carbonate soil fractions. The minimum solubility of hydrocerussite lies in the pH range 8-9 but solubility increases by several orders of magnitude at pH below 6 (Scheetz and Rimstidt, 2009).

Figure 3-10 Eh-pH diagram for Pb in shooting range soils, Jefferson National Forest, VA.

Rooney et al. (2007) also investigated the controls on Pb solubility in soils contaminated with Pb shot. Again, corrosion crusts were found to develop on Pb pellets. The concentrations of Pb in the soil solution were, however, much lower than if they were controlled by the solubility of the dominant crustal Pb compounds (mainly hydrocerussite). Instead it was suggested that the concentrations were being controlled by sorption of Pb by the soil solid phase. The pH range in this study was 4.5-6.5 and so again dissolution of hydrocerussite would be expected. Sorption to solid phases in the soil is also consistent with the findings of Scheetz and Rimstidt (2009). Overall, in contrast to less polluted forested and non-forested soils, considerable mobility was often, but not always observed in soils near roadways and mines and on shooting ranges, with colloid transport and soil pH playing an important role in Pb mobility. Although there have been steep declines in Pb deposition, surface soils in have been slow to recover (Bindler et al., 2008; Kaste et al., 2006). As was concluded in the 2006 Pb AQCD (U.S. EPA, 2006b), soils continue to act as a predominant sink for Pb.

While in some studies the flux of Pb, from the soil through aquatic ecosystems to lakes has peaked and declined. In other studies, no recovery of lake sediments in response to emission reductions was observed (Norton, 2007). For example, Klaminder et al. (2010) has shown that the Pb concentrations in sub-Arctic lake sediments remain unchanged in recent years, with the lack of recovery linked to the effects of soil warming, which affect

Pb-OM transport from soil to the receiving lake systems. Shotyk and Krachler (2010) also reported a disconnect between atmospheric deposition and recent changes in Pb concentration and isotope ratios in the lake sediments. Simulations of future metal behavior suggest that the more strongly sorbing metals such as Pb will respond to changes in metal inputs or acidification status only over centuries to millennia (Tipping et al., 2006).

Overall, recent research confirms the generally low mobility of Pb in soil. This limited mobility is strongly dependent on both colloid amount and composition, as well as pH, and may be greater in some contaminated soils. Mobility is so low that soils continue to act as a sink for atmospheric Pb even though atmospheric Pb concentrations peaked several decades ago.

3.4 Monitoring of Ambient Lead

3.4.1 Ambient Measurement Techniques

3.4.1.1 Sample Collection

Federal Reference Methods

The indicator for the Pb NAAQS is Pb in total suspended particles (Pb-TSP) (73 FR 66964). In order to be used in regulatory decisions judging attainment of the Pb NAAQS, ambient Pb concentration data must be obtained for this indicator using either the Federal Reference Method (FRM) or a Federal Equivalent Method (FEM) defined for this purpose. Accordingly, for enforcement of the air quality standards set forth under the Clean Air Act, EPA has established provisions in the Code of Federal Regulations under which analytical methods can be designated as FRM or FEM. Measurements for determinations of NAAQS compliance must be made with FRMs or FEMs. FRMs and FEMs for the Pb NAAQS exist for both sample collection and sample analysis.

There are two FRMs for sample collection in the Pb NAAQS monitoring network (described in Section 3.4.2 below): (1) Reference Method for the Determination of Lead in Suspended Particulate Matter Collected From Ambient Air (40 CFR part 50 Appendix G), and (2) Reference Method for the Determination of Lead in Particulate Matter as PM_{10} Collected From Ambient Air (40 CFR part 50, Appendix G). The Pb-TSP FRM sample collection method is required for all source-oriented NAAQS monitors, and the

FRM for Pb-PM_{10} is accepted for Pb NAAQS monitoring at non-source-oriented monitors in specified situations.

The Pb-TSP FRM sample collection method specifies use of a high-volume TSP sampler that meets specified design criteria (40 CFR part 50 Appendix B). Ambient airborne PM is collected on a glass fiber filter for 24 hours using a high volume air sampler. It has long been recognized that there is notable variability in high-volume TSP sample measurements associated with the effects of wind speed and wind direction on collection efficiency. This variability is predominantly associated with the capture efficiency for particles larger than 10 µm, but the sampler's size selective performance is known to be affected by wind speed and direction. For example, a directional difference of 45 degrees can result in a nearly two-fold difference in 15 µm particle collection efficiency and a nearly five-fold difference in 50 µm particle collection efficiency (Wedding et al., 1977). Effective D_{50} (size at 50% efficiency) was observed to decrease from 50 µm at a 2 km/h wind speed to 22 µm at 24 km/h (Rodes and Evans, 1985). Figure 3-11 illustrates the effect of sampler orientation on collection efficiency as a function of particle size.

Figure 3-11 Comparison of particle collection efficiency among different TSP sampler types (Modified Andersen Sampler, Hi-volume Sampler (for different incident wind direction (45°, 0°), Prototype Dichotomous Sampler, and Original Andersen Sampler).

Some existing commercially available sampler inlets are designed to collect particles larger than 10 µm with greater than 50% efficiency (Kenny et al., 2005), and these inlets can be tested as potential replacements for TSP sampling. Efficient collection of particles much larger than 10 µm is considerably more challenging because their greater inertia and higher settling velocities hinder their efficient intake by samplers. The sampling difficulties and the long history of research to develop adequate sampling technology for large particles have been thoroughly reviewed (Garland and Nicholson, 1991). High intake velocities and large inlet openings are necessary to minimize sampling bias for sampling ultra-coarse particles. At this time, no alternative to the FRM TSP sampler has been identified that has been adequately characterized. As such, there is a continued need to assess the feasibility of a revised TSP sampler design with improved control on collection efficiency over a wider range of particle sizes, including ultra-coarse particles (which are not captured with PM_{10} samplers).

The spatial scale for which ambient air Pb samples are representative varies depending on particle sizes present, as discussed further in Section 3.5.3. Concentrations of particles larger than 10 µm are likely to be very spatially and temporally heterogeneous, with higher concentrations in the vicinity of their emissions sources. Under typical conditions, $PM_{10-2.5}$ particles travel much shorter distances before settling out than finer particles (U.S. EPA, 2009). As a result, spatial and temporal heterogeneity is greater for $PM_{10-2.5}$ than for $PM_{2.5}$, because coarser particles have greater settling velocities (Hinds, 1999), and settling velocities are even greater for particles larger than 10 µm. Thus, spatial gradients are steepest near sources, such that measured concentrations of larger particle sizes tend to be most representative of the ambient air in areas in close proximity to the monitor, with higher concentrations likely to occur closer to the source and decreasing concentrations with increasing distance from the source. This issue has been thoroughly discussed in the previous AQCD (U.S. EPA, 2006b). It has also been acknowledged in previous AQCDs, with a lengthy discussion appearing in the 1977 AQCD (U.S. EPA, 1986b, 1977).

The Pb-PM_{10} FRM sample collection method specifies use of a high-volume PM_{10} sampler that meets specified design criteria (40 CFR part 50, Appendix Q). Ambient airborne PM is collected on a polytetrafluoroethylene (PTFE) filter for 24 hours using active sampling at local conditions with a low-volume PM_{10} sampler and analyzed by X-ray fluorescence (XRF). In recognition of the steep spatial gradients associated with sources of ultracoarse particles, ambient Pb sampled using the FRM for Pb-PM_{10} is allowed in certain instances where the expected Pb concentration does not approach the NAAQS and no sources of ultracoarse Pb are nearby.

Other Sample Collection Methods

In addition to the FRMs for ambient Pb sample collection, a range of other PM sampling methods are available for collecting samples for Pb analysis. These include FRM sampling methods for PM that have also been used for collection of samples for Pb analysis, sampling methods in use in other sampling networks such as the CSN, IMPROVE and National Air Toxics Trends Stations (NATTS) networks described in Section 3.4.2, and other sampling methods that have been used to measure airborne Pb concentrations in research studies unrelated to network applications. Some of the more commonly used methods are listed in Table 3-3. Most of these methods have been described in considerable detail in the 2004 PM AQCD (U.S. EPA, 2004). Table 3-3 also lists key conditions of capture for each method, including particle size, inlet type, collection medium, and flow rate.

Table 3-3 Airborne Pb sampling methods

Sampler	Network	Sampler Type	Mass Median Aerodynamic Diameter	Inlet Type	Collection Medium	Typical Flow Rate	Reference
High Volume TSP	Pb-FRM	Single Channel	TSP	None	Glass	1.13 m^3/min	U.S. EPA (2011e)
Low Volume PM_{10}	PM-FRM, NATTS	Single Channel	< 10 μm	Louvered Inlet + PM_{10} Impactor	Teflon	16.67 L/min	U.S. EPA (2011e)
$PM_{2.5}$	PM-FRM	Single Channel	< 2.5 μm	WINS Impactor	Teflon	16.67 L/min	U.S. EPA (2011e)
Met One SASS	CSN	Multiple Channel	< 2.5 μm	Cyclone	Teflon	6.7 L/min	MetOne (2009)
IMPROVE	IMPROVE	Multiple Channel	< 2.5 μm	Cyclone	Teflon	22.8 L/min	IMPROVE (2001)
MOUDI	None	Multistage Impactor	8 stages 0.056-18 μm	Impactor	Teflon	30 L/min	(Marple et al., 1991)
Noll Impactor	None	Multistage Impactor	4 stages < 108 μm	Impactor	Coated Mylar	Rotating arm	(Noll, 1970)
SEAS	None	Slurry	< 1.2 μm	Impactor	Slurry	90 L/min	(Pancras et al., 2006)

Size discrimination is usually accomplished with impactors or cyclones. With impactors, PM is forced through a jet at high speed, and particle inertia carries particles above a given size into a collection surface downstream of the jet, while smaller particles follow the air stream around the collector. In multistage impactors, a series of successive stages of jets are used to collect a range of particle sizes. The micoro-orifice uniform deposit impactor (MOUDI) is a widely used multistage impactor. The impaction process and performance of various impactors, including the WINS and MOUDI, has been described in detail in the 2004 PM AQCD (U.S. EPA, 2004). The biggest concern in collection by

impaction is particle bounce, which occurs when particles collide with the collection surface but bounce off the collection stage into the air stream and are not actually collected. Considerable effort has been devoted to minimizing errors due to bounce in FRM samplers, and this has been thoroughly discussed in the 2004 PM AQCD (U.S. EPA, 2004). An alternative to impaction that also eliminates particle bounce is the use of an air sampling cyclone. In the CSN and IMPROVE networks, cyclones are used to remove particles larger than 2.5 μm. An air sampling cyclone brings air into a tangential jet and directs flow against a circular wall, where particles larger than a given size are removed by centrifugal and gravitational forces.

Collection medium and flow rate are two other key features of a sampling method. One advantage of low volume sampling is its suitability for collection of samples for XRF analysis. Because Pb in $PM_{2.5}$ is analyzed by XRF in the CSN and IMPROVE networks, sampling methods that employ Teflon filters suitable for XRF analysis have been developed for these networks. In practice, this restricts sampling for airborne Pb to low volume samplers with a convenient filter size. This also holds true for the Pb-PM_{10} FRM sampling, which is also restricted to low volume PM_{10} samplers because XRF has been designated as the FRM for Pb-PM_{10} analysis. An additional practical advantage of available low volume samplers over the existing high volume Pb-TSP FRM is that established low volume $PM_{2.5}$ and PM_{10} sampling methods are not dependent on wind direction. However, this has to do with sampler design rather than flow rate, and there are high volume PM_{10} sampling methods, including the PM_{10} FRMs, that are also free of wind direction bias. These would be suitable for Pb measurement with other analytical methods, such as ICPMS, and could have a potential advantage of providing more material in locations with very low concentrations.

3.4.1.2 Sample Analysis: Federal Reference and Federal Equivalence Methods

As described in Section 3.4.1.1., measurements for determinations of NAAQS compliance must be made with FRMs or FEMs. As of October 12, 2011, 1 manual reference method and 25 manual equivalent methods for sample analysis had been approved for Pb (http://www.epa.gov/ttn/amtic/files/ambient/criteria/reference-equivalent-methods-list.pdf). The FRM for Pb (Pb-TSP) was promulgated in 1979 and is based on flame atomic absorption spectroscopy (AAS) (40 CFR Part 50, Appendix G). Ambient air suspended in PM is collected on a glass fiber filter for 24 hours using a high volume air sampler. Pb in PM is then solubilized by extraction with nitric acid (HNO_3), facilitated by heat, or by a mixture of HNO_3 and hydrochloric acid (HCl) facilitated by ultrasonication. The Pb content of the sample is analyzed by atomic absorption

spectrometry using an air-acetylene flame, using the 283.3 or 217.0 nm Pb absorption line, and the optimum instrumental conditions recommended by the manufacturer. Several FEMs have been approved based on a variety of principles of operation have been approved, including inductively coupled plasma optical emission spectrometry, and inductively-coupled plasma mass spectrometry (ICPMS).

Atomic Absorption Spectrometry

AAS is the basis for the existing FRM. Atomic absorption spectrometry was first developed in the 19th century, and became widely used in the 1950s. More than 70 elements can be analyzed by AAS. Typically a liquid sample is nebulized into a flame with sufficient heat for elements to be atomized. The liquid specified by the FRM is a nitric acid extract of a glass fiber filter used for collection of suspended PM with a high volume sampler. The atomized sample is then irradiated with visible light at a specific wavelength to promote an electronic transition to a short-lived excited state, resulting in absorption of the light. Elemental selectivity is achieved because light absorption is specific to a particular electronic transition in a particular element. As a result, absorption of light at a given wavelength generally corresponds to only one element. The flame is irradiated with a known quantity of light and intensity of light is measured on the other side of the flame to determine the extent of light absorption in the flame. Using the Beer-Lambert law the concentration of the element is determined from the decrease in light intensity due to sample absorption.

A more sensitive variation of atomic absorption spectrometry for most elements is graphite furnace atomic absorption spectrometry (GFAAS). Instead of introducing the sample into a flame, the liquid sample is deposited in a graphite tube that is then heated to vaporize and atomize the sample.

Inductively-Coupled Plasma Mass Spectrometry

Inductively coupled plasma mass spectrometry (ICPMS) is a sensitive method of elemental analysis developed in the late 1980s. Argon (Ar) plasma (ionized gas) is produced by transmitting radio frequency electromagnetic radiation into hot argon gas with a coupling coil. Temperatures on the order of 10,000 K are achieved, which is sufficient for ionization of elements. Liquid samples can be introduced into the plasma by extracting samples in an acid solution or water, and nebulizing dissolved elements. Resulting ions are then separated by their mass to charge ratio with a quadrupole and signals are quantified by comparison to calibration standards. While solid samples can be introduced by laser ablation, nebulization of liquid extracts of PM collected on Teflon filters is more typical. One major advantage of ICPMS over AAS is the ability to analyze

a suite of elements simultaneously. An additional advantage is low detection limits of 50-100 parts/trillion for Pb.

Inductively-Coupled Atomic Emission Spectroscopy

Inductively coupled atomic emission spectroscopy (ICP-AES) also generates ions from elements with a hot Ar plasma, similar to ICPMS. Excited atoms and ions are produced, and these emit electromagnetic radiation with frequencies characteristic of a particular element. Intensity of emission is used to determine the concentration of an element in the sample. Elements are extracted from filter samples and nebulized into the plasma.

Energy Dispersive X-ray Fluorescence

In energy dispersive X-ray fluorescence spectrometry a beam of X-ray photons from an external excitation source is applied to a sample, causing ejection of inner shell electrons from elements in the sample. Because inner shell electrons have higher electron binding energies than outer shell electrons, the ejection of the inner shell electron induces an energetically favorable electronic transition of an outer shell electron to replace the ejected electron. The energy released as a result of this transition is in the form of electromagnetic radiation, corresponding to the difference in electronic binding energies before and after the transition. The energy released is typically in the X-ray portion of the electromagnetic spectrum. The release of electromagnetic radiation as a result of an electronic transition is defined as fluorescence. Fluorescence energies associated with electronic transitions depend on atomic structure, and vary between elements. As a result, X-ray fluorescence energy is uniquely characteristic of an element, and X-ray intensity at a given energy provides a quantitative measurement of elemental concentration in the sample. The X-rays are detected by passing them through a semiconductor material, resulting in an electrical current that depends on the energy of the X-ray.

3.4.1.3 Other Analysis Methods for Total Lead

Several other methods that have not been designated as FRM or FEM methods have also been frequently used to obtain atmospheric Pb measurements. These include proton induced x-ray emission (PIXE), X-ray photoelectron spectroscopy (XPS), and other methods

PIXE

Proton-induced X-ray emission (PIXE) spectroscopy has been widely used to measure Pb in atmospheric PM. In PIXE, a high-energy proton beam passes through the sample, causing electrons to be excited from inner shells. The x-rays emitted when electronic transition occur to replace the inner shell electrons are characteristic of an element and can be used to identify it. Development of PIXE for analysis of airborne PM was reviewed by Cahill et al. (1981). Numerous applications of PIXE to analysis of airborne Pb-PM have been reported in the past five years (Cohen et al., 2010; Waheed et al., 2010; Sanchez-Ccoyllo et al., 2009; Chan et al., 2008; Johnson et al., 2008; Cong et al., 2007; Ariola et al., 2006; Johnson et al., 2006; Wåhlin et al., 2006).

XPS

X-ray photoelectron spectroscopy (XPS), also called electron spectroscopy for chemical analysis (ESCA) has been used to determine Pb concentrations on materials surfaces, including atmospheric PM (Finlayson-Pitts and Pitts, 2000). A fixed frequency X-ray beam causes inner shell electrons to be emitted and kinetic energy of ejected electrons is measured. Binding energy characteristic of an element can be calculated from the measured kinetic energy, allowing identification of the element. XPS can also provide information about an element's chemical environment or oxidation states because of chemical shifts in binding energy caused by differences in chemical environment. There have been some recent applications of XPS to airborne PM, concluding that Pb was mostly in the form of Pb sulfate (Qi et al., 2006). XPS analysis is a surface technique that is suitable only to a depth of 20-50Å.

Other Total Lead Methods

Anodic stripping voltammetry, atomic emission spectroscopy, and colorimetry have also been used for measurement of atmospheric Pb (Finlayson-Pitts and Pitts, 2000). In anodic stripping voltammetry, metal ions are reduced to metallic form and concentrated as an amalgam on a suitable electrode (e.g. a mercury amalgam on a mercury electrode). This is followed by re-oxidation in solution, which requires "stripping" the reduced metal from the electrode. Emission spectroscopy can be compared to the existing FRM for Pb based on AAS. In atomic absorption spectroscopy radiation absorbed by non-excited atoms in the vapor state is measured. In emission spectroscopy, radiation due to the transition of the electron back to ground state after absorption is measured, and the energy of the transition is used to uniquely identify an element in a sample. Colorimetric methods are wet chemical methods based on addition of reagents to a Pb containing solution to generate measurable light absorbing products. These methods are less

sensitive than ICPMS, XRF, and PIXE and their use is declining as more sensitive methods become more widely used, but have advantages regarding simplicity and cost.

3.4.1.4 Sequential Extraction

Sequential extraction has been widely used to further classify Pb for various purposes, including bioavailability, mobility, and chemical speciation. In general the more easily extractable Pb is considered more mobile in soil and is more bioavailable to organisms. This approach has also been used widely in characterization of airborne PM. In its original application (Tessier et al., 1979) metals extraction solvents were selected to correspond to common species present in soil, and metals were classified as exchangeable, bound to carbonates, bound to iron and manganese oxides, bound to OM, and residual. Extraction was carried out with successively stronger solutions, starting with magnesium chloride for removal of exchangeable metals and ending with hydrofluoric and perchloric acids for removal of residual metals. Pb was one of the elements originally studied by Tessier et al. (1979) as well as one the elements analyzed when Tessier's scheme was first applied to airborne PM (Fraser and Lum, 1983).

Tessier's scheme was modified and optimized for airborne PM over time (Fernandez Espinosa et al., 2002) and additional extraction schemes were also developed (Chester et al., 1989), including the simplest case of two fractions corresponding to soluble and insoluble fractions (Falta et al., 2008; Canepari et al., 2006; Voutsa and Samara, 2002). The variety of methods in current use was recently thoroughly reviewed by Smichowski et al. (2005). With the recognition that biological processes involving deposited PM metals were related to their solubility (U.S. EPA, 2009), sequential extraction methods or simpler schemes to divide metals into water and acid soluble fractions were increasingly applied to PM samples to obtain data not just on total metal concentration but also on water soluble concentration (Graney et al., 2004; Kyotani and Iwatsuki, 2002; Wang et al., 2002b). Compared to other elements, a large fraction of total Pb is soluble (Graney et al., 2004). Recent advances in this area have included application to size fractionated PM (Dos Santos et al., 2009; Birmili et al., 2006), time resolved measurements (Perrino et al., 2010), and an extensive comparison of different fractionation schemes (Canepari et al., 2010). Sequential extraction with two or more fractions is becoming more widely used for characterization of Pb-PM in a variety of sources (Canepari et al., 2008; Smichowski et al., 2008; Poykio et al., 2007; Sillanpaa et al., 2005) and locations (Perrino et al., 2010; Dos Santos et al., 2009; Cizmecioglu and Muezzinoglu, 2008; Dahl et al., 2008; Sato et al., 2008; Annibaldi et al., 2007; Richter et al., 2007; Al-Masri et al., 2006; Canepari et al., 2006; Fujiwara et al., 2006; Wang et al., 2006c; Yadav and Rajamani, 2006;

Gutierrez-Castillo et al., 2005; Heal et al., 2005), leading to a better understanding of mobility characteristics of Pb in airborne PM.

3.4.1.5 Speciation Techniques

XAFS

There have been few attempts to speciate Pb in atmospheric PM. However, recently X-ray absorption fine structure (XAFS) has been applied to PM and road dust to obtain Pb speciation data from direct analysis of particle surfaces. In XAFS the absolute position of the absorption edge can be used to determine the oxidation state of the absorbing atom, and scattering events that dominate in the near edge region provide data on vacant orbital energies, electronic configurations, and site symmetry of the absorbing atom that can be used to determine the geometry of the atoms surrounding the absorbing atom. XAFS can be divided into two spectral regions. X-ray absorption near edge structure (XANES) is the region of the x-ray absorption spectrum up to 50 eV above the absorption edge observed when an inner shell electron is electronically excited into unoccupied states, and Extended X-ray Absorption Fine Structure (EXAFS) up to 1 keV above the absorption edge. Both have been applied recently to Pb in PM. XANES spectra of Pb coordination complexes with a wide range of environmentally relevant ligands have been reported (Swarbrick et al., 2009). XANES has been used to show that several different Pb species are probably present in urban airborne PM (Funasaka et al., 2008) and urban road dust (Barrett et al., 2010). XANES has been used to differentiate between Pb chromate, Pb-sorbed minerals, Pb chloride, Pb oxide, Pb carbonate, Pb sulfide and Pb sulfate are probably present in urban PM and road dust samples (Barrett et al., 2010; Funasaka et al., 2008; Tan et al., 2006). XANES has also been used to quantify Pb complexed with humic substances from soil in road dust (Pingitore et al., 2009) and to investigate the speciation of atmospheric Pb in soil after deposition (Guo et al., 2006b). EXAFS has been applied to emission sources to show Pb from a sinter plant was mainly carbonate (Sammut et al., 2010). XAFS has only been applied to airborne PM very recently and shows promise for chemical speciation of airborne metals, including Pb.

GC- and HPLC-ICPMS

Environmental analytical methods for organolead compounds prior to 2000 were generally time consuming and costly, requiring extraction, derivatization, and detection (Quevauviller, 2000). These have been thoroughly reviewed (Pyrzyńska, 1996) and method intercomparison studies have been conducted (Quevauviller, 2000). More

recently, speciation of organometallic compounds in environmental samples has usually carried out by coupling a chromatographic separation step with a mass spectrometry-based multi-element detection system capable of analyzing a wide range of elements along with Pb, and these approaches have also been recently reviewed (Hirner, 2006). Chromatographic systems in common use are gas chromatography and high performance liquid chromatography. Detection systems most commonly used are ICPMS, electron impact ionization mass spectrometry (EI-MS), and electrospray ionization mass spectrometry (ESI-MS) (Hirner, 2006). Using these techniques, organometallic species are separated from each other based on differences in retention times on chromatographic columns, and elemental Pb is determined by the ICPMS used as a detector downstream of the column to measure elemental Pb in the pure compounds after chromatographic separation. Pb speciation analysis has benefited from the development of HPLC-ICPMS in particular (Quevauviller, 2000). Recent advances in metal speciation analysis in environmental samples by HPLC-ICPMS have been extensively reviewed (Popp et al., 2010). HPLC-ICPMS has been used for analysis of Pb complexes with humic substances (Vogl and Heumann, 1997), which could be relevant for resuspended soil and road dust. GC-ICPMS has been more widely used for separation and analysis of methyl and ethyl Pb species in atmospheric PM (Poperechna and Heumann, 2005; Jitaru et al., 2004; Leal-Granadillo et al., 2000).

Lead Isotope Ratio Analysis

Classifying Pb by its relative isotopic abundance has also proved useful for a variety of purposes, including the determination of its geochemical origins in natural samples and the relative contributions of coal burning, mining, smelting, and motor vehicle emissions in polluted samples (Farmer et al., 1996). Typically, isotopes of Pb (^{208}Pb, ^{207}Pb, ^{206}Pb, and ^{204}Pb) are measured in a sample using mass spectrometry, and then ratios of the isotopes are calculated to obtain a "signature." Isotopes of ^{208}Pb, ^{207}Pb, and ^{206}Pb are substantially more abundant than ^{204}Pb, but they vary depending on the geologic conditions under which the ore was produced through decay of different isotopes of uranium and thorium (Cheng and Hu, 2010). Isotope ratio analysis was first applied to airborne PM in 1965 to identify the impact of motor vehicle exhaust on marine and terrestrial Pb deposition in the Los Angeles area (Chow and Johnstone, 1965). More recently, high resolution ICPMS has also proved to be a sensitive tool for isotope ratio analysis. High resolution ICPMS was first applied to geological samples (Walder and Freedman, 1992), and has since been widely used for determination of Pb isotope ratios in airborne PM samples. Pb isotope ratios have been measured in a number of recent studies in a variety of locations to investigate the origin of airborne Pb (Knowlton and Moran, 2010; Noble et al., 2008; Hsu et al., 2006; Widory, 2006). Shotyk and Krachler

(2010) also used Pb isotopes to demonstrate that the fate of Pb from runoff can be different from Pb with different origins. They observed that humus PM impacted by leaded on-road gasoline that are derived from soil surfaces are likely to be more easily transferred to sediments than Pb of other origins, with substantial amounts retained by lakes.

Recent studies have examined the use of Pb isotope ratios as a tool for source apportionment. Duzgoren-Aydin and Weiss (2008) provide caveats for using isotope ratio analyses. They point out that Pb isotope ratios may vary when Pb from several sources of different geological origins are introduced to the same location. Duzgoren-Aydin (2007) warned that the presence of a complex mixture of contaminants containing common Pb isotopes can lead to an overestimation of the contribution of one source (e.g., soil contaminated by Pb emissions from on-road gasoline) and an underestimate of another source, such as that from industry. For this reason, Cheng and Hu (2010) suggest that Pb isotope analysis only be used when the investigators are confident that the isotopic signatures of various sources differ substantially. Pb recycling and international trading may cause more blending of Pb from various sources, so that there is less heterogeneity in the Pb isotopic signatures sampled. Additionally, Cheng and Hu (2010) point out that the isotopic signature of Pb in air or soil may change over time with changing source contributions, but historical Pb isotope data are lacking. Duzgoren-Aydin and Weiss (2008) suggest the use of GIS mapping of Pb isotopic information to help distinguish potential sources based on location of sources in addition to the sources' isotopic signature.

Gulson et al. (2007) examined the relationships between Pb isotope ratios and source apportionment metrics at urban and rural sites in New South Wales, Australia. In this study, Gulson et al. (2007) performed source apportionment with both principal component analysis (PCA) and a neural network technique called the self-organizing map (SOM) and compared results from each method with $^{206}Pb/^{204}Pb$, $^{207}Pb/^{206}Pb$, and $^{208}Pb/^{206}Pb$ obtained from PM samples, although only $^{206}Pb/^{204}Pb$ results were presented in detail. Wintertime "fingerprints" from both the PCA and SOM methods produced similarly linear relationships with $^{206}Pb/^{204}Pb$, with linearly decreasing relationships between the isotope ratios and the "secondary industry," "smoke," "soil," and "seaspray" source categories. However, the relationships of the isotope ratios with the SOM fingerprints and PCA factors, respectively, were very similar. This finding may have been due to the presence of elements such as black carbon and sulfur in several SOM fingerprints and PCA factors. The authors suggest that this might be related to the presence of several sources, which in combination result in a weak atmospheric signal. Additionally, both $PM_{2.5}$ and TSP samples were utilized for this study, and it was found that similar results were obtained for either size cut. At the urban site, they observed that

the $^{206}Pb/^{204}Pb$ ratio decreased over time with increasing contributions of industrial, soil, smoke, and sea spray sources. For the most part, these sources were not substantial contributions to Pb-$PM_{2.5}$ for the rural site. As for the Tan et al. (2006) speciation study described above, no notable differences were observed between the size fractions with regard to isotopic signature.

3.4.1.6 Continuous Lead Monitoring

Development of high time resolution measurement capabilities has advantages for determining peak exposure concentrations and diurnal exposure trends. High time resolution samplers suitable for analysis after sampling by XRF and ICPMS have been developed and applied. The eight-stage Davis Rotating Unit for Monitoring (DRUM) impactor (Raabe et al., 1988; Cahill et al., 1987) collects PM samples with a cascade impactor on Mylar film substrate on a slowly rotating drum, with samples analyzed by XRF. It has been used to measure size and time resolved Pb and other elements with a time resolution of less than 6 hours using x-ray fluorescence (Cahill, 2003; Bench et al., 2002). The University of Maryland Semi-continuous Elements in Aerosol Sampler (Kidwell and Ondov, 2004, 2001) uses direct steam injection to promote condensational growth of sampled at a high flow rate, and accumulates resulting droplets in a slurry by impaction. It has been successfully applied to measurement of Pb and other elements by AAS (Pancras et al., 2006; Pancras et al., 2005) with a 30-minute time resolution. This approach is also suitable for ICPMS analysis. A gas converter apparatus has also been developed to improve transfer of ions to the ICPMS, including Pb, and successfully tested with outdoor air (Nishiguchi et al., 2008). Other high time resolution methods suitable for Pb analysis in PM are under development, including near real-time XRF analysis.

Much of the recent progress in ambient aerosol instrumentation has been related to the development and improvement of single particle mass spectrometry (Prather et al., 1994). Preferential loss as a function of particle size is a concern with this method, but considerable effort has been devoted to optimizing transfer from atmospheric pressure down to time of flight operating pressures with minimal particle loss (Prather et al., 1994). This technique can also be considered as an effective method for real time Pb measurement in PM, including size-resolved measurements from 0.1 to 4.0 µm (Silva and Prather, 1997). Progress has continued in the development of single particle mass spectrometry to quantify elements and organic ion fragments and a number of recent applications that included (Snyder et al., 2009; Johnson et al., 2008; Bein et al., 2007; Reinard et al., 2007; Pekney et al., 2006) or specifically targeted (Salcedo et al., 2010; Moffet et al., 2008b; Murphy et al., 2007) Pb measurements.

3.4.2 Ambient Network Design

Four national monitoring networks collect data on Pb concentrations in ambient air and report it to the Air Quality System (AQS).1 State and local agencies carry out the monitoring at state and local monitoring stations (SLAMS) using FRMs and FEMs and report data to these national networks, which have been established for various purposes. Although these data may be used for other scientific purposes, the SLAMS network is designed primarily with the goal of evaluating compliance with the Pb NAAQS. In addition to FRM monitoring, Pb is also measured within the Chemical Speciation Network (CSN), IMPROVE, and the NATTS networks as described in Section 3.4.2.2. Measurements among these networks are not directly comparable in all cases because of method differences, including the PM size range sampled (TSP, PM_{10}, or $PM_{2.5}$). Data from these various networks are presented in Section 3.5.1 to provide information on ambient Pb concentrations in different size ranges.

3.4.2.1 NAAQS Monitoring Network

Monitors in the SLAMS network include predominantly those sited in compliance with regulatory requirements for the purposes of judging attainment with the NAAQS. For this purpose, these sites employ FRM samplers coupled with FRM/FEM analysis methods. At the time of the last review, there were approximately 250 sites operating in this network, although analyses at the time indicated incomplete coverage of the larger stationary sources of Pb (U.S. EPA, 2007h). As a result of the review, the Pb NAAQS monitoring requirements were revised. These revisions, some aspects of which were finalized in 2008 and the remainder in December 2010, call for expanded monitoring at both source-oriented and non-source-oriented sites (75 FR 81126, 40 CFR part 58, Appendix D, Section 4.5 to Part 58).[2] Source-oriented monitoring sites are required near sources of Pb air emissions which are expected to or have been shown to contribute to ambient air Pb concentrations in excess of the NAAQS. At a minimum there must be one source-oriented site located to measure the maximum Pb concentration in ambient air resulting from each non-airport Pb source estimated to emit Pb at a rate of 0.50 or more tons/year and in locations near those airports at which activities associated with the use of leaded aviation fuel are estimated to result in Pb emissions at a rate of 1.0 or more tons

[1] The Air Quality System (AQS) is EPA's repository of ambient air quality data. AQS stores data from over 10,000 monitors, 5,000 of which are currently active (http://www.epa.gov/ttn/airs/airsaqs/).

[2] EPA Regional Administrators may require additional monitoring beyond the minimum requirements where the likelihood of Pb air quality violations is significant. Such locations may include those near additional industrial Pb sources, recently closed industrial sources, airports where piston-engine aircraft emit Pb and other sources of re-entrained Pb dust (40 CFR, part 58, Appendix D, Section 4.5(c).

per year.1 The emission monitoring threshold was established to ensure monitoring near Pb air sources with the greatest potential to cause ambient air concentrations to exceed the Pb NAAQS. The Pb NAAQS measurements required at these sites may be as Pb-TSP or Pb-PM_{10} (75 FR 81126).

Monitoring agencies are also required to conduct non-source-oriented Pb monitoring at each National Core multipollutant monitoring network (NCore)2 site in a Core Based Statistical Area (CBSA) with a population of 500,000 or more. While non-source-oriented monitoring data can be used for purposes of NAAQS attainment designations, the main objective for non-source-oriented monitoring is to gather information on neighborhood-scale lead concentrations that are typical in urban areas so to better understand ambient air-related Pb exposures for populations in these areas.

Spatial scales defined for Pb monitoring range from microscale to neighborhood scale, with the most important spatial scales for source-oriented sites to effectively characterize emissions from point sources being microscale and middle scale, and the most important scale for non-source-oriented sites to characterize typical lead concentrations in urban areas being neighborhood scale (40 CFR Part 58, Appendix D, 4.5(d)):

- Microscale: This scale is intended to typify areas in close proximity to Pb point sources where it may represent an area impacted by the emissions plume with dimensions ranging from several meters up to about 100 m.
- Middle Scale: This scale is described as generally representing Pb air quality levels in areas up to several city blocks in size with dimensions on the order of approximately 100 m to 0.5 km.
- Neighborhood Scale: This scale is to characterize concentrations throughout some relatively uniform land use areas with dimensions in the 0.5 to 4.0 km range. Where a neighborhood site is located away from immediate Pb sources, the site may be very useful in representing typical air quality values for a larger residential area, and therefore suitable for population exposure and trends analyses.

[1]The requirement for monitoring near sources emitting 0.5 tons/year or more may be waived if it can be shown that the source will not contribute to a maximum 3-month average Pb concentration in ambient air in excess of 50 percent of the NAAQS level based on historical monitoring data, modeling, or other means (40 CFR, part 58, Appendix D, Section 4.5(a)(ii)).

[2] NCore is a new network of multipollutant monitoring stations intended to meet multiple monitoring objectives. The NCore stations are a subset of the SLAMS network are intended to support long-term trends analysis, model evaluation, health and ecosystem studies, as well as NAAQS compliance. The complete NCore network consists of approximately 60 urban and 20 rural stations, including some existing SLAMS sites that have been modified for additional measurements. Each state will contain at least one NCore station, and 46 of the states plus Washington, DC, will have at least one urban station.

Source oriented monitors near sources estimated to emit 1.0 tons/year Pb were required to be operational by January 1, 2010, and the remainder of the newly required monitors, including the non-source-oriented NCore sites, are required to be operational by December 27, 2011 (75 FR 81126). When the December 2010 Pb network requirements are fully implemented, the Pb NAAQS monitoring network is expected to consist of approximately 270 required monitors including approximately 210 source-oriented monitors and 60 non-source-oriented monitors. Figure 3-12 shows the estimated geographic distribution of Pb NAAQS monitors in the current Pb NAAQS monitoring network. This includes monitors that previously existed and are still in operation, along with those that are newly required.

With the December, 2010 regulations, EPA also required one year of Pb-TSP (FRM) monitoring near 15 airports in order to gather additional information on the likelihood of NAAQS exceedances near airports due to the combustion of leaded aviation gasoline (75 FR 81126). These airports were selected based on three criteria: annual Pb inventory between 0.5 tons/year and 1.0 tons/year, ambient air within 150 meters of the location of maximum emissions (e.g., the end of the runway or run-up location), and airport configuration and meteorological scenario that leads to a greater frequency of operations from one runway. These characteristics were selected because they are expected, collectively, to identify airports with the highest potential to have ambient Pb concentrations approaching or exceeding the Pb NAAQS. Data from this monitoring study will be used to assess the need for additional Pb monitoring at airports. These 15 sites (Figure 3-13 and Table 3-14) are required to be operational no later than December 27, 2011.

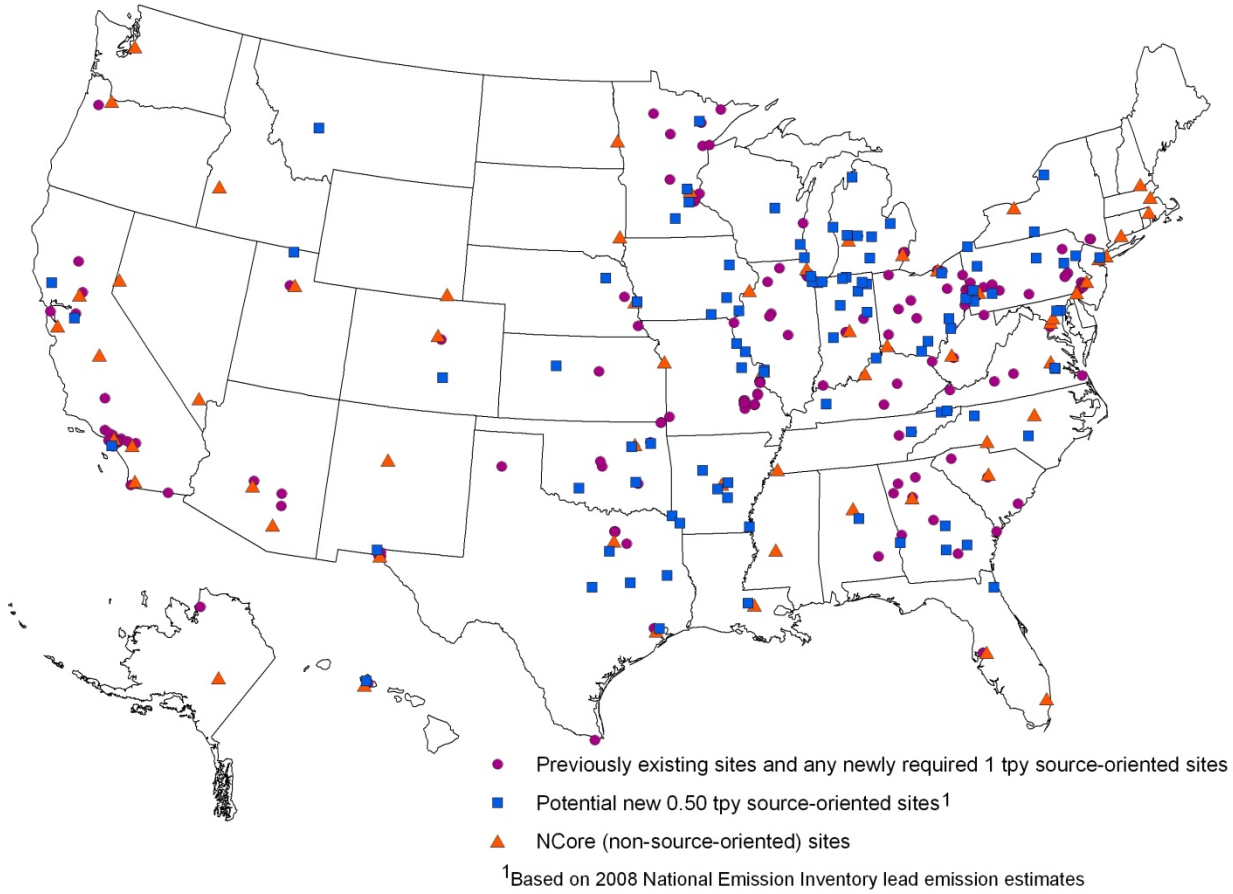

Figure 3-12 Map of Monitoring Sites in Current Pb NAAQS Monitoring Network.

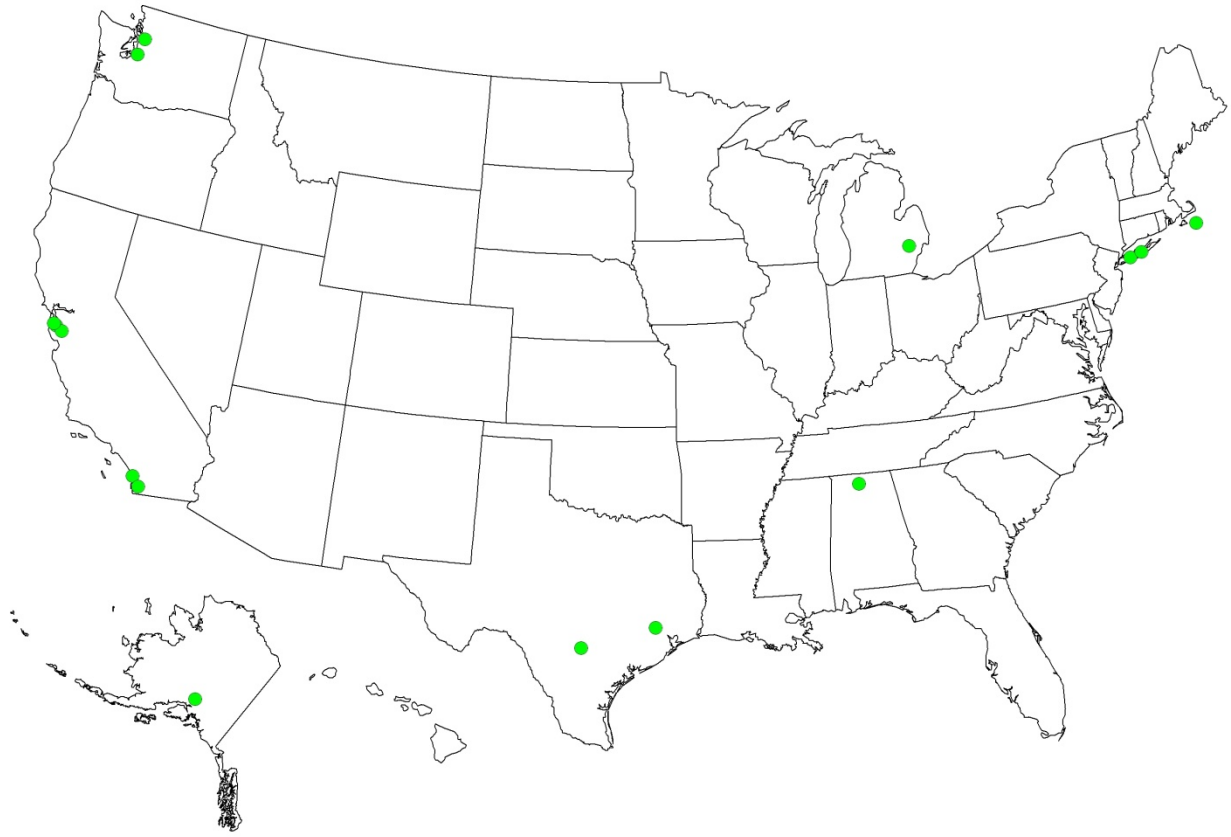
[1] Estimates for source-oriented monitors are based on Pb emissions estimates in the 2008 National Emissions Inventory.



Quality assured results of this study were not available in time for this assessment. Note that the two Santa Clara Co., CA airports are not distinguishable on the map.

Figure 3-13 Fifteen U.S. locations where a study is currently being performed on airport Pb emissions.

Table 3-4 List of 15 airports included in the airport study

Airport	County, State
Merrill Field	Anchorage, AK
Pryor Field Regional	Limestone, AL
Palo Alto Airport of Santa Clara County	Santa Clara, CA
Reid-Hillview	Santa Clara, CA
McClellan-Palomar	San Diego, CA
Gillespie Field	San Diego, CA
San Carlos	San Mateo, CA
Nantucket Memorial	Nantucket, MA
Oakland County International	Oakland, MI
Republic	Suffolk, NY
Brookhaven	Suffolk, NY
Stinson Municipal	Bexar, TX
Northwest Regional	Denton, TX
Harvey Field	Snohomish, WA
Auburn Municipal	King, WA

3.4.2.2 Other Lead Monitoring Networks

In addition to FRM monitoring, Pb is also measured within the Chemical Speciation Network (CSN), Interagency Monitoring of Protected Visual Environments (IMPROVE), and the National Air Toxics Trends Station (NATTS) networks. Pb in $PM_{2.5}$ is monitored as part of the CSN and IMPROVE networks, and Pb in PM_{10} as a part of the National Air Toxics Trends (NATTS) networks (Figure 3-14 and Figure 3-15). These networks are designed to meet different objectives than those of the Pb NAAQS monitoring network.

The purpose of the CSN is to monitor $PM_{2.5}$ species to assist in understanding $PM_{2.5}$ chemistry and for spatial and temporal analyses including annual, seasonal, and sub-seasonal trends (http://www.epa.gov/ttn/amtic/specgen.html). The CSN consists of about 50 long-term trends sites (commonly referred to as the Speciation Trends Network or STN sites) and about 150 supplemental sites, all operated by state and local monitoring agencies. Higher spatial and temporal resolution of the CSN facilitates increased utility in the scientific community, and the data from the CSN also assists states in formulating their emission control strategies, even if the network is not compliance-oriented. Pb is one of 33 elements in $PM_{2.5}$ collected on Teflon filters every third day and analyzed by energy dispersive XRF spectrometry.

In the IMPROVE networks, $PM_{2.5}$ monitors, operated by the National Park Service, largely with funding by EPA, are placed in "Class I" areas (including National Parks and wilderness areas) and are mostly in rural locations. IMPROVE monitoring is intended to establish current visibility conditions, track changes in visibility and determine causal mechanisms of visibility impairment in 156 national parks and wilderness areas. There are 110 formally designated IMPROVE sites and approximately 80 additional sites at various urban and rural areas, informally treated as part of this network and operating under IMPROVE protocols. At these sites, lead in $PM_{2.5}$ is monitored with is determined by XRF, including Pb (University of California Davis, 1995).

The NATTS network is designed to monitor concentrations of hazardous air pollutants (HAPs). The NATTS is intended to provide model input, to observe long-term trends in HAP concentrations, and to examine emission control strategies. The NATTS network measures several inorganic HAPs in PM_{10}, along with several volatile organic compounds (VOCs), carbonyls, and polycyclic aromatic hydrocarbons (PAHs). It is operated by state and local agencies and has less extensive national coverage than the other Pb monitoring networks. PM_{10} is collected either by high volume sampling with a quartz fiber filter or low volume sampling with a PTFE filter following EPA Compendium Method IO-3.5 (U.S. EPA, 1999). Pb is one of seven core inorganic HAPs collected on Teflon filters and analyzed by ICPMS. As of December 2009, the network consisted of 27 monitoring stations, including 20 urban and 7 rural stations operating on a one in six day sampling frequency.

Pb monitoring is also conducted at NCore monitoring sites. Monitoring for Pb-$PM_{2.5}$ is currently being conducted at NCore sites as part of the larger CSN (described above). As described in Section 3.4.2, monitoring for Pb-PM_{10} is required to be operational at NCore sites by December 27, 2011. Methods for Pb in $PM_{10-2.5}$ are being developed as part of the $PM_{10-2.5}$ speciation pilot project and may be implemented at some NCore sites in the future.

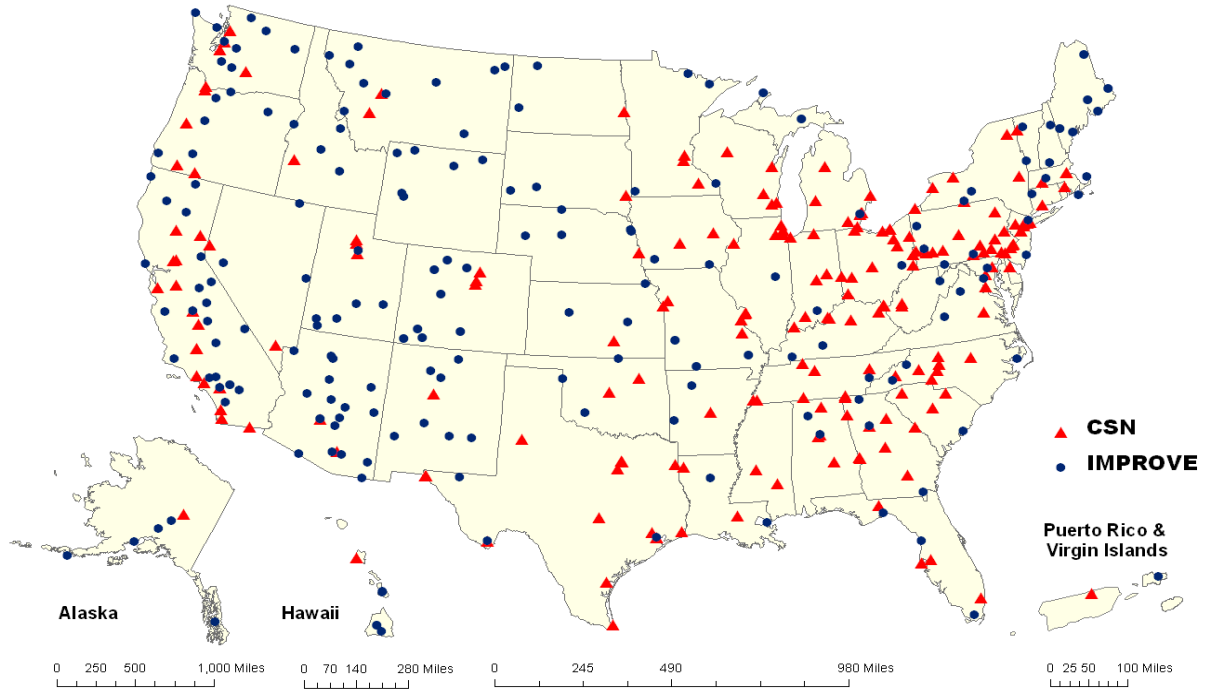


Figure 3-14 Pb-$PM_{2.5}$ monitoring sites for CSN and IMPROVE networks.

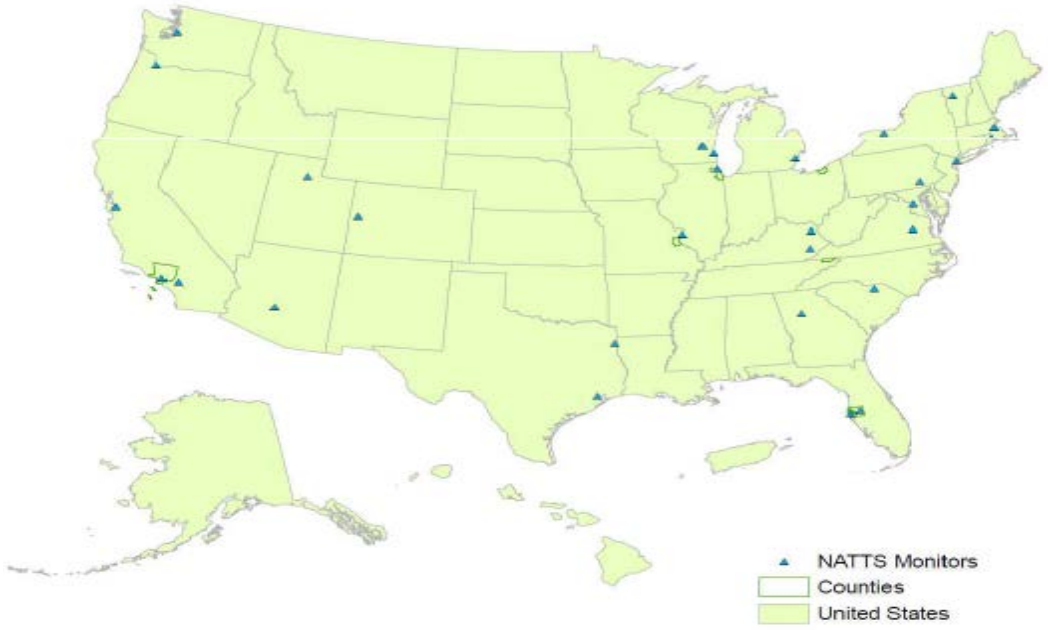

Figure 3-15 Pb-PM_{10} monitoring sites for NATTS network.

3.5 Ambient Air Lead Concentrations

The following section summarizes data on ambient air Pb concentrations during the years 2008-2010. Data used in this chapter are from the period 2008-2010. Data from SLAMS (i.e., source-oriented and non-source-oriented Pb-TSP) are presented. Data from other networks, such as the CSN, IMPROVE, and the NATTS networks, are also presented for scientific purposes to characterize ambient PM component concentrations in different size fractions and for different settings. Measurements among these networks are not directly comparable in all cases because there are method differences, including the PM size range sampled.

The 3-month averages presented here were created using a simplified approach of the procedures detailed in 40 CFR part 50 Appendix R and, as such, cannot be directly compared to the Pb NAAQS for determination of compliance with the Pb NAAQS. For the purpose of analyses within this ISA, monitors were initially designated to be source-oriented if either (1) they were designated in AQS as source-oriented, (2) they were located within one mile of a 0.5 ton/year or greater source as noted in the 2005 NEI (U.S. EPA, 2008a), or (3) they were located within one mile of a 0.5 tons/year or greater source as noted in the 2008 NEI (U.S. EPA, 2011a). The remainder of FRM monitors reporting to the AQS were classified as non-source-oriented. Following this initial classification, staff from the EPA Regional offices tasked with acting as liaisons to the states reviewed all monitors listed to fall within their Regions and reported any discrepancies between the initial classification and ground observations of the sites made by EPA Regional or state staff. The source and non-source monitor listing was edited accordingly. The definition of source-oriented monitoring is applied flexibly with input from regions in this ISA because 2008 data were obtained before the latest monitor designation requirements were implemented. For this analysis, 120 FRM monitors were considered source-oriented, while 184 were considered to be non-source-oriented.[1,2] However, the number of source-oriented and non-source-oriented monitors differed for each analysis year because there were changes in monitor siting.

The section begins with a description of concentrations observed in Pb-TSP measurements obtained for NAAQS compliance at source-oriented and non-source-oriented monitors across the U.S. Additionally, concentrations of Pb-PM_{10} and Pb-$PM_{2.5}$

[1] EPA Regional Administrators may require additional monitoring beyond the minimum requirements where the likelihood of Pb air quality violations is significant. Such locations may include those near additional industrial Pb sources, recently closed industrial sources, airports where piston-engine aircraft emit Pb and other sources of re-entrained Pb dust (40 CFR, part 58, Appendix D, Section 4.5(c).

[2] The requirement for monitoring near sources emitting 0.5 or 1.0 tons/year may be waived if it can be shown that the source will not contribute to a maximum 3-month average Pb concentration in ambient air in excess of 50 percent of the NAAQS level based on historical monitoring data, modeling, or other means (40 CFR, part 58, Appendix D, Section 4.5(a)(ii)).

are presented. Next, seasonal patterns and multi-year trends of Pb concentration are presented for the U.S. It is notable that Pb concentrations have declined substantially over the past 40 years; this is described further in Section 3.5.2. An examination of the peer-reviewed literature is provided to evaluate the size distribution of Pb-bearing airborne PM under varied ambient conditions. The relationship between Pb concentration and concentrations of copollutants are presented. Finally, estimates of transcontinental transport of Pb to the U.S. and current background Pb levels are provided. Summary information is presented within this section, and detailed data are included in an Appendix (Section 3.8) to this chapter.

3.5.1 Spatial Distribution of Air Lead

3.5.1.1 Variability across the U.S.

This section presents nationwide Pb concentration data measured using source-oriented and non-source-oriented Pb-TSP FRM monitors from 2008-2010 and PM_{10} and $PM_{2.5}$ monitors for 2007-2009. The source and non-source-oriented Pb-TSP FRM monitors present data pertaining to compliance with the current level of the NAAQS. The Pb-PM_{10} data are obtained from the NATTS network, and the Pb-$PM_{2.5}$ data are from the CSN. Although the Pb-PM_{10} and Pb-$PM_{2.5}$ data are not from compliance networks, data are presented from these networks because the additional data presents a picture of the nationwide distribution of Pb concentration in different classes of particle size. This information is useful to develop a sense of variability in Pb concentrations at a national scale.

Concentrations of Pb Measured using Pb-TSP Monitors (Source-Oriented and Non-Source-Oriented Monitors)

Maximum 3-month average Pb concentrations[1] were calculated for source-oriented Pb-TSP monitors for 50 counties across the U.S. (1.6% of U.S. counties) during the period 2008-2010. Figure 3-16 illustrates that the level of the NAAQS was exceeded in twenty counties where source-oriented monitoring was performed. Summary statistics for the monitor-specific one-month and three-month averages for these monitors are presented below in Table 3-5, and detailed statistics for the one-month and three-month averages are provided in Table 3-13, Table 3-15, Table 3-17, Table 3-19, Table 3-21, and Table 3-23 in the Appendix (Secton 3.8). The mean was skewed toward the 75th percentile of

[1] Maximum 3-month average Pb concentrations are calculated as the maximum 3-month average of 3 consecutive monthly averages within the 2008-2010 time period.

the distribution for both the monthly and three-month data sets. The primary difference between the one-month average and three-month rolling average data sets occurs at the upper tails of the distribution. Data for sites at which one-month or three-month annual site maxima1 were in the upper 90th percentile for 2008-2010 are presented in Table 3-6. The highest monthly and three-month average concentrations occurred in Iron Co., MO, Herculaneum, MO (Jefferson Co.), and Los Angeles, CA. The highest one-month annual site max value occurred in Cook County, IL in 2008 followed by Iron County, MO in 2008. The highest three-month annual site max concentrations occurred in Herculaneum in 2008, Los Angeles in 2008, and Iron County, MO in 2008. The majority of monitors reported data that did not exceed the NAAQS during this three-year period, but the generally higher values at a subset of the source-oriented monitoring locations tended to skew the nationwide distribution of Pb concentrations upwards.

[1] The one-month annual site max is defined as the highest one-month average for a monitoring site over a given year, and the three-month annual site max is defined as the highest three-month average for a monitoring site over a given year.

[a]The 3-month averages presented here were created using a simplified approach of the procedures detailed in 40 CFR part 50 appendix R and as such cannot be directly compared to the Pb NAAQS for determination of compliance with the Pb NAAQS.

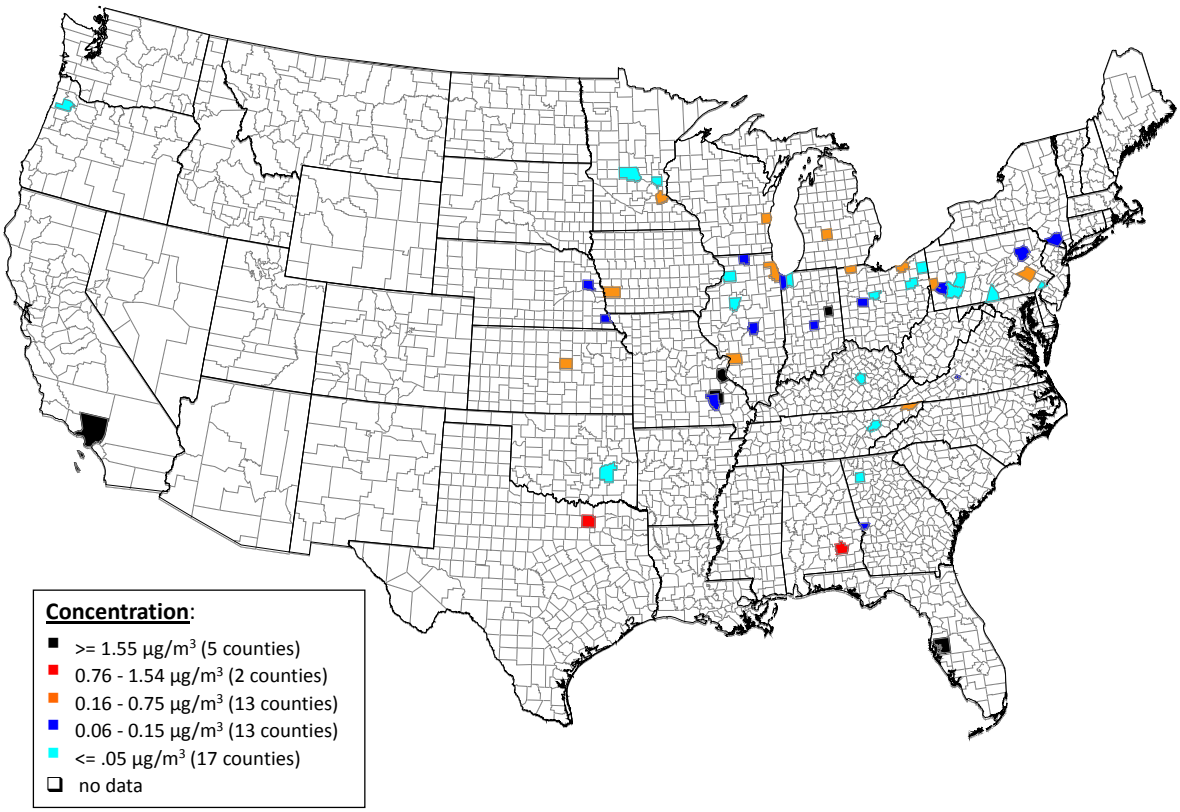

Figure 3-16 Highest county-level source-oriented Pb-TSP concentrations (µg/m^3), maximum 3-month average, 2008-2010.

Maximum 3-month average Pb concentrations were calculated for non-source-oriented Pb-TSP monitors for 47 counties across the U.S. (1.5% of U.S. counties) during the period 2008-2010. Figure 3-17 illustrates that the level of the NAAQS was never exceeded at non-source-oriented monitors. Summary statistics are presented below in Table 3-7, and detailed statistics for the one-month and three-month average and maxima non-source-oriented Pb-TSP concentrations are provided in Table 3-14, Table 3-16, Table 3-18, Table 3-20, Table 3-22, and

Table 3-24 in the Appendix (Section 3.8). The mean was slightly higher than the median for both the monthly and three-month data sets. The primary difference between the one-month average and three-month rolling average data sets occurs at the maxima of the distributions. Data for sites at which national maxima were reached for 2008-2010 are presented in Table 3-8. This table shows that all non-source-oriented monitor results were below the NAAQS. The highest monthly and three-month average concentrations

occurred at the same site in Cambria County, PA. The highest annual site max 1-month value occurred in Columbiana County, OH in 2010, followed by Cambria County, PA in 2009. The Columbiana and Cambria sites were also above the 90th percentile annual 3-month site max Pb concentrations.

Table 3-7 Summary data for non-source-oriented Pb monitors across the U.S., 2008-2010

[a]The 3-month averages presented here were created using a simplified approach of the procedures detailed in 40 CFR part 50 appendix R and as such cannot be directly compared to the Pb NAAQS for determination of compliance with the Pb NAAQS.

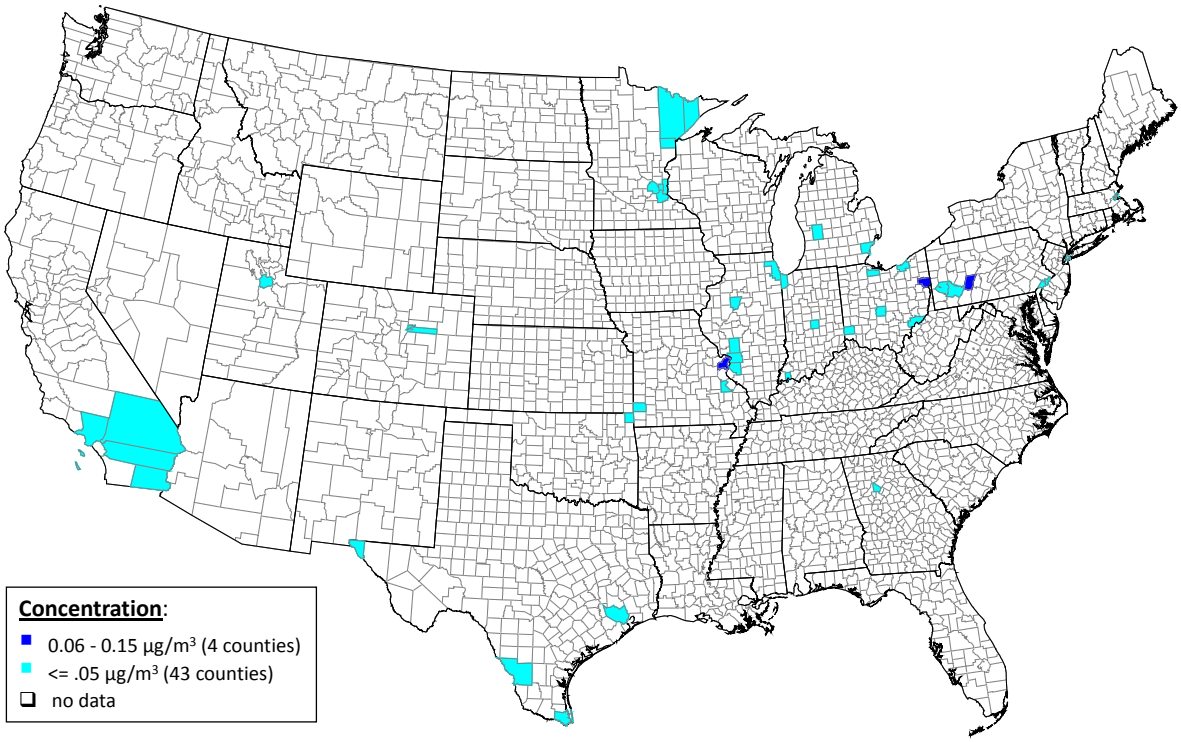

Figure 3-17 Highest county-level non-source-oriented Pb-TSP concentrations (µg/m^3), maximum 3-month average, 2008-2010.

Concentrations of Pb Measured using PM_{10} Monitors (for HAP Concentrations and Trends)

Figure 3-18 displays maximum 3-month averages for Pb-PM_{10} concentrations for 36 counties in which measurements were obtained. Among the 36 counties in which PM_{10} monitoring was conducted, only one county, Gila County, AZ, reported concentrations above 0.076 µg/m^3. Three other counties reported concentrations greater than 0.016 µg/m^3: Wayne County, MI, Boyd County, KY, and the county of St. Louis City, MO.

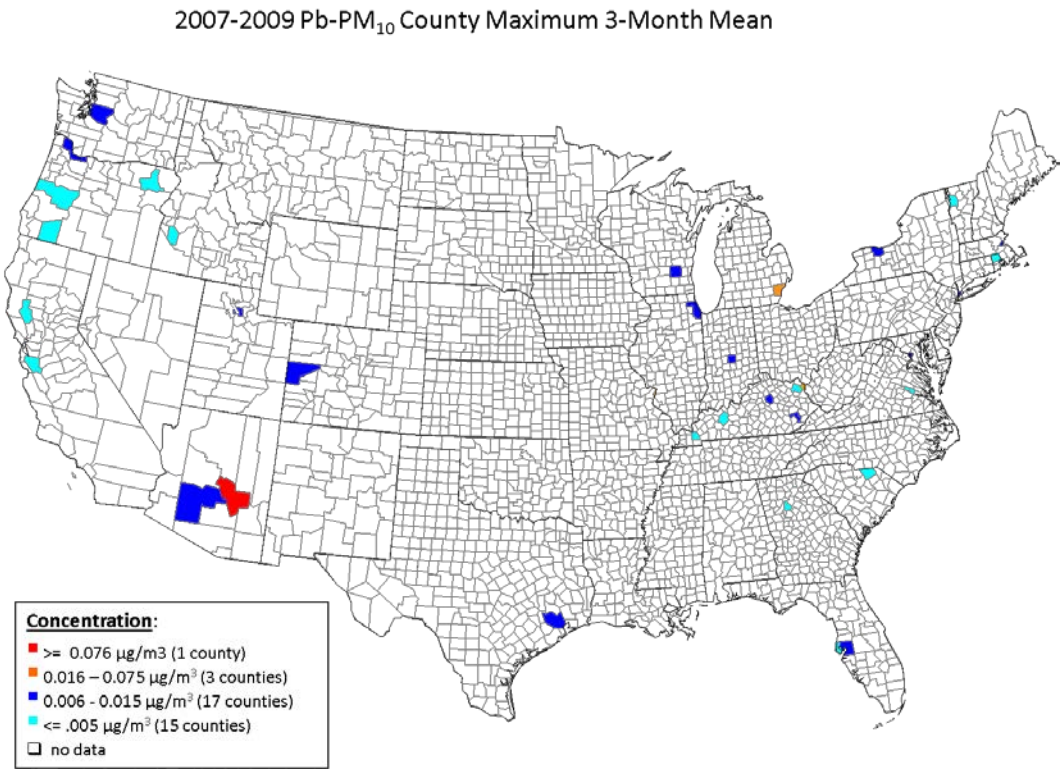

Figure 3-18 Highest county-level Pb-PM_{10} concentrations (µg/m^3), maximum 3-month average, 2007-2009.

Concentrations of Pb Measured using $PM_{2.5}$ Monitors (for Speciation Concentrations and Trends)

Figure 3-19 displays maximum 3-month average county-level data for Pb in $PM_{2.5}$ concentrations for 323 counties in which $PM_{2.5}$ measurements were obtained for speciation in the CSN and IMPROVE networks. The data presented here are not compared to the NAAQS because $PM_{2.5}$ monitors are not deployed for the purpose of evaluating compliance for the NAAQS. Among the 323 counties in which $PM_{2.5}$ monitoring was conducted, only eleven counties reported concentrations greater than 0.016 µg/m^3: Jefferson, AL, San Bernardino, CA, Imperial, CA, Wayne, MI, Jefferson, MO, Erie, NY, Lorain, OH, Allegheny, PA, Berks, PA, Davidson, TN, and El Paso, TX.

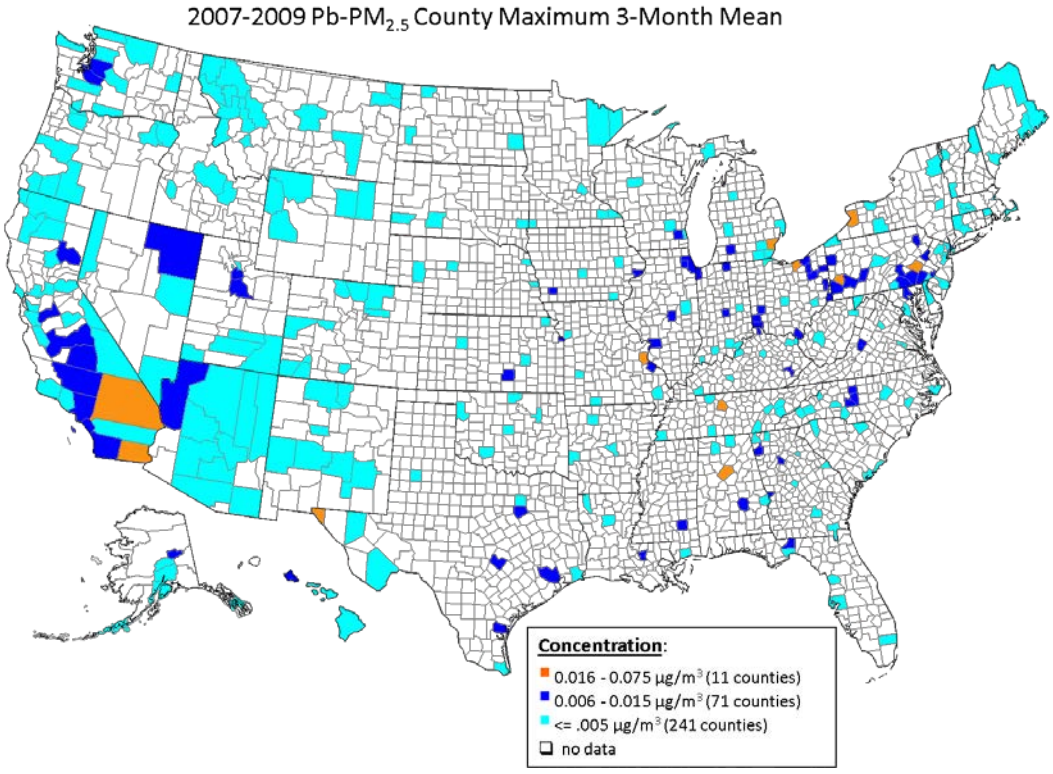

Figure 3-19 Highest county-level Pb-$PM_{2.5}$ concentrations (µg/m^3), maximum 3-month average, 2007-2009.

3.5.1.2 Intra-urban Variability

Intra-urban variability is defined as the variation in Pb concentration across an urban area. Because the source characteristics and size distribution of particle-bound Pb can vary considerably in urban areas, spatial variability of Pb concentrations in urban areas may also be high. Moreover, Pb-PM tends to settle quickly over short distances after becoming airborne because Pb has relatively high density; short settling distances also contribute to high spatio-temporal variability in ambient air Pb concentrations. Such variability may not be detected if one or a small number of central site monitors is in use, so cities with multiple monitors are used to characterize intra-urban variability. Intra-urban variability in Pb concentrations reported to AQS was described in detail in the Appendix in Section 3.8.1 Los Angeles County, CA (Los Angeles), Hillsborough and Pinellas Counties, FL (Tampa), Cook County, IL (Chicago), Jefferson County, MO (Herculaneum), Cuyahoga County, OH (Cleveland), and Sullivan County, TN (Bristol) were selected for this assessment to illustrate the variability in Pb concentrations measured across different metropolitan regions with varying Pb source characteristics. Four of the counties encompass large cities (Los Angeles, Tampa, Chicago, and

Cleveland). All six counties contain source-oriented monitors. Maps and wind roses are presented in the Appendix for each of the six urban areas. Additionally, annual and seasonal box plots of the Pb concentration distributions and intra-monitor correlation tables are presented to illustrate the level of variability throughout each urban area.

When collectively reviewing the data from the six counties, it became apparent that spatial and temporal variability of Pb concentrations were commonly high. Variability was high for areas that included a Pb source, with high concentrations downwind of the sources and low concentrations at areas far from sources. When no large sources of Pb were present, variability of Pb concentrations were lower, and more data were observed to lie below the MDL. For example, the Los Angeles County, CA data illustrated very high concentrations adjacent to a Pb recycling facility, but non-source-oriented concentrations were well below the level of the NAAQS at all times, including at sites near roads. As described in Section 3.3, PM size distribution influences how far the particle will travel upon initial emission or resuspension before being deposited. Meteorology, nature of the sources, distance from sources, and positioning of sources with respect to the monitors all appeared to influence the level of concentration variability across time and space for the monitoring data analyzed in the Appendix.

Airborne Pb near Roads

Five monitors were selected from the TSP network to examine Pb concentrations in the near road environment. The monitors were located in Los Angeles County, CA (06-037-4002), Riverside County, CA (06-065-1003), Cook County, IL (17-031-0052, 17-031-6003), and Suffolk County, MA (25-025-0002). These monitors were selected because they are located in the vicinity of major roadways in urban areas with different characteristics and because they each have long-term data are available. Further, based on reviews of emissions inventory information as well as satellite image searches, these sites are not known to be near metals-related industrial sites. The monitoring sites are described in Table 3-9, and time series of Pb-TSP monthly concentration for all five monitors are shown in Figure 3-20. The annual average over the two sites that were reporting data in 1980, the first year presented in Figure 3-20, was 0.90 $\mu g/m^3$. This Pb-TSP concentration from 1980 likely reflected the influence of Pb emissions from leaded automobile gasoline (Figure 3-6 for annual national consumption of leaded motor vehicle gasoline). By 1986, when all five monitors were reporting data, the annual average of Pb-TSP concentration over all five monitors dropped to 0.18 $\mu g/m^3$. Over 2001-2010, the annual average Pb-TSP concentration over all sites was 0.02 $\mu g/m^3$ with a standard deviation of 0.01 $\mu g/m^3$. The highest 2008-2010 design value was 0.04 $\mu g/m^3$, which occurred at the Chicago site (17-031-6003) located less than 10 m to Interstate-290 at a monitor height of 2 AGL. The multi-site average was not substantially larger than the

maximum three-month rolling average of 0.012 μg/m^3 for non-source-oriented monitors for the period 2008-2010, and the Pb-TSP concentration varied little over the period 2001-2010. Note that the monitor heights were 2-6 m AGL, which may be higher than the vertical distance likely traveled by some particles (depending on particle size) following initial resuspension (see Section 3.3.1.3).

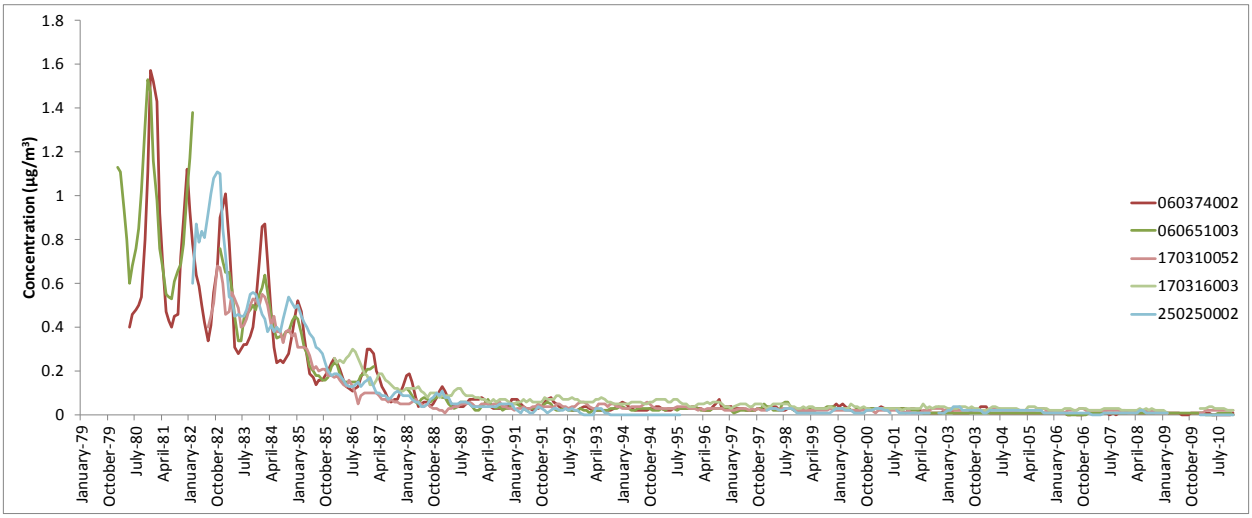
Table 3-9 Sample of U.S. near road Pb TSP monitors

County, State	Site ID	Latitude	Longitude	2008-2010 Design Value (μg/m^3)[a,b]	Monitor Height (m AGL)	Distance from Roads	Surrounding Area
Los Angeles, CA	06-037-4002	33.82376	-118.18921	0.01	6	500 m to I-405 (San Diego Freeway), 10 m to Long Beach Blvd	High intensity residential, urban
Riverside, CA	06-065-1003	33.94603	-117.40063	0.01	4	Within 20 m of intersection of Magnolia and Arlington Ave.	High intensity residential, mixed use urban
Cook, IL	17-031-0052	41.96548	-87.749928	0.02[c]	5	Near to intersection of I-90 and I-94, 80 m to I-90, 200 m to I-94, 70 m to railroad	Located at public utilities water pumping station, high density residential urban
Cook, IL	17-031-6003	41.872202	-87.826165	0.04[c]	2	Less than 10 m to I-290 (Dwight D. Eisenhower Expressway)	Parking lot of Circuit Court of Cook County, ¾ surrounded by Concordia Cemetary
Suffolk, MA	25-025-0002	42.348873	-71.097163	0.02[c]	5	95 m to I-90, inside median of Commonwealth Ave.	High intensity urban, mixed use residential and commercial

[a]The level of the 2008 NAAQS for lead is 0.15 micrograms per cubic meter (μg/m^3) not to be exceeded in any 3-month period. The design value for the 2008 Pb NAAQS is the maximum rolling 3-month Pb-TSP average within the 3-year design period.

[b]The design values shown here are computed for the latest design value period using Federal Reference Method or equivalent data reported by States, Tribes, and location agencies to EPA's Air Quality System (AQS) as of 7/12/2011. Concentrations flagged by States, Tribes, and local agencies as exceptional events (e.g., high winds, wildfires, volcanic eruptions, construction) and concurred by the associated EPA Regional Office are not included in the calculation of these design values. Although the indicator for the 2008 Pb NAAQS is Pb-TSP at "local conditions" (i.e., actual temperature and pressure; parameter 14129), 2008 Pb-TSP data reported in "standard temperature and pressure" (i.e., 25 ° C, 760 mmHg; parameter 12128) are also considered valid for NAAQS comparisons and related attainment/nonattainment determinations if the sampling and analysis methods that were utilized to collect that data were consistent with previous or newly designated FRMs or FEMs and quality assurance requirements were met.

[c]Fewer than 36 rolling 3-month lead-TSP average data are available at this site for this 3-year period; the value shown here is the highest valid 3-month mean.



Note: Monitor IDs: Los Angeles, CA: 06-037-4002; Riverside, CA: 06-065-1003; Cook, IL: 17-031-0052, 17-031-6003; Suffolk, MA: 25-025-0002.

Figure 3-20 Time series of monthly average Pb-TSP concentration at five near-road monitors.

Airborne Pb near Airports

Levin et al. (2008) summarized findings from environmental protection departments of the State of Illinois, the U.S., and Canada regarding ambient Pb concentrations at and near airports. Data presented in the Canadian report yielded median air Pb-PM_{10} level of 0.01 for ten sample days (with 37 24-hour and 3 11-hour samples) compared with an average reported background level of 0.007 µg/m^3 (Conor Pacific Environmental Technologies Inc, 2000). Median and average values were derived from all samples collected at the airport, both upwind and downwind from aircraft activity. The maximum 24-hour concentration measured in this 10-day study was 0.13 µg/m^3. The Illinois report noted that air Pb concentrations were elevated downwind of O'Hare airport compared with upwind levels (Illinois Environmental Protection Agency, 2002).

More recently, Carr et al. (2011) performed TSP monitoring and dispersion modeling of Pb emissions at the Santa Monica Airport and surrounding neighborhood in Santa Monica, CA. Ambient sampling was conducted in March and July, 2009. During winter, measurements of 24-hour Pb-TSP concentrations upwind of the airport ranged from 0.003 to 0.011 µg/m^3 and at the two downwind locations, concentrations ranged from 0.025 to 0.083 µg/m^3 approximately 70m from the location where piston engine aircraft emit the majority of Pb during ground-based operations and 0.028 to 0.050 µg/m^3 in an adjacent neighborhood roughly 85m further downwind. During summer, 24-hour Pb-TSP concentrations upwind from aircraft operations ranged from 0.001 to 0.006 µg/m^3. Three

locations downwind were monitored, the first of which was the same location as the winter site 70m from the location where piston engine aircraft emit the majority of Pb during ground-based operations. This location had concentrations ranging from 0.034 to 0.062 µg/m^3. At a site 100 m further downwind from this location, concentrations ranging from 0.027 to 0.044 µg/m^3 and at a distance of 175 m downwind, a 24-hour concentration of 0.023 µg/m^3 was measured. Modeling results suggest that three-month average Pb concentrations above local background extended beyond the airport property and that the preflight runup check, taxi, and takeoff emissions were the most important contributors to Pb concentrations. This airport had a Pb emissions inventory of 0.3 tons/year and is therefore not subject to Pb monitoring to evaluate compliance with the Pb NAAQS, which is described further in Section 3.4.2.

Airborne Pb at Urban and Rural Sites

A number of studies have characterized how Pb-bearing PM is distributed over the neighborhood scale in the air. Yu et al. (2011) measured Pb-PM_{10} concentration at four rooftop sites (10-13 m AGL) within Paterson, NJ: background, near-road, industrial, and commercial. Interstate-80 and Route 19 were both within 0.8 km from the near-road site. The industrial site was located 0.1-1 km from a metal recovery plant, a plating facility that emits Ni and Zn compounds, and another facility emitting Cu compounds. The commercial site was proximal to several restaurants and dry cleaners. Average concentrations at each site were: 2.95 ng/m^3 (background), 5.61 ng/m^3 (near road), 6.48 ng/m^3 (industrial), and 6.58 ng/m^3 (commercial) to yield a coefficient of variation coefficient of variation (CV, defined as the standard deviation of site measurements divided by the average) of 31.3%. Weekday and weekend ambient Pb-PM_{10} concentrations were not significantly different ($p = 0.45$). Martuzevicius et al. (2004) examined the spatial variability of Pb-$PM_{2.5}$ samples obtained in the greater Cincinnati, OH area at 6 urban, 4 suburban, and 1 rural site and found that Pb-$PM_{2.5}$ had a CV of 33.8%, compared with a CV for $PM_{2.5}$ of 11.3% over all sites. Average Pb-$PM_{2.5}$ concentration among the sites varied from 1.79-28.4 ng/m^3. Martuzevicius et al. (2004) suggested that differences between mass and Pb spatial variability implied that Pb originated primarily from local sources. Sabin et al. (2006a) measured Pb-PM with an upper cutpoint of 29 µm and found that urban concentrations ranged from 2.2 to 7.4 ng/m^3 with a CV of 40%. In contrast, a rural location had a concentration of 0.62 ng/m^3. Sabin et al. (2006a) also reported deposition flux at the same sites, which ranged from 8.3 to 29 µg/m^2·day at the rural sites, with a CV of 48%, and was 1.4 ng/m^3 at the rural site. Li et al. (2009a) observed that Pb concentration in $PM_{2.5}$ samples was 2.2-3.0 times higher near a bus depot than next to a rural-suburban road; in this study, the authors provided ratios but not actual concentrations. Ondov et al. (2006) measured Pb-

$PM_{2.5}$ concentration at three Baltimore sites. Average Pb-$PM_{2.5}$ concentrations at the different sites were 8.3 ng/$m^{3,}$ 7.2 ng/$m^{3,}$ and 1.9 ng/m^3, with the two higher concentration sites located within two miles of industrial facilities. The industrial sites include a major steel plant; several chemical manufacturing plants; and incinerators for municipal waste, medical waste, and sludge. However, the authors do not specify which industrial facilities were proximal to each monitor. Although these concentrations are low, they agree with the body of literature to suggest that intra-urban variability is most strongly related to source type, strength, and location.

3.5.2 Temporal Variability

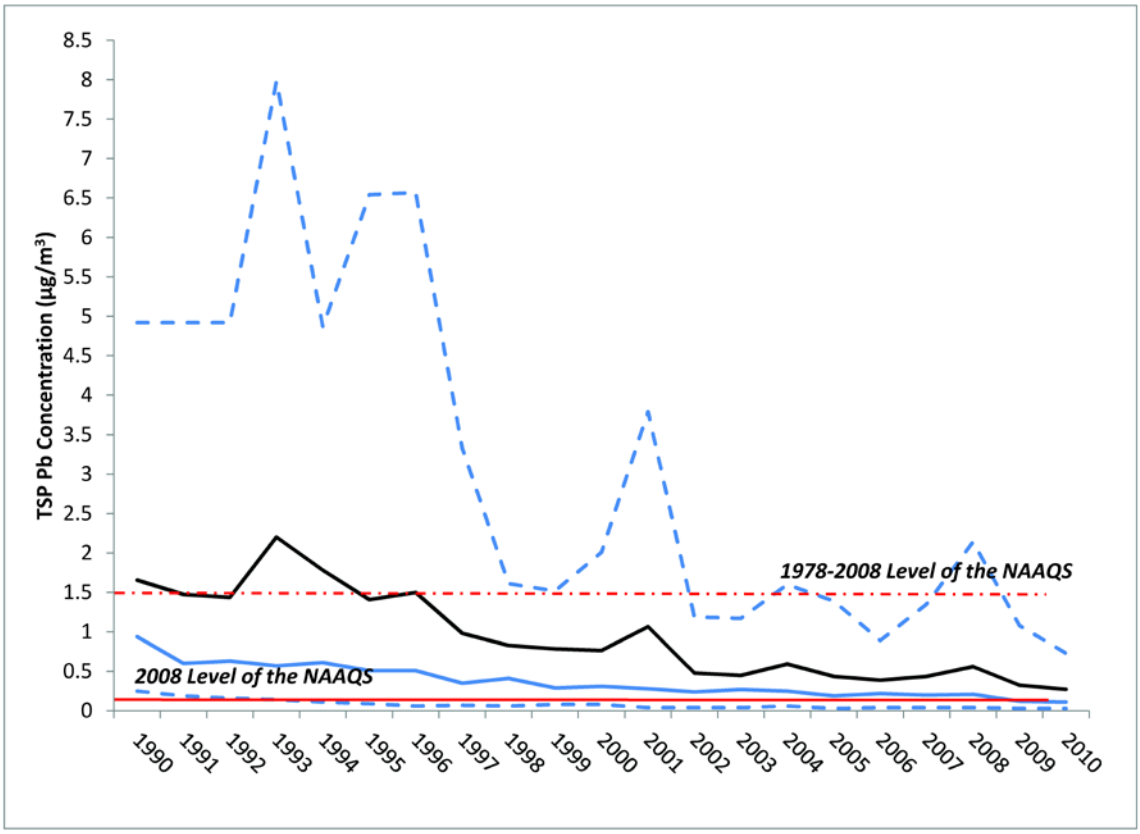
The following section presents data for multi-year trends and seasonal variability of Pb concentrations on a nationwide basis. The data presented here provide information on the success of Pb reduction efforts over past decades as well as on areas for continued attention with respect to Pb monitoring. The multi-year trends illustrate changes in air Pb concentrations resulting from the phase-out of leaded gasoline for automobiles and smaller reductions of industrial Pb usage. The seasonal variability plots demonstrate changes in concentration within a given year, potentially related to climate or source variation.

3.5.2.1 Multi-year Trends

Pb-TSP concentrations have declined substantially during the years 1980-2010. For source and non-source monitors combined, the annual average across Pb-TSP monitors reporting three-month average site max air Pb concentrations have dropped by 89% from 1.3 μg/m^3 in 1980 to 0.14 μg/m^3 in 2010. The median concentrations have declined by 97% from 0.87 μg/m^3 in 1980 to 0.03 μg/m^3 in 2010. While the sharpest drop in Pb concentration occurred during 1980-1990 as a result of the phase-out of Pb antiknock agents in on-road fuel, a declining trend can also be observed between 1990 and 2010 following reductions in industrial use and processing of Pb, as described in Section 3.2.1. In 1990, the average Pb concentration was 0.84 μg/m^3 and the median Pb concentration was 0.25 μg/m^3 to yield 84% and 71% reductions, respectively, from 1990 to 2010.

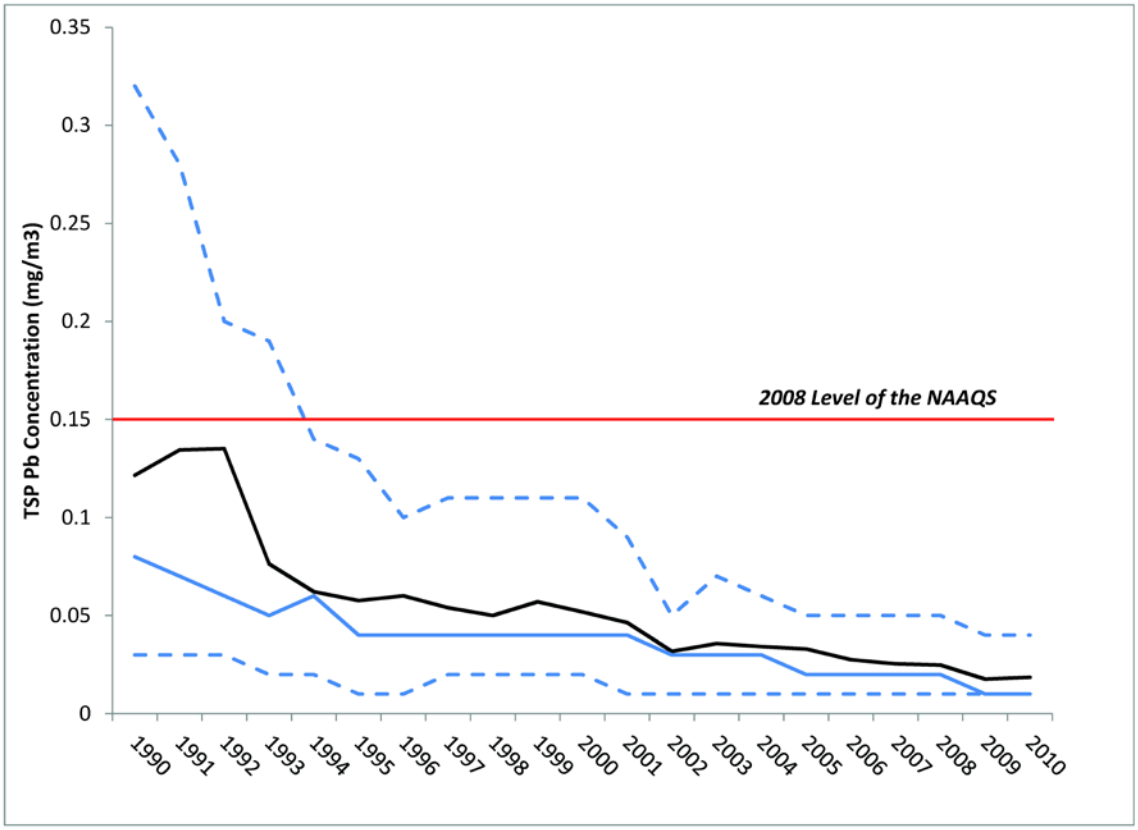
Average concentrations in these calculations are heavily influenced by the source-oriented monitors in the network. New Pb concentration data from expansion of the source-oriented portion of the network in 2010 will allow for greater assessment of changes of Pb concentrations on nationwide statistics and trends. Figure 3-21 and Figure 3-22 show ambient Pb concentrations from 1990 to 2010 for source-oriented monitors

and non-source-oriented monitors, respectively. In both cases concentration data are consistent with a downward trend, and concentrations were considerably lower at the end of the period than at the beginning of the period.



Note: Annual average of Pb-TSP monitors reporting three-month average site max concentration is shown by the solid black line, median concentration is shown by the solid blue line, and the 10th and 90th percentiles are shown by the dashed lines.

Figure 3-21 National trends in Pb concentration (µg/m^3), source-oriented FRM monitors, 1990-2010.



Note: Annual average of Pb-TSP monitors reporting three-month average site max. Concentration is shown by the solid black line, median concentration is shown by the solid blue line, and the 10th and 90th percentiles are shown by the dashed lines.

Figure 3-22 National trends in Pb concentration (µg/m^3), non-source-oriented FRM monitors, 1990-2010.

For source-oriented monitors, the annual average across Pb-TSP monitors reporting three-month average site max decreased from 1.7 µg/m^3 to 0.27 µg/m^3 (84% decline) and upper 90th percentile concentrations decreased from 4.9 µg/m^3 to 0.73 µg/m^3 (85% decline) over the 20-year period. A portion of the decrease can be attributed to reductions in emissions from the Herculaneum, MO smelter between 2001 and 2002 (U.S. EPA, 2010c). An abrupt decrease in average concentrations between these years is evident in Figure 3-21.

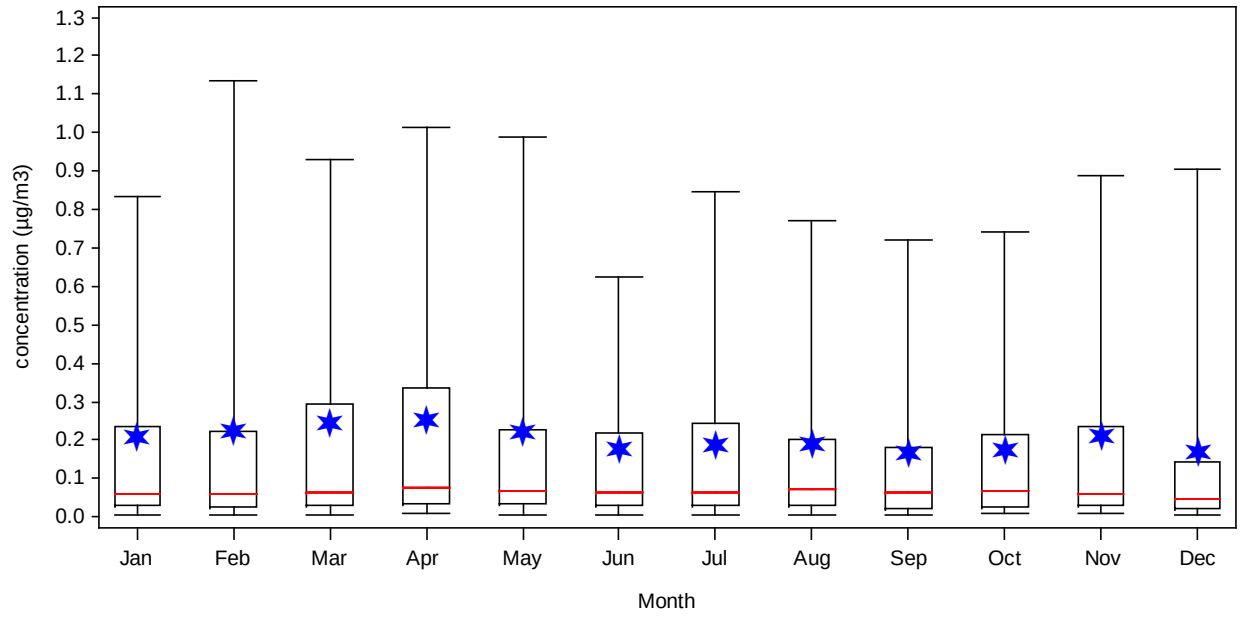
For non-source-oriented monitors, the annual average across Pb-TSP monitors reporting three-month average site max decreased from 0.12 µg/m^3 to 0.018 µg/m^3 (85% decline) and upper 90th percentile concentrations decreased from 0.32 µg/m^3 to approximately 0.04 µg/m^3 (88% decline) over the 20-year period. Average concentrations near stationary sources were 5 to 8 times typical concentrations from non-source-oriented monitoring locations between 1990 and 1999; during the subsequent decade, average source-oriented Pb concentrations were 13 to 24 times higher than non-source

concentrations (U.S. EPA, 2010c). This differential likely reflects the absence of Pb emissions from automobiles during 2000-2009.

3.5.2.2 Seasonal Variations

This section outlines seasonal variability among Pb monitors on a nationwide basis. Seasonal variation may provide insight related to differential influences of sources and climate throughout a year. Additionally, the magnitude of concentrations within the monthly data distributions and of variations between months sheds light on the influence of season as well as on differences between source-oriented, non-source-oriented, PM_{10}, and $PM_{2.5}$ data.

Monthly average Pb concentrations averaged over multiple sites and over 3 years from 2008-2010 are shown for Pb-TSP from source-oriented monitors (Figure 3-23), Pb-TSP from non-source-oriented monitors (Figure 3-24), Pb-PM_{10} (Figure 3-25), and Pb-$PM_{2.5}$ (Figure 3-26). For source-oriented Pb-TSP (Figure 3-23), monthly average concentrations were determined from between 146 and 154 samples in each month. For non-source-oriented TSP (Figure 3-24), monthly average concentrations were determined from between 141 and 151 samples in each month. A winter minimum was observed with December, January, and February exhibiting the three lowest monthly average. In both cases, there is little seasonal variation. Minor variations in monthly averages are probably driven by exceptional events. Monthly median concentrations are very similar for all months.



Note: Box and whisker plots are used for each month, with the box comprising the interquartile range of the data and the whiskers comprising the range within the 5th to 95th percentiles. The median is noted by the red line, and the blue star denotes the mean.

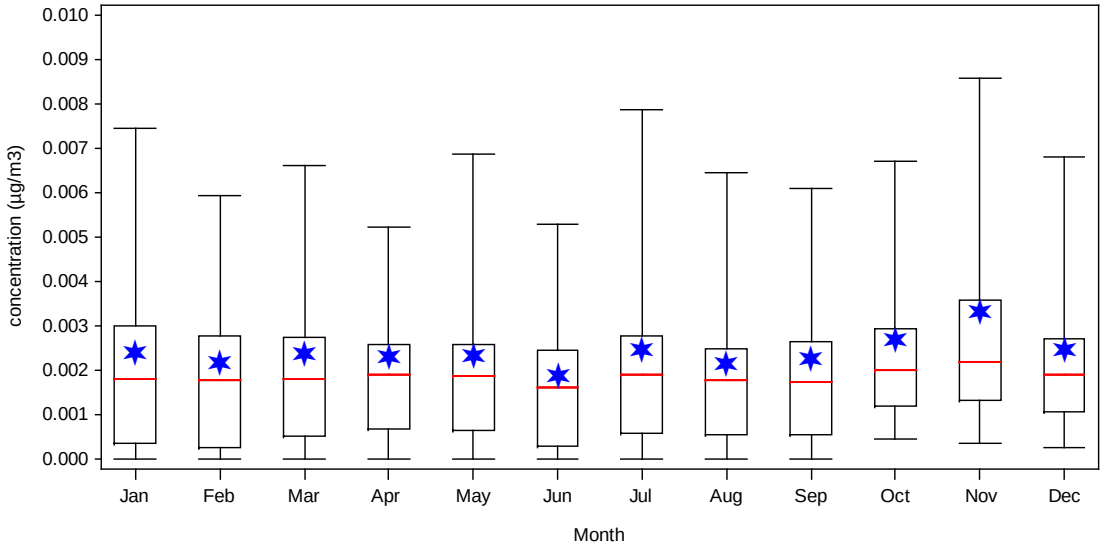
Figure 3-25 Monthly lead-PM_{10} average (µg/m^3) over 12 months of the year, 2007-2009.



Note: Box and whisker plots are used for each month, with the box comprising the interquartile range of the data and whiskers comprising the range from 5th to 95th percentiles. The median is noted by the red line, and the blue star denotes the mean.

Figure 3-26 Monthly lead-$PM_{2.5}$ average (µg/m^3) over 12 months of the year, 2007-2009.

For both Pb-PM_{10} (Figure 3-25) and Pb-$PM_{2.5}$, (Figure 3-26) there is also little seasonal variation, with minor fluctuations in monthly averages probably driven by exceptional events, and similar monthly median concentrations for all months. Pb-PM_{10} monthly average concentrations were determined from between 100 and 109 samples and Pb-$PM_{2.5}$ from between 866 and 1,034 samples each month.

3.5.3 Size Distribution of Lead-Bearing PM

The diverse nature of the main source types of ambient air Pb contributes to variations in Pb-PM size distribution. Such variation in the size distribution, along with size-dependent biases in Pb-TSP collection efficiency (Section 3.4.1), can lead to uncertainties in the interpretation of results from Pb-PM measurements. Accordingly, depending on the locations and magnitudes of nearby sources, ambient air Pb may be 1) mainly Pb in PM_{10}, for which good sampler performance is well established, 2) Pb-PM with a size distribution that ranges up to slightly larger than 10 µm, in which case the existing Pb-TSP FRM could potentially be subject to wind related bias, or 3) a Pb-PM size range that extends well above 10 µm, or too large to be efficiently collected even by an improved Pb-TSP method. In the latter case, air sampling is likely to be less representative of actual concentrations of Pb.

Because atmospheric lifetime is dependent on particle size, as described in Section 3.3.1.3 and in U.S. EPA (2009), sampling is likely to be representative only on a very small spatial scale. Ultra-coarse particles have a sharp concentration gradient with distance from source, because coarser particles have greater settling velocities. Hence, concentrations of particles larger than 10 µm are likely to be very spatially and temporally heterogeneous compared with finer particles (U.S. EPA, 2009; Hinds, 1999). As a consequence, in locations near sources of ultra-course particles, measurements may reflect true concentrations only in small areas in close proximity to the monitor. This issue has been thoroughly discussed in the 2006 Pb AQCD (U.S. EPA, 2006b), as well as in the 1977 Pb AQCD (U.S. EPA, 1977).

Size-selective monitoring data from the literature are examined in this section. Size distribution data enhances understanding of the relationship between sources and characteristics of airborne Pb-bearing PM and hence informs monitoring strategies. Several studies in the literature since the last review have been designed to characterize the size distribution of Pb concentrations in the vicinity of sources. In the subsections below, the currently available information is presented for locations in the vicinity of industrial sources (active and closed), near roadways, and in other urban and rural environments.

3.5.3.1 Airborne Pb Near Metals Industries

Size distributions of Pb-bearing PM have been measured near several active and closed industrial sites. Yi et al. (2006) collected Pb-PM size distribution in an industrial area of Jersey City, NJ and contrasted it with the Pb-PM size distribution in suburban New Brunswick, NJ, which is influenced only by traffic. Yi et al. (2006) sampled size distribution for Pb-bearing particles with a Multi-Orifice Uniform Deposit Impactor (MOUDI) (cut point range: 0.18-18 µm) along with a coarse particle rotary impactor (CPRI) collecting particles ranging in size from 14.4-100 µm. In the industrial area, 27% of Pb-PM were larger than PM_{10} (avg. Pb-TSP: 9.7 ng/m^3), while in the suburban area 7% of Pb-PM were larger than PM_{10} (avg. Pb-TSP: 6.6 ng/m^3). Bein et al. (2006) measured the size distribution of Pb in PM from the Pittsburgh Supersite using rapid single particle mass spectrometry and a MOUDI. The Pittsburgh, PA, Supersite had seventeen major PM sources within a 24-km radius; source apportionment illustrated that Pb was contained in a sub-population of particles of almost every major particle-containing class in this study, emanating from point sources including fuel combustion, steel processing, incinerators, foundries, battery manufacturing, and glass manufacturing (Pekney et al., 2006). Bein et al.'s (2006) measurements yielded different results on different days, with a bimodal distribution with modes around 140 nm and 750 nm during

an October, 2001 measurement and a single dominant mode around 800 nm during a March, 2002 measurement. Differences in the size distributions could have been related to differences among wind speed, wind direction, and source contributions on the respective dates. Concentrations of Pb-$PM_{3.2}$ measured by the MOUDI were 5.6 ng/m^3 in October, 2001 and 5.0 ng/m^3 in March, 2002; measurements by the hi-vol were 4.4 ng/m^3 in October, 2001 and 6.5 ng/m^3 in March, 2002. Singh et al. (2002) measured the mass distribution of Pb-PM_{10} in the coarse and fine PM size ranges (cut points range: 0.10-10 µm) for the Downey industrial site along the Alameda industrial corridor in Los Angeles and a site approximately 90 km downwind in Riverside, CA. At the industrial site, the Pb-PM_{10} size distribution was unimodal with a concentration peak in the 100-350 nm size range with 34% of the particles in this size bin. The sum of the geometric mean concentrations in each size bin was 13 ng/m^3 for the Downey data. At the downwind site, a bimodal distribution was observed with peaks in the 2.5-10 µm bin and the 350 nm-1 µm bin, comprising 42% and 26% of the mass measured as PM_{10}, respectively. Pb in the fine range only comprised 13% of the particles in the 100-350 nm bin. The sum of the geometric mean concentrations in each size bin was 7 ng/m^3 for the Riverside data. The authors suggested that higher wind speeds in Riverside compared with the Downey site are effective in resuspending larger particles from the ground to create a peak in the coarse mode of the distribution.

Industrial operations associated with Pb emissions include metal works and incineration. Dall'Osto et al. (2008) measured the size distribution of Pb emissions from a steel works facility in a coastal town within the United Kingdom (U.K.). A MOUDI was employed to measure Pb concentrations in the coarse to fine PM size range (cut points range: 0.196-18 µm). The size distribution was multimodal with a primary mode around 1 µm at a concentration of 40 ng/m^3, a secondary mode around 300 nm at a concentration of 25 ng/m^3, and a very small additional mode around 5 µm at a concentration of 7 ng/m^3. This multimodal distribution was thought to be associated with sintering and steel working processes, from which Pb was emitted. Weitkamp et al. (2005) measured Pb-bearing $PM_{2.5}$ concentrations across the river from a coke plant in the Pittsburgh, PA area. Pb was measured to comprise 0.088% of the $PM_{2.5}$ mass (avg. Pb-$PM_{2.5}$: 53 ng/m^3) , and background-corrected Pb mass concentration was reasonably correlated with background-corrected $PM_{2.5}$ mass concentration (R^2 = 0.55). Pekey et al. (2010) measured $PM_{2.5}$ and PM_{10} concentrations in a heavily industrialized area of Kocaeli City, Turkey and obtained an average $PM_{2.5}$ concentration of 47 ng/m^3 during summer and 72 ng/m^3 during winter. Average PM_{10} concentration was 78 ng/m^3 during summer and 159 ng/m^3 during winter, to produce $PM_{2.5}/PM_{10}$ ratios of 0.60 during summer and 0.45 during winter.

3.5.3.2 Airborne Pb Near Roadways

Traffic-induced turbulence can be a cause of resuspension of Pb-bearing particles from deposited contemporaneous wheel weights, industrial emissions, or historic sources. Pb in resuspended road dust exhibits a bimodal size distribution, with fine mode likely from vapor phase condensation from combustion engines and the coarse mode from vehicle wear (U.S. EPA, 2006b). However, mass is predominantly associated with coarse PM. The Pb fraction in resuspended dust generally ranges from 0.002 to 0.3%, with the highest fractions observed for paved road dust and lowest for agricultural soil. Sabin et al. (2006b) compared the size distribution of coarse Pb-PM measured using a Noll rotary impactor at an urban background site and at a location 10 m from the I-405 Freeway in the southern California air basin; data from Sabin et al. (2006b) are displayed in Figure 3-27; note that the Noll rotary impactor has been shown to sample with high efficiency for particles up to 100 µm in diameter (Noll, 1970). For both the urban background and near-road sites, the largest fraction was from PM sampled below the 6 µm cut point, but the near-road Pb-PM distribution appeared bimodal with a mode in the largest size fraction. Overall size fractions, the near-road site had a Pb concentration of 17 ng/m^3, compared with an urban background concentration of 9.7 ng/m^3. Sabin et al. (2006b) point out that the freeway tends to be a source of very large particles that are dispersed via the turbulent motion of the vehicular traffic. Song et al. (2011) used an eight-stage MOUDI (cut point range: 0.18-18 µm) to measure roadside PM 5 m from the New Jersey Turnpike in Carlstadt, NJ and speciated the samples. They observed a bimodal distribution of the Pb concentration in summer and a trimodal distribution in winter. 85% of the Pb-PM mass smaller than 2.5 µm during the summer and 68% was within the 2.5 µm fraction in the winter. Pb-PM mass measured in this study ranged from 1.2-2.8 ng/m^3. Similarly, Zereini et al. (2005) observed that roughly 80% of particle-bound Pb measured with a MOUDI was smaller than 5.8 µm for an urban main street (avg. conc.: 33 ng/m^3), and more than 90% were smaller than 5.8 µm for a rural area included in that study (avg. conc.: 12 ng/m^3). However, in a study of automotive emissions in a traffic tunnel, Lough et al. (2005) measured that 85% of Pb measured with a MOUDI was in the PM_{10}, with just 39% in the $PM_{2.5}$ fraction and 20% in the PM_1 fraction. In a near-road study conducted in Raleigh, NC, Hays et al. (2011) note that the concentration of Pb in ultrafine, fine, and coarse size ranges was roughly constant at 50 mg/kg; similar to Lough et al. (2005), mass concentrations were 0.4 ± 0.4 ng/m^3, 1.4 ± 0.6 ng/m^3, and 0.1 ± 0.02 ng/m^3 for $PM_{10-2.5}$, $PM_{2.5-0.1}$, and $PM_{0.1}$, respectively. The Pb-PM_{10} samples from Hays et al. (2011) were highly correlated with As samples ($\rho = 0.7$, $p < 0.0001$); both Pb and As are found in wheel weights (see Section 3.2.2.6). Likewise, the Pb samples were not well correlated with crustal elements in the coarse size distribution, so it is more likely that resuspended Pb originated from contemporary roadway sources rather than historic Pb

on-road gasoline emissions. Chen et al. (2010b) measured Pb in $PM_{10-2.5}$, $PM_{2.5-0.1}$, and $PM_{0.1}$ using a MOUDI at a roadside location and in a tunnel in Taipei, Taiwan in 2008. While roadside and tunnel concentrations of PM_{10} and $PM_{2.5}$ were roughly equivalent around 20-30 ng/m^3, Pb in $PM_{0.1}$ was approximately 15 times higher in the tunnel (during the hours 9:00 AM – 9:00 PM) than by the roadside (tunnel: 20 µg/m^3; roadside: 1 ng/m^3). The authors suggest that particle-bound Pb was emitted from on-road gasoline and diesel engines. This could possibly be attributed to trace levels of Pb in diesel fuel and lubricating oil. Birmili et al. (2006) compared concentrations of Pb in PM at various traffic and background sites in Birmingham, U.K.. captured at the stage below a 0.5 µm cutpoint and on the 1.5-3.0 µm stage for near-road, in a traffic tunnel, and remote and urban background sites. The highest concentrations were measured in the tunnel, at 3.3 ng/m^3 for Pb-$PM_{0.5}$ and 10 ng/m^3 for Pb-$PM_{1.5-3.0}$. Roadside concentrations were low. During the day, Birmili et al. (2006) measured 0.4 ng/m^3 for Pb-$PM_{0.5}$ and 1.2 ng/m^3 for Pb-$PM_{1.5-3.0}$. At night, roadside concentrations reduced to 0.17 ng/m^3 for Pb-$PM_{0.5}$ and 0.6 ng/m^3 for Pb-$PM_{1.5-3.0}$. In contrast, urban background was more enriched in the finer size fraction, with concentrations of 5.4 ng/m^3 for Pb-$PM_{0.5}$ and 0.84 ng/m^3 for Pb-$PM_{1.5-3.0}$. Remote background concentrations were on 0.16 ng/m^3 for Pb-$PM_{0.5}$ and 0.03 ng/m^3 for Pb-$PM_{1.5-3.0}$. Brüggemann et al. (2009) measured roadside distribution of Pb in PM in Dresden, Germany to analyze the effect of season and direction of the air mass. For all data combined as well as for data broken down by season or by wind direction, it was found that the data followed a unimodal distribution with a peak at the 0.42-1.0 µm size bin. When winds came from the east, the total concentration was approximately 22 ng/m^3, compared with a concentration of approximately 13 ng/m^3 when winds came from the west. Total winter concentrations of Pb were approximately 26 ng/m^3, while summertime concentrations were roughly 11 ng/m^3.

Figure 3-27 Comparison of urban background and near-road size fractions of lead-bearing PM.

Several studies have suggested that near-road ambient air Pb samples are derived from sources other than from the road. Harrison et al. (2003) measured the distribution of Pb in PM_{10} at a roadside sampler in Birmingham, U.K.. The size distribution was unimodal with approximately 2% of the Pb mass (0.5 ng/m^3) above the 10 µm cut point, 53% of the Pb mass (14 ng/m^3) in the 0.2-1.0 µm bin, and 24% (7 ng/m^3) collected below the 0.2 µm cut point. Regression analysis against NO_X concentration in the Harrison et al. (2003) paper provided a weak indication that Pb-$PM_{0.2}$ was associated with NO_X ($\beta = 0.067$, $R^2 = 0.38$) as well as PM_{10} ($\beta = 0.26$, $R^2 = 0.35$). Reactivity of NO_X may contribute to the somewhat low values for R^2 in these models. Brüggemann et al. (2009) observed a unimodal Pb size distribution with 51% of the mass in the 0.42-1.2 µm size bin. Observed Pb-PM_{10} concentration was 17 ng/m^3. During winter, Pb concentrations were more than twice as high as during the summer (0.42-1.2 µm mode, winter: 50 ng/m^3;

summer: 20 ng/m^3), and they were also higher when winds blew from the east (0.42-1.2 µm mode, east: 60 ng/m^3; west: 25 ng/m^3). Brüggemann et al. (2009) suggested that this finding reflected coal burning sources rather than road dust resuspension. Wang et al. (2006d) used a nine-stage cascade impactor (cut point range: 0.43-11 µm) to measure the Pb-PM size distribution in a heavily trafficked area of Kanazawa, Japan with incineration and generation facilities nearby. They observed a bimodal distribution with modes at the 0.65-1.1 µm and the 3.3-4.7 µm size bins. Average concentration in the coarse mode was 2.1 ng/m^3, while fine mode average concentration was 3.7 ng/m^3. Wang et al.'s (2006d) source apportionment work in this study suggested that the fine mode derives from incineration and combustion of oil and coal.

3.5.3.3 Airborne Pb at Other Urban and Rural Sites

Spatial and temporal concentration variability is also reflected in varying Pb-PM size distributions within and between cities. Martuzevicius et al. (2004) measured the size distribution of Pb in Cincinnati, OH at the city center site using a MOUDI and showed it to be bimodal with a primary peak at 0.56 µm and a slightly smaller secondary peak at 5.6 µm. Moreno et al. (2008) measured Pb concentrations in $PM_{2.5}$ and PM_{10} at urban, suburban, and rural sites around Mexico City, Mexico to illustrate differences among the land use categories. At the urban site, average Pb-$PM_{2.5}$ concentration was 30 ng/m^3 during the day and 92 ng/m^3 at night, and average Pb-PM_{10} concentration was 59 ng/m^3 during the day and 162 ng/m^3 at night, to yield $PM_{2.5}/PM_{10}$ ratios of 0.51 during the day and 0.57 at night. At the suburban site, average Pb-$PM_{2.5}$ concentration was 15 ng/m^3 during the day and 34 ng/m^3 at night, and average Pb-PM_{10} concentration was 24 ng/m^3 during the day and 42 ng/m^3 at night, to yield $PM_{2.5}/PM_{10}$ ratios of 0.63 during the day and 0.81 at night. Rural measurements were only made for Pb-PM_{10} and averaged 6 ng/m^3 during the day and 5 ng/m^3 at night. Goforth et al. (2006) measured TSP and $PM_{2.5}$ in rural Georgia and observed a $PM_{2.5}$ concentration of 6 ng/m^3 and a TSP concentration of 15 ng/m^3. Makkonen et al. (2010) measured concentrations of Pb in PM_1, $PM_{2.5}$, and PM_{10} during a spate of wildfires in rural southeastern Finland. They found that the ratio of PM_1/PM_{10} varied substantially from day to day (examples provided of 64% on 8/14/07 and 35% on 8/25/07, with $PM_{2.5}/PM_{10}$ ratio of 51% on 8/25/07), and they attributed the highest concentrations to long-range transport of wildfire emissions via southerly winds; variability in concentration and ratios was related to shifting wind conditions.

3.5.4 Lead Concentrations in a Multipollutant Context

The correlations between Pb and copollutant concentrations were investigated because correlation may indicate commonality of sources among the pollutants. For example, correlation between Pb and SO_2 may suggest common industrial sources. Correlation between Pb and NO_2 or CO may suggest roadway sources, such as trace Pb in unleaded on-road gasoline or resuspension of material from pulverized wheel weights or contaminated soil. Additionally, seasonality can influence correlations, potentially from differences among sources or the contaminants' responses to climate differences.

Pb concentrations exhibit varying degrees of association with other criteria pollutant concentrations. Spearman correlations of monitored Pb-TSP concentrations with concentrations of other criteria pollutants are summarized in Figure 3-28 for 2007-2008 data from 129 monitoring sites, and in Figure 3-29 for 2009 data from 16 monitoring sites. At most sites, Pb monitors are co-located with monitors for other criteria pollutants, but monitoring the full suite of criteria pollutants at a single monitoring site is rare. As a result the number of observations for each copollutant varies, ranging from 44 non-source-oriented sites for the association of Pb with SO_2 to 81 sites for the association of Pb with PM_{10}; in Figure 3-28, and fewer for each copollutant in Figure 3-29. Each of these figures illustrates co-pollutant correlations across the U.S. Additionally, seasonal correlations between Pb and co-pollutants are provided in Figure 3-60 through Figure 3-65 in the Section 3.8, with seasonal co-pollutant measurement data from the literature (Table 3-31). As evident in each figure, there were considerably fewer source-oriented sites available for co-located comparisons.

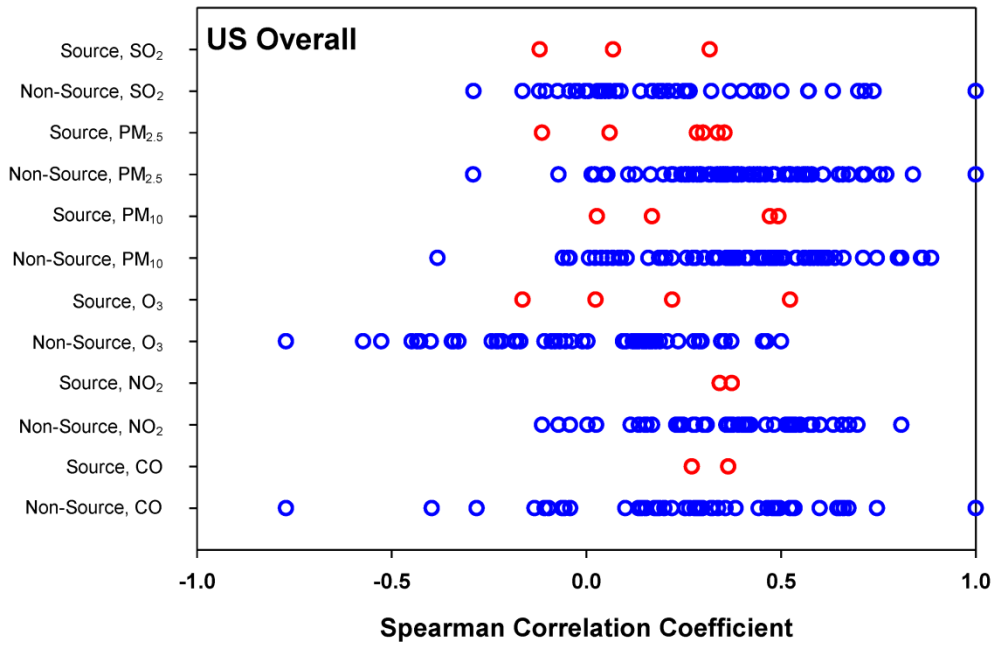

Figure 3-28 Correlations of monitored Pb-TSP concentration with copollutant concentrations, 2007-2008.

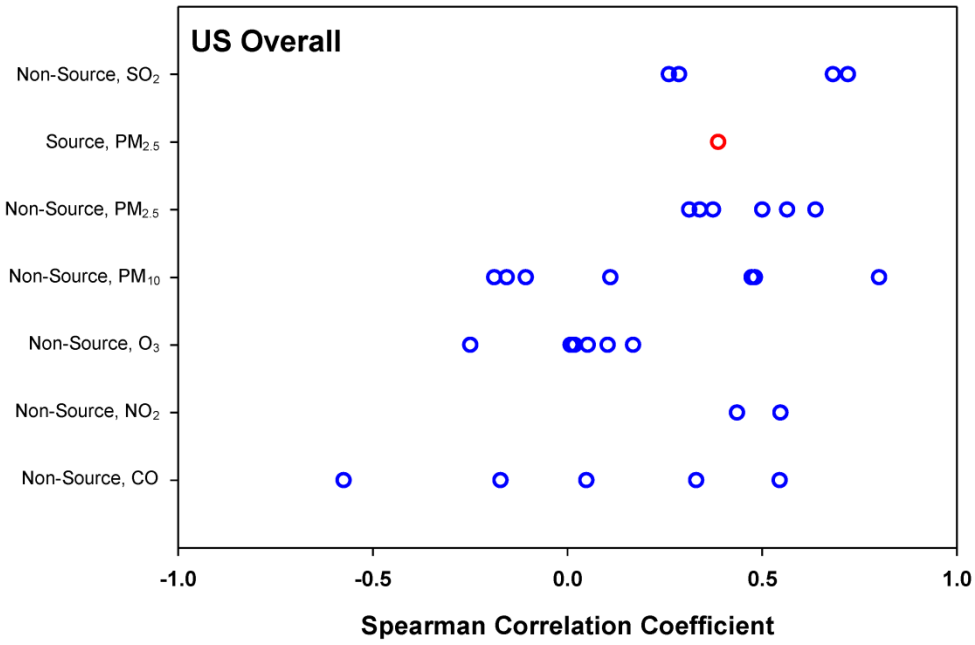

Figure 3-29 Correlations of monitored Pb-TSP concentration with co-pollutant concentrations, 2009.

Overall, Pb was most strongly associated with $PM_{2.5}$, PM_{10} and NO_2 (median R = 0.38 to 0.41), with positive Spearman correlation coefficients observed at nearly all sites. However, Pb was just as strongly associated with CO in fall and winter (median ρ = 0.48 to 0.58). Such correlations may suggest common sources affecting the pollutants. Overall correlation coefficients between Pb and SO_2 and between Pb and CO were also positive at most sites, but associations were generally weaker (median ρ = 0.29 for CO, 0.17 for SO_2). The poorest associations were observed between Pb and O_3 (median ρ = 0.00). Although the overall associations of Pb concentration with PM_{10} and $PM_{2.5}$ concentrations were similar, the association with PM_{10} was stronger in the spring and the association with $PM_{2.5}$ stronger in summer and fall. The strongest associations between Pb and other criteria pollutants were observed in fall and winter, and the weakest in summer.

The relationship between Pb and other species in $PM_{2.5}$ is explored in Figure 3-30, which describes data from 3 years of CSN results using Pearson R. These data provide a national perspective on relationships between the various bulk and elemental species monitored in the CSN network. The strongest association was with Zn (median R = 0.51). K, Cu, and Br concentrations also exhibited moderately strong associations with Pb concentrations (median R = 0.40 to 0.41). Such correlations may suggest some common sources affecting the pollutants. For example, as described in Section 3.2.2.1, piston-engine aircraft emit Pb as $PbBr_2$ so this source may explain the covariation in Pb and Br concentrations at the CSN sites. Other species more useful as diagnostic indicators of crustal, general combustion, industrial emission, and coal combustion processes exhibited weaker, but still remarkable associations with Pb, including Fe (median R = 0.34), EC (median R = 0.32), crustal elements (median R = 0.32), Mn (median R = 0.32), and OC (median R = 0.30). Summer associations between Pb and other species tended to be weaker than in other seasons, with a Correlation Coefficient greater than R = 0.35 observed only for Zn (median R = 0.37). The weakest associations were with non-volatile NO_3^-, Cl, As, Na^{+2}, Hg, Na, and Ni (median R = -0.02 to 0.10).

A few recent studies have used speciation techniques to characterize Pb and other components of PM_{10}, $PM_{2.5}$, and PM_1. Pingitore et al. (2009) used XAFS to speciate air samples obtained near a defunct smelter in El Paso, TX, in 1999 and 2005 and found that air Pb-TSP concentrations of 0.10 to 0.50 $\mu g/m^3$ could largely be attributed to Pb-humate. Wojas and Almquist (2007) used ICPMS to characterize trace metals in $PM_{2.5}$, PM_{10}, and TSP samples obtained in Oxford, OH. They observed that Pb correlation varied substantially with other elements across size distributions. Correlations were very high between Pb and several PM_{10} metals, and only Pb was only highly correlated with Mg in $PM_{2.5}$. These results suggested that Pb and copollutants emanated from a variety of sources including road dust and fuel combustion (Table 3-10). Variations in the relative

proportions of Pb-containing compounds may account for the difference in Pb solubility in aerosols (von Schneidemesser et al., 2010; Tan et al., 2006; Fernández Espinosa and Ternero-Rodríguez, 2004).

Murphy et al. (2008) studied weekly patterns of metals and other aerosol components using data collected from 2000 to 2006 at Interagency Monitoring of Protected Visual Environments (IMPROVE) sites that are described further in Section 3.4.2.2. The authors concluded that Pb concentrations were impacted by piston aircraft emissions, particularly on weekends when there is typically a peak in general aviation flights. The authors also note that Zn and Pb were highly correlated in atmospheric samples and they suggest that this is due to similar sources (i.e., electric utility and industrial sources). Murphy et al. (2007) also carried out a detailed study of the distribution of Pb in single atmospheric particles. During the fifth Cloud and Aerosol Characterization Experiment in the Free Troposphere (CLACE 5) campaign conducted at the Jungfraujoch research station, Switzerland, about 5% of analyzed aerosol particles in PM_1 contained Pb. Of these, 35% had a relative signal for Pb greater than 5% of the total mass spectrum measured by an aerosol time of flight mass spectrometer (ATOFMS). These “high Pb” particles also contained one or more positive ions (e.g., of Na, Mg, Al, K, Fe, Zn, Mo, Ag, Ba). Sulfate fragments were present in 99% of the negative ion spectra associated with high Pb particles and 50% also contained nitrite and nitrate. About 80% contained positive and/or negative polarity organic fragments. The average aerodynamic diameter of the Pb-rich particles (500 nm) was larger than the background aerosol (350 nm) but none had a diameter less than 300 nm.

Table 3-10 Correlations between Pb and copollutants, measured in TSP, PM_{10}, and $PM_{2.5}$

Element[a]	TSP	PM_{10}	$PM_{2.5}$

3.5.5 Background Lead Concentrations

To inform NAAQS decisions, EPA has historically estimated risk due to pollutant concentrations above background concentrations. In previous NAAQS reviews, a specific definition of background concentrations was used and referred to as policy relevant background (PRB). In those previous reviews, PRB concentrations were defined by EPA as those concentrations that would occur in the U.S. in the absence of anthropogenic emissions in continental North America (CNA), defined here as the U.S., Canada, and Mexico. For this document, we have focused on the sum of those background concentrations from natural sources everywhere in the world and from anthropogenic sources outside CNA. Background concentrations so defined facilitate separation of

pollution that can be controlled by U.S. regulations or through international agreements with other countries from those that are judged to be generally uncontrollable by the U.S. Over time, consideration of potentially broader ranging international agreements may lead to alternative determinations of which Pb source contributions should be considered by EPA as part of background.

The 2006 and 1986 Pb AQCDs evaluated evidence on Pb emissions from natural sources, such as volcanoes, sea-salt spray, biogenic sources, wild forest fires and wind-borne soil particles in rural areas without elevated Pb soil concentration. The 1986 Pb AQCD concluded that the natural particulate Pb concentration was probably lower than the concentration of 0.076 ng/m^3 reported at the South Pole [see pp 1-14, (U.S. EPA, 1986a)]. A 1980 National Academy of Sciences report estimated that average natural background levels of airborne Pb might range from 0.02 to 0.5 ng/m^3 (NAS Committee on Lead in the Human Environment, 1980).

Global transport can carry airborne Pb to remote areas with no industrial activity, thus it is difficult to estimate a natural background concentration of Pb. Hong et al. (1994) found that Pb concentrations in Greenland ice cores remained nearly constant (at about 0.55 pg Pb/g ice) from about 7,760 years ago to about 3,000 years ago. Ratios of Pb to major crustal elements were not enriched in this section of the ice core suggesting that Pb was natural in origin, produced by rock and soil dust. At about 2,500 years ago, Pb concentrations started to increase (to about 100 pg Pb/g snow averaged from 1930 to 1990) (Boutron et al., 1991) corresponding to an enrichment of ~ 200 times natural background levels.

Chemistry-transport models are not available for estimating background concentrations of airborne Pb is problematic because chemistry-transport model calculations are not available as they are for O_3 or for $PM_{2.5}$ and they would have to include the entire size range for particle-bound Pb. The only data that might be relevant are from the IMPROVE network, but only in the $PM_{2.5}$ size fraction. Pb in this size fraction is most amenable to long range transport because particles in the $PM_{2.5}$ size fraction have a much longer atmospheric lifetime compared to larger size fractions. It is impossible to obtain reliable estimates of background concentrations solely on the basis of measurements of $PM_{2.5}$, $PM_{10-2.5}$, or PM_{10}. It is preferable to quantify contributions from both background and non-background sources by using compositional data in techniques such as source apportionment modeling.

Measurements of Pb from IMPROVE sites and source apportionment modeling have been used to assess the potential input from intercontinental transport. Liu et al. (2003) used positive matrix factorization to attribute sources of Asian dust to the measurements at two western IMPROVE sites at high elevations, Crater Lake and Lassen Volcanic Park

from 1988 to 2000. Geometric mean concentrations of 0.34 and 0.48 ng/m^3 were found in the samples with only a few percent of these values attributable to transport from Asia. No enrichment in Pb and other metals (As, Cr, Cu, Ni, Pb, V and Zn) above reference Asian dust material was found. Their results suggest either that arriving air masses did not entrain contributions from Asian pollution sources or that these contributions were preferentially scrubbed out during transport. Large enrichments in S were found, however, which might have been due to pollution sources but also due to model artifacts. However, other studies have found some evidence of trans-Pacific transport. Murphy et al. (2007) measured single Pb particles off the coast of California in a NOAA aircraft elevated more than 2 km AGL. Given the elevation of the measurement and the timing of trans-Pacific plume events, the authors concluded that these Pb-bearing $PM_{2.5}$ originated in Asia. They also noted Pb/Zn ratios in $PM_{2.5}$ at the Mount Zirkel, CO IMPROVE site of 0.6 corresponding to measurements at Mauna Loa, HI in spring, when measurements at other times of year produced Pb/Zn ratios of 0.3-0.4. Ewing et al. (2010) used time series analysis of Pb isotope measurements to estimate Asian and local contributions to Pb-$PM_{2.5}$ concentrations measured at two observatories near San Francisco, CA. They estimated a springtime contribution of Asian dust to Pb-$PM_{2.5}$ measurements. In both the Murphy et al. (2007) and Ewing et al. (2010) studies, the authors conclude that the Asian contribution is still generally less than 1 ng/m^3.

The use of data for $PM_{2.5}$, $PM_{10-2.5}$, and PM_{10} from monitoring sites in the East will generally result in gross overestimates of background concentrations because anthropogenic sources will cause extensive contamination. Intercontinental transport of African dust contributes to PM and is observed mainly in the Southeast but is apparent on an episodic basis elsewhere in the eastern U.S. [see e.g., 2004 PM CD (U.S. EPA, 2004) and 2009 PM ISA (U.S. EPA, 2009)]. Data obtained at four eastern IMPROVE sites (Moosehorn NWR, ME; Acadia NP, ME; Swanquarter, NC; Cape Romain NWR, SC) from 2007 to 2009 indicate a median Pb-$PM_{2.5}$ concentration of 1.0 ng/m^3 with a 95th percentile value of 2.5 ng/m^3. As noted above, these sites are likely to be affected by upwind anthropogenic sources within the U.S.

Rough estimates for the natural source of Pb in different size fractions of Pb-PM can be made by multiplying the abundance of Pb in soils by the crustal component of PM in the different size fractions. It is assumed that there is no fractionation between size ranges in this approach. The mean abundance of Pb in surface rocks is ~ 20 mg/kg (Potts and Webb, 1992); the 2006 Pb AQCD (U.S. EPA, 2006b) reported Pb concentrations in different types of rocks to range from 3.5 to 32 ppm (Reuer and Weiss, 2002). There is substantial variation with location depending on composition, in particular on the abundances of U and Th, since Pb is produced mainly by radioactive decay of these elements. The mean Pb concentration of 863 soil samples taken across the U.S. at 2 m

depth is ~16 mg/kg; this value was derived by sampling residual Pb of the weathered rocks on which they formed (Wedepohl (1978) and references therein).

Concentrations of the Pb content of soils can be used with estimates of the crustal component of $PM_{2.5}$, $PM_{10-2.5}$ (which is mainly crustal), PM_{10}, and TSP produced by wind erosion of natural surfaces to estimate contributions to Pb concentrations in these size fractions. U.S. annual average PM_{10} concentrations in some arid counties most affected by windblown dust in the western U.S. are ~ 20 $\mu g/m^3$. If it is assumed that these levels of PM_{10} are entirely due to natural wind erosion without any anthropogenic contribution, an estimate of ~ 0.3 ng/m^3 for the contribution of wind erosion on natural surfaces to Pb in PM_{10} is obtained; however, it must be observed that the natural contribution is probably lower than this estimate. An assumed ratio 3.5 for TSP to PM_{10} in dust storms, derived by Bacon et al. (2011), indicates a contribution of ~ 1 ng/m^3 for Pb from natural sources in TSP. These estimates exceed estimates of natural background presented in the 1986 AQCD (U.S. EPA, 1986a) and the National Academy of Sciences Report (NAS Committee on Lead in the Human Environment, 1980) by a factor of 2 to 20. The more recent estimate still indicates that background airborne Pb concentrations are well below current ambient concentrations.

3.6 Ambient Lead Concentrations in Non-Air Media and Biota

There have been some major recent research efforts to characterize geographic and temporal trends in Pb concentrations across a variety of environmental media and biota. In general these concentrations reflect the decreases observed in atmospheric Pb concentrations due to reduced on-road Pb emissions.

The 2006 Pb AQCD (U.S. EPA, 2006b) describes several studies showing higher Pb concentrations in plants grown in Pb contaminated soil related to mine spoils, smelting operations, sludge amendment, contaminated irrigation water, and Pb containing agro-chemicals. In general, metal accumulation occurs more readily for Pb salts applied to soils than for the same quantity of metal in sewage sludge or fly ash. Root uptake is the dominant means of accumulation, and it is strongly influenced by pH. Root vegetables are the most strongly affected, and fruits and grains are the least susceptible. More Pb is also generally found in roots than in other parts of the plant.

The 2006 Pb AQCD (U.S. EPA, 2006b) identified ingestion and water intake as major routes of Pb exposure for aquatic organisms, and it identified food, drinking water, and inhalation as major routes of exposure for livestock and terrestrial wildlife. The 2006 Pb AQCD (U.S. EPA, 2006b) reports data from the U.S. Geologic Service National Water-Quality Assessment (NAWQA), which are updated every ten years. In the NAWQA

survey, maxima concentrations in surface waters, sediments, and fish tissues were 30 µg/L, 12,000 mg/kg, and 23 mg/kg, respectively, compared with median values of 0.50 µg/L, 28 mg/kg, and 0.59 mg/kg. Some of the highest levels of Pb contamination occur near major sources, like smelters, and fatal doses have been measured in tissue from sheep and horses near sources. High levels in cattle have also been observed. Wildlife in urban areas tend to contain higher Pb concentrations than in rural areas, and higher Pb accumulations have been observed for aquatic organisms living in polluted coastal zones than in the open sea. Ingestion of deposited Pb-PM on plant surfaces was consistently observed to be more important than Pb accumulated from soil. Some important variations between animals have been observed, and ruminants appear to be less susceptible to Pb uptake than other animals. Uptake of Pb by lowest trophic levels, including invertebrates, phytoplankton, krill, were described as the most important means of introduction into food chains. Elevated Pb levels have been observed in aquatic organisms that feed from sediments when the sediments contain appreciable Pb. In shrimp, a substantial fraction of Pb can be absorbed from prey, and considerably more accumulated Pb from food has been observed to be irreversibly retained than is the case for dissolved Pb from water. These examples all illustrated that substantial Pb uptake by livestock and wildlife readily occurs in Pb contaminated environments.

3.6.1 Soils

Several studies suggest that soil can act as a reservoir for contemporaneous and historical Pb emissions. In a recent review of soil data collected from 90 U.S. cities, Mielke et al. (2010a) cited studies, some of which were 35 years old but many from the last 15 years, reporting that median soil Pb concentrations ranged from 16 to 189 mg/kg. Soil Pb was thought to originate from present-day sources, such as industry, debrided paint, and piston-engine aircraft emissions, as well as historic sources, such as on-road gasoline emissions, as described in Section 3.2. At the same time, soils in remote or rural areas tend to have lower Pb concentrations. The most extensive survey of background soil Pb concentration in the conterminous U.S. was conducted between 1961 and 1976 and comprised 1,319 non-urban, undisturbed sample locations, where 250 cm^3 of soil was collected at a depth of 20 cm (Shacklette and Boerngen, 1984). The lower detection limit was 10 mg/kg, and 14% of the 1,319 samples were below it. The mean Pb concentration was 19.3 mg/kg, the median 15 mg/kg, and the 95th percentile was 50 mg/kg. Sixteen locations had Pb concentrations between 100 and 700 mg/kg. These results were in agreement with 3 previous surveys. When creating the Eco-SSL guidance document, the U.S. EPA (U.S. EPA, 2007d, 2003b) augmented these data with observations from an additional 13 studies conducted between 1982 and 1997, most of them limited to one

state. The resulting data were summarized using state means for each of the fifty states. Those means ranged between 5 and 38.6 mg/kg, with an overall national mean of 18.9 mg/kg. This is reasonably close to the values reported by Wedepohl (1978) and references therein with a mean soil Pb concentration of roughly 16 mg/kg when samples were taken at 2 m depths. Aelion et al. (2009) compared Pb soil levels in urban and two rural locations in the southeastern U.S. (specific sites were not disclosed). The urban and one of the rural areas had significantly high prevalence of mental retardation or developmental disabilities (MMDD), while the other urban area did not. Aelion et al. (2009) found that soil Pb concentration in the rural area without prevalence of MMDD ranged from 2.1-53 mg/kg dry basis, while in the rural area with high prevalence of MMDD, soil Pb ranged from 1.6-140 mg/kg; in the urban area with high MMDD, soil Pb ranged from 2.4-288 mg/kg. Biasioli et al. (2006) contrasted urban and rural soils of the same alluvial composition near Torino, Italy to assess the influence of anthropogenic inputs. The urban soils had a median Pb concentration of 117 mg/kg, while the median Pb concentration for rural soil was 19 mg/kg.

In North American forest soils, Pb concentrations have decreased substantially since the phase out of leaded motor vehicle gasoline. Evans et al. (2005) observed Pb concentrations ranging from 60 to 200 mg/kg in Vermont and Quebec, with lower concentrations in Quebec than in southern Vermont in 1979, but in 1996 concentrations had decreased to between 32 and 66 mg/kg with no spatial trend. Johnson and Richter (2010) also observed a substantial decrease in Pb concentrations in soil between 1978 and 2004 in West Virginia, Maryland, Pennsylvania, New Jersey, New York, and Connecticut, with a median change of -65%. However, elevation also appears to be an important factor in determining whether appreciable decreases in Pb concentration have occurred since the phase out of leaded gasoline (Kaste et al., 2006). At sites above 800 m in the northeastern U.S. concentrations ranged from 11 to 29 kg Pb/ ha, and little change in Pb concentration was observed between 1980 and 2000. In contrast, concentrations ranged from 10 to 20 kg Pb/ha at low elevation sites and decreased to 2 to 10 kg Pb/ha by 2000. This difference was likely due to greater organic turnover increasing Pb mobility at the lower elevations (Kaste et al., 2006).

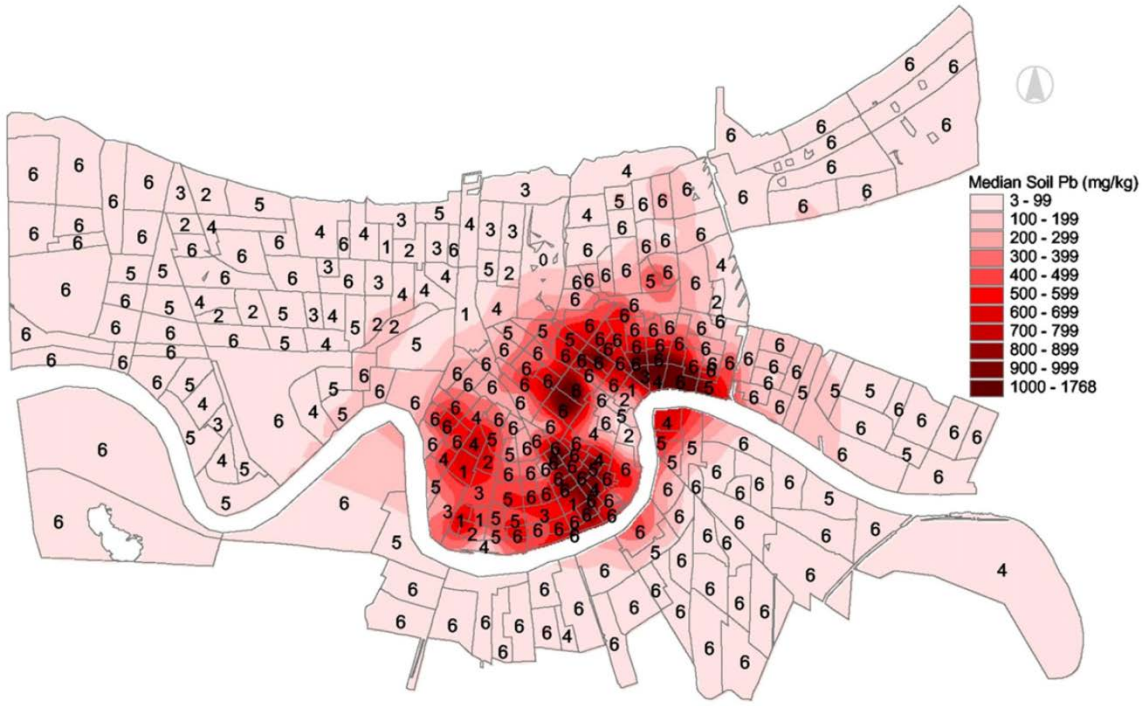
Emissions trends have shown that industrial activities are now one of the largest sources of soil Pb following phase out of Pb in on-road gasoline. Pruvot et al. (2006) compared urban and agricultural soils near a closed Pb smelter with soils in similar environments not exposed to smelter emissions in northern France. For samples near the smelter, Pruvot et al. (2006) observed that median soil Pb levels in lawns were roughly 2 times higher, while kitchen garden soil Pb concentrations were 10 times higher and agricultural soil Pb was almost 15 times higher than soil not exposed to smelter emissions. Bonnard and McKone (2009) reported surface soil Pb concentrations of 66-493 mg/kg outside

homes of children living within 1 km of a Pb smelter in France; air Pb levels reported by Bonnard and McKone (2009) for this town ranged from 0.025-0.20 μg/m^3. The air samples Pingitore et al. (2009) obtained near a defunct El Paso, TX smelter (described in Section 3.5.4) found that the air Pb-TSP concentrations could largely be attributed to Pb-humate, which is created by sorption of Pb onto humic substances in soil and can be resuspended. Spalinger et al. (2007) compared soil Pb samples from surrounding towns with those from the Bunker Hill Superfund remediation site in Idaho. Median background soil Pb concentrations was 48 mg/kg, while the median soil Pb concentration at Bunker Hill was 245 mg/kg.

Recent studies of brownfield soils have shown variable Pb concentrations. Van Herwijnen et al. (2007) measured soils near a defunct Zn smelter in Avonmouth, UK in areas termed low and high contamination by the authors. Total soil Pb concentration in the low contamination area was 315 mg/kg, while soil Pb concentration in the high contamination area was 1,688 mg/kg. Deng and Jennings (2006) tested various Pb extraction methods on soils obtained from over 50 brownfield sites in the greater Cleveland, OH area. Comparison of twelve extraction methods for three samples produced a range of 1,780-2,636 mg/kg for one sample, 283-491 mg/kg for a second sample, and 273-499 mg/kg for a third sample. Verstraete and Van Meirvenne (2008) measured Pb in soils at a remediated brownfield site in Belgium and reported average Pb concentrations to be 188 mg/kg and 224 mg/kg in two sampling campaigns. Dermont et al. (2010) fractionated soil by particle size class and measured the Pb concentration in each. Pb concentrations by size bin were as follows: 125-250 μm: 1,132 mg/kg; 63-125 μm: 1,786 mg/kg; 38-63 μm: 1,712 mg/kg; 20-38 μm: 2,465 mg/kg; 0-20 μm: 3,596 mg/kg. Hence, the highest concentration was in the smallest soil particle fraction. Bulk Pb concentration over 0-250 μm particle sizes was 2,168 mg/kg.

Several studies explore the relationship between soil Pb concentration and land use. Laidlaw and Filippelli (2008) displayed data for Indianapolis, IN showing the Pb concentration at the soil surface had a smoothed “bull’s eye” pattern, which suggested that the Pb in soil is continually resuspended and deposited within the urban area so that smooth air and soil concentration gradients emanating from the city center could be created over time. Cities generally have a similar pattern consisting of larger quantities of Pb accumulated within the inner city and smaller quantities of Pb in outer cities (i.e. near the outskirts or suburban areas) (Filippelli and Laidlaw, 2010). Similarly, Filippelli et al. (2005) reported soil Pb concentration distribution to have a maximum at the center of Indianapolis, IN, around the location where two interstate highways intersect, and to decrease with distance away from the center. However, the spatial distribution of Pb was presumed to be smoothed over time from resuspension and deposition with contributions from historic sources of on-road gasoline (Section 3.2.2.6) and Pb paint (Section 3.2.2.7).

In this paper, soil Pb concentrations were also shown to decrease with distance from roadways, but the levels were roughly four times higher in urban areas compared with suburban areas. This is also illustrated for urban scale Pb accumulation in New Orleans, LA in Figure 3-31. Brown et al. (2008) also measured soil Pb concentration along three transects of Lubbock, TX and observed that soil Pb decreased with increasing distance from the city center, which was the oldest part of the city.



Source: Reprinted with permission of Elsevier Publishing, Mielke et al. (2007a)

Note: At the urban scale, Pb quantities are largest within the inner-city residential communities that surround the Central Business District where pavement and concrete cover the soil. Note the several orders of magnitude difference between the interior and the exterior areas of the city. Note that the number on each census tract indicates the number of blood Pb samples taken from that tract during the six years from which the study data were obtained.

Figure 3-31 Map of median Pb content in soil in New Orleans.

Mielke et al. (2008) compared soil Pb concentrations for public and private housing at the center and outer sections of New Orleans and found that median and maximum soil Pb concentrations were substantially higher in the city center compared with the outer portions of the city. This study also found that private residences had higher soil Pb compared with public housing. In a separate study to examine surface soil Pb loading and concentration on 25 properties in New Orleans, Mielke et al. (2007b) observed median and maxima deposition values of roughly 25,000 and 265,000 µg/m^2, respectively. Median and maxima surface soil Pb concentrations were observed to be 1,000 and

20,000 mg/kg, respectively. Clark et al. (2006) performed isotopic analysis on urban garden soils in an area of Boston, MA with no large industrial sources of Pb and estimated that 60% of the soil Pb could be attributed to historic Pb on-road gasoline emissions in an urban area of the city while 14% was attributed to historic Pb on-road gasoline emissions in a suburban area. The remainder of the Pb was attributed to paint degradation. However, the Clark et al. (2006) model assumed that the only two sources of soil Pb were paint and historic Pb on-road gasoline emissions. So, the percentages provided are upper limits of the contribution of those two sources. Additional discussion of historic sources of Pb is provided in Section 3.2.2.7. Isotope ratios for paint and gasoline references used in the Clark et al. (2006) study were obtained from Rabinowitz (1986).

Several studies have examined the effects of roadway attributes on Pb content in roadside dust. Yesilonis et al. (2008) measured metal content in surface soil samples (0-10 cm) at selected land parcels throughout Baltimore based on a stratified random sampling design that accounted for land use factors. They compared soil metals within 100 m buffers of roadways and outside those buffers and found that median soil Pb concentration inside the buffer was significantly higher than median soil Pb concentration outside the buffers (outside: 38.7 kg/ha; inside: 134 kg/ha; $p < 0.0001$). In an analysis of the relationship between land use parameters and Pb concentration in soil in Los Angeles, Wu et al. (2010) observed that soil Pb concentration was higher near freeways and major traffic arteries compared with other locations. The (square-root transformed) age of the building on a sampled land parcel, length of highway within a 1,000 m buffer, and length of local road within a 20 m buffer in which the sample was obtained were significant predictors of Pb. Home age within 30 m of a soil sample and road length within 3,000 m of a road sample were also shown to be significant predictors of soil Pb concentration in areas not designated to be near a freeway or major traffic artery. Wu et al. (2010) concluded that both historical traffic and leaded paint contributed to Pb contamination in soils. However, Wu et al. (2010) acknowledged uncertainty in historical roadway and traffic count data, which introduces uncertainty into that conclusion. Study areas were classified as residential, commercial, park, and industrial (not specific to Pb emissions), although the authors were not able to distinguish the relative effects of each area on Pb content in roadside dust. Wu et al. (2010) reported that the highest median measured concentrations of Pb content in roadside dust were in residential freeway samples (112 mg/kg), followed by residential arterial samples (98 mg/kg), and industrial freeway samples (90 mg/kg). Additional sources of Pb to soil near roadways, such as traces of Pb in unleaded gasoline and Pb-containing wheel weights (described in Section 3.2.2.6) were not considered in this study. Amato et al. (2009) observed that deposited PM_{10} onto roadways, measured as dust samples, in Barcelona, Spain was differentially enriched with Pb. Pb concentration in PM_{10} was highest at ring roads (229 mg/kg) and in the city center (225 mg/kg),

followed by demolition and construction sites (177 mg/kg) and near a harbor (100 mg/kg). Joshi et al. (2009) also observed Pb dust concentrations to be highest at industrial sites (260 mg/kg) followed by commercial sites (120 mg/kg) and residential sites (60 mg/kg) in Singapore.

Two recent studies focused on Pb from paint degradation by examining Pb dust loading to hard surfaces located along transects of each of the five boroughs of New York City (Caravanos et al., 2006b; Weiss et al., 2006). Caravanos et al. (2006b) used GIS to examined Pb dust loadings on top of pedestrian traffic signals and observed "hot spots," defined by the authors as at least twice the Pb dust loading at adjacent samples near major elevated bridges in upper Manhattan, the Bronx, and Queens. In Brooklyn and Staten Island, areas with high dust loading were not clearly attributed to a source. "Low spots," defined by the authors as at least two times lower Pb dust loading compared with adjacent samples were observed in lower Manhattan, were thought to correspond with intensive cleaning efforts that followed the September 11, 2001 World Trade Center attack. Weiss et al. (2006) studied Pb concentrations of grit (granules of mixed composition found to accumulate alongside street curbs) along the transects and found that median Pb concentrations in grit under the elevated steel structures were 2.5-11.5 times higher than those obtained away from steel structures; 90th percentile values were up to 30 times higher near steel structures compared with those further from these structures.

Outdoor Pb dust has been also associated with demolition activities. Farfel et al. (2005, 2003) measured Pb dust within 100 m of a demolition site before, immediately after, and 1 month following the demolition. They found that the rate of Pb dust fall increased by a factor of more than 40 during demolition (Farfel et al., 2003). Immediately after demolition, one demolition site had dust loadings increase by a factor of 200% for streets (87,000 µg/m^2), 138% for alleys (65,000 µg/m^2), and 26% for sidewalks (23,000 µg/m^2) compared with pre-demolition Pb dust levels. One month following demolition, Pb dust levels dropped by a factor of 45% for the street (48,000 µ/m^2), compared with post-demolition concentrations, 67% for alleys (21,000 µg/m^2), and 41% for sidewalks (14,000 µg/m^2). At another demolition site, smaller increases were observed: 29% for streets (29,000 µg/m^2), 18% for alleys (19,000 µg/m^2) and 18% for sidewalks (22,000 µg/m^2). No values were reported for the 1-month follow-up for the second site (Farfel et al., 2005).

Soil Pb variability depends on the strength and prevalence of nearby sources. Griffith et al. (2002) investigated spatial autocorrelation of soil Pb concentration at three sites: urban Syracuse, NY, rural Geul River, The Netherlands, and an abandoned Pb Superfund site in Murray, UT. In both Syracuse and Geul River, the soil Pb concentrations were not

strongly correlated in space, with the exception of soil obtained near roads, which exhibited less variability. The smelting and shooting areas of the Superfund site were both demonstrated to have spatial clusters that were well correlated. Later work on the spatial distribution of metals in Syracuse produced similar results for that city (Griffith et al., 2009). These studies did not adjust for age of housing, although Griffith et al. (2009) did find that housing age and Pb co-vary. An association between housing age and soil Pb would likely be enhanced by such co-variation.

Pb can be elevated in soils located where ammunition is used for military or hunting purposes. In a study of Pb content in sand used to cover a firing range, Lewis et al. (2010) found that 93% of bullet mass was recovered in the top 0.3 m of the sand, and 6.4% was recovered at a depth of 0.3-0.45 m. Pb oxides were observed to be the dominant species in the contaminated sand. Berthelot et al. (2008) studied soil Pb concentrations in grounds used for testing military tanks and munitions and measured soil Pb levels to range from 250 to 2,000 mg/kg.

3.6.2 Sediments

The recently completed Western Airborne Contaminants Assessment Project (WACAP) is the most comprehensive database, to date, on contaminant transport and depositional effects on sensitive ecosystems in the U.S. (Landers et al., 2010). The transport, fate, and ecological impacts of semi-volatile compounds and metals from atmospheric sources were assessed on ecosystem components collected from 2002-2007 in watersheds of eight core national parks (Landers et al., 2008). The goals of the study were to assess where these contaminants were accumulating in remote ecosystems in the Western U.S., identify ecological receptors for the pollutants, and to determine the source of the air masses most likely to have transported the contaminants to the parks. Pb was measured in sediments, as well as snow, water, lichen, fish, and moose during the multiyear project, and although Pb was not measured in air as a part of this study, routine monitoring find particle Pb was monitored at IMPROVE sites in the majority of national parks included in the study.

Pb concentrations in sediments from all lakes in which Pb was measured in the conterminous 48 states exhibited higher Pb concentrations near the surface relative to preindustrial Pb levels measured at greater depth. This was not the case for other metals measured, except for cadmium (Cd) and mercury (Hg). Sediments in most lakes exhibited maximum concentrations between 1960 and 1980, followed by a decrease, as shown in Figure 3-32. A clear decline in Pb concentrations in sediments after the discontinued use of leaded on-road gasoline was observed at almost all WACAP locations, of nearly all

WACAP sites in the western U.S. Sediment Pb concentrations averaged over the year in which they were obtained correlated moderately well with annual average Pb-TSP concentrations from the AQS with R = 0.63 for 1980-2004, in which WACAP data were available (Landers et al., 2008). Pb concentrations in sediments were much lower in Alaska, and no such decline was observed. Pb in sediments was mainly attributed to on-road gasoline use, but for some lakes a strong influence from other local sources of Pb to lake sediments was shown to be important, including Pb mining, smelting, logging, and other industrial activities. The reduction in sediment Pb concentrations shown in Figure 3-32 for recent years coincides with declines in air Pb concentrations following the phase-out of Pb anti-knock agents in gasoline and reductions of air Pb emissions from industrial activities. Elevated Pb deposition at the Glacier, Rocky Mountain, and Sequoia and Kings Canyon National Park and Preserve sites was thought by Landers et al. (2008) to reflect regional scale bioaccumulation of airborne contaminants in remote ecosystems in the Western U.S. Accumulation of contaminants was shown to vary geographically; Landers et al. (2008) lists potentially influential factors causing variation in Pb deposition including proximity to individual sources or source areas, primarily agriculture, mining, and smelting operations. This finding was counter to the original working hypothesis that most of the contaminants found in western parks would originate from eastern Europe and Asia.

Figure 3-32 WACAP data for Pb concentration in sediment at eight National Parks and/or Preserves.

In a survey of 35 reservoirs and lakes in 16 continental U.S. states, Van Metre et al. (2006) collected data from sediment cores extending back as far as the early 1800s, and up to 2001. For most locations, they were able to match at least three bodies of water in rural (designated as 'reference'), light urban, and dense urban settings. In reference bodies of water, the median sediment Pb concentration corresponding to the 1990s was 48 mg/kg. It was 56 mg/kg in sediments from light urban bodies, and 214 mg/kg in dense urban ones (Mahler et al., 2006). Using the most distant past sediment records, Mahler et al. (2006) provided approximations of concentrations attributable to anthropogenic inputs. The median of these values for the 1990s were 28, 22, and 194 mg/kg in the reference, light urban, and dense urban bodies of water, respectively.

Data from select regions of the U.S. illustrate that Pb concentrations in surface waters and sediment are likely to be higher in urbanized areas compared with rural locations. Table 3-11 presents data from seven metropolitan areas (Cobb et al., 2006). Differences among the intraurban concentration ranges illustrate a high level of spatial variability within individual cities as well as high inter-urban variability. The rural New Orleans site reported relatively low Pb sediment concentrations, and the highest average Pb sediment concentrations were reported for the city of New Orleans. Figure 3-33 and Figure 3-34 illustrate such variability within a single watershed for the Apalachicola, Chattahoochee, and Flint River Basin, which runs south from north of the greater Atlanta, GA metropolitan area and drains into the Gulf of Mexico at the Apalachicola Bay in the Florida panhandle. Sediment concentrations peaked near the Atlanta area and diminished as distance from the Apalachicola Bay decreased. This observation suggests that rural areas have lower Pb sediment levels compared with urban areas. Consistent with the WACAP trends shown in Figure 3-32, the data also illustrated that Pb concentrations in sediment have declined in the U.S. since 1975 (Figure 3-34), prior to the phase-out of on-road leaded gasoline.

Table 3-11 Sediment concentrations in various cities, prior to 2005

City	Avg Pb Concentration (mg/kg)[a]	Pb Concentration Range (mg/kg)a
Baltimore, MD		1-10,900
Miami, FL	275	25-1,612
Mt. Pleasant, MI	320	100-840
New Orleans, LA	784	31.7-5,195
New Orleans, LA (rural outskirts)	11	4.8-17.3
St. Louis, MO	427	35-1,860
Syracuse, NY	80	20-800

Many recent studies have illustrated the effects of natural disasters on Pb concentrations in surface water and sediment in the wake of Hurricane Katrina, which made landfall on August 29, 2005 in New Orleans, LA, and Hurricane Rita, which made landfall west of New Orleans on September 23, 2005. Pardue et al. (2005) sampled floodwaters on September 3 and September 7, 2005 following the hurricanes and observed that elevated concentrations of Pb along with other trace elements and contaminants were not irregular for stormwater but were important because human exposure to the stormwater was more substantial for Hurricane Katrina than for a typical storm. Floodwater samples obtained throughout the city on September 18, 2005 and analyzed for Pb by Presley et al. (2006) were below the limit of detection. Likewise, Hou et al. (2006) measured trace metal concentration in the water column of Lake Pontchartrain and at various locations within New Orleans during the period September 19 through October 9, 2005 and found that almost all Pb concentrations were below the limit of detection. However, several studies noted no appreciable increase in Pb concentration within Lake Pontchartrain soils and

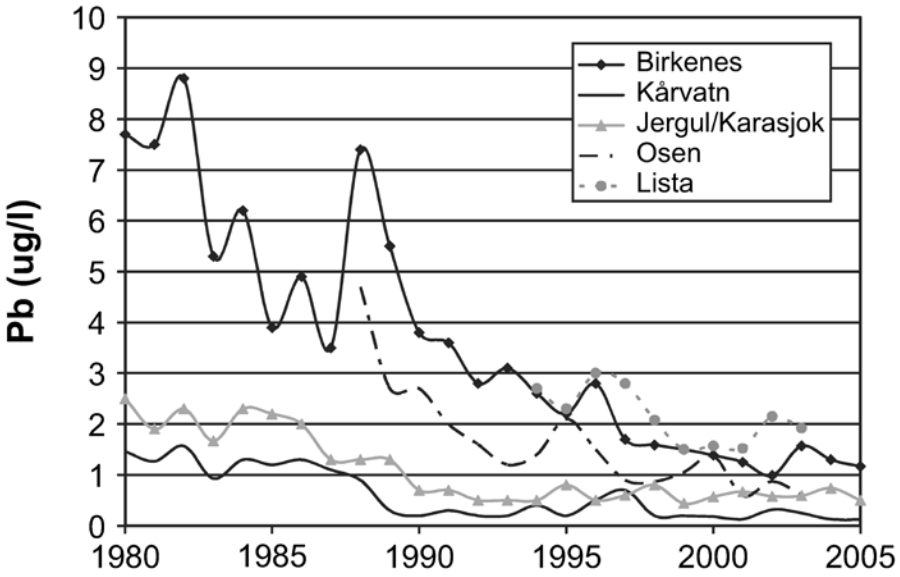
sediments (Abel et al., 2010; Abel et al., 2007; Schwab et al., 2007; Cobb et al., 2006; Presley et al., 2006). Shi et al. (2010) analyzed Lake Pontchartrain sediment samples using a factored approach and found that most Pb was sequestered in carbonate-rich, iron oxide-rich, and magnesium oxide-rich sediments in which it can be more readily mobilized and potentially more bioaccessible. Zahran et al. (2010) and Presley et al. (2010) noted that soil Pb samples obtained outside schools also tended to decrease in the wake of Hurricanes Katrina and Rita, with some sites observing substantial increases and others noting dramatic reductions. These studies suggest that floodwaters can change the spatial distribution of Pb in soil and sediments to result in increased or reduced concentrations.

3.6.3 Rain

The only network that provides a long-term record of precipitation chemistry across the U.S. is the National Trend Network operated by the National Atmospheric Deposition Program, a cooperative effort between EPA and other federal as well as state, tribal, and local government agencies, educational institutions, private companies, and non-governmental agencies. Precipitation is monitored for pH, conductance, and major cations and anions. A separate network, the Mercury Deposition Network, is operated by the same organization and monitors Hg concentrations in rain and a separate network. Neither of these networks includes Pb monitoring.

Recent results from locations outside the U.S. were consistent with decreasing rain water concentrations described in the 2006 Pb AQCD, reflecting the elimination of Pb from on-road gasoline in most countries. From the 2006 Pb AQCD (U.S. EPA, 2006b), volume weighted Pb concentrations in precipitation collected in 1993-94 from Lake Superior, Lake Michigan and Lake Erie ranged from ~0.7 to ~1.1 µg/L (Sweet et al., 1998). These values fit well with the temporal trend reported in Watmough and Dillon (2007), who calculated annual volume-weighted Pb concentrations to be 2.12, 1.17 and 0.58 µg/L for 1989-90, 1990-91 and 2002-03, respectively, in precipitation from a central Ontario, Canada, forested watershed. A similar value of 0.41 µg/L for 2002-03 for Plastic Lake, Ontario, was reported in Landre et al. (2009). For the nearby Kawagama Lake, Shotyk and Krachler (2010) gave Pb concentrations in unfiltered rainwater collected in 2008. For August and September 2008, the values were 0.45 and 0.22 µg/L, respectively, and so there had been little discernible change over the post-2000 period. In support, Pb concentrations in snow pit samples collected in 2005 and 2009 collected 45 km northeast of Kawagama Lake had not changed to any noticeable extent (0.13, 0.17, and 0.28 µg/L in 2005; 0.15 and 0.26 µg/L in 2009) (Shotyk and Krachler, 2010).

There have also been a few recently published, long-term European studies of Pb concentration in precipitation including Berg et al. (2008) and Farmer et al. (2010). Berg et al. (2008) compared the trends in Pb concentration in precipitation at Norwegian background sites in relation to the decreasing European emissions of Pb over the period 1980-2005. The Birkenes site at the southern tip of Norway is most affected by long-range transport of Pb from mainland Europe but there had been a 97% reduction in the concentration of Pb in precipitation over the 26-year time period. This was similar to the reductions of 95% and 92% found for the more northerly sites, Karvatn and Jergul/Karasjok, respectively (Figure 3-35). A decline of ~95% in Pb concentrations in moss (often used as a biomonitor of Pb pollution) from the southernmost part of Norway, collected every 5 years over the period 1977-2005, agreed well with the Birkenes precipitation results (Berg et al., 2008). The reductions in Pb concentration in both precipitation and moss appear to agree well with the reductions in emissions in Europe (~85%) and Norway (~99%). However, similarly to the situation in the U.S., the greatest reductions occurred by the late 1990s and only relatively minor reductions have occurred thereafter; Figure 3-35.



Source: Reprinted with permission of Pergamon Press, Berg et al. (2008)

Figure 3-35 Trends in Pb concentration in precipitation from various sites in Norway over the period 1980-2005.

Farmer et al. (2010) showed the trends in concentration of Pb in precipitation collected in a remote part of northeastern Scotland over the period 1989-2007. The 2.6- and 3.0-fold

decline in mean concentration from 4.92 µg/L (1989-1991) to 1.88 µg/L (1999) and then to 0.63 µg/L (2006-2007) is qualitatively but not quantitatively in line with the sixfold decline in annual total U.K. emissions of Pb to the atmosphere over each of these time periods. Since the outright ban on the use of leaded on-road gasoline in 2000, however, the ratio of Pb concentrations in rainwater to U.K. Pb emissions (metric tons) appears to have stabilized to a near-constant value of 0.009 µg/L per metric ton. The concentrations in precipitation reported in these studies are all at the lower end of the range reported in the 2006 Pb AQCD (U.S. EPA, 2006b), and similar to concentrations reported for those studies conducted after the removal of Pb from on-road gasoline. Overall, recent studies of wet deposition tended to confirm the conclusions of the 2006 Pb AQCD (U.S. EPA, 2006b) that wet deposition fluxes have greatly decreased since the removal of Pb from on-road gasoline.

3.6.4 Snowpack

The location of Pb deposition impacts its further environmental transport. For example, Pb deposited to some types of soil may be relatively immobile, while Pb deposited to snow is likely to undergo further transport more easily when snow melts. Deposition to snow was investigated in several studies. Measurements of Pb in snowmelt during the WACAP study, showed that median Pb concentration ranged form 20-60 ng/L, with 95th percentile values ranging from 30-130 ng/L; Figure 3-36 (Landers et al., 2008). Measurements in WACAP of Hg and particulate carbon deposition onto snow were thought to reflect coal combustion, and Pb was not significantly correlated with Hg in snow samples of concentration or of calculated enrichment factors normalized to Al concentrations. Shotyk and Krachler (2009) reported considerably higher concentrations at two North American sites, Johnson and Parnell, in Ontario, Canada. Mean Pb concentration for contemporary snow was 672 (Johnson, n = 6; Parnell, n = 3) ng/L. Shotyk et al. (2010) presented additional values for Pb in contemporary snow samples and these were again higher than for ground and surface waters. Luther Bog and Sifton Bog snow had mean Pb concentrations of 747 and 798 ng/L, respectively. The relatively high concentrations in snow were attributed to contamination with predominantly anthropogenic Pb, although it was noted that the extent of contamination was considerably lower than in past decades.

Seasonal patterns of heavy metal deposition to snow on Lambert Glacier basin, east Antarctica, were determined by Hur et al. (2007). The snow pit samples covered the period from austral spring 1998 to summer 2002 and Pb concentrations ranged from 1.29-9.6 pg/g with a mean value of 4.0 pg/g. This was similar to a mean value of 4.7 pg/g (1965-1986) obtained by Planchon et al. (2003) for Coats Land, northwest Antarctica.

Estimated contributions to the Pb in Lambert Glacier basin snow were ~1% from rock and soil dust (based on Al concentrations) and ~4.6% from volcanoes (based on the concentrations of nss-sulfate). There was almost negligible contribution from seaspray (based on Na concentrations), and so it was suggested that a substantial part of the measured Pb concentration must originate from anthropogenic sources. Highest Pb concentrations were generally observed in spring/summer with an occasional peak in winter. This contrasts with data for the Antarctic Peninsula, where highest concentrations occurred during autumn/winter, and again with Coats Land, where high concentrations were observed throughout the winter. These differences were attributed to spatial changes in input mechanism of Pb aerosols arriving at different sites over Antarctica, which could be due to their different source areas and transport pathways. Hur et al. (2007), however, suggested that the good correlation between Pb and crustal metals in snow samples shows that Pb pollutants and crustal PM are transported and deposited in Lambert Glacier basin snow in a similar manner.

(DENA = Denali, GAAR = Gates of the Arctic, GLAC = Glacier, MORA = Mount Ranier, NOCA = North Cascades, NOAT = Noatak, OLYM = Olympic, ROMO = Rocky Mountain, SEKI = Sequoia and Kings Canyon)

Figure 3-36 Box plots illustrating Pb concentration in snow melt at nine National Parks and Preserves.

Lee et al. (2008b) collected 42 snow samples during the period autumn 2004-summer 2005 from a 2.1 m snow pit at a high-altitude site on the northeast slope of Mount Everest, Himalayas. Pb concentrations ranged from 5-530 pg/g with a mean value of 77 pg/g. The mean value is clearly higher than the Hur et al. (2007) value for Antarctica but is substantially lower than a mean concentration of 573 pg/g for snow from Mont Blanc, France [1990-1991; Lee et al. (2008b)]. The mean Pb concentration for Mount Everest snow was lower during the monsoon (28 pg/g) compared with the non-monsoon periods (137 pg/g). From calculated enrichment factors (Pb/Alsnow:Pb/Alcrust), anthropogenic inputs of Pb were partly important but soil and rock dust also contributed. The low Pb concentrations during monsoon periods are thought to be attributable to low levels of atmospheric loadings of crustal dusts. K. Lee et al. (2008b) noted that their conclusions

differ from those in Kang et al. (2007), who stated that anthropogenic contributions of Pb to Mount Everest snow were negligible because the Everest concentrations were similar to those in Antarctica. Kang et al. (2007) did not take account of the difference in accumulation rates at the two sites and had also used Pb concentrations for Antarctic snow from a study by Ikegawa et al. (1999). Lee et al. (2008b) suggested that these Pb concentrations were much higher than expected and that their snow samples may have suffered from contamination during sampling and analysis.

3.6.5 Natural Waters

Monitoring data for streams, rivers and lakes are summarized in periodic national assessments of surface waters are carried out periodically by EPA, and they include measurement of major biological and chemical stressors. Pb concentrations in natural waters also may reflect deposition of Pb even in remote locations. WACAP data at five National Parks and Preserves show median Pb concentrations in surface waters to range from 6 to 75 ng/L (Landers et al., 2008); Figure 3-37. Four sites (Denali, Mt. Ranier, Glacier, and Olympic National Parks) were in the lower range of 6 to 20 ng/L. One site (Noatak) reported a single value of 75 ng/L. With the exception of the Noatak site, the WACAP values were in line with measurements by Shotyk and Krachler (2007) of Pb concentrations in six artesian flows in Simcoe County, near Elmvale, Ontario, Canada. The values ranged from 0.9 to 18 ng/L with a median (n = 18) of 5.1 ng/L. These are comparable with reports of a range of 0.3-8 ng/L for Lake Superior water samples (Field and Sherrell, 2003). Shotyk and Krachler (2007) also commented that such low concentrations for ground and surface waters are not significantly different from those (5.1 ± 1.4 ng/L) reported for Arctic ice from Devon Island, Canada, dating from 4,000-6,000 years ago. In a separate study, Shotyk and Krachler (2009) reported concentrations of Pb in groundwater (from two locations, Johnson and Parnell), surface water (Kawagama Lake) and contemporary snow (Johnson and Parnell, as described in Section 3.6.4). The lowest mean dissolved Pb concentrations were found for groundwater: 5.9 (Johnson, n = 11) and 3.4 (Parnell, n = 12) ng/L. For lake water the mean Pb concentration was 57 (Kawagama Lake, n = 12) ng/L. The extremely low concentrations of Pb in the groundwaters were attributed to natural removal processes. Specifically, at the sampling location in Canada, there is an abundance of clay minerals with high surface area and high cation exchange capacity and these, combined with the elevated pH values (pH=8.0) resulting from flow through a terrain rich in limestone and dolostone, provide optimal circumstances for the removal of trace elements such as Pb from groundwater. Although such removal mechanisms have not been demonstrated, the vast difference between Pb concentration in snow and that in the groundwaters indicate

that the removal process is very effective. Shotyk and Krachler (2010) speculate that even at these very low Pb concentrations, much if not most of the Pb is likely to be colloidal, as suggested by the 2006 Pb AQCD (U.S. EPA, 2006b). Finally, Shotyk et al. (2010) suggest that the pristine groundwaters from Simcoe County, Canada, provide a useful reference level against which other water samples can be compared.

Figure 3-37 Boxplots of Pb concentration in surface waters measured at five National Parks and Preserves.

Although Pb concentrations in Kawagama Lake water were approaching "natural values," the $^{206}Pb/^{207}Pb$ ratios for the samples that had the lowest dissolved Pb concentrations of 10, 10 and 6 ng/L were 1.16, 1.15 and 1.16, respectively. These values are inconsistent with those expected for natural Pb (the clay fraction from the lake

sediments dating from the pre-industrial period had values of 1.19-1.21) and it was concluded that most of the dissolved Pb in the lake water was of industrial origin. Shotyk and Krachler (2010) found that the full range of isotope ratios for Kawagama Lake water samples (Ontario, Canada) was 1.09 to 1.15; this was not only much lower than the stream water values entering the lake but also lower than the values attributed to leaded on-road gasoline in Canada (~1.15). The streamwater ratio values were ~1.16 to 1.17, while those for rainwater were as low as 1.09; in good agreement with the lower lake water values. This means that there must be an additional atmospheric source of Pb, which has a lower $^{206}Pb/^{207}Pb$ ratio than leaded on-road gasoline. Supporting evidence came from contemporary samples such as near surface peat, rainwater and snow, all of which confirmed a trend away from natural Pb (1.191 to 1.201) to lower $^{206}Pb/^{207}Pb$ ratios. The local smelting activities (Sudbury) were unlikely to be the source of anthropogenic Pb as Sudbury-derived emissions exhibit a typical $^{206}Pb/^{207}Pb$ ratio of ~1.15, similar to leaded on-road gasoline. Instead, it was suggested that long-range transport of Pb from the smelter at Rouyn-Noranda (known as the "Capital of Metal," NW Quebec) may still be impacting on Kawagama Lake but no Pb isotope data was quoted to support this supposition. Several studies, summarized in Mager (2012), reported Pb concentrations in matched reference and mining-disturbed streams in Missouri and the Western U.S. They are summarized in Table 3-12.

The range of Pb levels in saltwater are available from several studies although the values are not specific to the U.S. A range of 0.005-0.4 µg Pb/L for salt water was reported by Leland and Kuwabara (1985) and 0.01 to 27 µg Pb/L by Sadiq (1992). In general, Pb in seawater is higher in coastal areas and estuaries since these locations are closer to sources of Pb contamination and loading from terrestrial systems (U.S. EPA, 2008b).

3.6.6 Vegetation

The 2006 Pb AQCD (U.S. EPA, 2006b) presented data on Pb in vegetation. The main conclusions were that Pb uptake was strongly affected by pH, and acidic soils are most likely to have Pb in solution for absorption by plants. Additionally, the 2006 Pb AQCD (U.S. EPA, 2006b) states that most Pb stored within vegetation is stored in roots rather than fruits or shoots. Recent measurements from the WACAP study (Landers et al., 2008) have shown some Pb storage in lichens. Median Pb concentrations ranged from 0.3 mg/kg in Noatak National Park to 5 mg/kg in Glacier National Park, with substantial variation in the Glacier and Olympic National Park samples; Figure 3-38. Landers et al. (2008) state that lichen Pb concentrations have decreased substantially from the 1980s and that metal concentrations were within background levels for these remote Western sites.

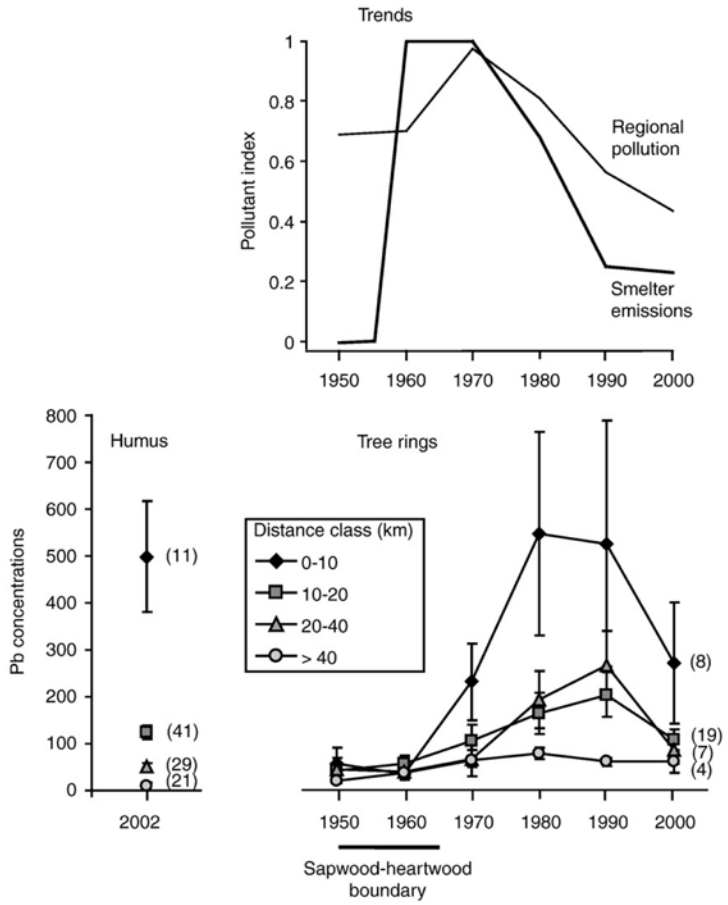
Figure 3-38 Boxplots of Pb concentration in lichen measured at seven National Parks and Preserves.

Mosses can be used effectively for monitoring trends in Pb deposition as demonstrated in many studies (Harmens et al., 2010; Harmens et al., 2008). For example, Harmens et al. (2008) showed that a 52% decrease in deposited Pb concentrations corresponded to a 57% decrease in Pb concentrations in moss. Farmer et al. (2010) showed that there was good agreement between the $^{206}Pb/^{207}Pb$ ratio for precipitation and mosses collected in northeast Scotland. A study in the Vosges mountains also found a ratio value of 1.158 for a moss sample and a surface soil litter value of 1.167 and concluded that 1.158 to 1.167 represented the current atmospheric baseline (Geagea et al., 2008). For rural northeast Scotland, a combination of sources is giving rise to a $^{206}Pb/^{207}Pb$ ratio of ~1.15 in recent precipitation and mosses (Farmer et al., 2010). Clearly, sources with a lower ratio than coal (~1.20) must be contributing substantially to the overall emissions. Pb from waste

incineration has been implicated as a possible current source (cf. typical $^{206}Pb/^{207}Pb$ ratios for Pb from European incineration plants are ~1.14 to 1.15 [de la Cruz et al. (2009) and references therein].

Trends in Pb concentration among flora have decreased in recent years. For example, Franzaring et al. (2010) evaluated data from a 20-year biological monitoring study of Pb concentration in permanent forest and grassland plots in Baden-Württemberg, southwest Germany. Grassland and tree foliage samples were collected from 1985-2006. The samples were not washed and so atmospheric deposition rather than uptake from the soil probably predominates. For all foliage (beech and spruce), Pb concentrations have shown large reductions over time, particularly in the early 1990s. The Pb concentrations in the grassland vegetation also decreased from the late 1980s to the early 1990s but the trend thereafter was found to be statistically non-significant. The reduction corresponded to the phase-out of leaded on-road gasoline in Germany. Similarly, Aznar et al. (2008b) observed that the decline in Pb concentrations in the outer level of tree rings corresponded with the decline in Cu smelter emissions in Gaspé Peninsula in Canada; Figure 3-39. Both Pb concentrations and Pb isotope ratios declined with distance from the smelter (Aznar et al., 2008a; Aznar et al., 2008b).



Source: Reprinted with permission of Elsevier Publishing, Aznar et al. (2008b)

Figure 3-39 Trends in regional pollution near a copper smelter in Canada and Pb concentrations at the boundary of heartwood trees within roughly 75 km of the smelter.

3.6.7 Aquatic Bivalves

Data from invertebrate waterborne populations can serve as in indicator of Pb contamination because animals such as mussels and oysters take in contaminants during filter feeding. Kimbrough et al. (2008) surveyed Pb concentrations in mussels, zebra mussels, and oysters along the coastlines of the continental U.S. In general, they observed the highest concentrations of Pb in the vicinity of urban and industrial areas. Company et al. (2008) measured Pb concentrations and Pb isotope ratios in bivalves along the Guadiana River separating Spain and Portugal. Analysis of Pb isotope ratio data suggested that high Pb concentrations were related to historical mining activities in the region. Elevated Pb concentrations were also observed by Company et al. (2008) in the vicinity of more populated areas. Couture et al. (2010) report data from a survey of the

isotopic ratios of Pb in *Mytilus edulis* blue mussel, collected off the coast of France from 1985-2005. The results indicated that the likely source of Pb in mussel tissue is from resuspension of contaminated sediments enriched with Pb runoff from wastewater treatment plants, municipal waste incinerators, smelters and refineries rather than from atmospheric deposition (Couture et al., 2010).

3.6.8 Vertebrate Populations

Pb concentrations in fish fillet and liver were measured through the WACAP study in eight National Parks and Preserves (Landers et al., 2008). For fish fillet, Pb concentrations ranged from 0.0033-0.30 mg/kg, with a median of 0.016 mg/kg. Liver stores were several times higher, with Pb concentrations ranging from 0.011-0.97 mg/kg and a median of 0.096 mg/kg. Pb concentrations in moose meat and liver were also measured at the Denali National Park and Preserve as part of WACAP (Landers et al., 2008). Moose meat Pb concentrations ranged from 0.021-0.23 mg/kg with a median of 0.037 mg/kg. Pb concentrations in moose liver ranged from 0.025-0.11 mg/kg with a median of 0.053 mg/kg. Boxplots of measured Pb concentrations in fish fillet and liver are shown in Figure 3-40, and boxplots of measured Pb concentrations for moose meat and liver are shown in Figure 3-41. For fish and meat tissues, median and maximum Pb concentrations were substantially lower than values reported in the 2006 Pb AQCD (U.S. EPA, 2006b). Still, the WACAP findings suggest some Pb accumulation in fish and moose in these remote locations.

3.7 Summary and Conculusions

3.7.1 Sources of Atmospheric Lead

The 2006 Pb AQCD (U.S. EPA, 2006b) documented the decline in ambient air Pb emissions following the ban on alkyl-Pb additives for on-road gasoline. Pb emissions declined by 98% from 1970 to 1995 and then by an additional 76% from 1995 to 2008, at which time national Pb emissions were 970 tons/year. As was the case for the 2008 NAAQS review, piston-engine aircraft emissions currently comprise the largest share (56%) of total atmospheric Pb emissions nationally; the 2008 NEI (U.S. EPA, 2011a) estimated that 550 tons of Pb were emitted from piston-engine aircraft. Other sources of

ambient air Pb, in approximate order of importance with regard to national totals, include metals processing, fossil fuel combustion, other industrial sources, roadway related sources, and historic Pb.

3.7.2 Fate and Transport of Lead

The atmosphere is the main environmental transport pathway for Pb, and on a global scale atmospheric Pb is primarily associated with fine PM. On a global scale, Pb associated with fine PM is transported long distances and found in remote areas. Atmospheric Pb deposition peaked in the 1970s, followed by a decline. Both wet and dry deposition are important removal mechanisms for atmospheric Pb. Because Pb in fine PM is typically fairly soluble, wet deposition is more important for fine Pb. In contrast, Pb associated with coarse PM is usually insoluble, and removed by dry deposition. However, local deposition fluxes are much higher near local industrial sources, and a substantial amount of emitted Pb is deposited near sources, leading to high soil Pb concentrations. Deposition is not an ultimate sink for Pb because particles are potentially resuspended and redeposited many times before reaching a site where further transport is unlikely, especially for dry deposition. Resuspension modeling has suggested that larger particles (10-100 μm) become more readily resuspended compared with smaller particles, because smaller particles must overcome stronger adhesion forces to be resuspended by air movement and lift forces are proportional to particle size to the approximate power of 1.5.

In water, Pb is transported as free ions, soluble chelates, or on surfaces of iron and organic rich colloids. In surface waters, atmospheric deposition is the largest source of Pb, but urban runoff and industrial discharge are also considerable. A substantial portion of Pb in runoff ultimately originates from atmospheric deposition, but substantial amounts of Pb from vehicle wear and building materials can also be transported by runoff waters without becoming airborne. Often a disproportionate amount of Pb is removed by runoff at the beginning of a rainfall event. Pb is rapidly dispersed in water, and highest concentrations of Pb are observed near sources where Pb is deposited.

Transport in surface waters is largely controlled by exchange with sediments. The cycling of Pb between water and sediments is governed by chemical, biological, and mechanical processes, which are affected by many factors. Organic matter in sediments has a high capacity for accumulating trace elements like Pb. In anoxic sediments binding to sulfides is a particularly important process that affects Pb bioavailability. Pb is relatively stable in sediments, with long residence times and limited mobility. However, Pb-containing sediment particles can be remobilized into the water column. Resuspended Pb is largely

associated with OM or iron and manganese particles. This resuspension of contaminated sediments strongly influences the lifetime of Pb in water bodies and can be a more important Pb source to the water column than atmospheric deposition. Resuspension of sediments largely occurs during discrete events related to storms.

A complex variety of factors influence Pb retention in soil, including hydraulic conductivity, solid composition, OM content, clay mineral content, microbial activity, plant root channels, animal holes, geochemical reactions, colloid amounts, colloidal surface charge, and pH. Leaf litter can be an important temporary sink for metals from the soil around and below leaves, and decomposition of leaf litter can reintroduce substantial amounts of Pb into soil "hot spots," where re-adsorption of Pb is favored. A small fraction of Pb in soil is present as the free Pb^{2+} ion. The fraction of Pb in this form is strongly dependent on soil pH.

In summary, environmental distribution of Pb occurs mainly through the atmosphere, from where it is deposited into surface waters and soil. Pb associated with coarse PM deposits to a great extent near sources, while fine Pb-PM can be transported long distances. Surface waters act as an important reservoir, with half-lives of Pb in the water column largely controlled by rates of deposition to and resuspension from bottom sediments. Pb retention in soil depends on Pb speciation and a variety of factors intrinsic to the soil.

3.7.3 Ambient Lead Monitoring

Since the publication of the 2006 Pb AQCD for Pb (U.S. EPA, 2006b) there has been little progress in the state of the science regarding monitoring technology and monitor siting criteria for representation of population exposures to airborne Pb and Pb of atmospheric origin. Our understanding of sampling errors in existing measurements, our understanding of possible alternatives to existing Pb-TSP sampling technology, and our understanding of particle size ranges of Pb particles occurring in different types of locations have changed little in that time.

The current Pb monitoring network design requirements include two types of monitoring sites: source-oriented and non-source-oriented. Source-oriented monitoring sites are required near sources of air Pb emissions which are expected to or have been shown to contribute to ambient air Pb concentrations in excess of the NAAQS. With the December 2010 completion of action on regulatorily required Pb monitoring, one-year of Pb-TSP monitoring is also required near 15 specific airports to gather additional information on the likelihood of NAAQS exceedances near airports due to combustion of leaded aviation

gasoline. Non-source-oriented monitoring is also required at NCore sites in CBSAs with a population of at least 500,000.

In addition to Pb-TSP monitoring for the purposes of judging attainment with the NAAQS, Pb is also routinely measured in smaller PM fractions in the CSN, IMPROVE, and the NATTS networks. While monitoring in multiple networks provides extensive geographic coverage, measurements between networks are not directly comparable in all cases because different PM size ranges are sampled in different networks. Depending on monitoring network, Pb is monitored in TSP, PM_{10}, or $PM_{2.5}$ using high-volume or low-volume samplers.

3.7.4 Ambient Air Lead Concentrations

Ambient air Pb concentrations have declined drastically over the period 1980-2010. The median annual concentrations for all monitors have dropped by 97% from 0.87 $\mu g/m^3$ in 1980 to 0.03 $\mu g/m^3$ in 2010. While the sharpest drop in Pb concentration occurred during 1980-1990, a declining trend was observed between 1990 and 2010. Slightly smaller reductions were observable among source-oriented Pb concentration (83%) and non-source-oriented Pb data (91%) for 2000-2010. For source-oriented monitoring over the period 2008-2010, the 3-month rolling average was measured to be above the level of the NAAQS in twenty counties across the U.S.

Pb concentrations, seasonal variations, inter-monitor correlations, and wind data were analyzed for six counties: Los Angeles County, CA, Hillsborough County, FL, Cook County, IL, Jefferson County, MO, Cuyahoga County, OH, and Sullivan County, TN. These sites were selected for analysis because they contained a mix of source-oriented and non-source-oriented monitors in urban areas. Spatial and temporal variability of Pb concentrations in each county were commonly high. Meteorology, distance from sources with respect to the monitors, and source strength all appeared to influence the level of concentration variability across time and space.

Pb concentrations exhibit varying degrees of association with other criteria pollutant concentrations. Overall, Pb was moderately associated with $PM_{2.5}$, PM_{10} and NO_2, with positive Spearman correlation coefficients observed at nearly all sites. However, Pb was just as strongly associated with CO in fall and winter The poorest associations were observed between Pb and O_3. Among trace metals, the strongest association was with Zn. Br, Cu, and K concentrations also exhibited moderate associations with Pb concentrations. Such correlations may suggest some common sources affecting the pollutants.

3.7.5 Ambient Lead Concentrations in Non-Air Media and Biota

Atmospheric deposition has led to measurable Pb concentrations observed in rain, snowpack, soil, surface waters, sediments, agricultural plants, livestock, and wildlife across the world, with highest concentrations near Pb sources, such as metal smelters. Since the phase-out of Pb from on-road gasoline, concentrations in these media have decreased to varying degrees. In rain, snowpack, and surface waters, Pb concentrations have decreased considerably. Declining Pb concentrations in tree foliage, trunk sections, and grasses have also been observed. In contrast, Pb is retained in soils and sediments, where it provides a historical record of deposition and associated ambient concentrations. In remote lakes, sediment profiles indicate higher Pb concentrations in near surface sediment as compared to pre-industrial era sediment from greater depth and indicate peak concentrations between 1960 and 1980, when leaded on-road gasoline was at peak use. Concentrations of Pb in moss, lichens, peat, and aquatic bivalves have been used to understand spatial and temporal distribution patterns of air Pb concentrations. Ingestion and water intake are the major routes of Pb exposure for aquatic organisms, and food, drinking water, and inhalation are major routes of exposure for livestock and terrestrial wildlife. Overall, Pb concentrations have decreased substantially in media through which Pb is rapidly transported, such as air and water. Substantial Pb remains in soil and sediment sinks. In areas less affected by major local sources, the highest concentrations are below the surface layers and reflect the previous use of Pb in on-road gasoline and emissions reductions from other sources.

[a]The 3-month averages presented here were created using a simplified approach of the procedures detailed in 40 CFR part 50 appendix R and as such cannot be directly compared to the Pb NAAQS for determination of compliance with the Pb NAAQS.

[b]Sites listed in the bottom six rows of the table fall in the upper 90th percentile of the data pooled by site.

[a]The 3-month averages presented here were created using a simplified approach of the procedures detailed in 40 CFR part 50 appendix R and as such cannot be directly compared to the Pb NAAQS for determination of compliance with the Pb NAAQS.

3.8.2 Intra-urban Variability

Maps of six areas (Los Angeles County, CA; Hillsborough/Pinellas Counties, FL; Cook County, IL; Jefferson County, MO; Cuyahoga County, OH; and Sullivan County, TN) are shown to illustrate the location of all Pb monitors meeting the inclusion criteria. Wind roses for each season are also provided to help put the source concentration data in context. Letters on the maps identify the individual monitor locations and correspond with the letters provided in the accompanying concentration box plots and pair-wise monitor comparison tables. The box plots for each monitor include the annual and seasonal concentration median and interquartile range with whiskers extending from the 5th to the 95th percentile. Data from 2008-2010 were used to generate the box plots, which are stratified by season as follows: 1 = winter (December-February), 2 = spring (March-May), 3 = summer (June-August), and 4 = fall (September-November). The comparison tables include the Pearson correlation coefficient (R), Spearman rank-ordered correlation coefficient (ρ), the 90th percentile of the absolute difference in concentrations (P90) in μg/m^3, the coefficient of divergence (*COD*) and the straight-line distance between monitor pairs (d) in km. The *COD* provides an indication of the variability across the monitoring sites within each county and is defined as follows:

$$COD_{jk} = \sqrt{\frac{1}{p}\sum_{i=1}^{p}\left(\frac{X_{ij} - X_{ik}}{X_{ij} + X_{ik}}\right)^2}$$

Equation 3A-1

where X_{ij} and X_{ik} represent the observed hourly concentrations for time period i at sites j and k, and p is the number of paired hourly observations. A *COD* of 0 indicates there are no differences between concentrations at paired sites (spatial homogeneity), while a *COD* approaching 1 indicates extreme spatial heterogeneity.

In certain cases, the information contained in these figures and tables should be used with some caution since many of the reported concentrations for the years 2008-2010 are near

or below the analysis method's stated method detection limit (MDL). The MDL is generally taken as 0.01 because it is the upper value of the range of MDLs reported for AA and Emissions Spectra ICAP methods, which were the two methods reported in the AQS to have been used for analysis of FRM samples (Rice, 2007). Generally, data are reported to the hundredth place, so this assumption is reasonable. The approximate percentage of data below the MDL (to the nearest 5%) is provided for each site along with box plots of seasonal Pb concentration at monitors within each urban area studied.

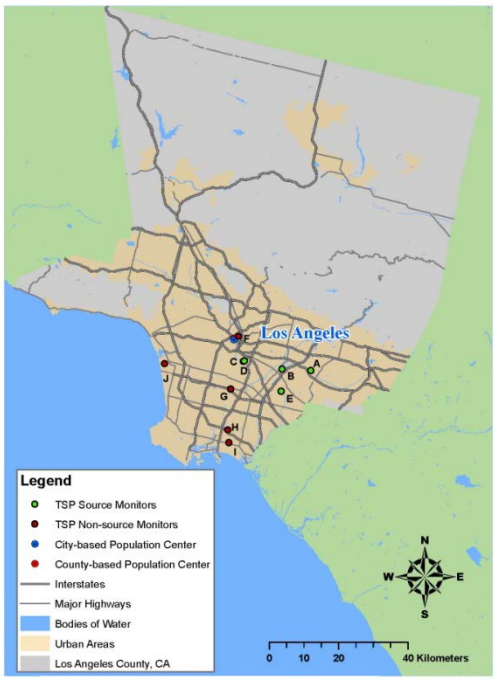
Figure 3-42 illustrates Pb monitor locations within Los Angeles County, CA. Ten monitors are located within Los Angeles County, five of which were source-oriented and the other five were non-source-oriented monitors. Monitor A was located immediately downwind of the Quemetco battery recycling facility in the City of Industry, CA. This source was estimated to produce 0.32 tons of Pb/yr (U.S. EPA, 2008c). Monitor C was sited in a street canyon just upwind of the Exide Pb recycling facility, which was estimated to produce 2.0 tons of Pb/yr (U.S. EPA, 2008c). Monitor D was situated slightly northwest of the same Pb recycling facility. It is still in relatively close proximity but not downwind on most occasions. Monitor B was located 12 km downwind of the Exide facility. Monitor E was located nearby the Trojan Battery recycling facility, which emitted 0.79 tons Pb/yr (U.S. EPA, 2008c). Location of the non-source-oriented monitors varied. Monitor F was positioned on a roof top 60 meters away from a 4-lane arterial road and 100 m from of a railroad. Monitor G was located on a rooftop approximately 20 m from an 8-lane arterial road, and monitor H was positioned at the curbside of a four-lane road roughly 650 m north of that road's junction with I-405. Monitor I was sited in a parking lot roughly 80 m from a four-lane road, and monitor J was located approximately 130 m south of a 4-lane highway. Figure 3-43 displays seasonal wind roses for Los Angeles County. In spring, summer, and fall, the predominant winds come from the west-southwest. During winter, wind direction varies with a portion from the west-southwest and the remainder from the east. The highest winds during winter come more frequently from the west-southwest.

The maps shown in Figure 3-42 for source-oriented monitors A-E illustrate the different conditions captured by the monitors; this informs analysis of the seasonal and year-round concentrations reported in Figure 3-44. The average annual concentration at monitor A was 0.074 $\mu g/m^3$. The 95th percentile exceeded the level of the NAAQS in the spring (0.16 $\mu g/m^3$) and summer (0.18 $\mu g/m^3$). Monitor C reported the highest concentrations in Los Angeles County, with a year-round mean of 0.68 $\mu g/m^3$. Given the position of this monitor with respect to the Exide facility, there is the potential for recirculation of fugitive Pb emissions in the air sampled by that monitor. The average annual Pb concentration at monitor D was 0.12 $\mu g/m^3$, and the 75th percentile of year-round data exceeded the level of the NAAQS; in spring, the 70th percentile exceeded 0.15 $\mu g/m^3$.

Monitor B reported the lowest values among the source-oriented monitors with an average annual concentration of 0.013 $\mu g/m^3$. Note that 75% of reported values were below the MDL for this site, and no data from this site exceeded the level of the NAAQS. The annual average concentration at monitor E was 0.068 $\mu g/m^3$, and the 95th percentile of concentration was 0.17 $\mu g/m^3$.

The non-source-oriented monitors located at sites F-J all recorded low concentrations, with average values ranging from 0.004 to 0.018 $\mu g/m^3$ (Figure 3-44). The highest average year-round concentrations were recorded at site F. The 95th percentiles at these sites ranged from 0.01 to 0.04 $\mu g/m^3$. There is much less certainty in the data recorded at the non-source-oriented sites, because 45-95% of the data from these monitors were below the MDL. Additionally, only one of the non-source-oriented monitors (monitor H) was positioned at roadside, and none of the non-source-oriented monitors were located at the side of a major highway.

Intersampler correlations (Table 3-25), illustrate that Pb has high intra-urban spatial variability. For the source-oriented monitors, the highest correlation ($R = 0.59$, $\rho = 0.57$) occurred for monitors C and D, which covered the same site. Because monitor D was slightly farther from the Exide source and slightly upstream of the predominant wind direction, the signal it received from the source site was correspondingly lower. Hence, the correlation between these sites was moderate despite their relatively close proximity. In general, low or even negative correlations were observed between the source-oriented and non-source-oriented monitors. The exception to this was the Spearman-ranked correlation between source-oriented monitor B and non-source-oriented monitor F, with $\rho = 0.74$. Pearson correlation was much lower for this pair ($R = 0.33$). Monitors B and F are roughly 16 km apart, whereas monitor B is only 12 km from monitors D and C, 8 km from monitor E, and 6 km from monitor A. It is possible that monitors B and F both captured a source that was either longer in range or more ubiquitous and so would have been obscured by the stronger source signals at sites A, C, D, and E. Comparisons between the non-source-oriented monitors revealed moderate correlation between sites (G to J [$R = 0.29$ to 0.71, $\rho = 0.37$ to 0.65]). Sites G, H, I and J are all located in the southwestern quadrant of Los Angeles. It is possible that they are also exposed to a ubiquitous source that produces a common signal at these four sites.



Note: Monitor locations are denoted by green markers, and source locations are denoted by red markers. Top: view of all Pb FRM monitors in Los Angeles County. Bottom left: Close up of the industrial site near monitors C and D. Bottom right: Close up of the populated area captured by monitor F.

Each comparison contains (in order): Pearson rank-order correlation (R), Spearman rank-order correlation (ρ), the difference between the 90th and 10th percentile data (P90), and the coefficient of divergence (*COD*).

Figure 3-45 illustrates Pb monitor locations within Hillsborough and Pinellas Counties in FL, which comprise the greater Tampa-St. Petersburg metropolitan area. Two source-oriented monitors (A and B) were located within Hillsborough County, and one non-source-oriented monitor (C) was located in Pinellas County. Monitor A was located 360 m north-northeast of the EnviroFocus Technologies battery recycling facility, which produced 1.3 tons/year (U.S. EPA, 2008d), and monitor B was located 320 m southwest of the same facility. Monitor C was located next to a two-lane road in Pinellas Park, FL.

Figure 3-46 displays seasonal wind roses for the Tampa-St. Petersburg metropolitan area. These wind roses suggest shifting wind directions throughout the winter, spring, and summer. During the winter, the highest winds came from the north and northeast with little influence from the west and southwest. During spring and summer, easterly and westerly winds were evident from the wind rose, with winds from the west being slightly higher in wind speed. During autumn, winds came predominantly from the northeast with little signal from the west or south.

Seasonal and year-round concentrations are reported for Hillsborough and Pinellas Counties in Figure 3-47. The average annual concentration at monitor A was 0.15 $\mu g/m^3$, and the 95th percentile was 0.70 $\mu g/m^3$. During winter, the 60th percentile of the data met the level of the NAAQS. At this site, the highest concentrations occurred during summer, which corresponded to the time when westerly winds were stronger. Concentration data at monitor B were much higher, with an annual average of 0.45 $\mu g/m^3$ and a 95th percentile of 1.9 $\mu g/m^3$. Annually, the 55th percentile exceeded the level of the NAAQS, and in autumn the 45th percentile exceeded the NAAQS. The highest concentrations occurred in autumn, coinciding with the time when winds blew from the northeast, when monitor B was most often downwind of the battery recycling facility. The non-source-oriented monitor C always reported concentrations of 0.0 $\mu g/m^3$. This is likely related to its location next to a quiet road in a small city.

Intersampler correlations, shown in Table 3-26, illustrate that Pb has high intra-urban spatial variability. The source-oriented monitors were anticorrelated ($R = -0.09$, $\rho = -0.08$). This was likely related to the fact that they were designated to monitor the same source and were downwind of the source at different times.

Figure 3-48 illustrates Pb monitor locations within Cook County, IL. Eight monitors were located within Cook County, four of which were designated by the Illinois Environmental Protection Agency (IEPA) in data reported to the AQS as source-oriented and the other four were non-source-oriented monitors. Monitor A was situated within 10 km of 6 sources ranging in emissions from 0.14 to 1.08 tons/year (U.S. EPA, 2008a). Monitor A was also sited in the median of I-90/I-94. Monitor B was located on the northern roadside of I-290 5 meters from the closest lane of traffic and was within 10 km of 2 Pb sources (0.41 and 1.08 tons/year) (U.S. EPA, 2008a). Monitor C was also located within 10 km of 6 sources in Cook County and Lake County, IN; the largest of those sources was 2.99 tons/year and was located 8 km southeast of monitor C (U.S. EPA, 2008a). Monitor C was placed on the roof of a high school. Monitor D was located roughly 60 m west of I-294 and adjacent to O'Hare International Airport. Monitor E was located on the rooftop of a building rented for government offices in Alsip, IL, a suburb south of Chicago. This location was roughly 1 km north of I-294 but not located on an arterial road; it was 9 km southeast of a 0.56 tons/year source (U.S. EPA, 2008a). Monitor F was sited in the parking lot of a water pumping station, 100 m north of I-90 and 300 m northwest of the junction between I-90 and I-94. This site was 2 km north-northwest of a 0.10 tons/year source (U.S. EPA, 2008a). Monitor G was situated atop an elementary school in a residential neighborhood on the south side of Chicago, roughly 100 m south of a rail line and over 300 m west of the closest arterial road. Although not designated as a source

monitor, monitor G was located 2 km southwest of facilities emitting 0.30 and 0.41 tons/year (U.S. EPA, 2008a). Monitor H was sited on the grounds of the Northbrook Water Plant. I-94 curves around this site and was approximately 700 m from the monitor to the east and around to the north. Figure 3-49 displays seasonal wind roses for Cook County. Wind patterns were quite variable during each season for this area. During the winter, winds mostly came from the west, with smaller contributions from the northwest, southwest, and south. In spring, measurable winds were omni-directional, with the highest winds coming from the south and northeast. Winds originated predominantly from the southwest and south during the summer, with measurable contributions from the northeast as well. In autumn, wind flow was predominantly from the south, but smaller contributions also came from the southwest, west, and northwest.

Figure 3-50 presents seasonal box plots of Pb concentration at the eight monitors located within Cook County. The maximum 95th percentile concentration on this plot was 0.14 $\mu g/m^3$, so the scale of this box plot makes the variability in these data appear wider than the data presented for Los Angeles County and Hillsborough/Pinellas Counties.

Monitor C was in closest proximity to the industrial steel facilities located in Lake County, IN. The average of concentrations measured at monitor C was 0.031 $\mu g/m^3$, with a median of 0.02 $\mu g/m^3$ and a maximum concentration of 0.31 $\mu g/m^3$. In winter, the 95th percentile of data was 0.14 $\mu g/m^3$. The higher values could potentially be attributed to transport of emissions; winds blow from the southeast roughly 10-15% of the time throughout the year. No other monitors in Cook County reported values above the level of the NAAQS.

Three “near-road” monitors, A, B, and D can be compared with the other monitors to consider the possibility of roadside resuspension of Pb dust from contemporaneous sources, as discussed in Section 3.2.2.5. It would be expected that resuspension would diminish with distance from the road. The 2 roadside monitors, A and B, reported average concentrations of 0.030 $\mu g/m^3$ and 0.024 $\mu g/m^3$, respectively. The median concentrations for monitors A and B were 0.02 $\mu g/m^3$. Fifteen percent of data were below the MDL for monitor A, and 25% were below the MDL for monitor B. Note that data obtained from monitor A may reflect industrial emissions as well. Monitor D was located roughly 60 m from the closest interstate and 570 m from the closest runway at O’Hare International Airport. The average concentration at this site was 0.012 $\mu g/m^3$, and 85% of data were below the MDL. Non-source monitors, E, F, G, and H had average concentrations of 0.011-0.017 $\mu g/m^3$. It is possible that the difference between Pb concentrations at monitors A and B and Pb concentrations at the other monitors was related to proximity to the roadway, although this cannot be stated with certainty without

source apportionment data to confirm or refute the influence of industrial plumes from Lake County, IN or local sources at each of the monitors.

Comparison among the monitor data demonstrates a high degree of spatial variability (Table 3-27). None of the source-oriented monitors were well correlated with each other. The highest correlation between source-oriented monitors occurred for monitors (A and B [$R = 0.32$, $\rho = 0.26$]). This might have reflected more substantial differences related to the additional influence of industrial sources nearby monitor A. Monitors (C and D) were uncorrelated with each other and with monitors (A and B), likely because their exposure to sources was substantially different. The source-oriented and non-source-oriented monitors were generally not well correlated. The highest Spearman correlation occurred between monitors D and H ($\rho = 0.53$), but Pearson correlation was much lower for this pair ($R = 0.19$). Both were located on the north side of Cook County, but monitor H was roughly 20 km northeast of monitor D. Winds blew from the southwest roughly 20-30% of the time throughout the year and from the northeast 20-25% of the time between the months of March and July, so the correlation may have been related to a common signal transported across both sites. Monitors B and F ($R = 0.52$, $\rho = 0.46$) were also moderately correlated. Monitor F is roughly 12 km northeast of monitor B, so the same common wind influence for monitors D and H may have also caused the moderate correlation between monitors (B and F). Monitor F was also moderately correlated with the other 3 non-source monitors ($R = 0.42$ to 0.54, $\rho = 0.36$ to 0.45), and the correlation between monitors (E and G) was moderate ($R = 0.65$, $\rho = 0.40$). The data from monitor H did not correlate well with those from monitors E and G. The non-source monitors were oriented from north to south over a distance of roughly 50 km in the following order: monitor H, monitor F, monitor G, and monitor E. The correlation pattern may have been related to distance between samplers. H was located in the suburb of Northbrook, monitors F and G were sited within the Chicago city limits, and monitor E was situated in a town near the south side of Chicago. Differences among land use may have been related to the lack of correlation of the monitor H data with those from monitors E and G. It is likely that data from monitor F was at times better correlated with monitors E and G and at other times with monitor H, since it had moderate correlation with all three other non-source monitors.

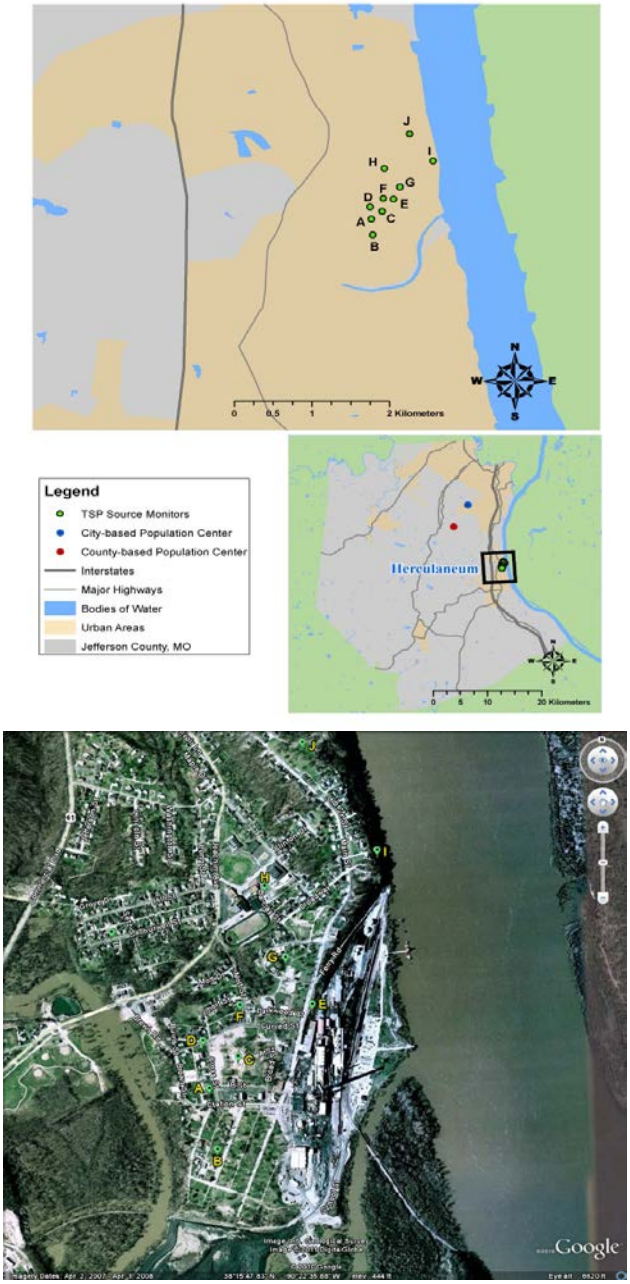
Figure 3-51 illustrates Pb monitor locations with Jefferson County, MO. Ten source-oriented monitors surrounded the Doe Run primary Pb smelter in Herculaneum, MO on

the west and northwestern sides. The largest distance between these monitors was approximately 1.5 km. Monitor E located on the Doe Run facility roughly 20 m west of the nearest building. Monitors A, B, C, D, F, G, and H were all located approximately 200 m west of the facility. Monitors D, E, and H were situated alongside service roads to the facility. Monitor I was sited 100 m north of the smelter, and monitor J was located approximately 600 m northwest of the facility. The Doe Run smelter was the only active primary smelter in the U.S. at the time of this review, and the facility was estimated to have emitted 41.1 tons Pb/yr (U.S. EPA, 2008f). Figure 3-52 displays seasonal wind roses for Jefferson County. During winter, predominant winds originated from the northwest, with a smaller fraction of calmer winds originating in the south-southeast. During the spring, the south-southeasterly winds became more prevalent with a measurable fraction of stronger winds still originating in the north-northwest. In the summer, winds were omni-directional and generally calmer. A slightly larger percentage came from the south compared with other wind directions. Autumn winds were most predominantly south-southeastern, with a smaller fraction from the west and northwest.

Figure 3-53 illustrates the seasonal distribution of concentrations at monitors A-J in Jefferson County. The annual average concentrations ranged from 0.18 to 1.36 $\mu g/m^3$ across the monitors. The maximum concentration was measured at monitor C to be 21.6 $\mu g/m^3$, which was 144 times higher than the level of the standard. For this monitor, the 25th percentile of the data was at the level of the standard. In general, median and 75th percentile concentrations were highest during the springtime and second highest during the fall. These seasons coincide with periods when the southeastern winds were stronger and more prevalent. Because the Doe Run facility had two 30-meter stacks (Bennett, 2007), it is possible that the emissions measured at the closer monitors were due to either fugitive emissions from the plant or, for the case where ground equipment or vehicles are operated nearby, that previously deposited emissions from the plant were resuspended.

Spatial variability among the monitors is lower than at many sites, because the monitors are relatively close together and are located on one side of the same source (Table 3-28). Correlations range substantially ($R = -0.03$ to 0.96, $\rho = -0.04$ to 0.96). High correlations ($R \geq 0.75$, $\rho \geq 0.75$) occurred for monitors (A and C), (A and D), (C and D), (D and F), (E and F), (G and H), and (I and J). Monitors (A and C), (A and D), (C and D), (D and F), (E and F), and (G and H) are all within 250 m of each other. For the highest correlation ($R = 0.96$, $\rho = 0.96$, [for monitors E and F]), monitor F is 250 m directly east of monitor E. Low correlation ($R \leq 0.25$, $\rho \leq 0.25$) generally occurred when monitors B, I, and J were compared with monitors A, C, D, E, F, G, and H. Monitors B, I, and J were on the outskirts of the measurement area and so were likely oriented such that the southeasterly

winds did not carry pollutants to these sites concurrently with the signal recorded by the other monitors.



Note: All monitors surround the Doe Run industrial facility. Top: Map view of all monitors in Jefferson County. Bottom: Satellite view of the monitors and the Doe Run facility.

Figure 3-54 illustrates Pb monitor locations with Cuyahoga County, OH. Five monitors are located within Cuyahoga County, three of which were designated by the Ohio EPA (OEPA) as source-oriented and the other two were non-source-oriented monitors. Monitors A, B, and C were all located within 1-10 km of six 0.1 tons/year source facilities and one 0.2 tons/year source (U.S. EPA, 2008g). Additionally, monitor B was located 30 m north of the Ferro Corporation headquarters. This facility was stated in the 2005 NEI to have no emissions, but it was thought by the OEPA to be the source of exceedances at this monitor (U.S. EPA, 2008g). Monitor A was sited roughly 300 m south of the Ferro Corporation facility. Monitor C was located 2.2 km west-northwest of the 0.5 tons/year Victory White Metal Co. facility. Monitor C was also roughly 250 m southeast of I-490. Monitors D and E were designated as non-source-oriented monitors, although monitor D was just 600 m further from the Victory White Metal facility than was monitor C. Monitor D was sited on a residential street located 50 m north of I-490. Monitor E was located on the rooftop of a building within 20 m of a four-lane arterial road. Figure 3-55 displays seasonal wind roses for Cuyahoga County. During winter, summer, and autumn, the predominant winds were from the southwest, with stronger winds recorded during the winter. In the spring, the strongest winds still emanated from the south-southwest, but measurable winds were also scattered from the northeast to the northwest.

Figure 3-56 illustrates the seasonal distribution of Pb concentration data at the five monitoring sites. The influence of southern winds, along with close proximity to a potentially-emitting facility, could have caused the elevated concentrations observed at monitor B (average: 0.10 $\mu g/m^3$). The 80th percentile of data was at the level of the NAAQS at this monitor, and during autumn the 60th percentile of data met the level of the NAAQS. The maximum concentration during fall and for the monitor year-round was 0.22 $\mu g/m^3$. Concentration data from all other monitors were below the level of the NAAQS. For monitor A, the average concentration was 0.025 $\mu g/m^3$, and the median reached 0.04 $\mu g/m^3$ during the summer. Maximum concentration at this monitor was 0.07 $\mu g/m^3$. Concentrations at monitor C averaged 0.017 $\mu g/m^3$, and those at monitors D

and E averaged 0.014 μg/m^3 and 0.013 μg/m^3, respectively. Maximum concentrations reached 0.04 μg/m^3 at all three monitors.

The level of spatial variability is illustrated by the intersampler correlations presented in Table 3-29. Monitors A and B appear to be anticorrelated (R = -0.06, ρ = -0.13). If the Ferro site was the dominant source in this area, then the anticorrelation was likely caused by the positioning of monitors A and B on opposite sides of that facility. At any given time, potential emissions from the Ferro plant may have affected monitors A and B at distinct times. Monitors C, D, and E correlated moderately to well with each other (R = 0.37 to 0.74, ρ = 0.67 to 0.77). Given that all 3 monitors are separated by roughly 2.8 km, it is possible that the relatively high correlations related to common sources, as suggested in the previous paragraph. Little correlation was observed between the source-oriented and non-source-oriented monitors.

Note: Top: view of all Pb FRM monitors in Cuyahoga County. Bottom left: Close up of industrial site around monitors A and B. Bottom right: Close up of monitor D north of I-490.

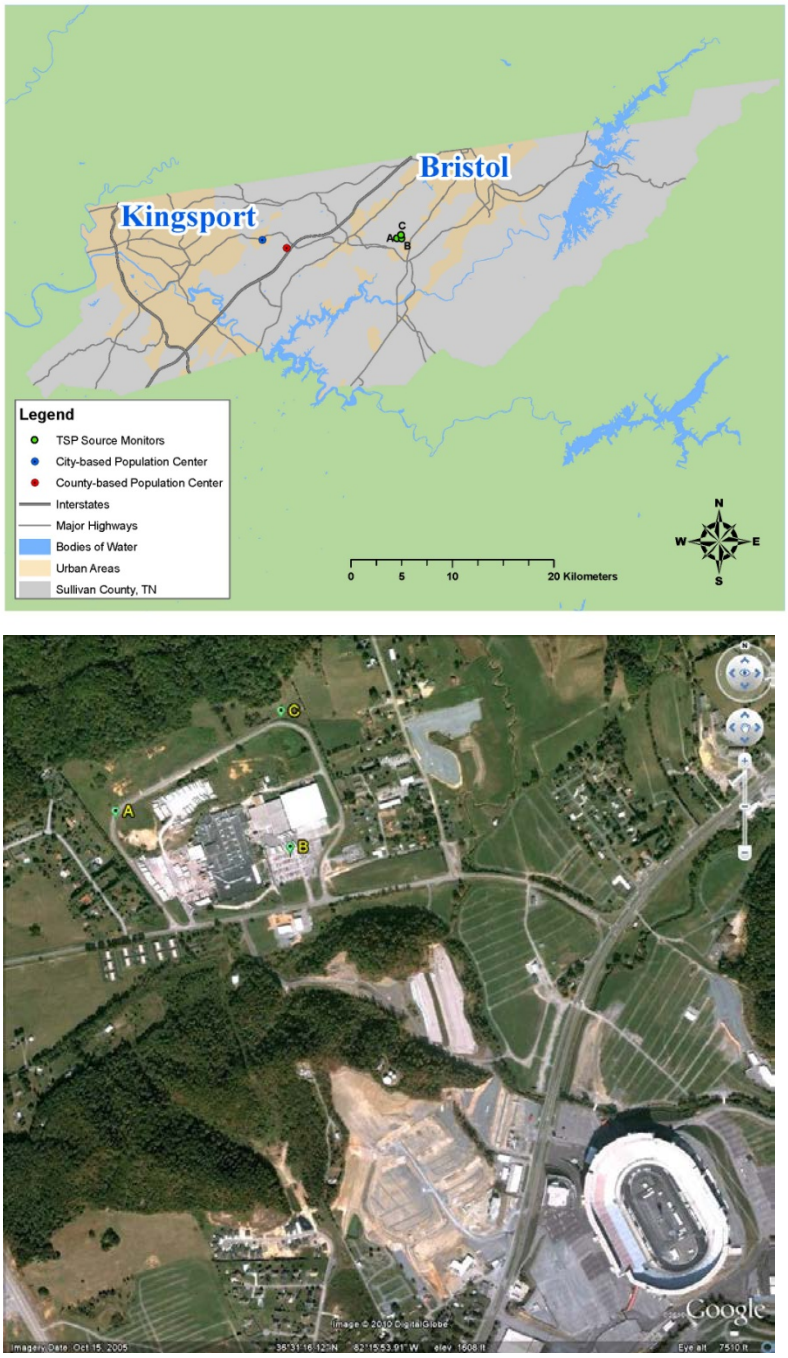
Figure 3-57 illustrates Pb monitor locations within Sullivan County, TN. Three source-oriented monitors were situated around an Exide Pb recycling facility emitting 0.78 tons/year (U.S. EPA, 2008h). Monitors A and C are positioned along the facility's service road and are approximately 100 m and 200 m away from the facility, respectively. Monitor A is directly next to the road, and monitor C is roughly 15 m from the road. Monitor B is located in the facility's parking lot roughly 50 m from the closest building. The facility and all three monitors are approximately 1.5 km northwest of the Bristol Motor Speedway and Dragway racetracks, which hosts a variety of auto races each year, including NASCAR, KART, and drag racing. Although the NASCAR circuit no longer uses tetraethyl Pb as an anti-knock agent in its fuel, some of the smaller racing circuits continue to do so. However, the speedway is rarely upwind of the monitoring sites and so likely had minimal influence on the reported concentrations. Figure 3-58 displays seasonal wind roses for Sullivan County. During winter and spring, the predominant

winds come from the southwest and west. In the summer, the percentage of wind coming from the west and southwest is roughly equal to that for wind coming from the east and northeast, although the easterly winds are calmer. During autumn, winds come predominantly from the northeast and east, although these winds tend to be calmer than those originating from the southwest and west.

The data presented in Figure 3-59 illustrates that concentrations above the level of the NAAQS occurred frequently at the monitors. The average concentrations at monitors A, B, and C were 0.11 $\mu g/m^3$, 0.051 $\mu g/m^3$, and 0.059 $\mu g/m^3$, respectively. Median concentrations were 0.08 $\mu g/m^3$, 0.03 $\mu g/m^3$, and 0.04 $\mu g/m^3$, respectively. The 75th percentile of year-round data at monitor A was at the level of the NAAQS, while the 95th percentile of data were below the NAAQS level for monitors B and C. The maxima at each monitor were 0.76 $\mu g/m^3$, 0.26 $\mu g/m^3$, and 0.43 $\mu g/m^3$ for monitors A, B, and C. It was surprising that the concentrations measured at monitor A tended to be higher because the predominant and stronger winds came from the southwest, so in many cases monitor A was upwind of the facility. It is possible that Pb that had either deposited or was stored in waste piles became readily resuspended by traffic-related turbulence and was measured at monitor A since that monitor was closest to the road. The slightly higher concentrations at monitor C compared with those from monitor C are consistent with the southwestern winds.

Not surprisingly, the correlations of monitor A with monitors B and C ($R = 0.06$ to 0.14, $\rho = -0.04$ to 0.13) were quite low (Table 3-30). The correlation between monitors B and C was moderate ($R = 0.31$, $\rho = 0.45$). It makes sense that the correlation for these monitors would be somewhat higher because they are both oriented to the east of the Pb recycling facility, although monitor C is to the northeast and monitor B to the east-southeast.



Note: Top: Map, bottom: Satellite image. Monitors A, B, and C surround the Exide Pb recycling facility. Just to the southeast is the Bristol motor speedway.

CHAPTER 4 EXPOSURE, TOXICOKINETICS, AND BIOMARKERS

4.1 Exposure Assessment

The purpose of this section is to present recent studies that provide insight about human exposure to Pb through various pathways. Pb is considered to be a multimedia contaminant with multiple pathways of exposure. The relative importance of various media in affecting Pb exposure changes with source strength and location, location and time activity of the exposed individuals, behavior of the exposed individuals, and risk factors such as age and socioeconomic factors (risk factors are discussed in detail in Chapter 6). Blood Pb and bone Pb biomarkers (discussed in Section 4.3, Section 4.4, Section 4.5, and Section 4.6), are often used to indicate composite Pb exposure resulting from multiple media and pathways of exposure.

The recent information provided here builds upon the conclusions of the 2006 Pb AQCD (2006b), which found that air Pb concentrations and blood Pb levels have decreased substantially following the restrictions on Pb in on-road vehicle gasoline, Pb in household paints, the use of Pb solder, and reductions in industrial Pb emissions that have occurred since the late 1970s. Nevertheless, detectable quantities of Pb have still been observed to be bioaccessible in various media types. It was reported in the 2006 Pb AQCD (U.S. EPA, 2006b) that airborne maximum quarterly Pb concentrations in the U.S. were in the range of 0.03-0.05 $\mu g/m^3$ for non-source-oriented monitors for the years 2000-2004 and were 0.10-0.22 $\mu g/m^3$ for source-oriented monitors during that time period, while blood Pb levels reached a median of 1.70 μg/dL among children (1-5 years of age) in 2001-2002. It was also observed that Pb exposures were associated with nearby industrial Pb sources, presence of Pb-based paint, and Pb deposited onto food in several of the studies described in the 2006 Pb AQCD.

4.1.1 Pathways for Lead Exposure

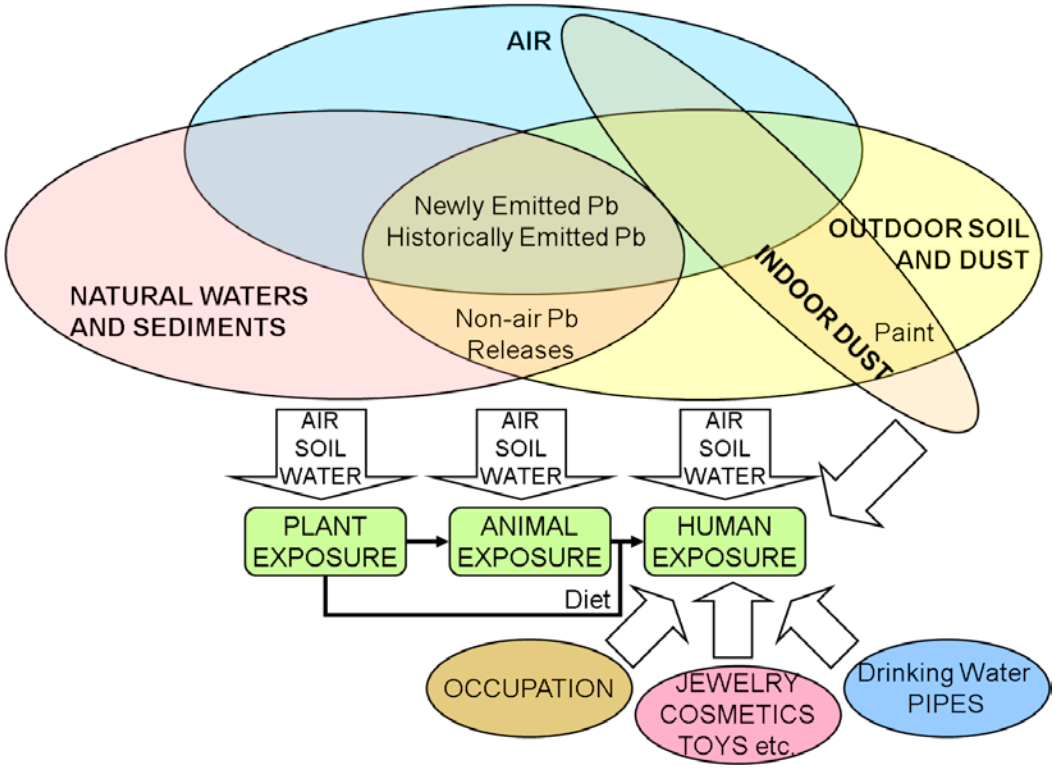
Pathways of Pb exposure are difficult to assess because Pb has multiple sources in the environment and passes through various environmental media. These issues are described in detail in Sections 3.2 and 3.3. Air-related pathways of Pb exposure are the focus of this ISA. Pb can be emitted to air, soil, or water and then cycle through any or all of these media. In addition to primary emission of particle-bound or gaseous Pb to the atmosphere, Pb can be resuspended to the air from soil or dust. Additionally, Pb-bearing PM can be deposited from the air to soil or water through wet and dry deposition. Air-

related Pb exposures also include inhalation and ingestion of Pb-contaminated food, water or other materials including dust and soil via hand-to-mouth contact. In general, air-related pathways include those pathways where Pb passes through ambient air on its path from a source to human exposure. Some non-air-related exposures of Pb include ingestion of indoor Pb paint, Pb in diet as a result of inadvertent additions during food processing, and Pb in drinking water attributable to Pb in distribution systems, as well as other generally less prevalent pathways.

Particle size of Pb-PM is relevant to transport through various media leading to exposure. The inhalability of airborne particles is a gradually decreasing function of particle size. Inhalability criteria established from experimental data obtained at wind speeds of 1-8 m/s describe PM inhalability of 77% for particles <10 μm (d_{ae}, aerodynamic diameter). Inhalability of particles ranging in size from 40 to 100 μm d_{ae} is 50%; above 100 μm, inhalability data are lacking (Soderholm, 1989; ACGIH, 1985). Of the particles that are not inhaled, their settling to surfaces makes them available for subsequent ingestion. The main pathway for Pb ingestion by children is by hand to mouth (Lanphear et al., 1998). In a playground environment in London, U.K., Duggan et al. (1985) reported that hand to mouth transfer was effectively limited to particles smaller than 10 μm, even when the soil itself exhibited a much larger particle size distribution. More recently, Yamamoto et al. (2006) reported for a cohort of children in Kanagawa Prefecture, Japan (greater Tokyo area) that the mode of size distributions of particles adhering to children's hands was 39 ± 26 μm, with the upper tail ranging from 200-300 μm. Differences in the size distribution results may be related to differences in the soil between the two locations and/or to differences between the analytical methods used to measure size distribution; Duggan and Inskip (1985) used optical microscopy of the dust wipes, while Yamamoto et al. (2006) used a laser scattering device measuring sampled particles suspended in an aqueous solution. Similar studies focusing on particle size distributions of ingestion of house dust are lacking. Ingestion of house dust has been reported to be the major source of lead intake during early childhood (Lanphear et al., 2002). If a similar particle size distribution holds for household dust, then ingestion of indoor Pb of atmospheric origin could also be strongly dependent on dust particle size. Therefore, larger particles of atmospheric origin, which may not be considered relevant for exposure by inhalation exposure, are still relevant for Pb exposure by ingestion. However, no studies in the literature have presented information on the relative contributions of Pb from different PM size fractions to blood Pb concentrations.

The complicated nature of Pb exposure is illustrated Figure 4-1, in which the Venn diagram depicts how Pb can cycle through multiple environmental media prior to human exposure. The "air/soil/water" arrows illustrate Pb exposures to plants, animals, and/or humans via contact with Pb-containing media. The exposures are air-related if the Pb

passed through the air compartment. When animals consume plant material exposed to Pb that has at some point passed through the air compartment, and when human diet includes animals and/or plants exposed to Pb that has passed through the air compartment, these are also considered air-related Pb exposures. As a result of the multitude of possible air-related exposure scenarios and the related difficulty of constructing Pb exposure histories, most studies of Pb exposure through air, water, and soil can be informative to this review. Figure 4-1 also illustrates other exposures, such as occupational exposures, contact with consumer goods in which Pb has been used, or ingestion of Pb in drinking water conveyed through Pb pipes. Most Pb biomarker studies do not indicate speciation or isotopic signature, and so exposures that are not related to Pb in ambient air are also reviewed in this section because they can contribute to Pb body burden. Many of the studies presented in the subsequent material focus on observations of Pb exposure via one medium: air, water, soil and dust, diet, or occupation.



Note: The Venn diagram is used to illustrate the passage of Pb through multiple environmental media compartments through which exposure can occur.

Figure 4-1 Conceptual model of multimedia Pb exposure.

The relative importance of different sources or pathways of potential exposure to Pb in the environment is often difficult to discern. Individual factors such as home

environment, location, and risk factors (described in more detail in Chapter 6) may influence exposures. The National Human Exposure Assessment Survey (NHEXAS) study sampled Pb, as well as other pollutants and VOCs, in multiple exposure media from subjects across six states in EPA Region 5 (Illinois, Indiana, Michigan, Minnesota, Ohio, and Wisconsin) (Clayton et al., 1999) as well as in Arizona (O'Rourke et al., 1999) and Maryland (Egeghy et al., 2005). Results from NHEXAS indicate that personal exposure concentrations of Pb are higher than indoor or outdoor concentrations of Pb (Table 4-1). Pb levels in windowsill dust were higher than Pb levels in surface dust collected from other surfaces. Clayton et al. (1999) suggested that higher windowsill levels could be attributed to the presence of Pb-based paint and/or to accumulation of infiltrated outdoor Pb-bearing PM. Pb levels in food were higher than in beverages, and Pb levels in standing tap water (also referred to as “first flush” or “first draw”) were higher than Pb levels obtained after allowing water to run for three minutes to flush out pipes.

Table 4-1 Estimates of Pb measurements for EPA Region 5 from the NHEXAS study

Medium[a]	N	Percentage measurable[b] (CLs)[c]	Mean (CLs)[c]	50th (CLs)[c]	90th (CLs)[c]
Personal air (ng/m^3)[d]	167	81.6 (71.3; 92.0)	26.83 (17.60; 36.06)	13.01 (11.13; 18.13)	57.20 (31.18; 85.10)
Indoor air (ng/m^3)[d]	213	49.8 (37.2; 62.3)	14.37 (8.76; 19.98)	6.61 (4.99; 8.15)	18.50 (12.69; 30.31)
Outdoor air (ng/m^3)[d]	87	73.8 (56.3; 91.3)	11.32 (8.16; 14.47)	8.50 (7.14; 10.35)	20.36 (12.60; 34.91)
Surface dust (ng/cm^2)	245	92.1 (87.4; 96.8)	514.43 (-336.6; 1365.5)	5.96 (3.37; 10.94)	84.23 (26.52; 442.63)
Surface dust (mg/kg)	244	92.1 (87.4; 96.8)	463.09 (188.15; 738.04)	120.12 (83.85; 160.59)	698.92 (411.84; 1,062.8)
Window sill dust (ng/cm^2)	239	95.8 (92.5; 99.0)	1,822.6 (481.49; 3,163.6)	16.76 (10.44; 39.41)	439.73 (106.34; 4,436.2)
Window sill dust (mg/kg)	239	95.8 (92.5; 99.0)	954.07 (506.70; 1,401.4)	191.43 (140.48; 256.65)	1,842.8 (1,151.3; 2,782.5)
Standing tap water (µg/L)	444	98.8 (97.6; 100.0)	3.92 (3.06; 4.79)	1.92 (1.49; 2.74)	9.34 (7.87; 12.35)
Flushed tap water (µg/L)	443	78.7 (70.7; 86.7)	0.84 (0.60; 1.07)	0.33 (0.23; 0.49)	1.85 (1.21; 3.04)
Solid food (µg/kg)	159	100.0 (100.0; 100.0)	10.47 (6.87; 14.07)	6.88 (6.44; 8.04)	14.88 (10.78; 19.08)
Beverages (µg/kg)	160	91.5 (85.2; 97.8)	1.42 (1.13; 1.72)	0.99 (0.84; 1.21)	2.47 (2.06; 3.59)
Food+Beverages (µg/kg)	156	100.0 (100.0; 100.0)	4.48 (2.94; 6.02)	3.10 (2.66; 3.52)	6.37 (4.89; 8.00)
Food intake (µg/day)	159	100.0 (100.0; 100.0)	7.96 (4.25; 11.68)	4.56 (3.68; 5.36)	12.61 (9.27; 16.38)
Beverage intake (µg/day)	160	91.5 (85.2; 97.8)	2.15 (1.66; 2.64)	1.41 (1.18; 1.60)	4.45 (3.15; 5.65)
Food+Beverage intake (µg/day)	156	100.0 (100.0; 100.0)	10.20 (6.52; 13.89)	6.40 (5.21; 7.78)	16.05 (13.31; 18.85)
Blood (µg/dL)	165	94.2 (88.2; 100.0)	2.18 (1.78; 2.58)	1.61 (1.41; 2.17)	4.05 (3.24; 5.18)

Note: EPA Region 5 includes six states: Illinois, Indiana, Ohio, Michigan, Minnesota, and Wisconsin. Participants were enrolled using a stratified, four-stage probability sampling design, and submitted questionnaire and physical measurements data. Summary statistics (percentage measurable, mean, median, 90th percentile) were computed using weighted sample data analysis. The estimates apply to the larger Region 5 target population (all non-institutionalized residents residing in households).

[a]Estimates for indoor air, outdoor air, dust media, and water media apply to the target population of Region 5 households; estimates for other media apply to the target population of Region 5 residents.

[b]Percentage measurable is the percentage of the target population of residents (or households) estimated to have Pb levels above limit of detection (LOD).

[c]The lower and upper bounds of the 95% confidence limits (CL) are provided.

[d]PM_{50}.

Several studies have used a combination of measured values and default model values to represent exposures and determine their relative contributions to blood Pb. Cornelis et al. (2006) used the Integrated Exposure Uptake Biokinetic model (IEUBK), described in detail in the 2006 Pb AQCD (U.S. EPA, 2006b) to model children's exposures to Pb emissions from a non-ferrous smelter in Hoboken, Belgium. They point out that ambient air Pb concentrations decrease with distance from the smelter while IEUBK is fairly insensitive to changes in ambient air concentration. They input the average ambient air Pb concentration of 0.81µg/m3 and assumed that the indoor air Pb concentration was 30% of the outdoor Pb. In the absence of indoor air Pb samples, the default assumption was adopted for the Cornelis et al. (2006) study. Similarly, Carrizales et al. (2006) analyzed exposures to children living near a copper smelter in San Luis Potosi, Mexico. They employed the IEUBK default options for assignment of Pb dust concentration as

70% of the soil Pb concentration, while air Pb concentration was assigned based on measurements by the Mexican government. Based on these assumptions, they attributed 87% of blood Pb to soil and dust exposure. Input soil and dust Pb levels were obtained from an average of 28 sites. Using defaults for all IEUBK values, the soil/dust Pb ingestion pathway has been predicted to contribute 63-75% (depending of a child's age) of blood Pb, whereas the air Pb inhalation pathway contributed <1% (SRC, 2007). This analysis did not specifically estimated the portion of the soil/dust Pb ingestion pathway that derives from air Pb, such as recently airborne Pb deposited to soil and dust which remains available for inhalation and ingestion. In the 1986 Pb AQCD, blood Pb-air Pb slopes were examined that included both direct (inhalation) and indirect (via soil, dust, etc.) air Pb contributions, resulting in the conclusion that slopes for the total air Pb contribution were roughly twice that of the slope due to inhaled air Pb alone. This "recent air" Pb was described in the 2007 Pb Risk Assessment (U.S. EPA, 2007f) to include those pathways involving Pb that is or has recently been in the outdoor ambient air, including inhalation and ingestion of indoor dust Pb derived from recent ambient air (e.g., air Pb that has penetrated into the residence recently and loaded indoor dust). Beyond the direct inhalation pathway (outdoor and indoor ambient air Pb), Appendix I of the 2007 Pb Risk Assessment (U.S. EPA, 2007f) provides estimates of the contribution of various other pathways (e.g., diet, drinking water, outdoor soil ingestion) as well as those involving recent air Pb to blood Pb. Estimates of recent air Pb contributions were highly dependent on the exposure scenario evaluated. For the General Urban Case Study in that assessment, "current conditions" at the time of the risk assessment (0.14 µg/m3, mean of maximum quarterly average concentration of Pb in TSP) were modeled as remaining constant throughout the 7 years of the exposure modeled in the biokinetic model. A median concurrent blood Pb concentration of 1.8-2.8 µg/dL (depending on the exposure and risk model) was estimated as the average of the results at 75 and 81 months of age. The recent air Pb ingestion pathways contributed a median of 12-28% (depending on the exposure model) to blood Pb beyond the 0.5-0.6% attributable to inhalation of recent airborne Pb. In simulations for the 95th percentile of current conditions (0.87 µg/m3, 95th percentile of maximum quarterly average concentration of Pb in TSP), median children's blood Pb increased to 2.0-3.1 µg/dL and the contribution of recent air Pb ingestion pathways increased to 22-37% of blood Pb. Results of other exposure scenarios for which greater or lesser contributions of recent air Pb to blood Pb were predicted are available in Appendix I of the 2007 Pb Risk Assessment (U.S. EPA, 2007f).

4.1.2 Environmental Exposure Assessment Methodologies

A number of monitoring and modeling techniques have been employed for exposure assessment. These are detailed in either the 2006 Pb AQCD (U.S. EPA, 2006b) or in the subsequent Risk and Exposure Assessment performed as part of the same NAAQS review (U.S. EPA, 2007g). Some of these methods are briefly described here to provide a context for the exposure studies described in Section 4.1.3. Blood Pb sampling is described in detail in Section 4.3.2.

Data collection to assess Pb exposure pathways may involve air, soil, and dust samples. Methods used for digesting air Pb samples are described in Section 3.4, as are ambient air Pb monitoring techniques. Factors affecting collection of ambient air Pb samples are described in detail in Section 3.4. For the monitors in the FRM network, the primary role is compliance assessment. Accordingly, this network includes monitors in locations near sources of air Pb emissions which are expected to or have been shown to contribute to ambient air Pb concentrations in excess of the Pb NAAQS. In such locations, Pb may be associated with relatively larger size particles, contributing to air Pb concentration gradients with distance from the source and greater deposition in the near-source locations. The FRM network also includes non-source-oriented monitors for which the main objective is to gather information on neighborhood-scale lead concentrations that are typical in urban areas so to better understand ambient air-related Pb exposures for populations in these areas. This part of the Pb NAAQS network, is required to be operational as of December 27, 2011. These monitor locations are distributed across a broad geographic area, representing approximately 63 large urban areas which contain approximately half of the total U.S. population (based on recently published 2010 Census Bureau data). In lieu of more detailed analysis of population proximity for these newly established monitors, population counts were calculated near previously existing monitors for which data are presented in Section 3.5. For the monitors in that limited dataset, among the total population of 311,127,619 people in the 2010 Census (ESRI, 2011), 181,100 (0.06%) lived within 1 km of a source-oriented monitor, while 918,351 (0.30%) lived within 1 km of a non-source-oriented monitor.

Dust sampling has not changed drastically since it was first proposed by Sayre et al. (1974), in which a disposable paper towel was soaked in 20% denatured alcohol and 1:750 benzalkonium chloride and then used to wipe a 1 ft^2 sampling area in a systematic fashion. Que Hee et al. (1985) and Sterling et al. (1999) compared wipe testing with vacuum methods. Sampling efficiency for the first attempt varied between 53-76% with vacuum pump flow rate and tube type and was 52% for the wipe method for the Que Hee et al. (1985) study, with 100% efficiency after five consecutive samples were obtained. Sterling et al. (1999) observed that two of three vacuuming methods had significantly

higher geometric mean collection (vacuum 1: 94.3 µg/ft^2; vacuum 2: 23.5 µg/ft^2) compared with dust wipes (5.6 µg/ft^2).

Models may also be used in exposure assessment. For example, two dispersion models, the American Meteorological Society/Environmental Protection Agency Regulatory Model (AERMOD), and Industrial Source Complex-Plume Rise Model Enhancements (ISC-PRIME) were employed to model dispersion of Pb emissions from specific industrial facilities (Cimorelli et al., 2005; Perry et al., 2005; EPRI, 1997), and to estimate ambient air Pb concentrations at some of the case studies included in the 2007 Risk and Exposure Assessment (U.S. EPA, 2007g). These models assume plume dispersion follows a Gaussian distribution from a point source. For the two point source case studies included in the 2007 risk assessment, the plume models were used to track emissions to ambient air near homes located within a few miles of emitting facilities. However, dispersion models can also be used to track long distance transport of Pb emissions, as performed by Krell and Roeckner (1988) to model the dispersion and deposition of Pb and Cd from European nations into the North Sea.

Several models estimate blood Pb levels resulting from estimated exposure to Pb in environmental media. These models, which are described in detail in the 2006 Pb AQCD (U.S. EPA, 2006b) include the IEUBK model, and the EPA All Ages Lead Model (AALM), which combines and expands the thorough exposure and absorption modules of the IEUBK model with the comprehensive biokinetic model of Leggett (1993).

The Stochastic Human Exposure and Dose (SHEDS) and NORMTOX models also are capable of modeling metals exposures through various routes including inhalation, ingestion, and dermal exposure (Loos et al., 2010; Burke et al., 2002). Pb exposure modeling can also be accomplished using the Modeling Environment for Total Risk (MENTOR) framework, in which airborne Pb levels could be modeled using AQS, dispersion modeling, or chemical transport modeling, while human exposure is modeled with SHEDS or a similar exposure model (Georgopoulos and Lioy, 2006). Additionally, housing data and time-activity data from the Consolidated Human Activity Database (CHAD) are incorporated into MENTOR to develop refined estimates of Pb exposure and tissue burden. However, a literature search did not produce any Pb exposure studies using the SHEDS, NORMTOX, or MENTOR modeling systems. In general, these models take input for several environmental Pb exposure media including soil, dust, food and water, outdoor air, and indoor air. The models are designed to evaluate different exposure scenarios based on specification of particular conditions.

4.1.3 Exposure Studies

4.1.3.1 Airborne Lead Exposure

Limited personal exposure monitoring data for airborne Pb were available for the 2006 Pb AQCD (U.S. EPA, 2006b). As described above, the NHEXAS study showed personal air Pb concentrations to be significantly higher than indoor or outdoor air Pb concentrations (Clayton et al., 1999). Indoor air Pb concentration was moderately correlated with floor dust and residential yard soil Pb concentration (Rabinowitz et al., 1985). Egeghy et al. (2005) performed multivariate fixed effects analysis of the NHEXAS-Maryland data and found that Pb levels measured in indoor air were significantly associated with log-transformed outdoor air Pb levels, ambient temperature, number of hours in which windows were open, homes built before 1950, and frequency of fireplace usage (Table 4-2).

Table 4-2 Estimates of fixed effects multivariate modeling of Pb levels measured during the NHEXAS-MD study

	Pb in Indoor Air		Pb in Dust		Dermal Pb		Blood Pb	
Fixed Effect	**β[a]**	**p-value**	**β[a]**	**p-value**	**β[a]**	**p-value**	**β[a]**	**p-value**
Intercept	-0.50	0.0051	6.22	<0.0001	6.23	<0.0001	0.02	0.91
Outdoor Pb concentration[b]	0.51	<0.0001

Some recent studies have measured personal exposure to particle-bound Pb along with other trace metals. Adgate et al. (2007) measured the concentrations of several trace elements in personal, indoor, and outdoor air samples of $PM_{2.5}$ and found that average personal Pb-$PM_{2.5}$ concentration was roughly three times higher than outdoor air Pb-$PM_{2.5}$ concentration and two times higher than indoor Pb-$PM_{2.5}$ concentration (Table 4-3). Another study of indoor and outdoor air concentrations of Pb was carried out by Molnar et al. (2007). $PM_{2.5}$ trace element concentrations were determined in homes, preschools and schools in Stockholm, Sweden. In all sampled locations, Pb-$PM_{2.5}$ concentrations were higher in the outdoor environment than in the proximal indoor environment. The indoor/outdoor ratios for Pb-$PM_{2.5}$ suggest an outdoor Pb-$PM_{2.5}$ net

infiltration of ~0.6 for these buildings. Outdoor air Pb concentrations did not differ between the central and more rural locations. Indoor air Pb concentrations were higher in spring than in winter, which the authors attributed to greater resuspension of elements that had accumulated in road dust over the winter period and increased roadwear on days with dry surfaces. Pekey et al. (2010) measured indoor and outdoor trace element composition of $PM_{2.5}$ and PM_{10} in Kocaeli, an industrial region of Turkey, and found that average airborne Pb concentrations were higher outdoors than indoors for both $PM_{2.5}$ and PM_{10} during summer and for PM_{10} during winter, but that indoor Pb concentration was higher than outdoor Pb concentration for $PM_{2.5}$ during winter. The indoor-to-outdoor ratio of airborne Pb varied by environment; it tended to be less than one, but the ratio varied from one microenvironment to another. In a pilot study in Windsor, Ontario, Rasmussen et al. (2007) observed that the concentration of Pb in $PM_{2.5}$ from a personal exposure sample was roughly 40% higher than the concentration of Pb in outdoor $PM_{2.5}$ and 150% higher than Pb in indoor $PM_{2.5}$. The three studies that included personal samples recorded measurements that were consistently higher than indoor or outdoor levels.

Domestic wood burning is a potential source of Pb compounds (Section 3.2.2.5). Molnar et al. (2005) measured trace element concentration in indoor and personal exposure $PM_{2.5}$ samples for homes in which wood is burned and in a reference group where no wood burning occurs in the home. For both indoor and personal samples, Molnar et al. (2005) observed that Pb concentrations were higher for the wood burning group, but that the differences were not significant (indoor concentration: 6.0 $\mu g/m^3$ vs. 4.3 $\mu g/m^3$, $p = 0.26$; personal exposure: 4.6 $\mu g/m^3$ vs. 3.0 $\mu g/m^3$, $p = 0.06$).

Indoor activity has been associated with resuspension of settled dust, which could cause airborne contact with particle-bound Pb. Qian et al. (2008) estimated a PM_{10} resuspension rate of 1.4×10^{-4} hr^{-1} for one person walking across a carpeted floor. Measurements of submicron particles illustrated a roughly two-fold increase of airborne particle concentration for particles smaller than 1.8 µm for activity vs. low activity periods, with maximum concentrations reaching 4-11 times the maximum value during low activity periods. For PM_{10}, average concentration was 2.5 times higher than background levels during activity periods, while peak concentration was 4.5 times higher. Qian and Ferro (2008) observed that resuspension rates depend on particle size, floor material, and ventilation position. Increases in walking speed and weight of the walker did not consistently produce increases in resuspension. 5-10 µm particles produced a higher resuspension rate compared with smaller particles. Newly carpeted areas produced significantly higher resuspension rates than vinyl floors. Zhang et al. (2008) modeled and conducted experiments of particle dispersion from walking and observed that human activity did affect resuspension. They found that larger particles were more readily

detached from the carpet by walking motion, but that smaller particles are more easily resuspended once detached. Hunt and Johnson (In Press) studied the duration and spatial extent of resuspension of 0.3-5.0 µm particles following walking by a soiled shoe. 0.3-0.5 µm particle concentration remained increased over a time period of 23 min, while 1-5 µm particles declined in concentration over the same time period. Experiments and computational fluid dynamics simulations by Eisner et al. (2010) for a mechanical foot moving on carpeting suggested that the rotating motion of the moving foot on the carpet induced rotating air movement beneath the foot that re-entrained the particles. If Pb adsorption onto particles varies with sources, size selectivity of resuspension processes could lead to enhanced Pb exposure from one source relative to another.

Several of the studies can be used to develop an understanding of how personal exposure to PM-bound Pb varies with other exposures. Molnar et al. (2007) reported Spearman correlations of Pb with $PM_{2.5}$ and NO_2 in three outdoor microenvironments (residence, school, and preschool) and found that Pb and other trace metals were generally well correlated with $PM_{2.5}$ (r = 0.72-0.85), but Pb was not always well-correlated with NO_2 (r = 0.24-0.75). In the case where Pb and NO_2 were well-correlated, it is possible that the Pb was traffic related from resuspended pulverized wheel weights or impurities in unleaded on-road gasoline. For the other two sites where the correlation between Pb and NO_2 was low, it is possible that they were less affected by traffic. Table 3-26 in the Appendix to Chapter 3 illustrates that Pb concentrations in the four studies summarized there are typically well below the level of the NAAQS. The higher personal air concentratoins occurred in a heavily industrialized area of Kocaeli, Turkey with an incinerator and several industrial facilities including metal processing, cement, petroleum refining, agriculture processing. Otherwise, concentrations were all between 0.002 and 0.006 µg/m^3. The proportion of Pb compared with other trace metals varied with location and component. It was typically several times lower than S as well as crustal elements such as Ca and Fe. In the industrial area of Kocaeli, Pb comprised a greater proportion of the PM compared with other areas.

Table 4-3 Comparison of personal, indoor, and outdoor Pb-PM measurements from several studies

4.1.3.2 Exposure to Lead in Soil and Dust

The 2006 Pb AQCD (U.S. EPA, 2006b) lists indoor Pb dust infiltrated from outdoors as a potential source of exposure to Pb soil and dust. Thus, outdoor soil Pb may present an inhalation exposure if resuspended indoors or an ingestion exposure during hand-to-mouth contact. A detailed description of studies of outdoor soil Pb concentration is provided in Section 3.6.1. Indoor measurements can reflect infiltrated Pb as well as Pb dust derived from debrided paint, consumer products, or soil that has been transported into the home via foot traffic. Table 4-4 presents indoor dust Pb concentrations for 2006-2011 observational studies in which indoor dust Pb was measured.

Table 4-4 Measurements of indoor dust Pb concentration from 2006-2011 studies

Reference	Study Location	Metric (units)	Sample Site	Indoor Pb Concentration
Caravanos et al. (2006a)	New York City, New York	Weekly dust loading ($\mu g/m^2$)	Glass plate next to open window of academic building	Median: 52
Khoder et al. (2010)	Giza, Egypt (extensive leaded gasoline use; industrial area)	Weekly dust loading ($\mu g/m^2$)	Glass plate in second-floor living room of apartments	Median: 408
Brattin and Griffin (2011)	Eureka, Utah near Eureka Mills Superfund Site	Dust concentration (mg/kg)	Indoor home site (not specified)	160-2000
	Denver, CO, near VBI70 Superfund Site		Indoor home site (not specified)	11-660
	East Helena, MT, near East Helena Superfund Site		Indoor home site (not specified)	68-1000
Yu et al. (2006)	Syracuse, New York	Dust concentration range (mg/kg)	Floor	Range: 209-1770
Turner and Simmonds (2006)	Birmingham, Plymouth, and 2 rural sites, UK	Dust concentration (mg/kg)	Floor	Median: 178
Gaitens et al. (2009)	U.S. (nationwide)	Dust loading ($\mu g/m^2$)	Smooth floor	Median: 1.7 Avg.: 4.4
			Rough floor	Median: 5.6 Avg.: 16
			Smooth windowsill	Median: 2.5 Avg.: 190
			Rough windowsill	Median: 55 Avg.: 480
Wilson et al. (2007)	Milwaukee, Wisconsin	Dust concentration ($\mu g/m^2$)	Central perimeter	Avg.: 107
			Entry	Avg.: 140
			Window	Avg.: 151
Zota et al. (2011)	Ottawa County, Oklahoma (area surrounding the Tar Creek Superfund Site)	Dust concentration (mg/kg)	Indoor (site not specified)	Avg.: 109 Median: 63 Max.: 881
Spalinger et al. (2007)	Rural towns, Idaho	Dust concentration (mg/kg)	Vacuum	Median: 120 Max: 830
			Floor	Median: 95 Max: 1,300
	Bunker Hill, Idaho Superfund site	Dust concentration (mg/kg)	Vacuum	Median: 470 Max: 2,000
			Floor	Median: 290 Max: 4,600

Several studies suggested the infiltration of Pb dust into buildings. For example, Caravanos et al. (2006a) collected dust on glass plates at an interior location near an open window, a sheltered exterior location, and an open exterior location for a two-year period in Manhattan, NY. Median weekly dust loading was reported to be 52 $\mu g/m^2$ for the indoor site, 153 $\mu g/m^2$ for the unsheltered outdoor site, and 347 $\mu g/m^2$ for the sheltered outdoor site. This paper demonstrated the likely role of outdoor Pb in influencing indoor dust Pb loading and indicated that under quiescent conditions (e.g., no cleaning) near an

open second-story window, the indoor dust Pb level might exceed EPA's hazard level for interior floor dust of 430 µg/m^2 (40 µg/ft^2). Khoder et al. (2010) used the same methodology to study Pb dust deposition in residential households in the town of Giza, Egypt, located between two industrial areas and where leaded gasoline is still in use; the investigators reported a median weekly deposition rate of 408 µg/m^2 and an exterior median deposition rate of 2,600 µg/m^2. In the latter study, Pb deposition rate correlated with total dust deposition rate (R=0.92), Cd deposition rate (R=0.95), and Ni deposition rate (R=0.90). Statistically significant differences in Pb deposition rates were observed between old and new homes ($p < 0.01$) in the Khoder et al. (2010) study, although the only quantitative information provided regarding home age stated that the oldest home was 22 years old when the study was performed in 2007. Khoder et al. (2010) found no statistically significant difference between Pb loadings when segregating the data by proximity to roadways. Recently, Brattin and Griffin (2011) performed linear regressions of dust Pb on soil Pb based on data collected previously for outdoor soil Pb and indoor dust Pb near mining and/or smelting Superfund sites in Utah, Colorado, and Montana (U.S. EPA, 2005f, 2002a, 2001). They observed that the dust Pb concentration was 4-35% of outdoor soil Pb. Excluding outliers on the regression, dust Pb concentration ranged from 160-2,000 mg/kg, 11-660 mg/kg, and 68-1,000 mg/kg at three sites.

Correlations between indoor and outdoor Pb content in dust can be partially explained with speciation. Beauchemin et al. (2011) used XANES to speciate in-home paint samples to assess the contributions of indoor paint and outdoor material to indoor dust Pb concentrations. In indoor dust samples of particles <150 µm in size, Pb oxide, Pb sulfate, and Pb carbonate were measured. These materials commonly were used in white paint. In the size fraction of particles <36 µm, half of the measured Pb was associated with Fe-oxyhydroxides such as ferrihydrite and goethite and presumably adsorbed onto these species. This finding suggested that a mix of indoor and outdoor sources may affect the composition of dust in this size fraction.

Residual Pb dust contamination following cleaning activities has been documented. For instance, Hunt et al. (2008) performed tests where a test soil prepared by drying, grinding, and sieving Pb-contaminated yard soil samples from Herculaneum, MO was tracked onto a tile test surface and then repeatedly cleaned with a moistened wipe and/or vacuumed until visual inspection of the tiles uncovered no surface discoloration. The authors then used wet wipe samples to collect residual soil and estimate Pb deposition and concentration. After the first walk, tile Pb dust loading was 2,670 µg/m^2; after the first vacuuming, it decreased to 398 µg/m^2. After multiple walks, tile Pb dust loading was 7,100 µg/m^2, and it decreased to 1,400 µg/m^2 after multiple vacuuming. Scanning electron microscopy (SEM) of the wipe samples revealed that most of the residual dust particles were in the range of 1-3 µm in area equivalent diameter. This result indicates

that Pb-bearing fine particles are not completely captured by home cleaning. Yu et al. (2006) analyzed dust samples from 50 homes in northern New Jersey (typically of older housing stock, although the study does not specify housing age). The investigators obtained dust from vacuuming carpet samples and found that total Pb concentration in carpet ranged from 209 to 1,770 mg/kg dust.

Pb dust on floors, windowsills, and other accessible surfaces are potential exposure sources to small children who use touch to explore their environments. Gaitens et al. (2009) used National Health and Nutrition Examination Survey (NHANES) data from 1999 through 2004 to examine Pb in dust in homes of children ages 12-60 months. The median value of Pb dust loading on floors was reported to be 1.7 $\mu g/m^2$ (mean: 4.4 $\mu g/m^2$), with floors that were not smooth and cleanable having a median Pb dust loading value of 5.6 $\mu g/m^2$ (mean: 16 $\mu g/m^2$). Floor Pb dust loading value was modeled against several survey covariates and was significantly associated ($p < 0.05$) with floor surface condition, windowsill Pb dust loading, race and ethnicity, poverty-to-income ratio, year of home construction, presence of smokers in the home, and year of survey. It was nearly significantly associated ($p = 0.056$) with renovations made to pre-1950 homes. Median Pb dust loading on smooth windowsills was 25 $\mu g/m^2$ (mean: 190 $\mu g/m^2$). When windowsills were not smooth, the median Pb dust loading was 55 $\mu g/m^2$ (mean: 480 $\mu g/m^2$). Windowsill Pb dust level was also significantly associated ($p < 0.05$) with race and ethnicity, year of home construction, window surface condition, presence of smokers in the home, deterioration of indoor paint, and year of survey. Sill surface was nearly significantly associated ($p = 0.076$) with deterioration of outdoor paint when homes were built prior to 1950. Dust Pb loading was found by Egeghy et al. (2005) to be significantly associated with the log-transform of soil Pb concentration, cement content in the home entryway, indoor pesticide use, frequency of fireplace usage, number of hours in which windows were open, and homes built before 1950 (Table 4-2). Wilson et al. (2007) studied Pb dust samples from homes in Milwaukee, WI children with and without elevated blood Pb $\geq$ 10 $\mu g/dL$. They found that Pb dust samples obtained from the floor were always significantly higher in residences of children with elevated blood Pb, with the exception of samples from the bathroom floor. Windowsill dust was not significantly higher in residences of children with elevated blood Pb.

Building demolition and renovation activities can create dust from interior and exterior paints with Pb content. Mielke and Gonzales (2008) measured Pb content in paint chips from paint applied prior to 1992 and found that median Pb levels were 420 mg/kg for interior paint and 77,000 mg/kg for exterior paint. Maximum levels were 63,000 mg/kg and 120,000 mg/kg for interior and exterior paint, respectively. Mielke et al. (2001) compared dust samples from two New Orleans houses that were prepared for painting. One home was power sanded, while the other was hand-scraped. Immediately after

sanding, Pb dust samples ranged from <3 to 28,000 mg/kg at the sanded house. Pb dust samples from the scraped house ranged from 7 to 1,200 mg/kg. Pb in dust or paint samples was not quantified.

Dust Pb concentrations have also been reported for homes in the vicinity of historic and active metals mining and smelting sources. Near an active smelter in Port Pirie, Australia, median hand dust Pb loadings increased with age among a cohort of fourteen children followed over age 0-36 months (2-5 months: 54 $\mu g/m^2$, 6-9 months: 173 $\mu g/m^2$, 10-15 months: 424 $\mu g/m^2$, > 15 months: 336 $\mu g/m^2$) (Simon et al., 2007). Zota et al. (2011) studied Pb dust and indoor Pb-$PM_{2.5}$ concentration in Ottawa County, OK near the Tar Creek Superfund Site, in which a metals mine had closed. Statistically significant correlations among outdoor soil Pb concentration, indoor dust Pb concentration, indoor dust Pb loading, and indoor air Pb-$PM_{2.5}$ concentrations were observed (r = 0.25-0.65), with an average dust Pb concentration of 109 mg/kg, dust Pb loading of 54 $\mu g/m^2$, soil Pb concentration of 201 mg/kg, and indoor Pb-$PM_{2.5}$ concentration of 1 ng/m^3. Dust Pb concentrations were found to increase significantly with proximity to two chat (i.e., dry mining waste) sources and to decrease with distance to the street and presence of central air conditioning. Spalinger et al. (2007) measured Pb in dust in homes in a 34 km^2 area surrounding a designated Superfund site where formerly a Pb and Zn smelter operated at Bunker Hill, ID. During spring of 1999, vacuum and floor mat samples were taken from homes in three towns within the 34 km^2 area and five “background” towns further from the Superfund site. For the background towns, Pb concentration in vacuum dust had a median of 120 mg/kg and a maximum of 830 mg/kg, and Pb concentration in floor dust had a median of 95 mg/kg and a maximum of 1,300 mg/kg. The median Pb dust loading rate was measured to be 40 $\mu g/m^2$ per day. Among the background homes, median vacuum and floor mat Pb dust samples were 3 and 2.5 times higher, respectively, when comparing homes built before 1960 with those built after 1960. Deposition rate of Pb dust was 5 times higher in the older homes. In contrast, Pb in vacuum dust and floor mats for the towns contained within the Bunker Hill Superfund site had a median Pb concentration of 470 mg/kg with a maximum of 2,000 mg/kg and a median of 290 mg/kg with a maximum of 4,600 mg/kg, respectively. The median Pb loading rate for indoor dust in houses in these towns was 300 $\mu g/m^2$ per day, and the maximum Pb dust loading rate was 51,000 $\mu g/m^2$ per day. These results suggest that those living in close proximity to large Pb and Zn smelters or mines that are now Superfund sites are at much greater risk of exposure to Pb dust compared to the general population.

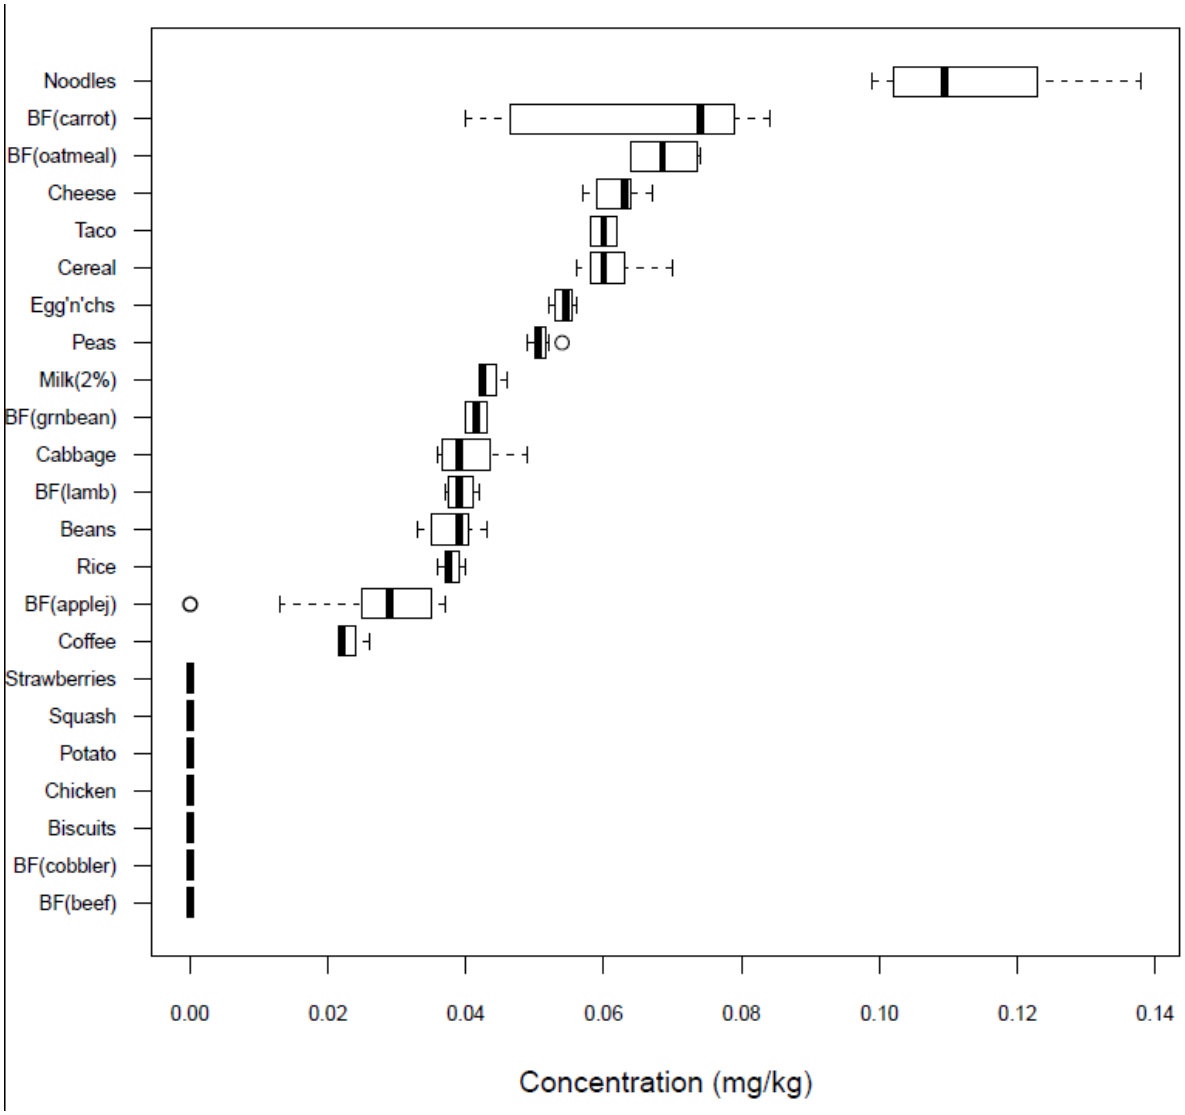
Pb exposure has been reported on children’s playgrounds. Mielke et al. (2011b) reported median soil Pb concentration of 558 mg/kg on playground soils at eleven New Orleans daycare or community centers. Following remediation efforts to cover playground soil with clean soil, median concentration dropped to 4.1 mg/kg. Duggan et al. (1985)

reported on the concentration and size distribution of wipe samples on the hands of 368 pre-school children from eleven schools in London, UK. Hand Pb residue (PbH) values were modeled as linear and power functions of Pb dust (PbD) from this study to obtain $PbH = 16.1 + 0.0064PbD$ or $PbH = 0.393PbD^{0.533}$. Given that the Duggan et al. (1985) study was performed when Pb additives were used in gasoline, dust Pb concentration values are not reported here. Measurements of the size distribution produced geometric mean diameters of 4.5 µm and 1.5 µm depending on the analysis method. The hand wipe samples were effectively limited to particles smaller than 10 µm, even when the soil itself exhibited a much larger particle size distribution. However, these studies focused on playground lead exposure. Que Hee et al. (1985) performed repeated wipe sampling of hands after rubbing in a reference dust sample and in reporting results for a "small adult hand" observed that loose particles up to 246 µm in diameter adhered, which is similar to the upper limit of 200-300 µm observed by Yamamoto et al. (2006). If a similar relationship holds for household dust, then exposure to Pb in dust by hand-to-mouth activity may be influenced by the dust particle size distribution and the relationship of Pb content to particle size fraction.

4.1.3.3 Dietary Lead Exposure

This subsection covers several dietary Pb exposures from a diverse set of sources. Included among those are drinking water, fish and meat, agriculture, urban gardening, dietary supplements, tobacco, cultural food sources, and breastfeeding. The breadth of dietary Pb exposures is illustrated in Figure 4-2, which illustrates the data obtained in the 2008 FDA Total Diet Study market basket survey (FDA, 2008). Among the highest Pb concentrations were those for noodles, baby food carrots, baby food oatmeal, Swiss cheese, beef tacos from a Mexican restaurant, and fruit-flavored cereal. The source of the Pb in each case is unclear. Possible sources of Pb in food samples include introduction during processing or preparation with drinking water contaminated with Pb, deposition of Pb onto raw materials for each food, and Pb exposure in livestock that produce dairy or meat ingredients. Manton et al. (2005) used Pb isotope ratios to estimate sources of dietary Pb among a cohort of mothers and children from Omaha, NE using a combination of food samples, hand wipes, house dust wipes, and aerosol samples collected between 1990 and 1997 and speciated for Pb isotopes. Drinking water Pb was not included in this study. The authors cited results from Egan et al. (2002) that imported vegetables contributed 55% of Pb dietary intake for infants, 30% for 2-6 y old children, and 20% for 25-30 y old women. Imported candy contributed 10% of Pb dietary intake for 2-6 y old children and 9% for 25-30 y old women. Isotopic data from Manton et al. (2005) suggested that, with the exception of children age 0-12 mos, house dust is a large

contributor to dietary Pb. The pattern of certain Pb-isotope ratios observed in the diet of children 0-12 mos are suggested to derive from Ca salts in limestone that may have been used in dietary supplements in baby formula. The contribution of ambient Pb aerosols to dietary Pb samples was not statistically significant for this urban exposure study.



Source Data: (FDA, 2008)

Note: from the 2008 FDA Total Diet Study. "BF" denotes baby food.

Figure 4-2 Market basket survey results for Pb concentration in foods.

Drinking Water

Differences in sources and transport of drinking water may cause variation in water Pb levels. For example, Shotyk and Krachler (2009) measured the Pb concentration in tap water, commercially bottled tap water and bottled natural water. They found that, in many cases, tap water contained less Pb than bottled water. Excluding bottled water in glass containers because Pb can be leached from the glass, the median Pb concentration in the bottled water samples was 8.5 ng/L (range ≤ 1 to 761 ng/L). This level (i.e., 8.5 ng/L) is significantly less than the Maximum Contaminant Level for Pb of 15 µg/L. Pb in drinking water supplies can derive from atmospheric deposition onto surface waters, as described in Section 3.3.1.2, or via corrosion of Pb in the distribution network exacerbated by contact with acidic disinfection byproducts, as described in the following paragraphs.

It is now recognized that environmental nanoparticles (NPs) (~1-100 nm) can play a key role in determining the chemical characteristics of engineered as well as natural waters (Wigginton et al., 2007). An important question is whether or not NPs from source waters affect the quality of drinking water. For example, if Fe-oxide NPs are not removed during the flocculation/coagulation stage of the treatment process, they may become effective transporters of contaminants such as Pb, particularly if these contaminants are leached from piping in the distribution system. Edwards and Dudi (2004) observed a red-brown particle-bound Pb in Washington, DC water that could be confused with innocuous Fe. The source of the particle-bound Pb was not known but was thought to originate from the source water.

Corrosion byproducts can influence Pb concentrations in drinking water. Schock et al. (2008) characterized Pb pipe scales from 91 pipes made available from 26 different municipal water systems from across the northern U.S. They found a wide range of elements including Cu, Zn and V as well as Al, Fe and Mn. Interestingly, V was present at nearly one percent levels in pipes from many geographically diverse systems. In a separate study, Gerke et al. (2009) identified the corrosion product, vanadinite ($Pb_5(VO_4)_3Cl$) in Pb pipe corrosion byproducts collected from 15 Pb or Pb-lined pipes representing 8 different municipal drinking water distribution systems in the Northeastern and Midwest regions of the U.S. Vanadinite was most frequently found in the surface layers of the corrosion products. The vanadate ion, VO_4^{3-}, essentially replaces the phosphate ion in pyromorphite and hydroxyapatite structures. It is not known whether the application of orthophosphate as a corrosion inhibitor would destabilize vanadinite, but this substitution would have implications for V release into drinking water. The stability of vanadinite in the presence of monochloramine is also not known, and its stability might have implications for both Pb and V release into drinking water.

In recent years, drinking water treatment plants in many municipalities have switched from using chlorine to other disinfecting agents because their disinfection byproducts may be less carcinogenic. However, chloramines are more acidic than chlorine and can increase Pb solubility (Raab et al., 1991) and increase Pb concentrations in tap water. For example, after observing elevated Pb concentrations in drinking water samples, Kim and Herrera (2010) observed Pb oxide corrosion scales occurring after using acidic alum as a disinfection agent. High Pb concentrations in Washington, DC drinking water were attributed to leaching of Pb from Pb-bearing pipes promoted by breakdown products of disinfection agents (Edwards and Dudi, 2004). Maas et al. (2007) tested the effect of fluoridation and chlorine-based (chlorine and chloramines) disinfection agents on Pb leaching from plumbing soldered with Pb. When using chlorine disinfection agents alone, the Pb concentration in water samples doubled during the first week of application (from 100 to 200 ppb) but then decreased over time. When adding fluorosilicic acid and ammonia, the Pb concentration spiked to 900 ppb and increased further over time. Similarly, Lasheen et al. (2008) observed leaching from pipes in Egypt. In this study, the authors tested polyvinyl chloride (PVC), polypropylene (PP), and galvanized iron pipes and observed leaching from both the PVC and PP pipes when exposed to an acid of pH = 6, with PVC having greatest amount of leaching. Exposure to basic solutions actually resulted in reduction of Pb concentration in the drinking water.

Miranda et al. (2007a) modeled blood Pb levels among children living in Wayne County, NC as a function of household age, use of chloramines and other covariates. Blood Pb levels were significantly associated with the year the home was built ($p < 0.001$), use of chloramines ($p < 0.001$), and the interaction between these two variables ($p < 0.001$). When year in which the home was built was broken into categories for the independent variables and interaction terms, Miranda et al. (2007a) found that significance increased with the age of the home. However, the study did not control for the presence of Pb paint in the dwellings, so it is difficult to distinguish the influence of Pb pipes from Pb in paint on blood Pb levels.

Several chemical mechanisms may contribute to release of Pb during use of chloramine disinfection agents. Edwards and Dudi (2004) hypothesized that Pb leaching occurs when chloramines cause the breakdown of brass alloys and solder containing Pb. After observing that nitrification also leads to increased Pb concentrations in water, they also proposed that chloramines may trigger nitrification and hence cause decreasing pH, alkalinity and dissolved oxygen that lead to corrosion after observing that nitrification also leads to increased Pb concentrations in water. However, Zhang et al. (2009b) found no evidence that nitrification brought about significant leaching of Pb from Pb pipes. Lytle et al. (2009) suggested that a lack of increased Pb(II) concentrations in drinking water following a change from free chlorine to chloramines disinfection is attributed to

the formation of the Pb(II) mineral hydroxypyromorphite ($Pb_5(PO_4)_3OH$) instead of Pb(IV) oxide. Xie et al. (2010) further investigated the mechanisms by which Pb(II) release is affected by chloramines. Two opposing mechanisms were proposed: $Pb(IV)O_2$ reduction by an intermediate species from decomposition of monochloramine; and increasing redox potential which decreases the thermodynamic driving force for reduction. They suggest that the contact time of monochloramine with PbO_2 and the Cl_2:N ratio in monochloramine formation will determine which mechanism is more important. Free chlorine can control Pb concentrations from dissolution under flowing conditions but for long stagnation periods, Pb concentrations can exceed the action level: 4-10 days were required for Pb concentrations to exceed 15 µg/L (for relatively high loadings of PbO_2 of 1 g/L). Thus, under less extreme conditions, it was concluded that chloramination was unlikely to have a major effect on the release of Pb into drinking water.

Agriculture

The 2006 Pb AQCD (2006b) states that surface deposition "represents a significant contribution to the total Pb in and on the plant", while uptake through a plants roots can also contribute to a plant's Pb concentration. Consequently, Pb content in plants may contribute to human dietary exposure. Uptake of Pb by plants growing in contaminated soil has been repeatedly demonstrated in some species during controlled potted plant experiments (Del Río-Celestino et al., 2006). In this study, most species retained Pb in the roots with little mobilization to the shoots of the plants. However, certain species *Cichorium intybus* [chicory], *Cynodon dactylon* [Bermuda grass], *Amaranthus blitoides* [matweed or mat amaranth], and *Silybum marianum* [milk thistle]) were able to mobilize Pb from the roots to the shoots of the plant; these specific species could lead to human exposures through consumption of grazing animals. Lima et al. (2009) conducted similar greenhouse experiments with several vegetable crops grown in soil contaminated by Pb-containing residue from battery recycling waste. In this study, carrots had high bioaccumulation, measured as the percent of Pb concentration measured in the plant compared with the Pb concentration in the soil, with little translocation of the Pb to the shoots, measured as the percent of Pb mass in the shoots compared to the Pb mass within the entire plant, of the Pb to the shoots. Conversely, beets, cabbages, sweet peppers, and collard greens had low bioaccumulation but moderate to high translocation. Okra, tomatoes, and eggplants had moderate bioaccumulation and moderate to high translocation. Sesli et al. (2008) also noted uptake of Pb within wild mushrooms. Vandenhove et al. (2009) compiled bioaccumulation data for plant groupings from various references; these data are reproduced in Table 4-5. Based on this review, grasses had the highest uptake, followed by leafy vegetables and root crops grown in sandy soils;

these references also suggested high transfer from roots to shoots among root crops, with shoots having roughly four times higher Pb bioaccumulation than roots. This is consistent with the 2006 Pb AQCD (2006b), which reported that Pb deposition onto leafy vegetables accounted for most Pb.

Uzu et al. (2010) found that Pb deposition from smelter emissions caused a linear increase in Pb concentrations of 7.0 mg/kg per day (R^2=0.96) in lettuce plants cultivated in the courtyard of a smelter. They reported that lettuce grown 250-400 m from the smelter had concentrations that were 10-20 times lower, which is consistent with findings described in Section 3.3 that deposition of Pb containing material drops off with distance from a source. Pb contamination of crops can occur through Pb emissions during aerial application of fertilizers and pesticides. In 2009, the U.S. Federal Aviation Administration (FAA) recorded 960,000 hours of flight time for aerial application. This term encompasses crop and timber production including seeding cropland and fertilizer and pesticide application. It is estimated that 42% of these flight-hours involved piston engine aircraft utilizing leaded fuel (FAA, 2009).

Fernandez et al. (2010; 2008; 2007) measured Pb from atmospheric deposition in two adjacent plots of land having the same soil composition but different uses: one was pasture land and one was agricultural. In the arable land, size distributions of soil particle-bound Pb, were uniformly distributed. In pasture land, size distributions of soil particle-bound Pb were bimodal with peaks around 2-20 μm and 50-100 μm (Fernandez et al., 2010). For the agricultural plot, Pb concentration was constant around 70 mg/kg in samples taken over the first 30 cm of soil, at which time it dropped below 10 mg/kg at soil depths between 35 and 100 cm. In contrast, Pb concentration in pasture land peaked at a depth of 10 cm at a concentration of roughly 70 mg/kg and then dropped off gradually to approach zero concentration at a depth of approximately 50 cm. The sharp change in concentration for the arable land was attributed to a combination of plowing the soil and use of fertilizers to change the acidity of the soil and hence the bioaccessibility of the Pb within the soil (Fernandez et al., 2007). They found that the surface layer was acidic (pH: 3.37-4.09), as was the subsurface layer (pH: 3.65-4.38).

There is some evidence that Pb in crops can originate with treatment of crops. For example, compost produced from wastewater sludge has the potential to add Pb to crops. Cai et al. (2007) demonstrated that production of compost from sludge enriched the Pb content by 15-43% prior to its application. Chen et al. (2008a) observed that the median concentration of Pb in California crop soil samples was 16.2 mg/kg (range: 6.0-62.2 mg/kg). Chen et al. (2008b) further observed that in three of the seven California agricultural regions sampled, concentrations of Pb increased following addition of fertilizer, but the increase was less than that for P and Zn indicators of fertilizer. In four

regions, there was no increase of Pb at all. Furthermore, Tu et al. (2000) observed a decrease in Pb fraction with increasing P application. Nziguheba and Smolders (2008) also surveyed phosphate-based fertilizers sold in European markets to determine the contribution of these fertilizers to heavy metal concentrations in agricultural products. They reported a median fertilizer Pb concentration of 2.1 mg/kg based on total weight of the fertilizer, with a 95th percentile concentration of 7.5 mg/kg. Across Europe, Nziguheba and Smolders (2008) estimated that the amount of Pb applied via fertilizers to be only 2.6% of that resulting from atmospheric deposition.

Although Pb in on-road vehicle gasoline has been phased out in the U.S., some imported crops are produced in countries that still use Pb antiknock agents in on-road gasoline. For example, high concentrations of Pb have been found in chocolate from beans grown in Nigeria, during the time when leaded gasoline was still legally sold. Rankin et al. (2005) observed that the ratios of ^{207}Pb to ^{206}Pb and ^{208}Pb to ^{207}Pb were similar to those of Pb in gasoline. Although this study showed that Pb concentration in the shelled cocoa beans was low (~1 ng/g), manufactured cocoa powder and baking chocolate had Pb concentrations similar to those of the cocoa bean shells, on the order of 200 ng/g, and Pb concentration in chocolate products was roughly 50 ng/g (Rankin et al., 2005). It is possible that the increases were attributed to contamination of the cocoa by the shells during storage or manufacture, but the authors note that more research is needed to verify the source of contamination. Likewise, it is possible that resuspended Pb that originated from legacy mobile and industrial sources could deposit on crops.

The extent to which soil Pb contributes Pb to agricultural crops varies with soil characteristics. For example, Jin et al. (2005) tested soil Pb, bioaccessibility of soil Pb (determined by $CaCl_2$ extraction), and Pb in tea samples from tea gardens. They observed that the Pb concentration in tea leaves was proportional to the bioaccessible Pb in soil.

Table 4-5 Pb bioaccumulation data for various plants. Bioaccumulation is expressed as percent of Pb concentration in the plant to the Pb concentration in the soil

Plant Group	Plant Compartment	Soil	n	GM	GSD	AM	SD	Min	Max

Findings from Pb uptake studies have implications for urban gardening if urban soils may be contaminated with Pb, as described in Section 4.1.3.2. For instance, Clark et al. (2006) tested the soil in 103 urban gardens in two Boston neighborhoods. They found that Pb-based paint contributed 40-80% of Pb in the urban garden soil samples, with the rest coming from historical gasoline emissions. Furthermore, Clark et al. (2006) estimated

that Pb consumption from urban gardens can be equivalent to 10-25% of the exposure to Pb from drinking water for children living in the Boston neighborhoods studied. Because soil Pb levels in urban areas will depend on surrounding sources (Pruvot et al., 2006), Pb exposures in urban garden vegetables will vary.

Game

Game meat consumption also may pose a risk of Pb exposure. In Pb mining or smelting areas, several studies have documented Pb concentrations in game [e.g., (Nwude et al., 2010; Reglero et al., 2009a)]. Jankovská et al. (2010) studied Pb accumulation in sheep infected with tapeworm and found that sheep harboring the parasites contained significantly less Pb compared with their uninfected counterparts ($p \leq 0.05$).

Potential Pb exposure through consumption of animals exposed to or killed with Pb shot has also been well documented (Hunt et al., 2009; Tsuji et al., 2009; Tsuji et al., 2008; Hunt et al., 2006). For example, Martínez-Haro et al. (2010) observed Pb in the feces of mallards that ingested gunshot of 34-13,930 mg/kg with a median of 1,104 mg/kg, while mallards that did not ingest gunshot had feces Pb levels < 12.5 mg/kg. Mateo et al. (2011) studied Pb bioaccessibility as a function of cooking method for breast meat from partridges killed with gunshot. They observed that preparation in cold or hot vinegar increased bioaccessibility compared with total Pb in the samples.

Fish

Accumulation in fish could also lead to human exposure to Pb (U.S. EPA, 2006b, 1986a). Ghosh et al. (2007) demonstrated in laboratory experiments that exposure to Pb in water can lead to linearly increasing accumulation in fish. Several studies have documented the potential for human exposure through fish and seafood. Welt et al. (2003) conducted a survey of individuals who fished in Bayou St. John, Louisiana in conjunction with sampling Pb content in sediment. They found that median sediment Pb concentrations ranged from 43 to 330 mg/kg in different locations, while maximum sediment Pb concentrations ranged from 580 to 6,500 mg/kg. In total, 65% of the surveyed individuals fished for food from the Bayou, with 86% consuming fish from the Bayou each week. In a study of the effect of coal mining on levels of metals in fish (measured as blood Pb) in northeastern Oklahoma, Schmitt et al. (2005) found that Pb concentrations in blood varied with respect to species of fish, but Pb concentrations were higher in fish in areas close to mining activities. Similarly, Besser et al. (2008) observed higher levels of blood Pb in fish close to mining activities in southeastern Missouri. In a related study of fish species in the same region of Missouri, blood Pb levels in fish were found to be significantly higher in sites within 10 km downstream of active Pb-Zn mines ($p < 0.01$)

compared with fish located further from the mines (Schmitt et al., 2007a), and elevated blood Pb levels in fish were again noted near a Pb-Zn mine (Schmitt et al., 2009). It was noted that the Ozark streams where these studies were performed were often used for recreational fishing.

Breast Milk

Studies breastfeeding women suggest that infants may be exposed to Pb in breast milk. Ettinger et al. (2004a) observed among Mexico City women studied in 1994-1995 that at 1 month postpartum, 88 women breastfeeding exclusively (with mean blood Pb level of 9.4 µg/dL) had breast milk Pb concentrations of 1.4 ± 1.1 µg/L, and 165 women breastfeeding partially (with mean blood Pb level of 9.5 µg/dL) had breast milk Pb concentrations of 1.5 ± 1.2 µg/L. During the same time period, Ettinger et al. (2006) studied breastfeeding women in Mexico City over a child's first year of life and sampled Pb concentration in breast milk at 1, 4, and 7 mo post-partum. They observed that mean breast milk concentrations dropped from 1.4 µg/L at 1 mo (mean maternal blood Pb = 9.3 µg/dL) to a mean of 1.2 µg/L at 4 mo (mean maternal blood Pb = 9.0 µg/dL) to 0.9 µg/L at 7 mo (mean maternal blood Pb = 8.1 µg/dL); this reduction was statistically significant ($p < 0.00001$). Among the 310 women included in the study, 181 had previous pregnancies. In one study of nursing mothers living in Pb contaminated city in Australia, 10 of the 11 mothers had breast milk concentrations <5 µg/L (Simon et al., 2007). The authors hypothesized that breast milk concentration was too low to be a major contributor to blood Pb level in these infants relative to other factors such as hand loading of lead. However, one mother with a blood Pb level of 25 µg/dL had a breast milk Pb level of 28 µg/L (Simon et al., 2007).

4.1.3.4 Occupational

Occupational environments have the potential to expose individuals to Pb. Some modern day occupational exposures are briefly discussed below in the context of understanding potential exposures that are not attributed to ambient air. For example, Miller et al. (2010) obtained personal and area samples of particle-borne Pb in a precious metals refinery; year of the study was not reported. It was not stated explicitly, but it is likely that Miller et al. (2010) measured the PM as TSP because the Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) for Pb is based on TSP rather than a smaller size cut, and the OSHA PEL was used for comparison. Concentrations measured by personal samples ranged from 2 to 6 µg/m^3, and concentrations from area samples ranged from 4 to 14 µg/m^3. The OSHA PEL is 5 µg/m^3.

In steel production, sintering was found to be the largest source of airborne Pb exposure in a survey of operations (Sammut et al., 2010), with Pb enrichment in PM reported to be 20,000 mg/kg, although total PM concentration, reported to have 75% of particulate mass below 2.5 µm diameter, was not reported; year of the study was also not reported.

Operations involving PM in various industries are a source of occupational Pb exposure, in addition to a residential exposure. Rodrigues et al. (2010) reported exposures to airborne Pb among New England painters, who regularly use electric grinders to prepare surfaces for painting. Two-week averaged airborne Pb concentrations, sampled with an Institute of Medicine inhalable PM sampler designed to capture PM smaller than 100 µm, were reported to be 59 µg/m^3, with a maximum daily value of 210 µg/m^3. The Pb concentrations reported here were corrected by the National Institute for Occupational Safety and Health (NIOSH) respirator protection factors, although the respirator protection factors were not reported by Rodrigues et al. (2010). Information on the air Pb-blood Pb relationship can be found in Section 4.5.1. Nwajei and Iwegbue (2007) measured Pb contamination in sawdust; such contamination has been reported to occur when trees are grown in soil contaminated with Pb (Andrews et al., 1989). Sawdust samples from fifteen locations in Nigerian sawmills were reported to have Pb concentrations ranging from 2.0 to 250 mg/kg.

4.1.3.5 Exposure to Lead from Consumer Products

Pb is present in varying amounts in several consumer products including alternative medicines, candies, cosmetics, pottery, tobacco, toys, and vitamins (Table 4-6). Several of these categories suggest children may incur regular exposures. Pb concentrations were reported to range from non-detectable levels up to 77% by mass, for the case of one medicinal product. Exposure to these products, which originate in a range of different countries, can account for substantial influence on Pb body burden (Miodovnik and Landrigan, 2009; Levin et al., 2008).

Table 4-6 Pb content in various consumer products.

Product Category	Product	Location of Purchase	Pb Content (units)	Reference
Alternative and Traditional Medicines	*Cissus quadrangularis, Caulophyllum thalictroides, Turnera diffusa, Centella asiatica, Hoodia gordonii, Sutherlandia frutescens, Curcuma longa, fucoxanthin, Euterpe oleracea* (dietary supplements claimed to be from *Hoodia gordonii*)	U.S. (Mississippi)[a]	Not detected (N.D.) -4.21 mg/kg	Avula et al. (2010)
	Malva sylvestris	Turkey	1.1-2.0 mg/kg	Hiçsömnez et al. (2009)

Product Category	Product	Location of Purchase	Pb Content (units)	Reference
	Yugmijihwang-tang, Bojungigki-tang, Sibjeondaebo-tang, Kuibi-tang, Ojeogsan	Korea	7.9×10^{-6} to 2.5×10^{-5} mg/kg body weight/day	Kim et al. (2009a)
	Lemongrass, licorice, holy basil, cloves, ginger	India	Average: Lemongrass & Holy Basil Leaves: 6.1 mg/kg; Licorice Stolons: 6.1 mg/kg, Clove Dried Flower Buds: 7.8 mg/kg, Ginger Rhizome: 5.8 mg/kg	Naithani and Kakkar (2006)
	B-Success 28, Operation Sweep, Aloe Vera Plus Bitter Aloes, Zarausmacine, Virgy-Virgy Computer Worm-Expeller, Dorasine Powder, Sexual Energy, U&DEE Infection Cleansing Powder, U&DEE Sweet Bitter, Natural Power Stone, Chama Black Stone, Portugal Antiseptic Soap, Edysol Antiseptic Soap, H-Nal, M-Reg, Veins Flocher, Diabor, C-Candi, C-Cysta, Firas, D-Diab, P-Pile, Infecta, Ribacin Forte, Aloe Vera Cure Formula	Nigeria	925-27,000 µg	Obi et al. (2006)
	Shell of Hen's Egg	India	14 mg/kg	Sharma et al. (2009)
	Berberis (*B. aristata, B. chitria, B. asiatica, B. lyceum*), Daruharidra	India	Berberis: Roots: 3.1-24.7 mg/kg Stems: 8.0-23.8 mg/kg Daruharidra: 16.9-49.8 mg/kg	Srivastava et al. (2006)
	Greta powder	U.S. (California)	770,000 ppm	CDC (2002)
Candy	Tamarind Candy	U.S. (Oklahoma)	Product: 0.15-3.61 mg/kg Stems: 0.36-2.5 mg/kg Wrappers: 459-27,125 mg/kg	Lynch et al. (2000)
	Tamarind Candy	U.S. (California)	Product: 0.2-0.3 mg/kg Stems: 400 mg/kg Wrappers: 16,000-21,000 mg/kg	CDC (2002)
Cosmetics	Lipsticks	U.S.	Average: 1.07 mg/kg	Hepp et al. (2009)
	Eye Shadows	Nigeria	N.D.-55 mg/kg	Omolaoye et al. (2010a)
Pottery	Foods prepared in Pb-glazed pottery	Mexico	N.D.-3,100 mg/kg	Villalobos et al. (2009)
Tobacco	Smokeless Tobacco	U.K.	0.15-1.56 mg/kg	McNeill et al. (2006)
	Cigarette Tobacco (^{210}Pb concentrations)	Pakistan	Activity conc.: 7-20 Bq/kg	Tahir and Alaamer (2008)
Toys	Red and yellow painted toy vehicles and tracks	Brazil	500-6,000 mg/kg	Godoi et al. (2009)
	535 PVC and non-PVC toys from day care centers	U.S. (Nevada)	PVC: avg. 325 mg/kg Non-PVC: avg. 89 mg/kg Yellow: 216 mg/kg Non-yellow: 94 mg/kg	Greenway and Gerstenberger (2010)
	Soft plastic toys	India	Average (by city): 21-280 mg/kg	Kumar and Pastore (2007)

4.2 Kinetics

This section summarizes the empirical bases for our understanding of Pb toxicokinetics in humans. The large amount of empirical information on Pb biokinetics in humans and animal models has been integrated into mechanistic biokinetics models (U.S. EPA, 2006b). These models support predictions about the kinetics of Pb in blood and other selected tissues based on the empirically-based information about Pb biokinetics. In Section 4.3 (and Section 4.2.2.1), Pb biokinetics is described from the context of model predictions.

4.2.1 Absorption

The focus of the following sections within absorption is on inhalation and ingestion because these are the major exposure routes of Pb in humans. The 2006 Pb AQCD also presented dermal absorption of inorganic and organic Pb compounds, which is generally considered to be much less than by inhalation or ingestion. A study published subsequent to the 2006 Pb AQCD measured rates of absorption of Pb in skin patches harvested from nude mice (Pan et al., 2010). Following application of 12 mg Pb as Pb-acetate or Pb nitrate, the absorption rate (measured over a 10-hour observation period) was approximately 0.02 µg Pb/cm^2 per hour. Absorbed Pb was detected in liver and kidney of nude mice following a 120-hr occluded dermal application of approximately 14 mg Pb as either Pb-acetate or Pb nitrate. Uptake of Pb into the skin at the site of application was greater when Pb-acetate was applied to the skin compared to lead nitrate; however, liver and kidney Pb concentrations observed at the conclusion of the study (120 hours following the application of Pb) were not different for the two Pb compound. No additional information provides evidence of dermal absorption being a major exposure route of environmental Pb.

The term absorption refers to the fraction of the amount of Pb ingested or inhaled that is absorbed from the respiratory or gastrointestinal tract. The term bioavailability, as it is used in this section, refers to the fraction of the amount of Pb ingested or inhaled that enters the systemic circulation. If properly measured (e.g., time-integrated blood Pb), under most conditions Pb bioavailability is equivalent (or nearly equivalent) to Pb absorption. Bioaccessibility is a measure of the physiological solubility of Pb in the respiratory or gastrointestinal tract. Pb must become bioaccessible in order for absorption to occur. Processes that contribute to bioaccessibility include physical transformation of Pb particles and dissolution of Pb compounds into forms that can be absorbed (e.g., Pb^{2+}). Bioaccessibility is typically assessed by measuring the fraction of Pb in a sample that can

be extracted into a physiological or physiological-like solution (e.g., gastric juice or solution similar to gastric juice).

4.2.1.1 Inhalation

Systemic absorption of Pb deposited in the respiratory tract is influenced by particle size and solubility, as well as by the pattern of regional deposition within the respiratory tract. Fine particles (<1 µm) deposited in the bronchiolar and alveolar region can be absorbed after extracellular dissolution or can be ingested by phagocytic cells and transported from the respiratory tract (Bailey and Roy, 1994). Larger particles (>2.5 µm) that are primarily deposited in the ciliated airways (nasopharyngeal and tracheobronchial regions) can be transferred by mucociliary transport into the esophagus and swallowed, thus being absorbed via the gut.

Inhaled Pb lodging deep in the respiratory tract seems to be absorbed equally and totally, regardless of chemical form (Morrow et al., 1980; Chamberlain et al., 1978; Rabinowitz et al., 1977). Absorption half-times ($_{t1/2}$) have been estimated for radon decay progeny in adults who inhaled aerosols of Pb and bismuth isotopes generated from decay of ^{220}Rn or ^{222}Rn. The absorption half-time for Pb from the respiratory tract to blood was estimated to be approximately 10 hours in subjects who inhaled aerosols having an activity median particle diameter of approximately 160 nm (range 50-500 nm) (Marsh and Birchall, 1999), and approximately 68 min for aerosols having diameters of approximately 0.3–3 nm (Butterweck et al., 2002). Given the submicron particle size of the exposure, these rates are thought to represent, primarily, absorption from the bronchiolar and alveolar regions of the respiratory tract.

Several studies have quantified the bioaccessibility of Pb in atmospheric PM, based on various in vitro extraction methods. In a study of PM_{10} and $PM_{2.5}$ samples from downtown Vienna, Austria, Falta et al. (2008) used synthetic gastric juice to investigate the bioaccessibility of metals including Pb. The rationale was that inhaled particles in the 2.5-10 µm size range are mostly deposited in the tracheal and bronchial regions of the lung from where they are transported within hours by mucociliary clearance, i.e., they are mainly swallowed. In contrast, the <2.5 µm particles are deposited in the pulmonary alveoli where they can stay for months to years. The study aimed to determine the bioaccessibility of the 2.5-10 µm PM. It is important to note that they do not isolate the 2.5-10 µm size range; instead, they infer the characteristics from the difference between the $PM_{2.5}$ and PM_{10} fractions. The Pb concentrations associated with the two fractions were almost identical, as was the percentage extracted by synthetic gastric juice (86% and 83% Pb for $PM_{2.5}$ and PM_{10} fractions, respectively). The mean daily bioavailable mass

was calculated to be 16 ng for the $PM_{2.5-10}$ size range. Since the quantitative clearance of these particles to the stomach was assumed, this value represents an upper estimate for the amount of bioavailable Pb. Niu et al. (2010) determined the bioaccessibility of Pb in fine (100-1,000 nm) and ultrafine-sized (<100 nm) urban airborne PM from two sites within the city of Ottawa, Canada. For all size fractions, the median Pb concentrations for particles smaller than 10 µm were 8,800 and 7,800 mg/kg for the two different locations. The bioaccessibility was based on ammonium acetate extractability and it was found that, within the fine and ultrafine-size ranges, 13-28% Pb was extracted. The Falta et al. (2008) and Niu et al. (2010) results illustrate that different extraction techniques result in different bioavailable fractions. The main finding from Niu et al. (2010) was that the highest values (~28% and ~19% for the two different locations) were found for the <57 nm particles, with percent bioaccessibility decreasing with increasing particle size. This result indicated that Pb was potentially most bioavailable in the ultrafine-size range.

A recent study by Barrett et al. (2010) investigated the solid phase speciation of Pb in urban road dust in Manchester, UK, and considered the health implications of inhalation and ingestion of such material. Human exposure via inhalation is likely to involve only the finest grained fractions (up to 10 µm) and unfortunately this study characterized only the <38 µm fraction. Pb-goethite and $PbCrO_4$ comprised the largest fractions, 45% and 21% respectively, of Pb in the <38 µm fraction. These forms tend to be less bioaccessibility if ingested compared with PbO or Pb-acetate because they are less soluble.

The above considerations indicate that the relationship between air Pb exposure and blood Pb will depend on numerous exposure variables (e.g., particle size, solubility, exposure frequency and duration) and physiological variables (age, activity level, transport and absorption in the respiratory tract, blood Pb kinetics). Mechanistic models provide one means for integrating these variable into predictions of blood Pb – air Pb relationships; although, predictions are subject to simplifications and generalizations made in constructing the models. As an example, the ICRP (Pounds and Leggett, 1998; ICRP, 1994; Leggett, 1993) model (Section 4.3 for a brief description) can be used to predict blood Pb – air Pb slopes for specific direct Pb inhalation exposure scenarios. For a long-term continuous (24 hours/day) exposure of a typical adult male engaged in light exercise (ventilation rate 20-22 m^3/day) to Pb-bearing particles having a 1 µm uniform particle size, the predicted blood Pb – air Pb slopes range from 0.7 µg/dL per µg/m^3 (for low solubility particles; e.g., Pb oxide) to 3 µg/dL per µg/m^3 (for highly soluble Pb; e.g., Pb salts). Empirical estimates of blood Pb – air Pb slopes for various populations, derived from epidemiological studies, are summarized in Section 4.5.1.

Organic Lead

Alkyl Pb compounds can exist in ambient air as vapors. Inhaled tetraalkyl Pb vapor is nearly completely absorbed following deposition in the respiratory tract. As reported in the 2006 Pb AQCD, a single exposure to vapors of radioactive (^{203}Pb) tetraethyl Pb resulted in 37% initially deposited in the respiratory tract, of which ~20% was exhaled in the subsequent 48 hours (Heard et al., 1979). In a similar experiment conducted with ^{203}Pb tetramethyl Pb, 51% of the inhaled ^{203}Pb dose was initially deposited in the respiratory tract, of which ~40% was exhaled in 48 hours (Heard et al., 1979).

Estimation of bioavailability of organic Pb is relevant to some aviation fuel exposures (e.g., persons exposed to leaded gasoline used piston-engine aircraft). Mahaffey (1977) estimated that 40% of inhaled Pb in urban air (largely attributed to combustion of gasoline containing tetraethyllead) is bioavailable to adults. Chamberlain et al. (1975) suggested that 35% of inhaled combustion products of tetraethyl ^{203}Pb fuel are deposited and then retained in adult lungs with a half-life of 6 hours. Fifty percent of that ^{203}Pb was detectable in the blood within 50 hours of inhalation, and the rest was found to deposit in bone or tissue. Chamberlain et al. (1975) estimated that continuous inhalation of Pb in engine exhaust from fuel containing tetraethyllead at a concentration of 0.001 μg/m^3 for a period of months could produce a 1 μg/dL increment in blood Pb.

4.2.1.2 Ingestion

The extent and rate of GI absorption of ingested inorganic Pb are influenced by physiological states of the exposed individual (e.g., age, fasting, nutritional calcium and iron status, pregnancy) and physicochemical characteristics of the Pb-bearing material ingested (e.g., particle size, mineralogy, solubility). Pb absorption in humans may be a capacity-limited process, in which case the percentage of ingested Pb that is absorbed may decrease with increasing rate of Pb intake. Numerous observations of nonlinear relationships between blood Pb concentration and Pb intake in humans provide support for the likely existence of a saturable absorption mechanism or some other capacity-limited process in the distribution of Pb in humans (Sherlock and Quinn, 1986; Sherlock et al., 1984; Pocock et al., 1983; Sherlock et al., 1982). While evidence for capacity-limited processes at the level of the intestinal epithelium is compelling, the dose at which absorption becomes appreciably limited in humans is not known.

In adults, estimates of absorption of ingested water-soluble Pb compounds (e.g., Pb chloride, Pb nitrate, Pb-acetate) range from 3 to 10% in fed subjects (Maddaloni et al., 1998; Watson et al., 1986; James et al., 1985; Heard and Chamberlain, 1982; Rabinowitz et al., 1980). The absence of food in the GI tract increases absorption of water-soluble Pb

in adults. Reported estimates of soluble Pb absorption range from 26 to 70% in fasted adults (Maddaloni et al., 1998; James et al., 1985; Blake et al., 1983; Heard and Chamberlain, 1982; Rabinowitz et al., 1980). Reported fed:fasted ratios for soluble Pb absorption in adults range from 0.04 to 0.2 (James et al., 1985; Blake et al., 1983; Heard and Chamberlain, 1982; Rabinowitz et al., 1980).

Limited evidence demonstrates that GI absorption of water-soluble Pb is higher in children than in adults. Estimates derived from dietary balance studies conducted in infants and children (ages 2 weeks to 8 years) indicate that ~ 40-50% of ingested Pb is absorbed (Ziegler et al., 1978; Alexander et al., 1974). Experimental studies provide further evidence for greater absorption of Pb from the gut in young animals compared to adult animals (Aungst et al., 1981; Kostial et al., 1978; Pounds et al., 1978; Forbes and Reina, 1972). The mechanisms for an apparent age difference in GI absorption of Pb have not been completely elucidated and may include both physiological and dietary factors (Mushak, 1991). Eating breakfast was shown to be significant predictor of blood Pb concentrations in 1,344 children 3-5 year s old (Liu et al., 2011b). Blood Pb concentrations were lower in children who regularly ate breakfast compared to children who did not eat breakfast, and the difference persisted after controlling for nutritional variables (blood iron, calcium, copper, magnesium, zinc). This observation may be explained by lower GI absorption of Pb ingested with or in close temporal proximity to meals. Direct evidence for meals lowering GI absorption of Pb has been reported for adults (Maddaloni et al., 1998; James et al., 1985).

Nutritional deficiencies have also been linked to Pb absorption in the GI tract, particularly in children. Children who are iron-deficient have higher blood Pb concentrations than similarly exposed iron-replete children, suggesting that iron deficiency may result in higher Pb absorption or, possibly, other changes in Pb biokinetics that contribute to altered blood Pb concentrations (Schell et al., 2004; Marcus and Schwartz, 1987; Mahaffey and Annest, 1986). Studies conducted in animal models have provided direct evidence for interactions between iron deficiency and increased Pb absorption, perhaps by enhancing binding of Pb to iron-binding proteins in the intestine (Bannon et al., 2003; Morrison and Quarterman, 1987; Barton et al., 1978b). An analysis of data from a sample 448 woman (age 20-55 years) did not find a significant association between iron body stores (indicated from serum ferritin concentration) and blood Pb concentrations, although depleted irons stores (serum ferritin of <12 µg/L) was associated with higher blood concentrations of cadmium, cobalt and manganese higher (Meltzer et al., 2010).The effects of iron nutritional status on blood Pb include changes in blood Pb concentrations in association with genetic variation in genes involved in iron metabolism. For example, genetic variants in the hemochromatosis (HFE) and transferrin genes are associated with higher blood Pb concentrations in children (Hopkins et al., 2008). In

contrast, HFE gene variants are associated with lower bone and blood Pb levels in elderly men (Wright et al., 2004).

Several studies have suggested that dietary calcium may have a protective role against Pb by decreasing absorption of Pb in the GI tract and by decreasing the mobilization of Pb from bone stores to blood. In experimental studies of adults, absorption of a single dose of Pb (100-300 µg Pb chloride) was lower when the Pb was ingested together with calcium carbonate (0.2 g calcium carbonate) than when the Pb was ingested without additional calcium (Blake and Mann, 1983; Heard and Chamberlain, 1982). A similar effect of calcium occurs in rats (Barton et al., 1978a). Similarly, an inverse relationship was observed between dietary calcium intake and blood Pb concentration in children, suggesting that children who are calcium-deficient may absorb more Pb than calcium-replete children (Elias et al., 2007; Schell et al., 2004; Mahaffey et al., 1986; Ziegler et al., 1978). These observations suggest that calcium and Pb share and may compete for common binding and transport mechanisms in the small intestine which are regulated in response to dietary calcium and calcium body stores (Fullmer and Rosen, 1990; Bronner et al., 1986). However, animal studies have also shown that multiple aspects of Pb toxicokinetics are affected by calcium nutritional status. For example, feeding rats a calcium deficient diet is associated with increased Pb absorption, decreased whole body Pb clearance, and increased volume of distribution of Pb (Aungst and Fung, 1985). These studies suggest that associations between calcium nutrition and blood Pb that have been observed in human populations may not be solely attributable to effects of calcium nutrition on Pb absorption. Other potential mechanisms by which calcium nutrition may affect blood Pb and Pb biokinetics include effects on bone mineral metabolism and renal function.

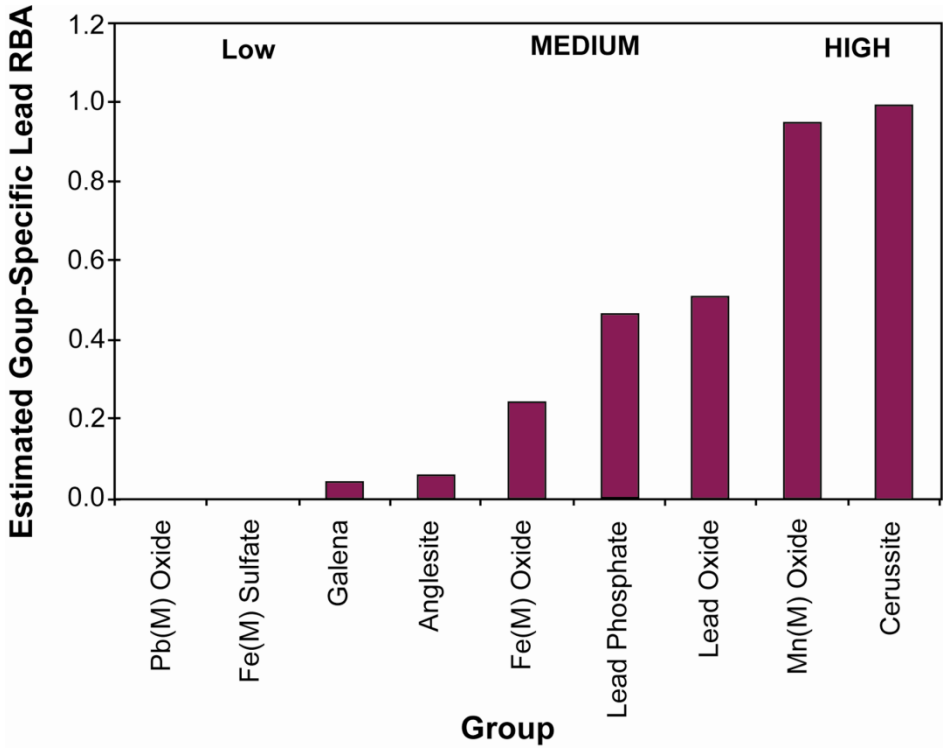
Blood Pb concentrations in young children have also been shown to increase in association with lower dietary Zn levels (Schell et al., 2004). Mechanisms for how Zn affects blood Pb concentration, i.e., whether it involves changes in absorption or changes in distribution and/or elimination of Pb, have not been determined.

Dissolution of Pb from the soil/mineralogical matrix in the stomach appears to be the major process that renders soil Pb bioaccessible for absorption in the GI tract. Absorption of Pb has been shown to vary depending upon the Pb mineralogy and physical characteristics of the Pb in the soil (e.g., encapsulated or exposed) and size of the Pb-bearing grains. GI absorption of larger Pb-containing particles (>100 µm) tends to be lower than smaller particles (Healy et al., 1992; Barltrop and Meek, 1979). Absorption of Pb in soils and dust has been most extensively studied in the in vivo swine model. Gastric function of swine is thought to be sufficiently similar to that of humans to justify use of swine as a model for assessing factors that may affect GI absorption of Pb from soils in

humans (Juhasz et al., 2009; U.S. EPA, 2007b; Casteel et al., 2006; Casteel et al., 1997; Weis and Lavelle, 1991). Other practical advantages of the swine model over rodent models have been described, and include: absence of coprophagia; ease with which Pb dosing can be administered and controlled; and higher absorption fraction of soluble Pb (e.g., Pb-acetate) in swine, which is more similar to humans than rats (Smith et al., 2009a). The swine studies measure blood and/or tissue Pb (e.g., kidney, liver, bone) concentrations following oral dosing of swine with either soil or with a highly water soluble and fully bioaccessible form of Pb (e.g., Pb-acetate). A comparison of the internal concentrations of Pb under these two conditions provides a measure of the bioavailability (i.e., absorption) of Pb in soil relative to that of Pb-acetate, which is typically referred to as relative bioavailability (RBA). Relative bioavailability measured in the swine assay is equivalent to the ratio of the absorbed fraction (AF) of ingested dose of soil Pb to that of water-soluble Pb-acetate (e.g., RBA = $AF_{Soil\ Pb}/AF_{Pb\text{-}acetate}$).

Collectively, published studies conducted in swine have provided 39 estimates of Pb RBA for 38 different soil or "soil-like" test materials (Bannon et al., 2009; Smith et al., 2009a; Casteel et al., 2006; Marschner et al., 2006). The mean of RBA estimates from 25 soils is 49% (± 29[SD]), median is 51%, and 5th to 95th percentile range is 12 to -89%. RBA estimates for soils collected from 8 firing ranges were approximately 100% (Bannon et al., 2009). The relatively high RBA for the firing range soils may reflect the high abundance of relatively un-encapsulated Pb carbonate (30-90% abundance) and Pb oxide (1-60%) in these soils. Similarly, a soil sample (low Pb concentration) mixed with a NIST paint standard (55% Pb carbonate, 44% Pb oxide) also had a relatively high bioavailability (72%) (Casteel et al., 2006). Samples of smelter slag, or soils in which the dominant source of Pb was smelter slag, had relatively low RBA (14-40%, n = 3), as did a sample from a mine tailings pile (RBA = 6%), and a sample of finely ground galena mixed with soil (Casteel et al., 2006).

Based on data for 18 soil materials assayed in swine, RBA of Pb mineral phases were categorized into "low" (<0.25 [25%]), "medium" (0.25-0.75 [25 to 75%]), and "high" (>0.75 [75%]) categories (Casteel et al., 2006). Figure 4-3 shows some of the materials that fall into these three categories. Mineral phases observed in mineralogical wastes can be expected to change over time (i.e., weathering), which could change the RBA over time. The above observations in swine are supported by various studies conducted in rats that have found RBA of Pb in soils to vary considerably and to be less that 100% (Smith et al., 2009a, 2008; Freeman et al., 1996; Freeman et al., 1994; Freeman et al., 1992).



Source: Casteel et al. (2006).
Note: based on results from juvenile swine assays.

Figure 4-3 Estimated relative bioavailability (RBA, compared to Pb-acetate) of ingested Pb in mineral groups.

Drexler and Brattin (2007) developed an in vitro bioaccessibility (IVBA) assay for soil Pb that utilizes extraction fluid comprised of glycine, deionized water, and hydrochloric acid at a pH of 1.50 that is combined with sieved test material (<250 µm) for 1 hour. The assay was tested for predicting in vivo RBA of 18 soil-like test materials that were assayed in a juvenile swine assay (Casteel et al., 2006). A regression model relating IVBA and RBA was derived based on these data (Equation 4-1):

$$\mathbf{RBA} = (\mathbf{0.878} \times \mathbf{IVBA}) - \mathbf{0.028}$$

Equation 4-1

where RBA and IVBA are expressed as fractions (i.e., not as percent). The weighted r^2 for the relationship (weighted for error in the IVBA and RBA estimates) was 0.924 ($p < 0.001$). The IVBA assay reported in Drexler and Brattin (2007) has been identified by the U.S. EPA as a validated method for predicting RBA of Pb in soils for use in risk assessment (U.S. EPA, 2007e). A review of soil Pb RBA estimates made using the IVBA assay described above and Equation 4-1 identified 270 estimates of Pb RBA in soils obtained from 11 hazardous waste sites. The mean for the site-wide RBA estimates (n =

11 sites) was 57% (SD 15), median was 63%, and 5th to 95th percentile range was 34 to 71%.

Equation 4-1 cannot be reliably extrapolated to other in vitro assays that have been developed for estimating Pb bioaccessibility without validation against in vivo RBA measurements made on the same test materials. Comparisons of outcomes among different in vitro assays applied to the same soil test materials have found considerable variability in IVBA estimates (Juhasz et al., 2011; Smith et al., 2011; Saikat et al., 2007; Van de Wiele et al., 2007). This variability has been attributed to differences in assay conditions, including pH, liquid:soil ratios, inclusion or absence of food material, and differences in methods used to separate dissolved and particle-bound Pb (e.g., centrifugation versus filtration). Smith et al. (2011) found that algorithms for predicting RBA based on two different IVBA assays did not yield similar predictions of RBA when applied to the same material. Given the dependence of IVBA outcomes on assay conditions, in vitro assays used to predict in vivo RBA should be evaluated against in vivo RBA estimates to quantitatively assess uncertainty in RBA predictions (U.S. EPA, 2007e).

Absorption of Pb in house dusts has not been rigorously evaluated quantitatively in humans or in experimental animal models. The RBA for paint Pb mixed with soil was reported to be approximately 72% (95% CI: 44, 98) in juvenile swine, suggesting that paint Pb dust reaching the gastrointestinal tract maybe highly bioavailable (Casteel et al., 2006). The same material yielded a bioaccessibility value (based on IVBA assay) of 75% (Drexler and Brattin, 2007), which corresponds to a predicted RBA of 63%, based on Equation 4-1. A review of indoor Pb RBA estimates made using the IVBA assay and Equation 4-1 identified 100 estimates of Pb RBA in dusts obtained from two hazardous waste sites. Mean Pb RBAs for the Herculaneum site were 47% (SD 7, 10 samples) for indoor dust and 69% (SD 3, 12 samples) for soil. At the Omaha site, mean Pb RBAs were 73% (SD 10, 90 samples) for indoor dust and 70% (SD 10, 45 samples) for soil. Yu et al. (2006) applied an IVBA method to estimate bioaccessibility of Pb in house dust samples collected from 15 urban homes. Homes were selected for inclusion in this study based on reporting to the state department of health of at least on child with a blood Pb concentration >15 µg/dL and Pb paint dust may have contributed to indoor dust Pb. The mean IVBA was 64.8% (SD 8.2, age: 52.5 to 77.2 months).

The above results, and the IVBA assays used in studies of interior dust, have not been evaluated against in vivo RBA estimates for dust samples. Although, expectations are that a validated IVBA methodology for soil would perform well for predicting RBA of interior dust, this validation has not actually been experimentally confirmed. Factors that may affect in vitro predictions of RBA of interior dust Pb could include particle size

distribution of interior dust Pb and the composition of the dust matrix, which may be quite different from that of soil.

Other estimates of bioaccessibility of Pb in house dusts have been reported, based on results from in vitro extraction assays that have not been validated for predicting in vivo bioavailability. Bioaccessibility assays that sequentially extract soil at gastric pH followed by intestinal pH tend to show higher bioaccessibility of soil and dust Pb when incubated at gastric conditions (Juhasz et al., 2011; Lu et al., 2011; Smith et al., 2011; Roussel et al., 2010; Yu et al., 2006). Yu et al. (2006) dissolved Pb dust, obtained from vacuuming carpet samples into simulated gastric and intestinal acids (also Section 4.1.3.2). The carpet samples were obtained from homes located in northern New Jersey. Pb concentration in carpet ranged from 209 to 1,770 mg/kg dust, with 52-77% of Pb dissolving in simulated gastric acid and 5-32% dissolving in simulated intestinal acids. In a similar test in the U.K., Turner and Simmonds (2006) observed median Pb dust concentrations of 178 mg/kg with approximately 80% bioaccessibility in simulated gastric acid. Jin et al. (2005) observed that bioaccessibility of Pb in soil was proportional to the soil acidity and organic matter content of the soil.

4.2.2 Distribution

A simple conceptual representation of Pb distribution is that it contains a fast turnover pool, comprising mainly soft tissue, and a slow pool, comprising mainly skeletal tissues (Rabinowitz et al., 1976). The highest soft tissue concentrations in adults occur in liver and kidney cortex (Gerhardsson et al., 1995; Oldereid et al., 1993; Gerhardsson et al., 1986; Barry, 1975; Gross et al., 1975). Pb in blood (i.e., plasma) exchanges with both of these compartments.

4.2.2.1 Blood

Blood comprises ~1% of total Pb body burden. Pb in blood is found primarily (>99%) in the RBCs (Smith et al., 2002; Manton et al., 2001; Bergdahl et al., 1999; Bergdahl et al., 1998; Hernandez-Avila et al., 1998; Bergdahl et al., 1997a; Schutz et al., 1996). δ-aminolevulinic acid dehydratase (ALAD) is the primary binding ligand for Pb in erythrocytes (Bergdahl et al., 1998; Xie et al., 1998; Bergdahl et al., 1997a; Sakai et al., 1982). Two other Pb-binding proteins have been identified in the RBC, a 45 kDa protein (K_{max} 700 µg/dL; K_d 5.5 µg/L) and a smaller protein(s) having a molecular weight <10 kDa (Bergdahl et al., 1998; Bergdahl et al., 1997a; Bergdahl et al., 1996). Of the three principal Pb-binding proteins identified in RBCs, ALAD has the strongest affinity

for Pb (Bergdahl et al., 1998) and appears to dominate the ligand distribution of Pb (35 to 84% of total erythrocyte Pb) at blood Pb levels below 40 µg/dL (Bergdahl et al., 1998; Bergdahl et al., 1996; Sakai et al., 1982). Pb binding to ALAD is saturable; the binding capacity was estimated to be ~850 µg/dL RBCs (or ~40 µg/dL whole blood) and the apparent dissociation constant has been estimated to be ~1.5 µg/L (Bergdahl et al., 1998). Binding to fetal hemoglobin within the RBC has a higher affinity for Pb than adult hemoglobin. This suggests that erythrocytes of neonates should be able to store more Pb than infants (Simon et al., 2007). Hematocrit is somewhat higher in the neonate at birth (51%) than in later infancy (35% at 6 months), which may lead to a decrease in the total binding capacity of blood over the first 6 months of life that results in a redistribution of Pb among other tissues (Simon et al., 2007).

Saturable binding to RBC proteins contributes to an increase in the plasma/blood Pb ratio with increasing blood Pb concentration and curvature to the blood Pb–plasma Pb relationship (Kang et al., 2009; Jin et al., 2008; Barbosa et al., 2006b; Smith et al., 2002; Manton et al., 2001; Bergdahl et al., 1999; Bergdahl et al., 1998; Bergdahl et al., 1997b; DeSilva, 1981; Rentschler et al., In Press). An example of this is shown in Figure 4-4. Saturable binding of Pb to RBC proteins has several important consequences. As blood Pb increases and the higher affinity binding sites for Pb in RBCs become saturated, a larger fraction of the blood Pb is available in plasma to distribute to brain and other Pb-responsive tissues. This change in distribution of Pb contributes to a curvature in the relationship between Pb intake (at constant absorption fraction) and blood Pb concentration. Plasma Pb also exhibits faster kinetics. Following exposures of 5 adults that resulted in relatively high blood Pb concentrations (56-110 µg/dL), the initial (fast-phase) elimination half-time for plasma Pb (38 ± 20 [SD] days) was approximately half that of blood (81 ± 25 days) (Rentschler et al., In Press).

Typically, at blood Pb concentrations <100 µg/dL, only a small fraction (<1%) of blood Pb is found in plasma (Marcus, 1985; Manton and Cook, 1984; DeSilva, 1981). However, as previously noted, plasma Pb may be the more biologically labile and toxicologically active fraction of the circulating Pb. Approximately 40-75% of Pb in the plasma is bound to proteins, of which albumin appears to be the dominant ligand (Al-Modhefer et al., 1991; Ong and Lee, 1980a). Pb in serum that is not bound to protein exists largely as complexes with low molecular weight sulfhydryl compounds (e.g., cysteine, homocysteine) and other ligands (Al-Modhefer et al., 1991).

Figure 4-4 Plot of blood and plasma Pb concentrations measured in adults and children.

As shown in Figure 4-4, the limited binding capacity of Pb binding proteins in RBCs produces a curvilinear relationship between blood and plasma Pb concentration. The limited binding capacity of RBC binding proteins also confers, or at least contributes, to a curvilinear relationship between Pb intake and blood Pb concentration. A curvilinear relationship between Pb intake and blood Pb concentration has been observed in children (Sherlock and Quinn, 1986; Lacey et al., 1985; Ryu et al., 1983). As shown in Figure 4-5, the relationship becomes pseudo-linear at relatively low daily Pb intakes (i.e., <10 µg/day/kg) and at blood Pb concentrations <25 µg/dL.

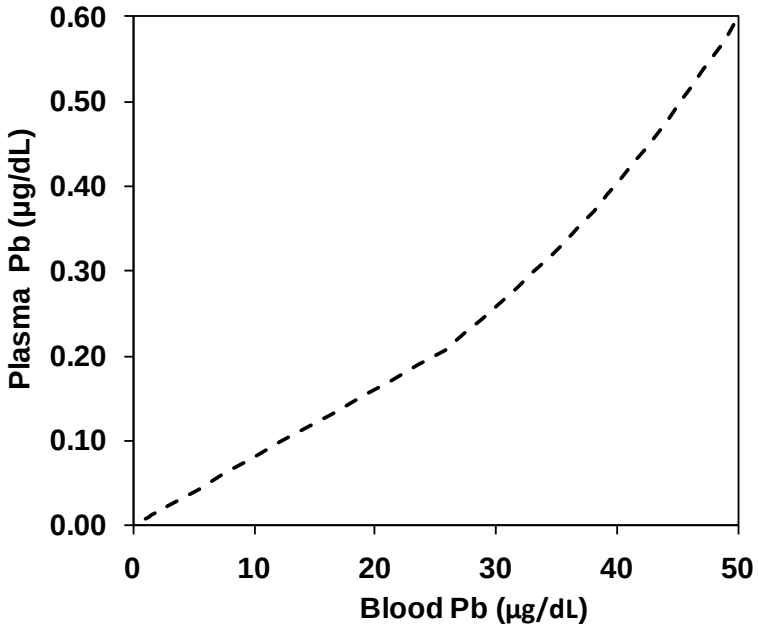
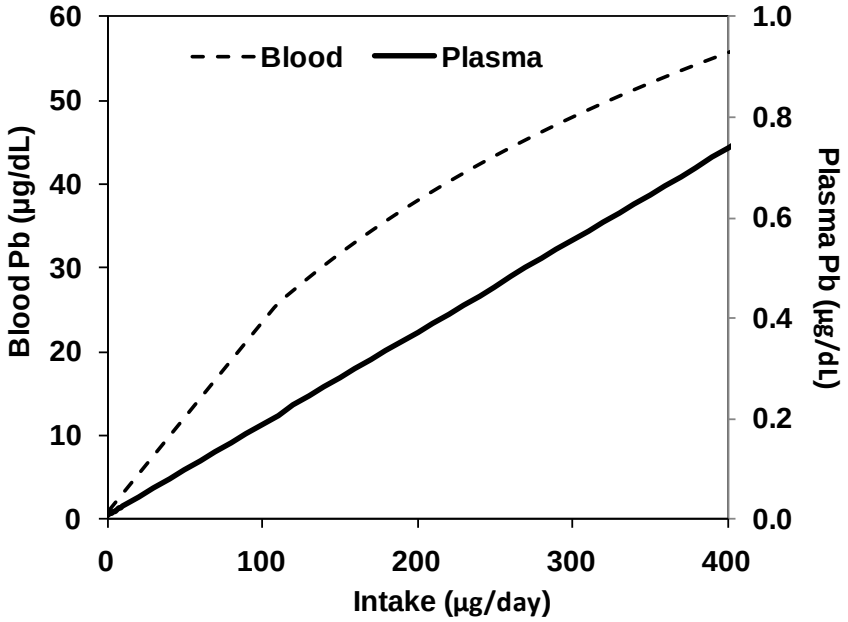
Data represent mean and standard errors for intake; the line is the regression model (blood Pb = 3.9 + 2.43 (Pb intake [µg/week]$^{1/3}$).

Figure 4-5 Relationship between Pb intake and blood Pb concentration in infants (n = 105, age 13 weeks, formula-fed).

Figure 4-6 shows the predicted relationship between quasi-steady state blood and plasma Pb concentrations in a 4-year old child using the ICRP model (Pounds and Leggett, 1998; ICRP, 1994; Leggett, 1993), see Section 4.3 for a brief description of the ICRP model]. The abrupt inflection point that occurs at approximately 25 µg/dL blood Pb is an artifact of the numerical approach to simulate the saturation of binding using discontinuous first-order rate constants for uptake and exit of Pb from the RBC. A continuous function of binding sites and affinity, using empirical estimates of both parameters, yield a similar but continuous curvature in the relationship (Bergdahl et al., 1998; O'Flaherty, 1995). Nevertheless, either approach predicts a pseudo-linear relationship at blood Pb concentrations below approximately 25 µg/dL which, in this model, corresponds to an intake of approximately 100 µg/day (absorption rate ≈ 30 µg/day) (upper panel). An important consequence of the limited Pb binding capacity of RBC proteins is that the plasma Pb concentration will continue to grow at a linear rate above the saturation point for RBC protein binding. One implication of this is that a larger fraction of the Pb in blood will become available to distribute to brain and other Pb-responsive tissues as blood Pb increases. This could potentially contribute to non-linearity in dose-response relationships in studies in which blood Pb is the used as the internal dose metric.





Simulation based on ICRP Pb biokinetics model (Leggett, 1993).

Figure 4-6 Simulation of quasi-steady state blood and plasma Pb concentrations in a child (age 4 years) associated with varying Pb ingestion rates.

Studies conducted in swine provide additional evidence in support of RBC binding kinetics influencing distribution of Pb to tissues. In these studies, the relationship between the ingested dose of Pb and tissue Pb concentrations (e.g., liver, kidney, bone) was linear, whereas, the relationship between dose and blood Pb was curvilinear with the

slope decreasing as the dose increased (Casteel et al., 2006). Saturable binding of Pb to RBC proteins also contributes to a curvilinear relationship between urinary Pb excretion and plasma Pb concentration (Section 4.2.3) (Besser et al., 2008; Bergdahl et al., 1997b).

4.2.2.2 Bone

The dominant compartment for Pb in the body is in bone. In human adults, 94% of the total body burden of Pb is found in the bones, whereas bone Pb accounts for 73% of the body burden in children (Barry, 1975). Bone is comprised of two main types, cortical (or compact) and trabecular (or spongy or cancellous). The proportion of cortical to trabecular bone in the human body varies by age, but on average is about 80 to 20 percent (O'Flaherty, 1998; Leggett, 1993; ICRP, 1973).

The exchange of Pb from plasma to the bone surface is a rapid process (i.e., adult $t_{1/2}$ =0.19 and 0.23 hours for trabecular and cortical bone, respectively) (Leggett, 1993). Some Pb diffuses from the bone surface to deeper bone regions (adult $t_{1/2}$=150 days) where it is relatively inert (in adults) and part of a "nonexchangeable" pool of Pb in bone (Leggett, 1993).

Pb distribution in bone includes uptake into cells that populate bone (e.g., osteoblasts, osteoclasts, osteocytes) and exchanges with proteins and minerals in the extracellular matrix (Pounds et al., 1991). Pb forms highly stable complexes with phosphate and can replace calcium in the calcium-phosphate salt, hydroxyapatite, which comprises the primary crystalline matrix of bone (Meirer et al., 2011; Brès et al., 1986; Miyake, 1986; Verbeeck et al., 1981). Several intracellular kinetic pools of Pb have been described in isolated cultures of osteoblasts and osteoclasts which appear to reflect physiological compartmentalization within the cell, including membranes, mitochondria, soluble intracellular binding proteins, mineralized Pb (i.e., hydroxyapatite) and inclusion bodies (Long et al., 1990; Pounds and Rosen, 1986; Rosen, 1983). Approximately 70-80% of Pb taken up into isolated primary cultures of osteoblasts or osteocytes is associated with mitochondria and mineralized Pb (Pounds et al., 1991).

Pb accumulates in bone regions having the most active calcification at the time of exposure. Pb accumulation is thought to occur predominantly in trabecular bone during childhood and in both cortical and trabecular bone in adulthood (Aufderheide and Wittmers, 1992). Early Pb uptake in children is greater in trabecular bone due to its larger surface area and higher metabolic rate. With continued exposure, Pb concentrations in bone may increase with age throughout the lifetime beginning in childhood, indicative of a relatively slow turnover of Pb in adult bone (Park et al., 2009a; Barry and Connolly, 1981; Barry, 1975; Gross et al., 1975; Schroeder and Tipton, 1968). The cortical and

trabecular bones have distinct rates of turnover and Pb release. For example, tibia has a turnover rate of about 2% per year whereas trabecular bone has a turnover rate of more than 8% per year in adults (Rabinowitz, 1991).

A high bone formation rate in early childhood results in the rapid uptake of circulating Pb into mineralizing bone; however, bone Pb is also recycled to other tissue compartments or excreted in accordance with a high bone resorption rate (O'Flaherty, 1995). Thus, most of the Pb acquired early in life is not permanently fixed in the bone (60-65%) (O'Flaherty, 1995; Leggett, 1993; ICRP, 1973). However, some Pb accumulated in bone does persist into later life. McNeill et al. (2000) compared tibia Pb levels and cumulative blood Pb indices in a population of 19- to 29-year-olds who had been highly exposed to Pb in childhood from the Bunker Hill, Idaho smelter; they concluded that Pb from exposure in early childhood had persisted in the bone matrix until adulthood.

A key factor affecting Pb uptake into bone is the fraction of bone surface in trabecular and cortical bone adjacent to active bone marrow. Of the total bone surface against red marrow, 76% is trabecular and 24% is cortical endosteal (Salmon et al., 1999). The fraction of total bone marrow that is red and active decreases from 100% at birth to about 32% in adulthood (Cristy, 1981). However, bone marrow has much lower Pb concentrations than bone matrix (Skerfving et al., 1983).

4.2.2.3 Soft Tissues

Most of the Pb in soft tissue is in liver and kidney (Gerhardsson et al., 1995; Oldereid et al., 1993; Gerhardsson et al., 1986; Barry, 1975; Gross et al., 1975). Presumably, the Pb in these soft tissues (i.e., kidney, liver, and brain) exists predominantly bound to protein. High affinity cytosolic Pb-binding proteins have been identified in rat kidney and brain (DuVal and Fowler, 1989; Fowler, 1989). The Pb-binding proteins in rat are cleavage products of α2μ globulin, a member of the protein superfamily known as retinol-binding proteins that are generally observed only in male rats (Fowler and DuVal, 1991). Other high-affinity Pb-binding proteins (K_d ~14 nM) have been isolated in human kidney, two of which have been identified as a 5 kDa peptide, thymosin 4 and a 9 kDa peptide, acyl-CoA binding protein (Smith et al., 1998). Pb also binds to metallothionein, but does not appear to be a significant inducer of the protein in comparison with the inducers Cd and Zn (Waalkes and Klaassen, 1985; Eaton et al., 1980).

The liver and kidneys rapidly accumulate systemic Pb ($t_{1/2}$=0.21 and 0.41 hours, respectively), which amounts to 10-15% and 15-20% of intravenously injected Pb, respectively (Leggett, 1993). A linear relationship in dose-tissue Pb concentrations for kidney and liver has been demonstrated in swine, dogs, and rats (Smith et al., 2008;

Casteel et al., 2006; Casteel et al., 1997; Azar et al., 1973). In contrast to Pb in bone, which accumulates Pb with continued exposure in adulthood, concentrations in soft tissues (e.g., liver and kidney) are relatively constant in adults (Treble and Thompson, 1997; Barry, 1975), reflecting a faster turnover of Pb in soft tissue relative to bone.

4.2.2.4 Fetus

Evidence for maternal-to-fetal transfer of Pb in humans is derived from cord blood to maternal blood Pb ratios. Group mean ratios range from about 0.7 to 1.0 at the time of delivery for mean maternal blood Pb levels ranging from 1.7 to 8.6 µg/dL (Amaral et al., 2010; Kordas et al., 2009; Patel and Prabhu, 2009; Carbone et al., 1998; Goyer, 1990; Graziano et al., 1990). In a study of mothers having blood Pb levels of <14 µg/dL, the ratio of cord blood Pb to maternal blood Pb decreased with decreasing maternal blood Pb (r=0.82) (Carbone et al., 1998). In addition, the similarity of isotopic ratios in maternal blood and in blood and urine of newly-born infants provide further evidence for placental transfer of Pb to the fetus (Gulson et al., 1999).

Transplacental transfer of Pb may be facilitated by an increase in the plasma/blood Pb concentration ratio during pregnancy (Montenegro et al., 2008; Lamadrid-Figueroa et al., 2006). Maternal-to-fetal transfer of Pb appears to be related partly to the mobilization of Pb from the maternal skeleton. Evidence for transfer of maternal bone Pb to the fetus has been provided by stable Pb isotope studies in cynomolgus monkeys exposed during pregnancy. Approximately 7-39% of the maternal Pb burden transferred to the fetus was derived from the maternal skeleton, with the remainder derived from contemporaneous exposure (O'Flaherty, 1998; Franklin et al., 1997).

4.2.2.5 Organic Lead

Information on the distribution of Pb in humans following exposures to organic Pb is extremely limited. However, as reported in the 2006 Pb AQCD, the available evidence demonstrates near complete absorption following inhalation of tetraalkyl Pb vapor and subsequent transformation to trialkyl Pb metabolites. One hour following brief inhalation exposures to ^{203}Pb tetraethyl or tetramethyl Pb (1 mg/m^3), ~50% of the ^{203}Pb body burden was associated with liver and 5% with kidney; the remaining ^{203}Pb was widely distributed throughout the body (Heard et al., 1979). The kinetics of ^{203}Pb in blood showed an initial declining phase during the first 4 hours (tetramethyl Pb) or 10 hours (tetraethyl Pb) after the exposure, followed by a reappearance of radioactivity back into the blood after ~20 hours. The high level of radioactivity initially in the plasma indicates the presence of

tetraalkyl/trialkyl Pb. The subsequent rise in blood radioactivity, however, probably represents water-soluble inorganic Pb and trialkyl and dialkyl Pb compounds that were formed from the metabolic conversion of the volatile parent compounds (Heard et al., 1979).

Alkyl Pb compounds undergo oxidative dealkylation catalyzed by cytochrome P450 in liver and, possibly, in other tissues. Trialkyl Pb metabolites have been found in the liver, kidney, and brain following exposure to the tetraalkyl compounds in workers (Bolanowska et al., 1967); these metabolites have also been detected in brain tissue of nonoccupational subjects (Nielsen et al., 1978).

4.2.3 Elimination

The rapid-phase (30-40 days) of Pb excretion amounts to 50-60% of the absorbed fraction (Chamberlain et al., 1978; Rabinowitz et al., 1976; Kehoe, 1961a, b, c). Absorbed Pb is excreted primarily in urine and feces, with sweat, saliva, hair, nails, and breast milk being minor routes of excretion (Kehoe, 1987; Chamberlain et al., 1978; Rabinowitz et al., 1976; Griffin et al., 1975; Hursh et al., 1969; Hursh and Suomela, 1968).

Approximately 30% of intravenously injected Pb in humans (40-50% in beagles and baboons) is excreted via urine and feces during the first 20 days following administration (Leggett, 1993). The kinetics of urinary excretion following a single dose of Pb is similar to that of blood (Chamberlain et al., 1978), likely due to the fact that Pb in urine derives largely from Pb in plasma. Evidence for this is the observation that urinary Pb excretion is strongly correlated with the rate of glomerular filtration of Pb (Araki et al., 1986) and plasma Pb concentration (Bergdahl et al., 1997b; Rentschler et al., In Press) (i.e., glomerular filtration rate × plasma Pb concentration), and both relationships are linear. While the relationship between urinary Pb excretion and plasma Pb concentration is linear, the plasma Pb relationship to blood Pb concentration is curvilinear (as described in Section 4.2.2.1 and demonstrated in Figure 4-6). This relationship contributes to an increase in the renal clearance of Pb from blood with increasing blood Pb concentrations (Chamberlain, 1983). Similarly, a linear relationship between plasma Pb concentration and urinary excretion rate predicts a linear relationship between Pb intake (at constant absorption fraction) and urinary Pb excretion rate, whereas the relationship with blood Pb concentration would be expected to be curvilinear (Section 4.3.7).

Estimates of urinary filtration of Pb from serum (or plasma) range from 13-22 L/day, with a mean of 18 L/day (Araki et al., 1986; Manton and Cook, 1984; Manton and Malloy, 1983; Chamberlain et al., 1978), which corresponds to half-time for transfer of

Pb from plasma to urine of 0.1-0.16 days for a 70-kg adult who has a plasma volume of ~3 L. The rate of urinary excretion of Pb was less than the rate of glomerular filtration of ultrafilterable Pb, suggesting that urinary Pb is the result of incomplete renal tubular re-absorption of Pb in the glomerular filtrate (Araki et al., 1986); although, net tubular secretion of Pb has been demonstrated in animals (Victery et al., 1979; Vander et al., 1977). On the other hand, estimates of blood-to-urine clearance range from 0.03-0.3 L/day with a mean of 0.18 L/day (Diamond, 1992; Araki et al., 1990; Berger et al., 1990; Koster et al., 1989; Manton and Malloy, 1983; Ryu et al., 1983; Chamberlain et al., 1978; Rabinowitz et al., 1973), consistent with a plasma Pb to blood Pb concentration ratio of ~0.005–0.01 L/day (Klotzback et al., 2003). Based on the above differences, urinary excretion of Pb can be expected to reflect the concentration of Pb in plasma and variables that affect delivery of Pb from plasma to urine (e.g., glomerular filtration and other transfer processes in the kidney).

The value for fecal:urinary excretion ratio (~0.5) was observed during days 2-14 following intravenous injection of Pb in humans (Chamberlain et al., 1978; Booker et al., 1969; Hursh et al., 1969). This ratio is slightly higher (0.7-0.8) with inhalation of submicron Pb-bearing PM due to ciliary clearance and subsequent ingestion. The transfer of Pb from blood plasma to the small intestine by biliary secretion in the liver is rapid (adult $t_{1/2}$ = 10 days), and accounts for 70% of the total plasma clearance (O'Flaherty, 1995).

Organic Lead

Pb absorbed after inhalation of tetraethyl and tetramethyl Pb is excreted in exhaled air, urine, and feces (Heard et al., 1979). Fecal:urinary excretion ratios were 1.8 following exposure to tetraethyl Pb and 1.0 following exposure to tetramethyl Pb (Heard et al., 1979). Occupational monitoring studies of workers exposed to tetraethyl Pb showed that tetraethyl Pb is excreted in the urine as diethyl Pb, ethyl Pb, and inorganic Pb (Vural and Duydu, 1995; Zhang et al., 1994; Turlakiewicz and Chmielnicka, 1985).

4.3 Lead Biomarkers

This section describes the biological measurements of Pb and their interpretation as indicators of exposure or body burden.

For any health endpoint of interest, the most useful biomarker of exposure is one that provides information about the Pb dose at the critical target organ and, moreover, reflects the exposure averaging time that is appropriate to the underlying pathogenetic processes

(e.g., instantaneous, cumulative over lifetime, or cumulative over a circumscribed age range). In recent studies of Pb and health, the exposure biomarkers most frequently used are Pb in blood and bone. For outcomes other than those relating to hematopoiesis and bone health, these biomarkers provide information about Pb dose that is some distance from the target organ. For example, given that the central nervous system is considered the critical target organ for childhood Pb toxicity, it would be most helpful to be able to measure, in vivo, the Pb concentrations at the cellular site(s) of action in the brain. However, because such measurements are not currently feasible, investigators must rely on measurements of Pb in the more readily accessible but peripheral tissues. The relationship between brain Pb and Pb in each of these surrogate tissues is still poorly understood, although the pharmacokinetics clearly differs among these compartments.

As an exposure biomarker, blood Pb concentration has other limitations. Only about 5% of an individual's total body Pb burden resides in blood. Furthermore, blood consists of several subcompartments. More than 90% of Pb in whole blood is bound to red cell proteins such as hemoglobin, with the balance in plasma. From a toxicological perspective, the unbound fraction is likely to be the most important subcompartment of blood Pb because it distributes into soft tissues. The concentration of Pb in plasma is much lower than in whole blood (<1%). The greater relative abundance of Pb in whole blood makes its measurement much easier (and more affordable) than measurement of Pb in plasma. The use of whole blood Pb as a surrogate for plasma Pb could be justified if the ratio of whole blood Pb to plasma Pb were well characterized, but this is not so. At least some studies suggest that it varies several-fold among individuals with the same blood Pb level. Moreover, binding Pb in red blood cells is limited, so the ratio of blood Pb to plasma Pb would be expected to be nonlinear. Thus, interpreting whole blood Pb level as a proxy for plasma Pb level, which, itself, is a proxy for brain Pb level, will result in some exposure misclassification.

Another limitation of blood Pb as an exposure biomarker is that the kinetics of Pb in blood is relatively fast compared to the kinetics of Pb in bone, and therefore, of the whole body burden. Thus, a high blood Pb concentration measured at any given time does not necessarily indicate a high body Pb burden. Similarly, individuals who have the same blood Pb level will not necessarily have similar body burdens or exposure histories. The rate at which blood Pb changes with time/age depends on exposure history due to re-equilibration of Pb stored in the various body pools.

The development of X-ray-fluorescence (XRF) methods for measuring Pb in mineralized tissues offers another approach for characterization and reconstruction of exposure history. Such tissues are long-term Pb storage sites, with a half-life measured in decades

and contain ~90% of the total body Pb burden in adults and 70% in children. Thus, bone Pb reflects a long exposure averaging time.

Mechanistic models are used throughout the section as a means to describe basic concepts that derive from the wealth of information on Pb toxicokinetics. Although predictions from models are inherently uncertain, models can serve to illustrate expected interrelationships between Pb intake and tissue distribution that are important in interpreting human clinical and epidemiologic studies. Thus, models serve as the only means we have for synthesizing our extensive, but incomplete, knowledge of Pb biokinetics into a holistic representation of Pb biokinetics. Furthermore, models can also be used to make predictions about biokinetics relationships that have not been thoroughly evaluated in experiments or epidemiologic studies. In this way, models can serve as heuristic tools for shaping data collection to improve our understanding of Pb biokinetics.

Mechanistic toxicokinetics models can make predictions about hypothetical populations and exposure scenarios. When a model is run as a single simulation, the output represents average outcomes from what is in reality a distribution of possible outcomes that would be expected in the population (or in any single individual) where intra-individual and inter-individual variability in exposure and toxicokinetics exist. More realistic predictions for the population can be developed by running a series of model simulations in which ranges (i.e., distributions) of parameter values are considered that may better represent the population of interest. In this section, only single simulations are used to demonstrate relationships between various biomarkers (e.g., blood Pb and bone Pb) that would apply to a population having "typical" or "average" exposure and toxicokinetics. These single simulations are used for illustrative purposes to describe general concepts and patterns. Variability would be expected in real populations.

Numerous mechanistic models of Pb biokinetics in humans have been proposed, and these are described in the 2006 Pb AQCD (U.S. EPA, 2006b) and in the supporting literature cited in that report. In this section, for simplicity and for internal consistency, we have limited the discussion to predictions from a single model, the ICRP Pb biokinetics model (Pounds and Leggett, 1998; ICRP, 1994; Leggett, 1993). The ICRP model consists of a systemic biokinetics model (Leggett, 1993) and a human respiratory tract model (ICRP, 1994). The Leggett model simulates age-dependent kinetics of tissue distribution and excretion of lead ingestion and inhalation intakes. This model was originally developed for the purpose of supporting radiation dosimetry predictions and it has been used to develop cancer risk coefficients for internal radiation exposures to lead and other alkaline earth elements that have biokinetics similar to those of calcium (ICRP, 1993). Although the ICRP model has not been validated by U.S. EPA as a regulatory model for lead risk assessment, it has been applied in Pb risk assessment (Abrahams et

al., 2006; Lorenzana et al., 2005; Khoury and Diamond, 2003). Portions of the model have been incorporated into an AALM that is being developed by EPA (2005a). In addition to the above considerations regarding previous applications of the ICRP model, the model was selected for use in the ISA because it has several useful features for predicting exposure-body burden relationships. The model simulates blood Pb and tissue Pb concentration dynamics associated with the uptake and elimination phases of exposures of ≥ 1 day in duration; and it simulates age-dependent and particle size-dependent deposition and clearance of inhaled lead in the respiratory tract. These types of simulations can only be approximated with the U.S. EPA IEUBK Model for lead in children because it simulates exposures in time steps of 1 year (i.e., age-year average exposures); lumps the simulation of deposition, mechanical clearance, and absorption of inhaled lead into a single absorption term representing the combined processes of gastrointestinal and respiratory tract absorption of inhaled lead; simulates steady state blood Pb concentrations and was does not allow access to the underlying simulations of tissue Pb concentrations which serve as intermediate variables in the model for predicting steady state blood Pb concentrations. Other models have been developed that allow simulations of tissue Pb concentrations (e.g., O'Flaherty, 1995; Leggett, 1993) and comparisons of these models have been previously described (Maddaloni et al., 2005).

Pb biokinetics in adolescents is poorly characterized by all existing Pb biokinetics models. Individuals undergo rapid changes in sexual development, growth, food and water intake, bone growth and turnover, behavior, etc. during adolescence. There is a paucity of experimental measurements of Pb biomarkers during this time developmental window. The individual biological and kinetic parameters for adolescents are largely interpolated rather than based on solid experimental and toxicological measurements. These deficiencies limit the validity of model predictions in this age group.

4.3.1 Bone Lead Measurements

For Pb measurements in bone, the most commonly examined bones are the tibia, calcaneus, patella, and finger bone. For cortical bone, the midpoint of the tibia is measured. For trabecular bone, both the patella and calcaneus are measured. The tibia consists of more than 95% cortical bone, the calcaneus and patella comprise more than 95% trabecular bone, and finger bone is a mixed cortical and trabecular bone although the second phalanx is dominantly cortical. Recent studies favor measurement of the patella for estimating trabecular bone Pb, because it has more bone mass and may afford better measurement precision than the calcaneus.

Bone Pb measurements are typically expressed in units of Pb/g bone mineral. This convention may potentially introduce variability into the bone Pb measurements related to variation in bone density. Typically, potential associations between bone density and bone Pb concentration are not evaluated in epidemiologic studies (Theppeang et al., 2008a; Hu et al., 2007a). An important consequence of expressing bone Pb measures relative to bone mineral content is that lower bone mineral density is associated with greater measurement uncertainty in bone Pb. This can have important implications for studies in older women for whom low bone mineral density is more common than in other populations including men and younger adults.

Methods of direct analysis of bone tissue samples include flame atomic absorption spectrometry (AAS), anode stripping voltammetry (ASV), inductively coupled plasma atomic emission spectroscopy (ICP-AES), inductively coupled plasma mass spectrometry (ICP-MS), laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS), thermal ionization mass spectrometry (TIMS), synchrotron radiation induced X-ray emission (SRIXE), particle induced X-ray emission (PIXE), and X-ray fluorescence (XRF). Non-invasive, in vivo measurements of bone Pb is achieved with XRF. The upsurge in popularity of the XRF method has paralleled a decline in the use of the other methods. More information on the precision, accuracy, and variability in bone Pb measurements can be found in the 2006 Pb AQCD (U.S. EPA, 2006b).

Two main approaches for XRF measurements have been used to measure Pb concentrations in bone, the K-shell and L-shell methods. The K-shell method is the most widely used, as there have been relatively few developments in L-shell devices since the early 1990s. However, Nie et al. (2011) recently reported on the use of a new portable L-shell device for human in vivo Pb measurements. Advances in L-shell device technology resulted in much higher sensitivity than previous L-shell devices. The new L-shell device showed sensitivity similar to that of K-shell methods (detection limit was approximately 8 µg/g bone mineral with 2 mm of soft tissue overlay targeted bone) and a high correlation with results obtained from K-shell methods (intraclass correlation = 0.65). Behinaen et al. (2011) described application of a 4-detector system (“*clover leaf array*”) for the K-shell method that provided higher precision and lower minimum detection limits (MDL) for tibia and calcaneus Pb measurements (3.25 and 4.78 µg/g bone mineral, respectively) compared to measurements made with single detectors (8-12 µg/g and 14-15 µg/g, respectively).

Since 1986, several investigators have reported refinements to hardware and software to improve the precision and accuracy of XRF measurements and there have been a number of investigations into the precision, accuracy and variability in XRF measurements [e.g., (Todd et al., 2002; Todd et al., 2001; Aro et al., 2000; Todd et al., 2000)]. Todd

et al. (2000) provided a detailed discussion of factors that influence the variability and measurement uncertainty, including repositioning, sample measurement duration, overlying tissue, operator expertise, detector resolution, and changes to measurement process over time. Some of these aspects were also discussed by Hu et al. (1995). From their cadaver and in vivo measurements, Todd et al. (2000) concluded that the uncertainty in an individual measurement was an underestimate of the standard deviation of replicate measurements, suggesting a methodological deficiency probably shared by most current ^{109}Cd-based K-shell XRF Pb measurement systems. In examining the reproducibility of the bone Pb measurements over a 4½ month period, Todd et al. found the average difference between the XRF results from short term and longer term measurements was 1.2 µg/g, indicating only a small amount of variability in the XRF results over a sustained period of time.

In the epidemiologic literature, XRF bone Pb data have typically been reported in two ways: one that involves a methodological approach to assessing the minimum detection limit and the other termed an epidemiologic approach by Rosen and Pounds (1998). In the former approach, a minimum detection limit is defined using various methods, including two or three times the square root of the background counts; one, two, or three times the SD of the background; or two times the observed median error. This approach relies upon the minimum detection limit to define a quantitative estimate that is of sufficient precision to be included in the statistical analysis, as demonstrated by Bellinger et al. (1994a), Gerhardsson et al. (1993), and Christoffersson et al. (1986).

With the epidemiologic approach, all values are used (including negative values) to determine the minimum detection limit of an instrument that results in extremely low detection limits. Rosen and Pounds (1998) noted that this approach yields population bone Pb averages that were artificially low. However, not including values that are negative or below the detection limit, or assigning these values a fixed number is also of concern. Using the epidemiologic approach of retaining all point estimates of measured bone Pb concentrations provided the least amount of bias and the greatest efficiency in comparing the mean or median levels of bone Pb of different populations (Kim et al., 1995).

4.3.2 Blood Lead Measurements

Analytical methods for measuring Pb in blood include AAS, graphite furnace atomic absorption spectrometry (GFAAS), ASV, ICP-AES, and ICP-MS. GFAAS and ASV are generally considered to be the methods of choice (Flegal and Smith, 1995). Limits of detection for Pb using AAS are on the order of 5-10 µg/dL for flame AAS measurements

and approximately 0.1 µg/dL for flameless AAS measurements (Flegal and Smith, 1995; NIOSH, 1994). A detection limit of 0.005 µg/dL has been achieved for Pb in blood samples analyzed by GFAAS.

For measurement of Pb in plasma, ICP-MS provides sufficient sensitivity (Schutz et al., 1996). While the technique has been applied to assessing Pb exposures in adults, ICP-MS has not received widespread use in epidemiologic studies.

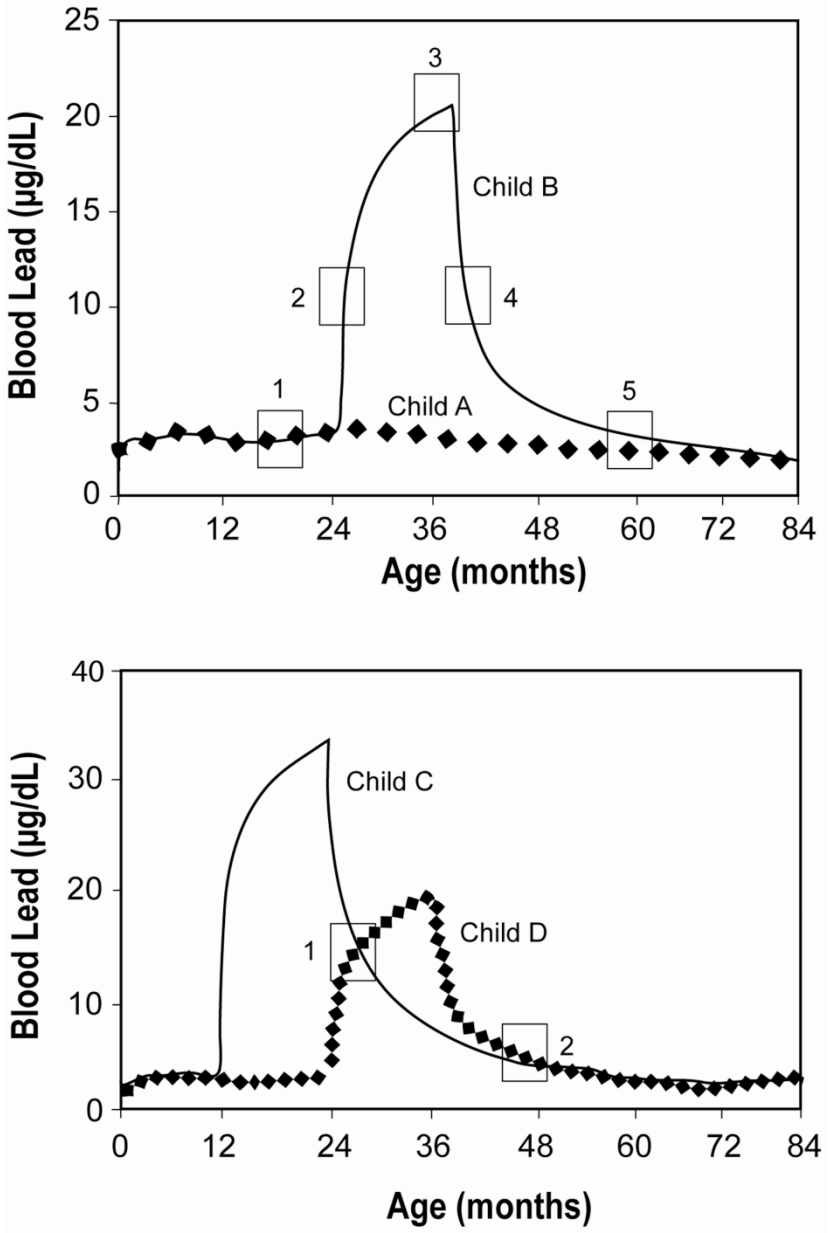
The primary binding ligand for Pb in RBC, ALAD, is encoded by a single gene in humans that is polymorphic in two alleles (ALAD1 and ALAD2) (Scinicariello et al., 2007). Since the ALAD1 and ALAD 2 alleles can be co-dominantly expressed, 3 different genotypes (ALAD 1-1, ALAD 1-2, and ALAD 2-2) are possible. The ALAD 1-1 genotype is the most common. Scinicariello et al. (2010) tested genotypes in civilian, non-institutionalized U.S. individuals that participated as part of NHANES III from 1988–1994 and found that 15.6% of non-Hispanic whites, 2.6% non-Hispanic blacks, and 8.8% Mexican Americans carried the ALAD2 allele.

The 2006 Pb AQCD document reports that many studies have shown that, with similar exposures to Pb, individuals with the ALAD-2 allele have higher blood Pb levels than those without (Kim et al., 2004; Pérez-Bravo et al., 2004; Bergdahl et al., 1997b; Smith et al., 1995a; Wetmur, 1994; Wetmur et al., 1991a; Astrin et al., 1987). More recent meta analyses provide further support for ALAD2 carriers having higher blood Pb levels than ALAD1-1 homozygotes (Scinicariello et al., 2007; Zhao et al., 2007). The mechanism for this association may be higher Pb binding affinity of ALAD2. Although, this interpretation would be consistent with the structural differences that result in greater electronegativity of ALAD1 compared to ALAD2 (Wetmur, 1994; Wetmur et al., 1991b), measurements of Pb binding affinity to ALAD1 and ALAD2 (i.e., Pb^{2+} displacement of Zn^{2+} binding to recombinant ALAD1 and ALAD2) have not revealed differences in Pb binding affinity (Jaffe et al., 2000). In a meta-analysis of 24 studies, Scinicariello et al. (2007), observed the greatest differences for ALAD2 compared to ALAD1 in highly exposed adults with little difference among environmentally-exposed adults; large differences were also observed for children at low exposures. However, there are few studies that evaluated children and the largest study contributing to the meta analysis may have been influenced by selection bias (Scinicariello et al., 2007). Individual studies find similar results in occupationally-exposed adults, with blood Pb levels being higher in individuals with ALAD2 alleles (Miyaki et al., 2009; Shaik and Jamil, 2009). A subsequent meta analysis of adult data from NHANES III did not find any differences in blood Pb level between all carriers of either the ALAD 1-1 or ALAD 1-2/2-2 allele (Scinicariello et al., 2010). Other studies provide further support for no blood Pb differences among ALAD1 and ALAD2 carriers (Sobin et al., 2009; Rabstein et

al., 2008; Montenegro et al., 2006; Wananukul et al., 2006) or lower blood Pb levels for individuals with ALAD 1-2/2-2 (Krieg et al., 2009; Chia et al., 2006).

Genetic polymorphism in the gene that encodes for peptide transporter 2 (PEPT2) has been associated with variability in blood Pb concentrations in children (Sobin et al., 2009). PEPT2 expression in the brain and renal proximal tubule has been associated with transport of di- and tri-peptides and may function in the transport of δ-ALA into brain and renal tubular re-absorption of peptides. The PRPT2*2 polymorphism was associated with increased blood Pb concentrations in a sample of 116 children of Mexican-American/Hispanic (age 4-12 years, mean blood Pb concentration 3-6 µg/dL).

Analyses of serial blood Pb concentrations measured in longitudinal epidemiologic studies found relatively strong correlations (e.g., r = 0.5-0.8) between individual blood Pb concentrations measured after 6-12 months of age (Schnaas et al., 2000; Dietrich et al., 1993b; McMichael et al., 1988; Otto et al., 1985a; Rabinowitz et al., 1984). These observations suggest that, in general, exposure characteristics of an individual child (e.g., exposure levels and/or exposure behaviors) tend to be relatively constant across age. However, a single blood Pb measurement may not distinguish between a history of long-term lower-level Pb exposure from a history that includes higher acute exposures (Mushak, 1998). This concept is illustrated in Figure 4-7. Two hypothetical children are simulated. Child A has a relatively constant Pb intake from birth, whereas Child B has the same Pb intake as Child A for the first two years of life, then a 1-year elevated intake beginning at age 24 months (Figure 4-7, upper panel) that returns to the same intake as Child A at 36 months. The absorption fraction is assumed to be the same for both children. Blood Pb samples 1 and 5 for Child A and B, or 2 and 4 for Child B, will yield similar blood Pb concentrations (~3 or 10 µg/dL, respectively), yet the exposure contexts for these samples are very different. Two samples (e.g., 1 and 2, or 4 and 5), at a minimum, are needed to ascertain if the blood Pb concentration is changing over time. The rate of change can provide information about the magnitude of change in exposure, but not necessarily about the time history of the change (Figure 4-7, lower panel). Time-integrated measurements of Pb concentration may provide a means for accounting for some of these factors and, thereby, provide a better measure of long-term Pb exposure.



Note: Child A and Child B have a relatively constant basal Pb intake (µg/day/kg body weight) from birth; Child B experiences 1-year elevated intake beginning at age 24 months (upper panel). Blood Pb samples 1 and 5 for Child A and B, or 2 and 4 for Child B, will yield similar blood Pb concentrations (~3 or 10 µg/dL, respectively), yet the exposure scenarios for these samples are very different. As shown in the example of Child C and Child D, two samples can provide information about the magnitude of change in exposure, but not necessarily the temporal history of the change (lower panel). Simulation based on ICRP Pb biokinetics model (Leggett, 1993).

Figure 4-7 Simulation of temporal relationships between Pb exposure and blood Pb concentration in children.

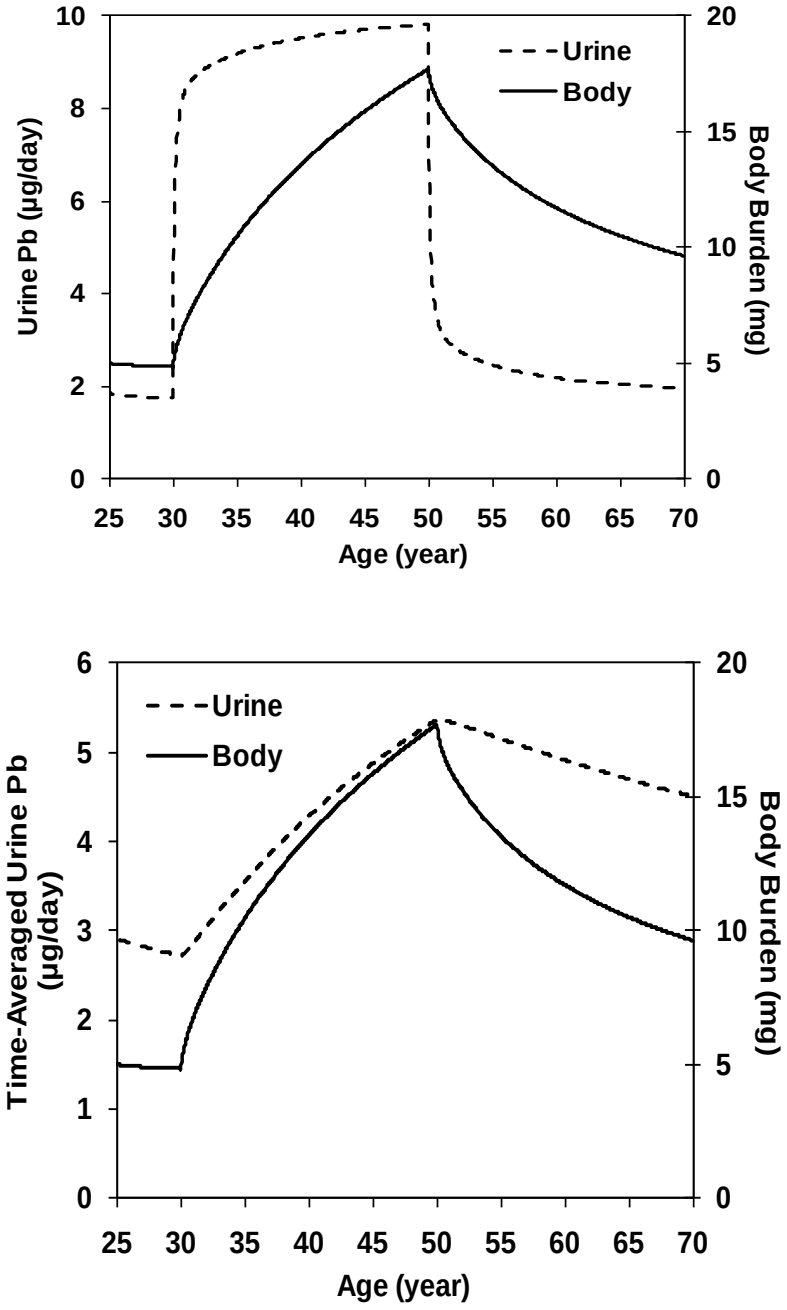
4.3.3 Urine Lead Measurements

Standard methods that have been reported for urine Pb analysis are, in general, the same as those analyses noted for determination of Pb in blood. Reported detection limits are ~50 µg/L for AAS, 5-10 µg/L for ICP AES, and 4 µg/L for ASV for urine Pb analyses.

The concentration of Pb in urine is a function of the urinary Pb excretion (Section 4.2.3) and the urine flow rate. Urine flow rate requires collection of a timed urine sample, which is often problematic in epidemiologic studies. Collection of untimed ("spot") urine samples, a common alternative to timed samples, requires adjustment of the Pb measurement in urine to account for variation in urine flow (Diamond, 1988). Several approaches to this adjustment have been explored, including adjusting the measured urine Pb concentration by the urine creatinine concentration, urine osmolality, or specific gravity (Fukui et al., 1999; Araki et al., 1990). Urine flow rate can vary by a factor or more than 10, depending on the state of hydration and other factors that affect glomerular filtration rate and renal tubular reabsorption of the glomerular filtrate. All of these factors can be affected by Pb exposure at levels that produce nephrotoxicity (i.e., decreased glomerular filtration rate, impaired renal tubular transport function). Therefore, urine Pb concentration measurements provide little reliable information about exposure (or Pb body burden), unless they can be adjusted to account for unmeasured variability in urine flow rate (Araki et al., 1990).

Urinary Pb concentration reflects, mainly, the concentration of Pb in the blood. As such, urinary concentrations by reflect both recent and past exposures to Pb (see Section 4.3.5). A single urinary Pb measurement cannot distinguish between a long-term low level of exposure or a higher acute exposure. Urinary Pb measurements would be expected to correlate with concurrent blood Pb (see Section 4.3.6 for additional discussion of the relationship between blood and urine Pb). Chiang et al. (2008) reported a significant, but relatively weak correlation between urinary Pb levels (µg/dg creatinine) and individual Pb intakes (µg/day) estimated in a group of 10- to 12-year-old children (β: 0.053, R = 0.320, p = 0.02, n = 57). A contributing factor to the relatively weak correlation may have been the temporal displacement between the urine sampling and measurements used to estimate intake, which may have been as long as 6 months for some children.

Thus, a single urine Pb measurement, or a series of measurements taken over short-time span, is likely a relatively poor index of Pb body burden for the same reasons that blood Pb is not a good indicator of body burden. On the other hand, long-term average measurements of urinary Pb can be expected to be a better index of body burden (Figure 4-8).



Note: A change in Pb uptake results in a relatively rapid change in urinary excretion of Pb, to a new quasi-steady state, and a relatively small change in body burden (upper panel). The long-term average urinary Pb excretion more closely tracks the pattern of change in body burden (lower panel). Simulation based on ICRP Pb biokinetics model (Leggett, 1993).

Figure 4-8 Simulation of relationship between urinary Pb excretion and body burden in adults.

4.3.4 Lead in Other Biomarkers

There was extensive discussion in the 2006 Pb AQCD regarding the utility of other Pb biomarkers as indicators of exposure or body burden. Due to the fact that most epidemiologic studies continue to use blood Pb or bone Pb, and other potential biomarkers (i.e., teeth, hair, and saliva) have not been established to the same extent as blood or bone Pb, only summaries are provided below.

4.3.4.1 Teeth

Tooth Pb is a minor contributor to the total body burden of Pb. As teeth accumulate Pb, tooth Pb levels are generally considered an estimate of cumulative Pb exposure. The tooth Pb-blood Pb relationship is more complex than the bone Pb-blood Pb relationship because of differences in tooth type, location, and analytical method. Although mobilization of Pb from bone appears well established, this is not the case for Pb in teeth. Conventional wisdom has Pb fixed once it enters the tooth. Although that may be the case for the bulk of enamel, it is not true for the surface of the enamel and dentine (Gulson et al., 1997; Rabinowitz et al., 1993). Limited studies have demonstrated moderate-to-high correlations between tooth Pb levels and blood Pb levels (Rabinowitz, 1995; Rabinowitz et al., 1989).

Teeth are composed of several tissues formed pre- and postnatal. Therefore, if a child's Pb exposure during the years of tooth formation varied widely, different amounts of Pb would be deposited at different rates (Rabinowitz et al., 1993). This difference may allow investigators to elucidate the history of Pb exposure in a child. Robbins et al. (2010) found a significant association between environmental Pb measures that correlated with leaded gasoline use and tooth enamel Pb in permanent teeth. Costa de Almeida et al. (2007) discerned differences between tooth enamel Pb concentration in biopsy samples from children who lived in areas having higher or lower levels of Pb contamination. Gulson and Wilson (1994) advocated the use of sections of enamel and dentine to obtain additional information compared with analysis of the whole tooth (e.g., (Tvinnereim et al., 1997; Fosse et al., 1995). For example, deciduous tooth Pb in the enamel provides information about in utero exposure whereas that in dentine from the same tooth provides information about postnatal exposure until the tooth exfoliates at about 6-7 years of age.

4.3.4.2 Hair

The 2006 Pb AQCD discussed applications of hair Pb measurements for assessing Pb body burden or exposure and noted methodological limitations (e.g., external contamination) and lack of a strong empirical basis for relating hair Pb levels to body burden or exposure. No new methodological or conceptual advances regarding hair Pb measurements have occurred since 2006, and widespread application of hair Pb measurements in epidemiologic studies has not occurred.

Pb is incorporated into human hair and hair roots (Bos et al., 1985; Rabinowitz et al., 1976) and has been explored as a noninvasive approach for estimating Pb body burden (Wilhelm et al., 2002; Gerhardsson et al., 1995; Wilhelm et al., 1989). Hair Pb measurements are subject to error from contamination of the surface with environmental Pb and contaminants in artificial hair treatments (i.e., dyeing, bleaching, permanents) and are a relatively poor predictor of blood Pb concentrations, particularly at blood Pb levels less than 10-12 µg/dL (Rodrigues et al., 2008; Campbell and Toribara, 2001; Esteban et al., 1999; Drasch et al., 1997). Temporal relationships between Pb exposure and hair Pb levels, and kinetics of deposition and retention of Pb in hair have not been evaluated. Although hair Pb measurements have been used in some epidemiologic studies (Shah et al., 2011; U.S. EPA, 2006b), an empirical basis for interpreting hair Pb measurements in terms of body burden or exposure has not been firmly established.

4.3.4.3 Saliva

A growing body of literature on the utility of measurements of salivary Pb has developed since the completion of the 2006 Pb AQCD (U.S. EPA, 2006b). Earlier reports suggested a relatively strong correlation between salivary Pb concentration and blood Pb concentration (Omokhodion and Crockford, 1991; Brodeur et al., 1983; P'an, 1981); however, more recent assessments have shown relatively weak or inconsistent associations (2011; 2010; Costa de Almeida et al., 2009; Barbosa et al., 2006c; Nriagu et al., 2006). The differences in these outcomes may reflect differences in blood Pb concentrations, exposure history and/or dental health (i.e., transfer of Pb between dentin and saliva) and possibly methods for determining Pb in saliva. Barbosa et al. (2006c) found a significant but relatively weak correlation (log[blood PB] versus log[saliva Pb], r = 0.277, p = 0.008) in a sample of adults, ages 18-60 years (n = 88). The correlation was similar for salivary and plasma Pb. Nriagu et al. (2006) found also found a relatively weak association (R^2 = 0.026) between blood Pb (µg/dL) and salivary Pb (µg/L) in a sample of adults who resided in Detroit, MI (n = 904). Costa de Almeida et al. (2009) found a significant correlation between salivary and blood Pb concentrations in children

in a Pb-contaminated region in Sao Paulo State, Brazil (r = 0.76. p = 0.04, n = 7) prior to site remediation; however, the correlation degenerated (r = 0.03, p = 0.94, n = 9) following remediation. Nevertheless, salivary Pb concentrations in the group of children who lived in the contaminated area were significantly elevated compared to a reference population. It is possible, that salivary Pb measurements may be a useful non-invasive biomarker for detecting elevated Pb exposure; however, it is not clear based on currently available data, if salivary Pb measurements would be a more reliable measure of exposure than blood Pb measurements.

4.3.4.4 Serum δ-ALA and ALAD

The association between blood Pb and blood ALAD activity and serum δ-aminolevulinic acid (δ-ALA) levels was recognized decades ago as having potential use as a biomarker of Pb exposure (Mitchell et al., 1977; Hernberg et al., 1970). More recently reference values for blood ALAD activity ratio (the ratio of ALAD activity in the blood sample to that measured after fully activating the enzyme in the sample) have been reported (Gultepe et al., 2009). Inhibition of erythrocyte ALAD by Pb results in a rise in the plasma concentration of the ALAD substrate δ-ALA. The δ-ALA biomarker can be measured in serum and has been used as a surrogate for Pb measurements in studies in which whole blood samples or adequately prepared plasma or serum samples were not available for Pb measurements (Opler et al., 2008; Opler et al., 2004).

4.3.5 Relationship between Lead in Blood and Lead in Bone

The kinetics of elimination of Pb from the body reflects the existence of fast and slow pools of Pb in the body. The dominant phase of Pb kinetics in the blood, exhibited shortly after a change in exposure occurs, has a half-life of ~20-30 days (Leggett, 1993; Rabinowitz et al., 1976). Studies of a limited number of adults (four individuals with hip or knee replacement, a married couple, and 10 female Australian immigrants) in which the Pb exposure was from historical environmental sources have found that bone Pb stores can contribute 40-70% to blood Pb (Smith et al., 1996; Gulson et al., 1995; Manton, 1985). Bone Pb burdens in adults are slowly lost by diffusion (heteroionic exchange) as well as by resorption (O'Flaherty, 1995). Half-times for the release of Pb in bone are dependent on age and intensity of exposure. Bone compartments are much more labile in infants and children than in adults as reflected by half-times for movement of Pb from bone into the plasma (e.g., cortical $t_{1/2}$ = 0.23 years at birth, 1.2 years at 5 years of age, 3.7 years at 15 years of age, and 23 years in adults; trabecular $t_{1/2}$ = 0.23 years at

birth, 1.0 years at 5 years of age, 2.0 years at 15 years of age, and 3.9 years in adults) (Leggett, 1993). Slow transfer rates for the movement of Pb from nonexchangeable bone pools to the plasma are the dominant transfer process determining long-term accumulation and elimination of bone Pb burden.

The apparent slow clearance of Pb from the blood over months and years following the cessation or reduction in exposures reflects elimination of Pb stores in bone. Longer fast-phase elimination half-times (60-120 days) were reported for five adults with lead poisoning following roughly a month to 12 years of exposure and relatively high blood Pb concentrations of 70-110 µg/dL (Rentschler et al., In Press). A slower phase becomes evident with longer observation periods following a decrease in exposure. Nilsson et al. (1991) reported in tri-exponential decay in the blood Pb concentrations of 14 individuals having a median occupational exposure period of 26 years. Representing 22% of blood Pb, the fast compartment had a clearance half time of 34 day. The intermediate compartment, 27% of blood Pb, had a clearance half time of 1.12 year. And, the slow compartment, 50% of blood Pb, had a clearance half time of 13 years. The authors attributed the fast, intermediate, and slow compartment clearance to elimination of Pb from blood and some soft tissues, from trabecular bone, and cortical bone, respectively. Children who have been removed from a relatively brief exposure to elevated environmental Pb also exhibit faster slow-phase kinetics than children removed from exposures that lasted several years, with half-times of 10 and 20-38 months, respectively (Manton et al., 2000). Rothenberg et al. (1998) also showed that exposures in the first 6 months of life could contribute to elevated blood lead through at least 3 years relative to children with lower early life exposures, despite similar environmental exposures at later time points. In both adults and children, the longer half-times measured under the latter conditions reflect the contribution of bone Pb stores to blood Pb following a change in exposure.

The longer half-life of Pb in bone compared to blood Pb, allows a more cumulative measure of Pb dose. Pb in adult bone can serve to maintain blood Pb levels long after external exposure has ceased (Fleming et al., 1997; Inskip et al., 1996; Smith et al., 1996; Kehoe, 1987; O'Flaherty et al., 1982), even for exposures that occurred during childhood (McNeill et al., 2000). The more widespread use of in vivo XRF Pb measurements in bone and indirect measurements of bone processes with stable Pb isotopes have enhanced the use of bone Pb as a biomarker of Pb body burden.

Several studies have found a stronger relationship between patella Pb and blood Pb than tibia Pb and blood Pb (Park et al., 2009a; Hu et al., 1998; Hernandez-Avila et al., 1996; Hu et al., 1996b). Hu et al. (1998) suggest that trabecular bone is the predominant bone type providing Pb back into circulation under steady-state and pathologic conditions. The

stronger relationship between blood Pb and trabecular Pb compared with cortical bone is probably associated with the larger surface area of trabecular bone allowing for more Pb to bind via ion exchange mechanisms and more rapid turnover making it more sensitive to changing patterns of exposure.

4.3.5.1 Children

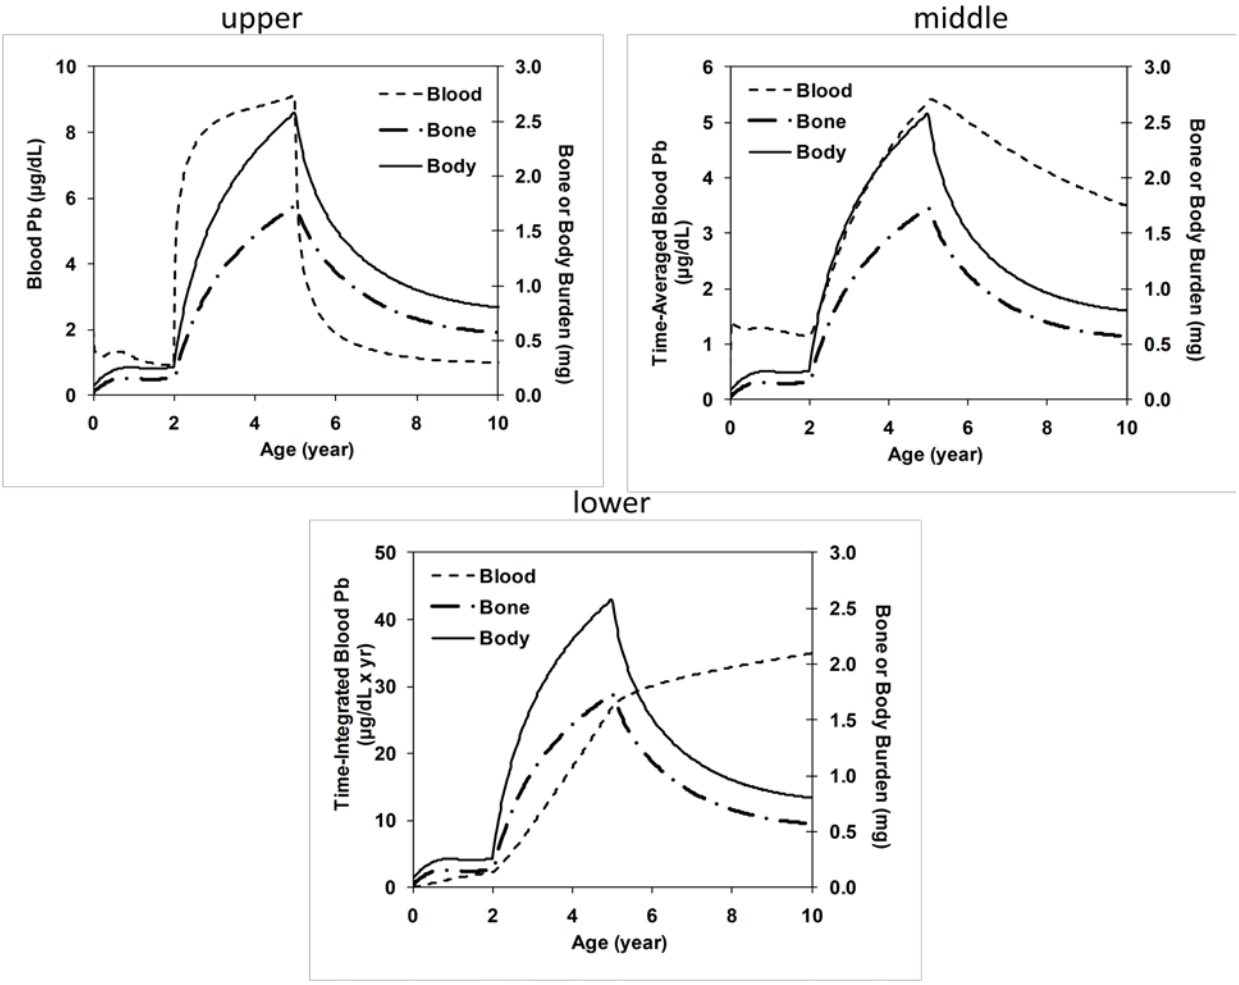
As mentioned in Section 4.2.2.2, bone growth in children will contribute to accumulation of Pb in bone, which will comprise most of the Pb body burden. As a result, Pb in bone will more closely reflect Pb body burden than blood Pb. However, changes in blood Pb concentration in children (i.e., associated with changing exposures) are thought to more closely parallel changes in total body burden. Figure 4-9 shows a simulation of the temporal profile of Pb in blood and bone in a child who experiences a period of constant Pb intake (from age 2-5) via ingestion (µg Pb/day) followed by an abrupt decline in intake. The figure illustrates several important general concepts about the relationship between Pb in blood and bone. While blood Pb approaches a quasi-steady state after a period of a few months with a constant rate of Pb intake (as demonstrated by the vertical dashed line), Pb continues to accumulate in bone with continued Pb intake after the quasi-steady state is achieved in blood. The model also predicts that the rate of release of Pb from bone after cessation of exposure is faster than in adults. This difference has been attributed to accelerated growth-related bone mineral turnover in children, which is the primary mechanism for release of Pb that has been incorporated into the bone mineral matrix.

Empirical evidence in support of this conclusion comes from longitudinal studies in which relatively high correlations were found between concurrent ($r = 0.75$) or average lifetime (obtained at 6-month intervals from birth to age 10 or 12) blood Pb concentrations ($r = 0.85$) and tibia bone Pb concentrations (measured by XRF) in a sample of children in which the group mean concurrent blood Pb concentration exceeded 20 µg/dL; the correlations was much weaker ($r < 0.15$) among the group of children with a mean concurrent blood Pb concentration <10 µg/dL (Wasserman et al., 2003).

Two alternative blood Pb metrics depicted in Figure 4-9 include the time-averaged and time-integrated blood Pb concentrations. Both the time-averaged and time-integrated blood Pb metrics display rates of change in response to the exposure event that more closely approximate the slower kinetics of bone Pb and body burden, than the kinetics of blood Pb concentration, with notable differences. The time-averaged blood Pb concentration increases during the exposure event and decays following the event, consistent with the changing body burden. The time-integrated blood Pb concentration

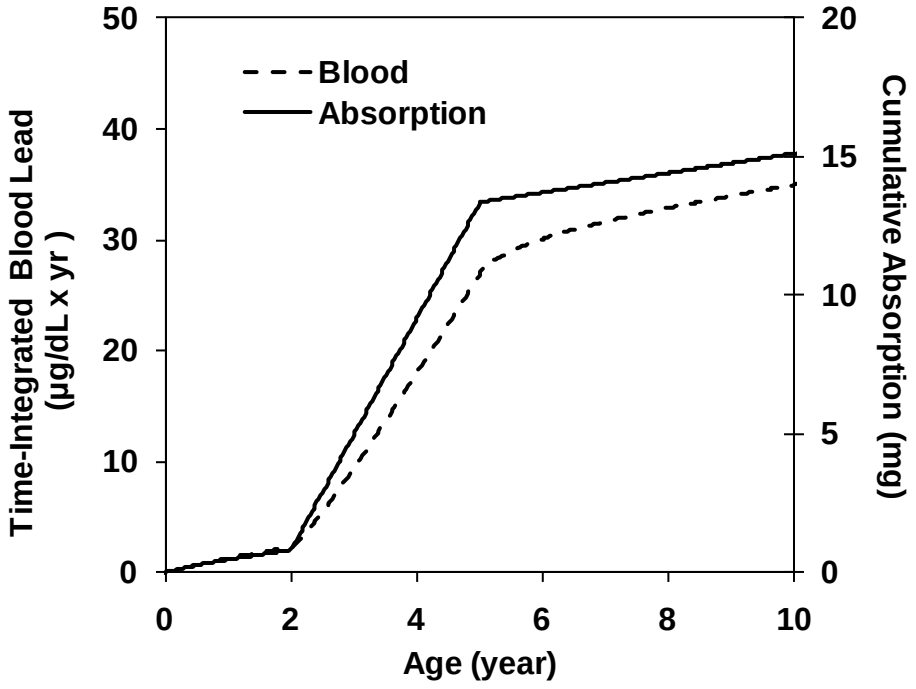
(conceptually identical to cumulative blood lead index [CBLI] used in epidemiologic studies) is a cumulative function and increases throughout childhood; however, the slope of the increase is higher during the exposure event than prior to or following the event. Following cessation of exposure, the time-integrated blood Pb and body burden diverge. This result is expected, as the time-integrated blood Pb curve is a cumulative function which cannot decrease over time and bone Pb levels will decrease with cessation of exposure.

The time-integrated blood Pb concentration will be a better reflection of the total amount of Pb that has been absorbed, than the body burden at any given time. The time-integrated blood Pb concentration will also reflect cumulative Pb absorption, and cumulative exposure if the absorption fraction is constant. This is illustrated in the hypothetical simulations of an exposure event experienced by a child (Figure 4-10). This pattern is similar for adults.



Note: Blood Pb concentration is thought to parallel body burden more closely in children than in adults, due to more rapid turnover of bone and bone-Pb stores in children (upper panel). Nevertheless, the time-averaged blood Pb concentration more closely tracks the pattern of change in body burden (middle panel). The time-integrated blood Pb concentration increases over time (lower panel). Simulation based on ICRP Pb biokinetics model (Leggett, 1993).

Figure 4-9 Simulation of relationship between blood Pb concentration and body burden in children, with a constant Pb intake from age 2 to 5.



Note: The simulations include a 3-year period of elevated Pb intake during ages 2-5 years. The time-integrated blood Pb concentration closely parallels cumulative Pb absorption. Simulation based on ICRP Pb biokinetics model (Leggett, 1993).

Figure 4-10 Simulation of relationship between time-integrated blood Pb concentration and cumulative Pb absorption in children.

4.3.5.2 Adults

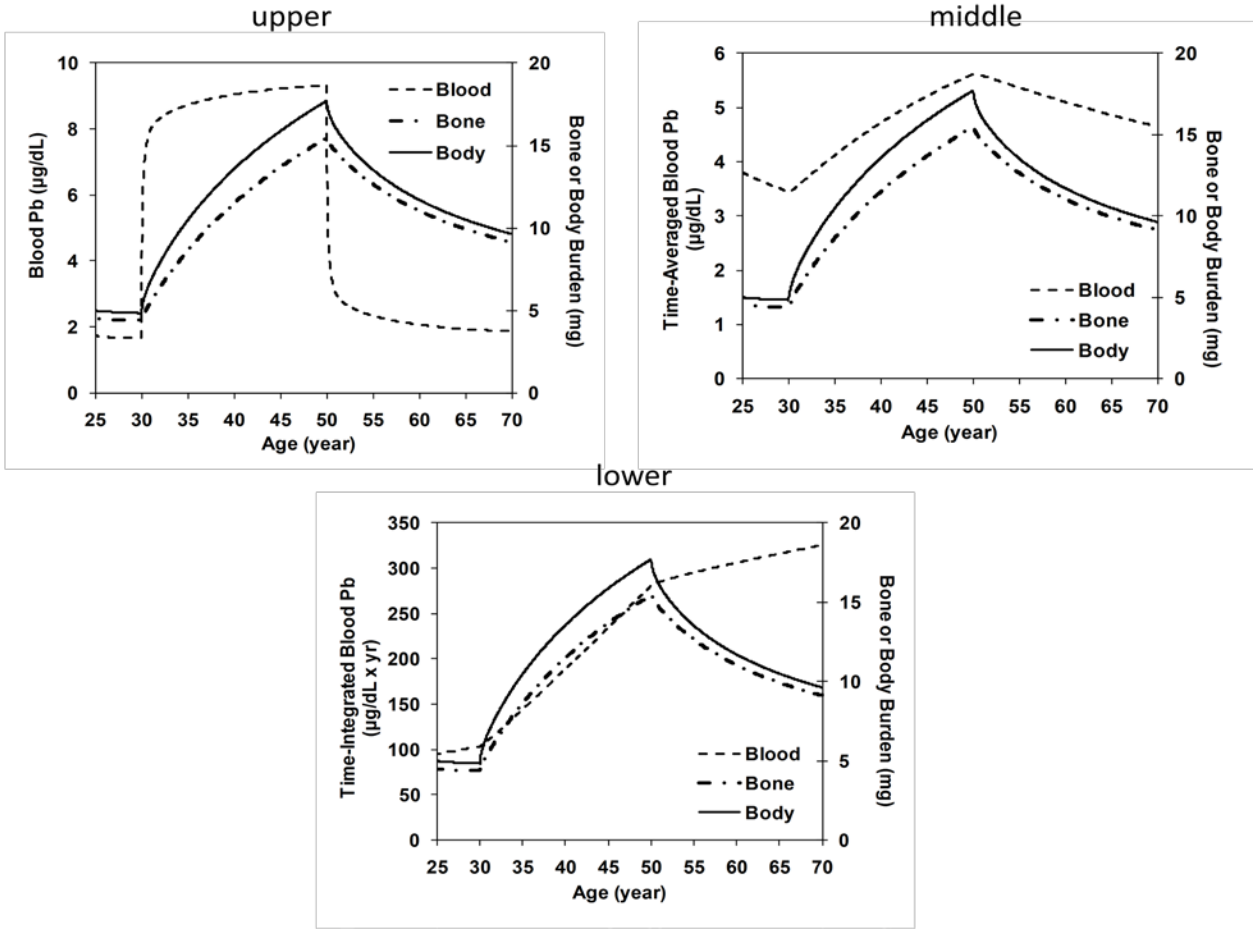
In adults, where a relatively large fraction of the body burden residing in bone has a slower turnover compared to blood, a constant Pb uptake (or constant intake and fractional absorption) gives rise to a quasi-steady state blood Pb concentration, while the body burden continues to increase over a much longer period, largely as a consequence of continued accumulation of Pb in bone. This pattern is illustrated in Figure 4-11 which depicts a hypothetical simulation of an exposure event consisting of a 20-year period of daily ingestion of Pb in an adult. The exposure event shown in the simulations gives rise to a relatively rapid increase in blood Pb concentration, to a new quasi-steady state, achieved in ~75-100 days (i.e., approximately 3-4 times the blood elimination half-life). In contrast, the body burden continues to increase during this period. Following cessation of the exposure, blood Pb concentration declines relatively rapidly compared to the slower decline in body burden. Careful examination of the simulation shown in Figure 4-11 reveals that the accumulation and elimination phases of blood Pb kinetics are not

symmetrical; elimination is slower than accumulation as a result of the gradual release of bone Pb stores to blood. This response, known as the prolonged terminal elimination phase of Pb from blood, has been observed in retired Pb workers and in workers who continued to work after improved industrial hygiene standards reduced their exposures. In the adult simulation shown in Figure 4-11, the initial phase of elimination (the first 5 years following cessation of exposure at 50 years) has a half-time of approximately 14 years; however, the half-time increases to approximately 60 years during the period 5-30 years after cessation of exposure. These model predictions are consistent with the slow elimination of Pb from blood and elimination half-times of several decades for bone Pb (e.g., 16-98 years) that have been estimated from observations made on Pb workers (Wilker et al., 2011; Fleming et al., 1997; Gerhardsson et al., 1995). Based on this hypothetical simulation, a blood Pb concentration measured 1 year following cessation of a period of increased Pb uptake would show little or no appreciable change from prior to the exposure event, whereas, the body burden would remain elevated. These simulations in Figure 4-11 illustrate how a single blood Pb concentration measurement, or a series of measurements taken over a short-time span, could be a relatively poor index of Pb body burden.

One important potential implication of the profoundly different kinetics of Pb in blood and bone is that, for a constant Pb exposure, Pb in bone will increase with increasing duration of exposure and, therefore, with age. In contrast, blood Pb concentration will achieve a quasi-steady state. As a result, the relationship between blood Pb and bone Pb will diverge with increasing exposure duration and age. This divergence can impart different degrees of age-confounding when either blood Pb or bone Pb is used as an internal dose metric in dose-response models. In a review of epidemiologic studies that evaluated the associations between blood Pb, bone Pb and cognitive function, the effects of bone Pb were more pronounced than blood Pb (particularly for longitudinal studies) for older individuals with environmental Pb exposures and low blood Pb levels (Shih et al., 2007). In contrast, occupational workers with high current Pb exposures had the strongest associations for blood Pb levels with cognitive function, thus providing evidence for this divergence (Shih et al., 2007).

The aforementioned expectation for an increase in bone Pb and body burden with age applies to scenarios of constant exposure but not necessarily to real world populations in which individual and population exposures have changed over time. Longitudinal studies of blood and bone Pb trends have not always found strong dependence on age (Nie et al., 2009; Kim et al., 1997). Kim et al. (1997) found that bone Pb levels increased with increasing age in elderly adults (age 52-83) years), only when the data were analyzed cross-sectionally. When analyzed longitudinally, the trend for individual patella Pb was a 23% decrease over a 3-year period (approximate $t_{1/2}$ of 8 years), whereas tibia Pb levels

did not change with over the same period. Therefore, although older individuals tended to have higher bone Pb levels, the 3-year temporal trend for individuals was a loss of Pb from the more labile Pb stores in trabecular bone. Nie et al. (2011) observed that longitudinal observations of blood and bone Pb in elderly adults did not show a significant age effect on the association between blood Pb and bone Pb (patella and tibia), when the sample population (n=776) was stratified into age tertiles (mean age 62, 69 or 77 years). Nie et al. (2009) did find that regressed function bone Pb and appeared to level off at bone Pb levels >20 µg/g bone mineral.



Note: A constant baseline intake results in a quasi-steady state blood Pb concentration and body burden (upper panel). A change in Pb uptake gives rise to a relatively rapid change in blood Pb, to a new quasi-steady state, and a slower change in body burden. The long-term time-averaged blood Pb concentration more closely tracks the slower pattern of change in body burden (middle panel). The time-integrated blood Pb concentration increases over the lifetime, with a greater rate of increase during periods of higher Pb uptake (lower panel). Simulation based on ICRP Pb biokinetics model (Leggett, 1993).

Figure 4-11 Simulation of relationship between blood Pb concentration, bone Pb and body burden in adults.

Tibia bone Pb is correlated with time-integrated blood Pb concentration (i.e., CBLI). McNeill et al. (2000) compared tibia Pb levels and cumulative blood Pb indices in a population of 19- to 29-year-olds who had been highly exposed to Pb in childhood from the Bunker Hill, Idaho smelter. They concluded that Pb from exposure in early childhood had persisted in the bone matrix until adulthood. The bone Pb/CBLI slopes from various studies range from 0.022 to 0.067 μg/g bone mineral per μg-year/dL (Healey et al., 2008; Hu et al., 2007a). Because the CBLI is a cumulative function which cannot decrease over time, CBLI and bone Pb would be expected to diverge following cessation of exposure, as bone Pb levels decrease. This divergence was observed as a lower bone Pb/CBLI slope in retired Pb workers compared to active workers and in worker populations whose exposures declined over time as a result of improved industrial hygiene (Fleming et al., 1997; Gerhardsson et al., 1993).

Although differences in kinetics of blood and bone Pb degrade the predictive value of blood Pb as a metric of Pb body burden, within a population that has similar exposure histories and age demographics, blood and bone Pb may show relatively strong associations. A recent analysis of a subset of data from the Normative Aging Study (an all male cohort) showed that cross-sectional measurements of blood Pb concentration accounted for approximately 9% (tibia) to 13% (patella) of the variability in bone Pb levels. Inclusion of age in the regression model accounted for an additional 7-10% of the variability in bone Pb (Park et al., 2009a).

Mobilization of Lead from Bone in Adulthood

In addition to changes in exposure (e.g., declines in exposure discussed in prior section), there are physiological processes during different life circumstances that can increase the contribution of bone Pb to blood Pb. These life circumstances include times of physiological stress associated with enhanced bone remodeling such as during pregnancy and lactation (Hertz-Picciotto et al., 2000; Silbergeld, 1991; Manton, 1985), menopause or in the elderly (Silbergeld et al., 1988), extended bed rest (Markowitz and Weinberger, 1990), hyperparathyroidism (Kessler et al., 1999) and severe weight loss (Riedt et al., 2009).

During pregnancy, bone Pb can serve as a Pb source as maternal bone is resorbed for the production of the fetal skeleton (Gulson et al., 2003; Gulson et al., 1999; Franklin et al., 1997; Gulson et al., 1997). Increased blood Pb during pregnancy has been demonstrated in numerous studies and these changes have been characterized as a "U-shaped" pattern of lower blood Pb concentrations during the second trimester compared to the first and third trimesters (Lamadrid-Figueroa et al., 2006; Gulson et al., 2004a; Hertz-Picciotto et al., 2000; Gulson et al., 1997; Lagerkvist et al., 1996; Schuhmacher et al., 1996;

Rothenberg et al., 1994a). The U-shaped relationship reflects the relatively higher impact of hemodilution in the second trimester versus the rate of bone Pb resorption accompanying calcium releases for establishing the fetal skeleton. In the third trimester, fetal skeletal growth on calcium demand is greater, and Pb released from maternal skeleton offsets hemodilution. Gulson et al. (1998a) reported that, during pregnancy, blood Pb concentrations in the first immigrant Australian cohort (n = 15) increased by an average of about 20% compared to non-pregnant migrant controls (n = 7). Skeletal contribution to blood Pb, based on the isotopic composition for the immigrant subjects, increased in an approximately linear manner during pregnancy. The mean increases for each individual during pregnancy varied from 26% to 99%. Interestingly, the percent change in blood Pb concentration was significantly greater during the post-pregnancy period than during the second and third trimesters. This is consistent with Hansen et al. (2011b) that demonstrated the greatest blood Pb levels at 6 weeks postpartum compared to the second trimester in 211 Norwegian women. Increased calcium demands of lactation (relative to pregnancy) may contribute to the greater change in blood Pb observed post pregnancy compared to the second and third trimesters. The contribution of skeletal Pb to blood Pb during the post-pregnancy period remained essentially constant at the increased level of Pb mobilization.

Gulson et al. (2004a) observed that calcium supplementation was found to delay increased mobilization of Pb from bone during pregnancy and halved the flux of Pb release from bone during late pregnancy and postpartum. In another study, women whose daily calcium intake was 850 mg per day showed lower amounts of bone resorption during late pregnancy and postpartum than those whose intake was 560 mg calcium per day (Manton et al., 2003). Similarly, calcium supplementation (1,200 mg/day) in pregnant Mexican women resulted in an 11% reduction in blood Pb level compared to placebo and a 24% average reduction for the most compliant women (Ettinger et al., 2009). When considering baseline blood Pb levels in women who were more compliant in taking calcium supplementation, the reductions were similar for those <5 µg/dL and those ≥ 5 µg/dL (14% and 17%, respectively). This result is in contrast to a study of women who had blood Pb concentrations <5 µg/dL, where calcium supplementation had no effect on blood Pb concentrations (Gulson et al., 2006b). These investigators attributed their results to changes in bone resorption with decoupling of trabecular and cortical bone sites.

Miranda et al. (2010) studied blood Pb level among pregnant women aged 18-44 years old. The older age segments in the study presumably had greater historic Pb exposures and associated stored Pb than the younger age segments. Compared with the blood Pb levels of a reference group in the 25-29 years old age category, pregnant women ≥ 30 years old had significant odds of having higher blood Pb levels (aged 30-34: OR =

2.39, p <0.001; aged 35-39: OR = 2.98, p <0.001; aged 40-44: OR = 7.69, p <0.001). Similarly, younger women had less chance of having higher blood Pb levels compared with the reference group (aged 18-19: OR = 0.60, p = 0.179; aged 20-24: OR = 0.54, p = 0.015). These findings indicate that maternal blood Pb levels are more likely the result of Pb mobilization of bone stores from historic exposures as opposed to contemporaneous exposures.

Blood Pb levels increase during lactation due to alterations in the endogenous bone Pb release rate. After adjusting for patella Pb concentration, an increase in blood Pb levels of 12.7% (95% CI: 6.2, 19.6) was observed for women who practiced partial lactation and an increase of 18.6% (95% CI: 7.1, 31.4) for women who practiced exclusive lactation compared to those who stopped lactation (Tellez-Rojo et al., 2002). In another Mexico City study, Ettinger et al. (2006; 2004b) concluded that an interquartile increase in patella Pb was associated with a 14% increase in breast milk Pb, whereas for tibia Pb the increase was ~5%. Breast milk:maternal blood Pb concentration ratios are generally <0.1, although values of 0.9 have been reported (Koyashiki et al., 2010; Ettinger et al., 2006; Gulson et al., 1998b). Dietary intake of polyunsaturated fatty acids (PUFA) has been shown to weaken the association between Pb levels in patella and breast milk, perhaps indicating decreased transfer of Pb from bone to breast milk with PUFA consumption (Arora et al., 2008).

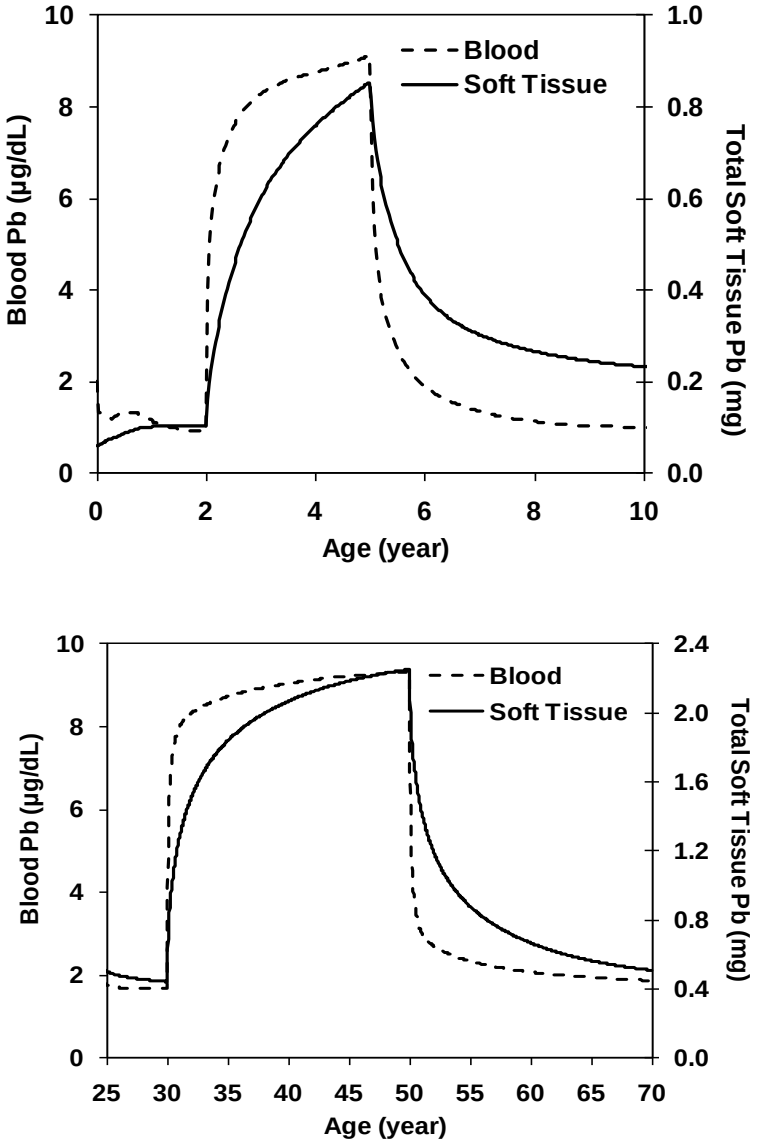
The Pb content in some bones (i.e., mid femur and pelvic bone) plateau at middle age and then decreases at older ages (Drasch et al., 1987). This decrease is most pronounced in females and may be due to osteoporosis and release of Pb from resorbed bone to blood (Gulson et al., 2002). Two studies indicate that the endogenous release rate in postmenopausal women ranges from 0.13-0.14 µg/dL in blood per µg/g bone and is nearly double the rate found in premenopausal women (0.07-0.08 µg/dL per µg/g bone) (Popovic et al., 2005; Garrido Latorre et al., 2003). An analysis of data on blood lead concentrations and markers of bone formation (serum alkaline phosphatase) and resorption (urinary cross-linked N-telopeptides, NTx) in a sample of U.S. found that blood Pb concentrations were higher in women (pre- or post-menopausal) who exhibited the highest bone formation or resorption activities (Jackson et al., 2010). Calcium or vitamin D supplementation decreased the blood lead concentrations in the highest bone formation and resorption tertiles of the population of post-menopausal women. Significant associations between increasing NTx and increasing blood Pb levels (i.e., increased intercept of regression model relating the change in blood Pb per change in bone Pb) has also been observed in elderly males (Nie et al., 2009).

Studies of the effect of hormone replacement therapy on bone Pb mobilization have yielded conflicting results (Popovic et al., 2005; Berkowitz et al., 2004; Garrido Latorre

et al., 2003; Korrick et al., 2002; Webber et al., 1995). In women with severe weight loss (28% of BMI in 6 months) sufficient to increase bone turnover, increased blood Pb levels of approximately 2.1 µg/dL (250%) were reported, and these blood Pb increases were associated with biomarkers of increased bone turnover (e.g., urinary pyridinoline cross-links) (Riedt et al., 2009).

4.3.6 Relationship between Lead in Blood and Lead in Soft Tissues

Figure 4-12 shows simulations of blood and soft tissues Pb (including brain) for the same exposure scenarios previously displayed. Pb uptake and elimination in soft tissues is much faster than bone. As a result, following cessation of a period of elevated exposure, Pb in soft tissues is more quickly returned to blood. The terminal elimination phase from soft tissue mimics that of blood, and it is similarly influenced by the contribution of bone Pb returned to blood and being redistributed to soft tissue.

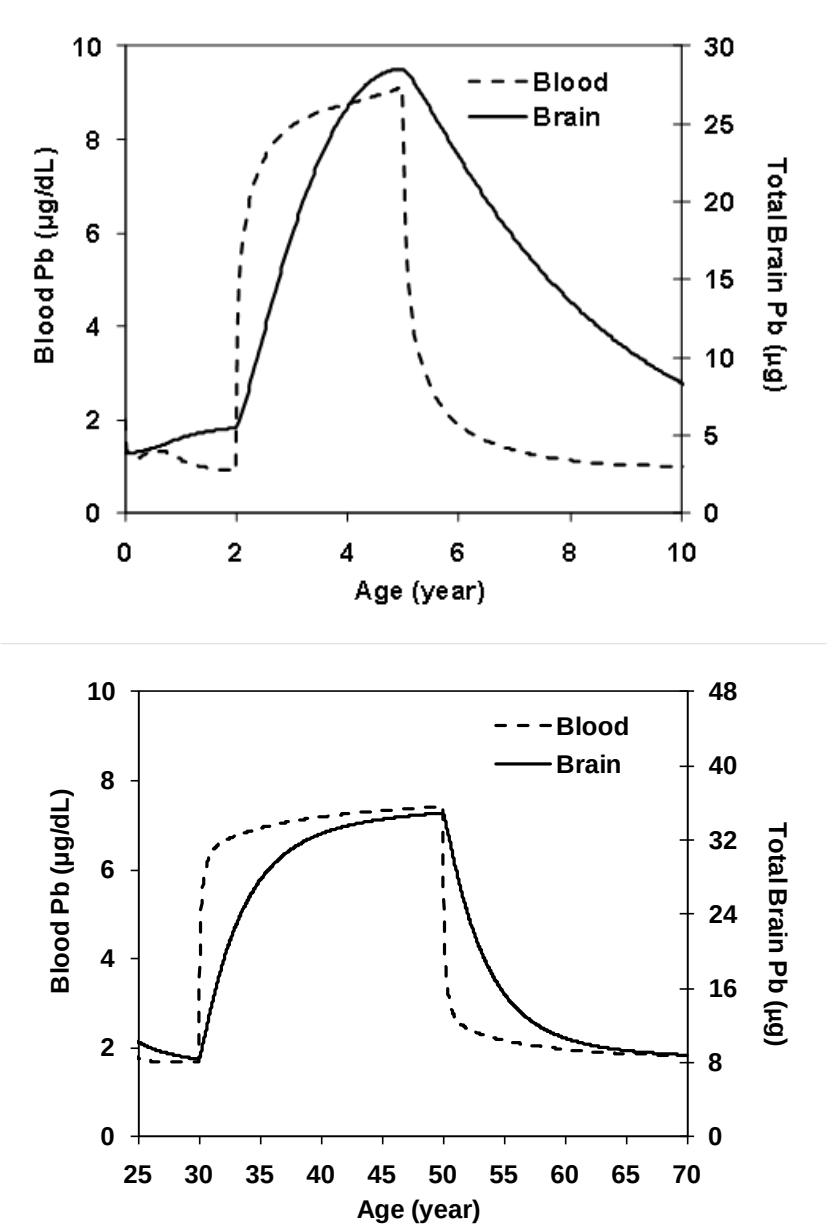


Note: Simulation based on ICRP Pb biokinetics model (Leggett, 1993).

Figure 4-12 Simulation of blood and soft tissue (including brain) Pb in children and adults who experience a period of increased Pb intake.

Information on Pb levels in human brain are limited to autopsy data and the simulation of brain Pb shown in Figure 4-13 reflects general concepts derived from observations made in non-human primates, dogs and rodents. These observations suggest that peak Pb levels in the brain are reached 6 months following a bolus exposure and within two months approximately 80% of steady state brain Pb levels are reached (Leggett, 1993). There is a relatively slow elimination of Pb from brain ($t_{1/2} \approx 2$ years) compared to other soft tissues

(Leggett, 1993). This slow elimination rate is reflected in the slower elimination phase kinetics in shown Figure 4-13. Although in this model, brain Pb to blood Pb transfer half-times are assumed to be the same in children and adults, uptake kinetics are assumed to be faster during infancy and childhood, which achieves a higher fraction of the soft tissue burden in brain, consistent with higher brain/body mass relationships. The uptake half times predicted by Leggett (1993) vary from 0.9 to 3.7 days, depending on age. Brain Pb kinetics represented in the simulations are simple outcomes of modeling assumptions and cannot currently be verified with available observations in humans.

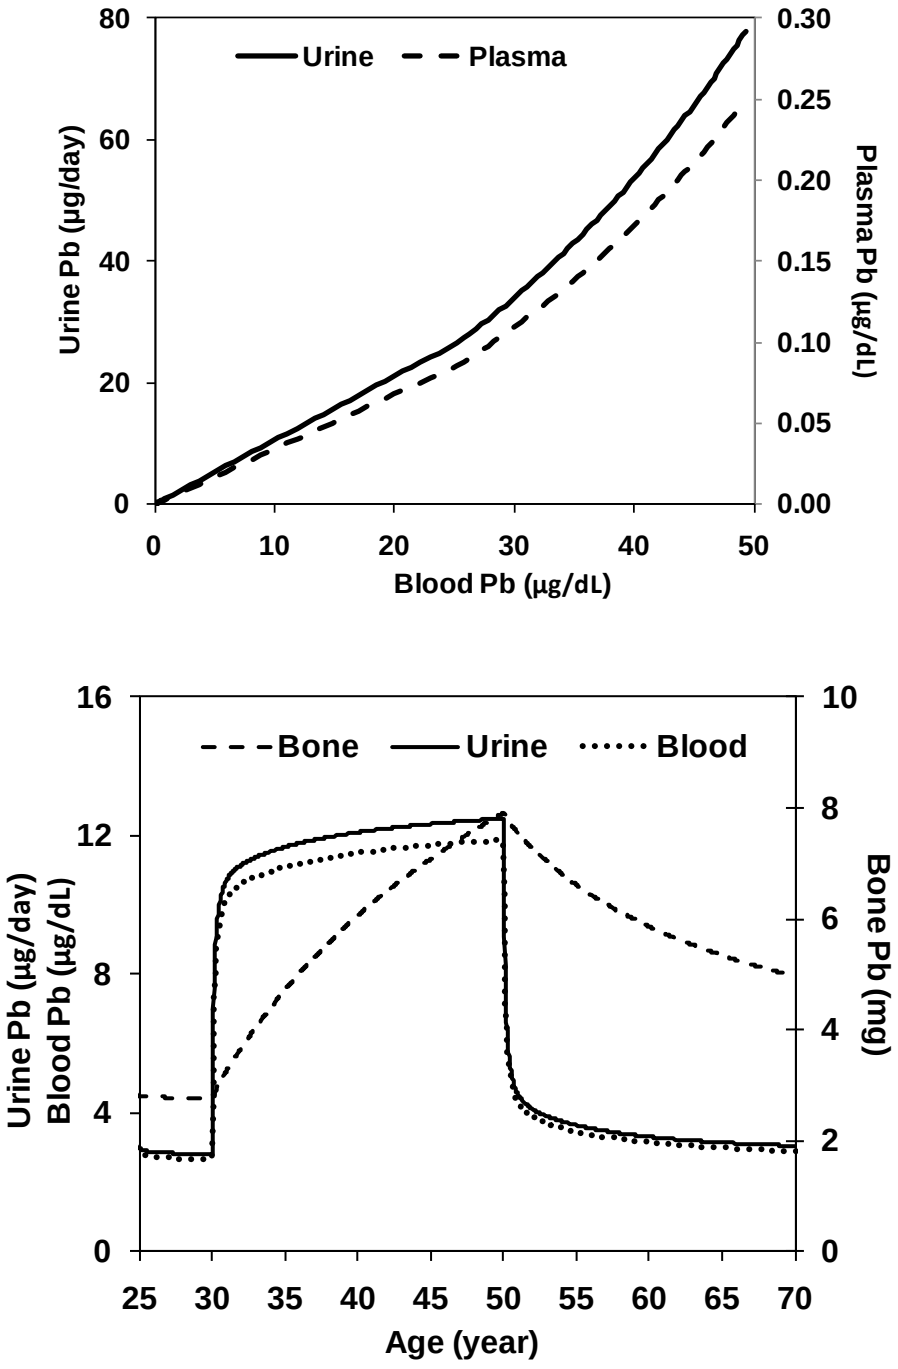


Note: Simulation based on ICRP Pb biokinetics model (Leggett, 1993).

Figure 4-13 Simulation of blood and brain Pb in children and adults who experience a period of increased Pb intake.

Urinary filtering and excretion of Pb is associated with plasma Pb concentrations. Given the curvilinear relationship between blood Pb and plasma Pb, a secondary expectation is for a curvilinear relationship between blood Pb and urinary Pb excretion that may become evident only at relatively high blood Pb concentrations (e.g., >25 µg/dL). Figure 4-14 shows these relationships predicted from the model. In this case, the exposure

scenario shown is for an adult (age 40 years) at a quasi-steady state blood Pb concentration; the same relationships hold for children. At lower blood Pb concentrations (<25 µg/dL), urinary Pb excretion is predicted to closely parallel plasma Pb concentration for any given blood Pb level (Figure 4-14, top panel). It follows from this that, similar to blood Pb, urinary Pb will respond much more rapidly to an abrupt change in Pb exposure than will bone Pb. One important implication of this relationship is that, as described previously for blood Pb, the relationships between urinary Pb and bone Pb will diverge with increasing exposure duration and age, even if exposure remains constant. Furthermore, following an abrupt cessation of exposure, urine Pb will quickly decrease while bone Pb will remain elevated (Figure 4-14, lower panel).



Note: Lower panel: Simulation of blood Pb, bone Pb and urinary excretion of Pb in an adult who experiences a period of increased Pb intake. Simulation based on ICRP Pb biokinetics model (Leggett, 1993).

Figure 4-14 Relationship between Pb in urine and Pb in blood.

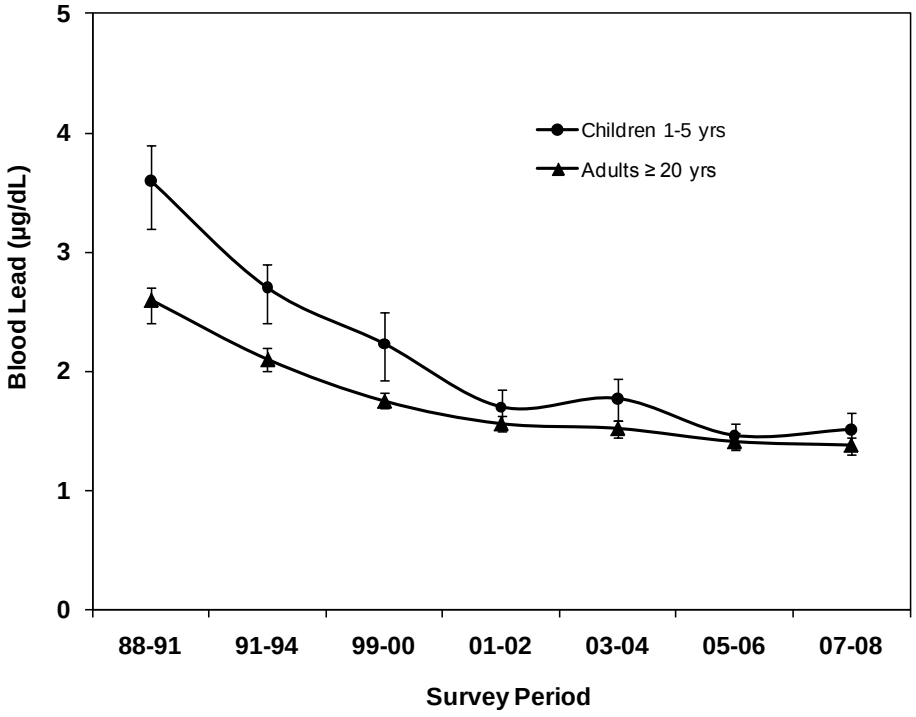
4.4 Observational Studies of Lead Biomarker Levels

4.4.1 Lead in Blood

Overall, trends in blood Pb levels have been decreasing among U.S. residents over the past 20 years. Blood Pb concentrations in the U.S. general population have been monitored in the NHANES. Analyses of these data show a progressive downward trend in blood Pb concentrations during the period 1976-2008, with the most dramatic declines coincident with the phase out of leaded gasoline (Pirkle et al., 1998; Brody et al., 1994; Pirkle et al., 1994; Schwartz and Pitcher, 1989). The temporal trend for the period 1988-2008 is shown in Figure 4-15. Summary statistics from the most recent publically available data (1999-2008) are presented in Table 4-7 (CDC, 2011). The geometric mean Pb concentration among children 1-5 years of age, based on the sample collected during the period 2007-2008, was 1.51 µg/dL (95% CI: 1.37, 1.66), which was a slight increase from the previous year (1.46 µg/dL, 95% CI: 1.36, 1.57). Figure 4-16 uses NHANES data to illustrate temporal trends in the distribution of blood Pb levels among U.S. children aged 12-60 months. The median blood Pb in this age group was 1.4 µg/dL with a 95th percentile value of 4.1 µg/dL in 2007-2008 (NCHS, 2010). For 2005-2008, 95% of childhood blood Pb levels were less than 5 µg/dL. The geometric mean blood Pb concentration among adults ≥ 20 years of age was 1.38 µg/dL (95% CI: 1.31, 1.46) for the sample collected during the period 2007-2008 (CDC, 2011). Based on these same data, the geometric mean for all males (aged ≥ 1 y) was 1.47 µg/dL (95% CI: 1.39, 1.56), and for females (aged ≥ 1 y) was 1.11 µg/dL (95% CI: 1.06, 1.16).

There has been a steep decline in mean blood Pb levels from 1975 through 2010 among all birth cohorts from 1975 to 2010; Figure 4-17. For all cohorts, blood Pb generally decreases with age during childhood until adolescence; following adolescence (in the early 20s), blood Pb generally levels off or even increases with age. It is possible that bone growth in young people and occupational exposure for adults influences the shape of these curves. For the 1960 to 1970 birth cohort, the mean blood Pb is the highest of the cohorts in the 1970s, but beginning in 1993 the mean blood Pb is one of the lowest of the cohorts. This interaction between time and cohort may be due to the faster release of Pb from bone in younger people (Rabinowitz, 1991). This interaction is also apparent for some of the other more recently born cohorts. In comparison, the slopes of blood Pb over time are nearly parallel among the cohorts born before 1930. This suggests that the time-cohort-interaction diminishes among older people. Also, the leveling of the blood Pb in the 2000s could be due to aging of the birth cohort and consequent slowing of their Pb release from bone.

When race/ethnicity groups were compared for years 1999-2004, blood Pb levels in children were highest in the ethnicity category non-Hispanic black (GM 2.8, 95% CI: 2.5, 3.0) compared to the categories Mexican-American (GM 1.9, 95% CI: 1.7, 2.0) and non-Hispanic white (GM 1.7, 95% CI: 1.6, 1.8) (Jones et al., 2009a). Figure 4-18 demonstrates the change in percent of children (aged 1-5 years) with various blood Pb levels by race/ethnicity between the survey during 1988-1991 and that during 1999-2004. When these data for children aged 1-5 years were aggregated for all survey years from 1988 to 2004, residence in older housing, poverty, age, and being non-Hispanic black were significant predictors of higher Pb levels (Jones et al., 2009a).



Note: Shown are geometric means and 95% CIs based on data from NHANES III Phase 1 (Brody et al., 1994; Pirkle et al., 1994); NHANES III Phase 2 (Pirkle et al., 1998); and NHANES IV (CDC, 2011). Data for adults during the period 1988-1994 are for ages 20-49 years, and ≥ 20 years for the period 1999-2008.

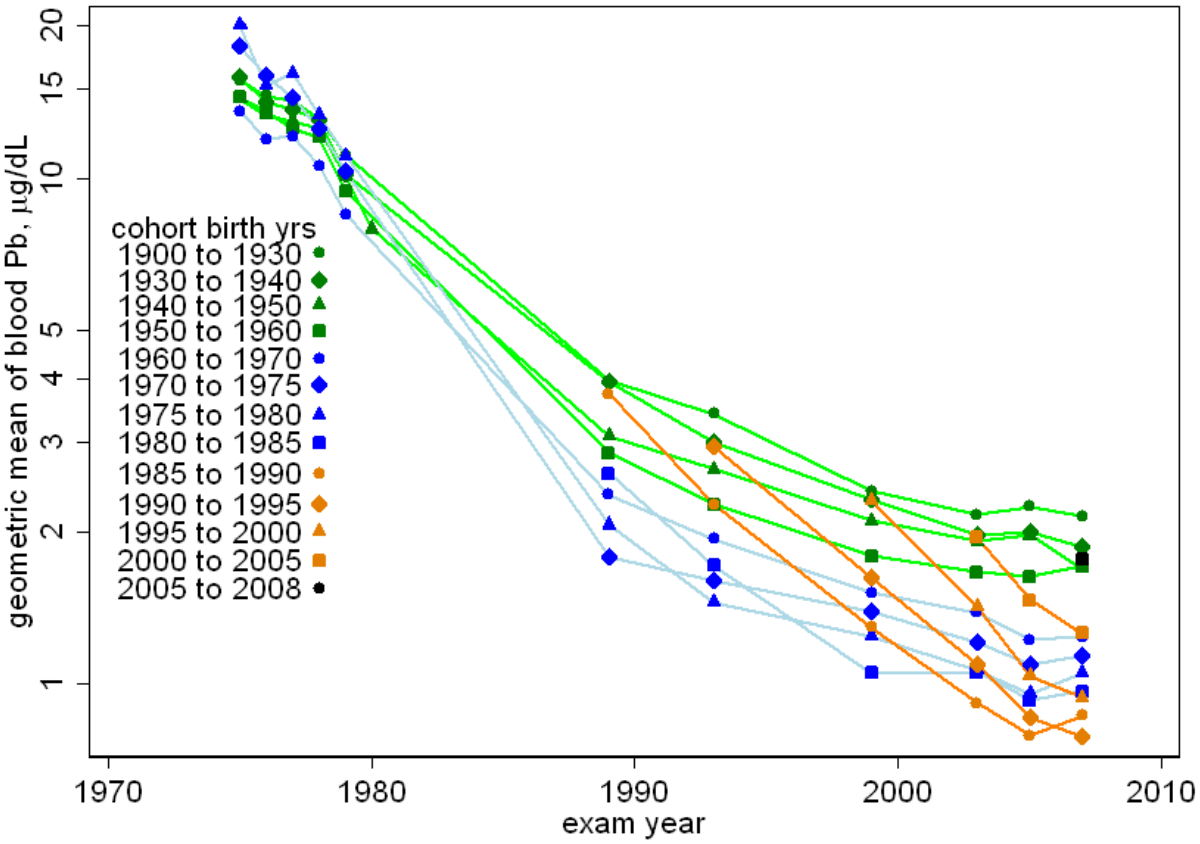
Note: Top: all data. Bottom: data for subjects having blood Pb levels less than 15 µg/dL.

Figure 4-16 Box plots of blood Pb levels among U.S. children (1-5 years old) from the NHANES survey, 1988-2008.



Source: Adapted from data from the NHANES (NCHS, 2010)

Note: The means of logged blood Pb were weighted to represent national averages. Data were from the publically NHANES II, NHANES III for 1988-1991 and 1992-1994, and the continuous NHANES in 1999-2000, 2003-2004, 2005-2006, 2007-2008. Continuous NHANES data from 2001-2002 and 2009-2010 are not included because there were only 551 blood Pb samples in each of those data sets. The year plotted for exam year was the reported exam year for NHANES II, the middle year of each of the phases of NHANES III, and the second year of each of the continuous NHANES.

Figure 4-17 Blood Pb cohort means versus year of exam.

Figure 4-18 Percent distribution of blood Pb levels by race/ethnicity among U.S. children (1-5 years) from the NHANES survey, 1988-1991 (top) and 1999-2004 (bottom).

Several studies have shown seasonal variation in blood Pb concentrations in children [e.g., (Gulson et al., 2008; Laidlaw et al., 2005; Haley and Talbot, 2004; Johnson et al., 1996)]. Seasonal variation in blood Pb concentration was evident in Australian children (n=107) with a group mean blood Pb level of 2.57 µg/dL when repeated blood Pb measurements were made over a 5-year period, with lower levels in summer compared

with winter (Gulson et al., 2008). A cross-sectional study conducted in New York State from 1995-1998 demonstrated seasonality, with the greatest percent of one and two year old children with blood Pb ≥ 10 µg/dL (n=262,687) occurring in August and the lowest percent in March and April (Haley and Talbot, 2004). Meteorological factors appear to contribute to blood Pb seasonality. Laidlaw et al. (2005) analyzed the temporal relationships between child blood Pb concentrations and various atmospheric variables in three cites (Indianapolis, IN: 1999-2002; Syracuse, NY: 1994-1998; New Orleans, LA: 1998-2003). Blood Pb data was obtained from public health screening programs conducted in the three cities. Blood Pb samples were dominated by children <5 years of age and age distribution varied across the three cities. The number of blood Pb measurements included in the analyses were as follows: Indianapolis, 15,969; Syracuse, 14,457 (Johnson and Bretsch, 2002; Johnson et al., 1996); New Orleans, 2,295 (Mielke et al., 2007a). The temporal variation in blood Pb concentrations in each city were predicted by multivariate regression models that included the following significant variables: PM_{10}, wind speed, air temperature, and soil moisture; as well as dummy variables accounting for temporal displacement of the effects of each independent variable on blood Pb. Laidlaw et al. (2005) reported R^2 values for the regression models, but did not report the actual regression coefficients. The R^2 values were as follows: Indianapolis 0.87 ($p = 0.004$); Syracuse 0.61 ($p = 0.0012$); New Orleans 0.59 ($p < 0.00001$).

Studies have examined the change in blood Pb with changes in potential Pb sources. Gulson et al. (2004b) observed that children living near a Zn-Pb smelter in Australia had blood Pb levels ranging from 10 to 42 µg/dL, with 55-100% of Pb attributed to the smelter based on isotope ratio analysis. Rubio-Andrade et al. (2011) followed a cohort of 6-8 y old children living within 3.5 km of a Mexican smelter at 0, 6, 12, and 60 months after environmental intervention took place. Soil Pb was concurrently obtained but not reported at 6, 12, or 60 months. Median blood Pb level at initiation of the study was 10.1 µg/dL for the 598 initial participants, and median soil Pb was 3,300 mg/kg at the start of the study. After 60 months, median blood Pb level was 4.4 µg/dL for the remaining 232 participants, and median soil Pb concentration was 370 mg/kg at that time. Bonnard and McKone (2009) modeled blood Pb of French children ages 21-74 months living within a village containing a Pb smelter and estimated blood Pb levels of 3.2-10.9 µg/dL. It should be noted that these studies are suggestive but not conclusive in showing that exposure to sources elevates blood Pb because these studies do not control for factors such as non-ambient in-home exposures. For this reason, Newhook et al. (2003) point out that they utilize World Health Organization guidelines on fenceline concentrations in lieu of blood Pb levels in the vicinity of industrial sources to quantify exposures related to the sources. Lanphear et al. (1998) noted that the probability of children having blood Pb ≥ 10 µg/dL increases both with exterior soil Pb content and interior Pb dust loading. Mielke et al. (2011a) noted significant increases in percentages

of children younger than 7 y old with blood Pb level ≥ 10 µg/dL for those living in inner city New Orleans housing developments (22.9%) compared with children living in communities located on the city outskirts (9.1%). At the same time, median soil Pb was significantly higher in the inner city (438 mg/kg) compared with the city outskirts (117 mg/kg).

For infants <1 year old, very little data are available on blood Pb levels. Simon et al. (2007) followed a cohort of 13 children living near an Australian smelter from birth through 36 months. In general, immediately after birth blood Pb levels fell for 1-2 months to approximately 47% of birth blood Pb level. After this initial fall, all infants' blood Pb levels rose with age until approximately 12 months old (Simon et al., 2007). Median blood Pb level among the children was 1.9 µg/dL at 2 months and increased to 13.6 µg/dL at 16 months. Geometric mean hand-Pb loading of the child and the mother were significant contributors to the area under the curve for infant blood Pb, with 46% and 60% of the variance being explained by these variables, respectively; geometric mean mothers' blood Pb explained 46% of the variance (Simon et al., 2007). Across all the data, there was a good correlation between child blood Pb level and child hand Pb loading (R^2 = 0.70). In another study, blood Pb levels of 15 infants aged 6-12 months were compared with cord blood Pb levels, resulting in significantly lower blood Pb levels later in life (2.24 µg/dL vs. 4.87 µg/dL) (Carbone et al., 1998)

Pb body burden has been reported among individuals known to consume wild game hunted with Pb shot. For example, fifty men from Nuuk, Greenland participated in a study in which they recorded their diet and produced blood samples (Johansen et al., 2006). Men who regularly ate hunted game had an average blood Pb concentration of 12.8 µg/dL, in contrast with those who did not and had an average blood Pb concentration of 1.5 µg/dL. Umbilical cord blood was collected from a cohort of Inuit newborns from northern Quebec, where the Inuit population consumes game killed with Pb shot (Lévesque et al., 2003). The geometric mean cord blood Pb level was 0.19 µmol/L, with a range of 0.01-1.31 µmol/L; the Canadian level of concern for cord blood Pb is 0.48 µmol/L. The authors contrasted the finding that 7% of Inuit newborns had cord blood Pb concentration ≥ 0.48 µmol/L in contrast with 0.16% of the Caucasian population in southern Quebec.

Recent studies have sought to characterize human exposure to Pb from piston-engine aircraft emissions. Section 3.2.2.1 describes a study by Carr et al. (2011) in which Pb concentrations, both modeled and monitored, extended beyond airport property. Miranda et al. (2011) used GIS to study the association between blood Pb level and distance from airports in six North Carolina Counties. They observed that the trend in blood Pb level decreases monotonically with distance class from the airports, with subjects within 500 m

of the airports having significantly increased blood Pb levels with residential proximity to airports ($\beta = 0.043$, 95% CI (0.006,0.080), $p < 0.05$) compared with the general population for a given county after controlling for proportion of black, Hispanic, percent receiving public assistance, and household median income at the census block group level and including dummy variables for season during which the children were screened for blood Pb.

Trends in blood Pb levels have been accompanied by changes in Pb isotope ratios for blood Pb. Isotopic ratios, described in Sections 3.2 and 3.3 as a tool for source apportionment, have been used to associate blood Pb measurements with anthropogenic sources of Pb in the environment. Changes in Pb isotopic ratios in blood samples reflect the changing influence of sources of Pb following the phase-out of tetraethyl Pb antiknock agents in automotive gasoline and changes in Pb usage in paints and other industrial and consumer products (Gulson et al., 2008; Ranft et al., 2008; Gulson et al., 2006a; Ranft et al., 2006). Gulson et al. (2006a) illustrated how a linear increase in the isotopic ratio $^{206}Pb/^{204}Pb$ occurred in concert with a decrease in blood Pb levels among selected study populations in Australia during the period 1990-2000 (Figure 4-19). Gulson et al. (2006a) point out that the isotopic signature of $^{206}Pb/^{204}Pb$ derived from Australian mines (median ~16.8) differs from that of European and Asian mines, where $^{206}Pb/^{204}Pb$ varies between ~17.4 and ~18.1. Liang et al. (2010) also examined the trends in blood Pb level over the period 1990 to 2006 in Shanghai and saw a reduction corresponding to the phase out of Pb in gasoline. A plot of $^{208}Pb/^{206}Pb$ to $^{207}Pb/^{206}Pb$ for blood and environmental samples showed overlap between the isotopic signature for coal combustion ash and that measured in blood. This result suggests a growing influence of Pb from coal ash in Shanghai in the absence of Pb in automobile emissions. Oulhote et al. (2011) examined Pb isotope ratios in blood Pb samples of 125 French children aged 6 m-6 y. The study found that Pb isotope ratios could be used to attribute Pb exposure to one source for 32% of children and to eliminate an unlikely source of Pb exposure in 30% of children.

4.4.2 Lead in Bone

An extensive national database (i.e., NHANES) is available for blood Pb concentrations in children and adults, as described in Section 4.4.1. Bone Pb concentrations are less well characterized. Table 4-8 and Table 4-9 are compilations of data from epidemiologic studies that provided bone Pb concentrations by K-XRF and/or variability in concentrations among individuals without reported occupational exposure and those with occupational exposures, respectively. In non-occupationally exposed individuals, typical group mean tibia bone Pb concentrations ranged from 10 to 30 µg/g. Patella bone Pb levels are typically higher than tibia bone Pb levels in the studies considered (Table 4-8). For example, in the Normative Aging Study, patella bone Pb concentrations were approximately 32 µg/g, whereas tibia bone Pb concentrations were about 22 µg/g. Occupationally exposed individuals generally had greater bone Pb concentrations than seen in control groups (i.e., unexposed). Bone Pb data in Table 4-9 for occupationally exposed individuals were also generally higher compared to non-occupationally exposed individuals (Table 4-8).

Table 4-8 Epidemiologic studies that provide bone Pb measurements for non-occupationally exposed populations

4.4.3 Lead in Urine

Urine Pb concentrations in the U.S. general population have been monitored in the NHANES. Data from the most recent survey (CDC, 2011) are shown in Table 4-10. The geometric mean for the entire sample for the period 2007-2008 (n = 2,627) was 0.52 µg/g creatinine (95% CI: 0.48, 0.55). The geometric means for males (n = 1,327) and females (n = 1,300) were 0.50 µg/g creatinine (95% CI: 0.47, 0.53) and 0.53 µg/g creatinine (95% CI: 0.49, 0.57), respectively.

4.4.4 Lead in Teeth

The influence of historical Pb exposures was recently studied by Robbins et al. (2010). Tooth enamel samples from 127 subjects born between 1936 and 1993 were analyzed for Pb concentration and Pb isotope ratios of the tooth enamel and compared with those parameters for sediment cores and estimates of Pb emissions from gasoline during the years when 50% enamel formation was estimated to occur. They found that the log-transform of tooth enamel concentration was significantly predicted by the log-transform of Lake Erie sediment core data obtained by Graney et al. (1995) ($p < 0.00001$) and by the log-transform of U.S. consumption of Pb in gasoline ($p < 0.00001$); Figure 4-20. Additionally, Robbins et al. (2010) found that $^{207}Pb/^{206}Pb$ was significantly predicted by the $^{207}Pb/^{206}Pb$ observed in the Lake Erie sediment cores obtained by Graney et al. (1995) ($p < 0.0001$) and for this study ($p < 0.0002$).

Note: (solid line) with newly obtained Pb sediment Lake Erie cores (open triangles), previously obtained Lake Erie sediment [open circles, Graney et al. (1995)], and U.S. gasoline usage (closed circles). All values are normalized by the peak observation for that parameter.

Figure 4-20 Comparison of relative temporal changes in tooth enamel Pb concentration.

Several Brazillian studies have found increased levels of Pb in teeth in areas where Pb sources are present. For example, Costa de Almeida et al. (2007) reported Pb concentration in tooth enamel among 4-6 y old kindergarteners in São Paulo, Brazil to be significantly higher for children living near a Pb-acid battery processing plant in the Baruru neighborhood compared with 4-6 y old children in other parts of the city (non-exposed median: 206 mg/kg, n = 247; exposed median: 786 mg/kg, n = 26; $p < 0.0001$). Subsequent analysis revealed that 55% of 4-6 y old children from Baruru had tooth enamel Pb concentrations greater than 600 mg/kg, forming a significant comparison with other neighborhoods having 0-33% of 4-6 y old children with tooth enamel Pb greater than 600 mg/kg ($p < 0.0001$) (de Almeida et al., 2008). The authors did not describe controlling for additional factors, such as socioeconomics or housing conditions. Arruda-Neto et al. (2009) studied Pb in tooth samples among São Paulo children to compare exposures of children age 4-12 living near a dam with heavy metal sediments with those of children ages 4-13 living in a control area thought to have few exposures. They observed a significant comparison (near dam: avg 1.28 ± 0.11 mg/kg, n = 50; control region: avg 0.91 mg/kg, n = 24). In a related study of Pb measures in teeth among the general population ages 7-60 y, Arruda-Neto et al. (2009) observed peak Pb concentrations of 115% of age 7 y concentrations at age 10 y followed by a steep drop to 50% among 20 y old subjects. Tooth Pb concentrations stayed fairly constant throughout adulthood but then dropped to just above 30% among 65 y old subjects. Note that the

authors did not clarify if average or median values were presented, nor did they adjust for potentially confounding factors.

4.5 Empirical Models of Lead Exposure-Blood Lead Relationships

Multivariate regression models, commonly used in epidemiology, provide estimates of the contribution of variance in the internal dose metric to various determinants or control variables (e.g., air Pb concentration, surface dust Pb concentration). Structural equation modeling links several regression models together to estimate the influence of determinants on the internal dose metric. Regression models can provide estimates of the rate of change of blood or bone Pb concentration in response to an incremental change in exposure level (i.e., slope factor). One strength of regression models is that they are empirically verified within the domain of observation and have quantitative estimates of uncertainty imbedded in the model structure. However, regression models are based on (and require) paired predictor-outcome data, and, therefore, the resulting predictions are confined to the domain of observations and are typically not generalizable to other populations. Regression models also frequently exclude numerous parameters that are known to influence human Pb exposures (e.g., soil and dust ingestion rates) and the relationship between human exposure and tissue Pb levels, parameters which are expected to vary spatially and temporally. Thus, extrapolation of regression models to other spatial or temporal contexts, which is often necessary for regulatory applications of the models, can be problematic.

4.5.1 Air Lead-Blood Lead Relationships

The 1986 Pb AQCD (U.S. EPA, 1986a) described epidemiological studies of relationships between air Pb and blood Pb. Of the studies examined, the total blood Pb-air Pb slope (when considering both direct and indirect exposures derived from air) was estimated to be approximately double the slope estimated from the direct contribution due to inhaled air alone (U.S. EPA, 1986a). Much of the pertinent earlier literature (e.g., prior to 1984) was summarized by Brunekreef (1984). Based on the studies available at that time that considered multiple air-related Pb exposure pathways in the aggregate, the 1986 Pb AQCD concluded that "the blood Pb versus air Pb slope β is much smaller at high blood and air levels." This is to say that the slope β was much smaller for occupational exposures where high blood Pb levels (>40 μg/dL) and high air Pb levels (much greater than 10 $\mu g/m^3$) prevailed relative to lower environmental exposures which showed lower blood Pb and air Pb concentrations (<30 μg/dL and <3 $\mu g/m^3$). For those environmental exposures, it was concluded that the relationship between blood Pb and air Pb "for direct

inhalation appears to be approximately linear in the range of normal ambient exposures (0.1-2.0 μg/m^3)" (pp 1–98 of the 1986 Pb AQCD). Based on meta-analysis of 18 studies of urban or industrial-urban populations, Brunekreef (1984) estimated the blood Pb-air Pb slope for children to be 0.3485 ln[μg/dL blood Pb] per ln[μg/m^3 air Pb] (R^2 = 0.69; Figure 4-21). This slope corresponds to an increase of 4.6 μg/dL blood Pb per μg/m^3 air Pb at an air Pb concentration of 1.5 μg/m^3 for all groups included in the study (n=96). The 1.5 μg/m^3 value is the median of the air Pb concentrations that match the 96 blood Pb concentrations in Figure 3 of Brunekreef et al. (1984), taken from the Appendix to the same paper. When the analysis was limited to children whose blood Pb concentrations were <20 μg/dL, the slope was 0.2159 (R^2=0.33), which corresponds to an increase of 4.8 μg/dL blood Pb per μg/m^3 air Pb at the median air concentration (0.54 μg/m^3, n=43).

Newer studies that provide estimates for the blood Pb-air Pb slope are described below. In some studies, the blood Pb-air Pb relationship was described with a non-linear regression function, in which the blood Pb-air Pb slope varied with air Pb concentration. In Table 4-11, slopes corresponding to the central estimate of the air Pb concentrations are provided, which are considered to be the best estimate of the slope from each study. These were calculated by evaluating each regression function at ± 0.01 μg/m^3 from the central estimate of the air Pb concentration. Air Pb concentration ranges and central estimates varied across studies, making it difficult to interpret comparisons based solely on the central estimates of the slopes; therefore, Figure 4-21 depicts the relationship between the blood Pb-air Pb slope as a function of air Pb concentration for the range of air Pb concentrations evaluated in each study (the central estimate is also shown). Figure 4-21 provides a more informative picture of the extent to which slope estimates vary (and overlap) within and between studies. In the Schnaas et al. (2004) analysis, the effect of air Pb on blood Pb may have been underestimated due to inclusion of location and SES terms in their regression model. It was specifically noted by the authors that air Pb differed significantly between the locations and the poorer residential areas were usually the more industrialized areas with higher pollution. Hence, the inclusion of these terms may have accounted for some of the variance in blood Pb attributable to air Pb. With the exception of Ranft et al. (2008), all studies included in Table 4-11 and Figure 4-22 include a blood Pb-air Pb relationship that reflects all air-related pathways of exposure. The Ranft et al. (2008)study includes a separate term for soil Pb, so the blood Pb-air Pb slope presented for that study underestimates the slope that would reflect all air-related pathways, since soil Pb encompasses deposited ambient air Pb. The Ranft et al. (2008) model is log-linear, with the natural logarithm of blood Pb being a function of linear increase in air Pb. This results an upward curvature of the blood Pb-air Pb relationship. By comparison, log-log models predict an increase in the blood Pb-air Pb slope with decreasing air Pb concentration, whereas linear models predict a constant blood Pb-air Pb slope across all air Pb concentrations.

Table 4-11 Summary of estimated slopes for blood Pb to air Pb relationships in humans

Reference	Study Methods	Model Description	Blood Pb–Air Pb Slopea
Children Populations			
Brunekreef et al. (1984)	**Location:** Various countries **Years:** 1974-1983 **Subjects**: Children (varying age ranges; n>190,000) **Analysis:** Meta analysis of 18 studies	**Model:** Log-Log **Blood Pb:** 5-41 µg/dL (mean range for studies) **Air Pb:** 0.1-24 µg/m^3 (mean range for studies)	**All children:** 4.6 (1.5)[c] **Children <20 µg/dL:** 4.8 (0.54)[d]
Hayes et al. (1994)	**Location:** Chicago, IL **Years:** 1974-1988 **Subjects:** 0.5-6 yr (n = 9,604) **Analysis:** Regression of quarterly median blood Pb and quarterly mean air Pb	**Model:** Log-Log **Blood Pb:** 12-30 µg/dL (annual median range) **Air Pb:** 0.05-1.2 µg/m^3 (annual mean range)	8.2 (0.62)[e]
Hilts et al. (2003)	**Location:** Trail, BC **Years:** 1989-2001 **Subjects:** 0.5-6 yr (Estimated n = 220-460, based on 292-536 blood Pb measurements/yr with 75-85% participation) **Analysis:** Regression of blood Pb screening and community air Pb following upgrading of a local smelter	**Model:** Linear **Blood Pb:** 4.7-11.5 µg/dL (annual geometric mean range) **Air Pb:** 0.03-1.1 µg/m^3 (annual geometric mean range)	6.5 (0.48)[f]

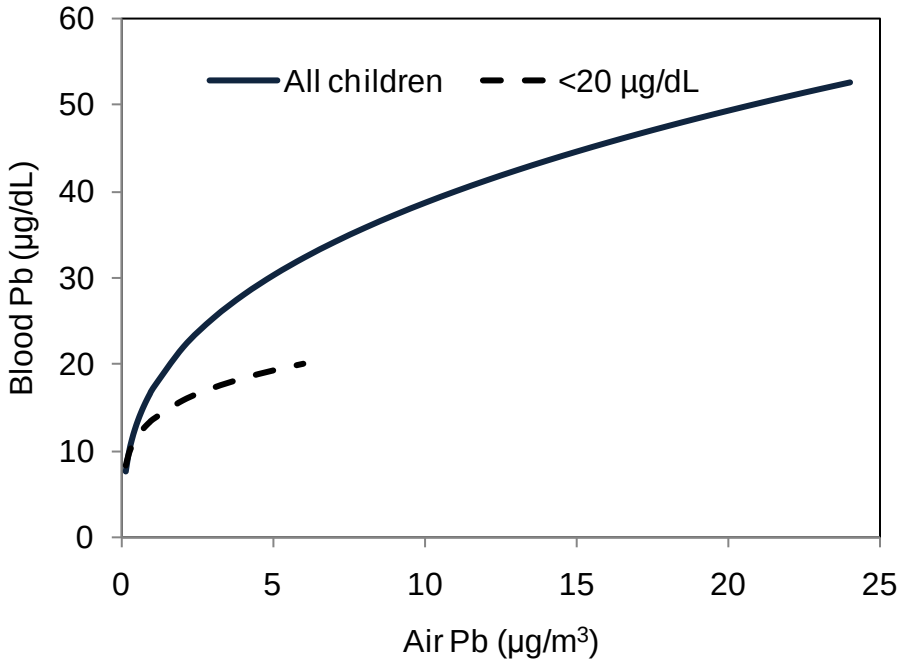
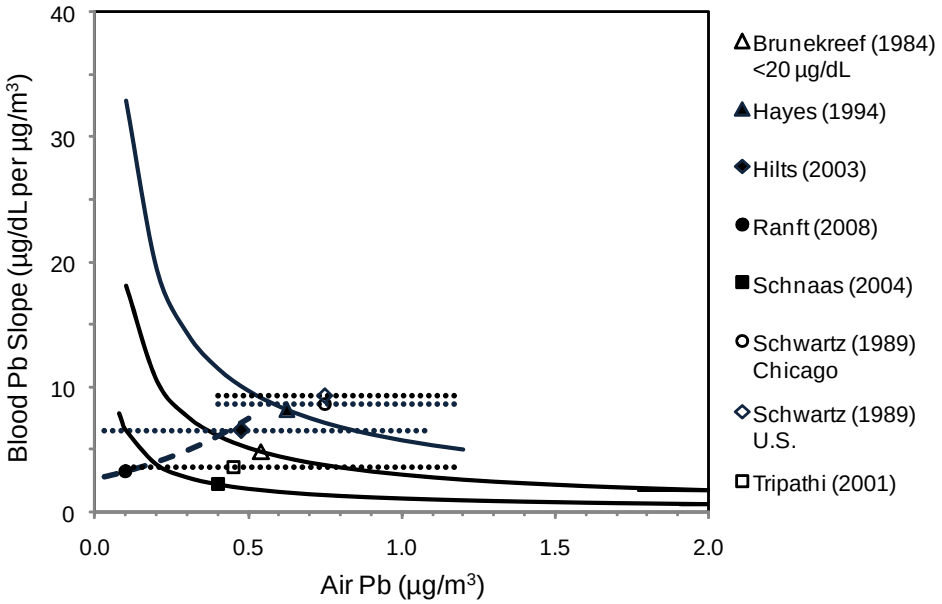
[a]Slope is predicted change in blood Pb (µg/dL per µg/m3) evaluated at ± 0.01 µg/m3 from central estimate of air Pb for the study (shown in parentheses)
[b]Based on data for U.S. (1986 Pb AQCD)
[c] ln(PbB) = ln(PbA) x 0.3485 +2.853
[d] ln(PbB) = ln(PbA) x 0.2159 + 2.620
[e] ln(PbB) = ln(PbA) x 0.24 +3.17
[f] PbB = PbA x 6.5
[g] PbB =1.5 x EXP(0.9361 x (PbA-0.1)/0.44), where 1.5 µg/dL is the background PbB, and 0.1 µg/m^3 is the median PbA for the study; model also adjusted for soil Pb concentration, which may reduce estimated slope
[h] ln(PbB) = Ln(PbA) x 0.213 +1.615 for the 1987 cohort, see text for more study details.
[i] PbB = PbA x 8.6
[j] PbB =Pb A x 3.6
[k] ln(PbB) = ln(PbA) x 0.05 +2.12
[l] PbB = PbA x 9.63
GM, geometric mean; GSD, geometric standard deviation; PbB, blood Pb concentration (µg/dL); PbA, air lead concentration (µg/m^3)



Data provided from Brunekreef (1984).

Note: The regression model is: (ln[µg/dL blood Pb] = 0.3485·ln[µg/m^3 air Pb] + 2.85) for all children (n=96 subject groups) and (ln[µg/dL blood Pb] = 0.2159·ln[µg/m^3 air Pb] + 2.62) when the sample was restricted to populations that had blood Pb concentrations <20 µg/dL (n=44 subject groups).

Figure 4-21 Predicted relationship between air Pb and blood Pb based on a meta analysis of 18 studies.



Note: Slopes are calculated for a change in air Pb (±0.01 µg/m^3) over ranges of air Pb concentrations reported in each study (lines). The air Pb axis is truncated at 2 µg/m^3; the actual range for the Brunkreefe et al. (1984) study was 0.1-6.4 µg/dL per µg/m^3 and for the Schnaas et al. (2004) study was 0.08-2.8 µg/dL per µg/m^3. The slope axis has been truncated at 40; the actual range for the Hayes et al. (1994) study was 5-56 µg/dL per µg/m^3 (the high end of the range was estimated for the minimum annual average air Pb of 0.05 µg/m^3). The two estimates for Schwartz and Pitcher (1989) represent data for U.S. and Chicago. Models are log-log (solid lines), log-linear (dashed line), and linear (dotted lines). Symbols show the slope at the central estimate of air Pb (e.g., mean or median reported for each study).

Figure 4-22 Blood Pb – air Pb slope (µg/dL per µg/m^3) predicted from various epidemiologic studies (links available in Table 4-11).

4.5.1.1 Children

Hilts et al. (2003) reported child blood Pb and air Pb trends for the city of Trail, British Columbia, over a period preceding and following installation of a new smelter process in 1997 which resulted in lower air Pb concentrations. Blood Pb data were obtained from annual (1989-2001) surveys of children 6-60 months of age who lived within 4 km from the smelter (n: 292-536 eligible per year, 75-85% participation). Air Pb concentrations were obtained from high volume suspended particulate samplers placed within 2 km of the smelter that operated 24 hours every 6th day. Data on Pb levels in air, residential soil, interior dust, and blood for three sampling periods are summarized in Table 4-12. Based on these data, blood Pb decreased 6.5 µg/dL per 1 µg/m^3 air Pb and by 0.068 µg/dL per mg/kg soil Pb (based on linear regression with air or soil Pb as the sole independent variable). Several uncertainties apply to these estimates. Potential mismatching of air Pb concentrations (often termed misclassification) with individual blood Pb levels may have occurred as a result of air Pb being measured within 2 km of the smelter, whereas, the

blood Pb data included children who resided >2 km from the smelter. The regression estimates were based on group mean estimates for three sampling dates, rather than on the individual blood Pb estimates, which included repeated measures on an unreported fraction of the sample. The limited number of data pairs (three) constrained parameter estimates to simple regression coefficients. Other important factors probably contributed to blood Pb declines in this population that may have been correlated with air, soil and dust Pb levels. These factors include aggressive public education and exposure intervention programs (Hilts et al., 1998; Hilts, 1996). Therefore, the coefficients shown in Table 4-12 are likely to overestimate the influence of air, dust, or soil Pb on blood Pb concentrations at this site.

Table 4-12 Environmental Pb levels and blood Pb levels in children in Trail, British Columbia

Date	1996	1999	2001	Regression Coefficient (µg/dL per µg/m3)
Blood Pb (µg/dL)	11.5	5.9	4.7	NA
Air Pb (µg/m^3)	1.1	0.3	0.03	6.5 ± 0.52 (R^2=0.99, p=0.050)
Soil Pb (mg/kg)	844	756	750	0.069 ± 0.008 (R^2=0.99, p=0.069)
Interior Dust Pb (mg/kg)	758	583	580	0.035 ± 0.005 (R^2=0.98, p=0.097)

A new smelter process began operation in 1997. Values for air, soil and dust Pb are annual geometric means; values for blood Pb are annual geometric means. Regression coefficients are for simple linear regression of each exposure variable on blood Pb.

Source: Data from Hilts et al. (2003).

Ranft et al. (2008) reported a meta-analysis of five cross-sectional surveys of air and soil Pb levels and blood Pb concentrations in children living in Duisburg, Germany. The analysis included observations on 843 children (6-11 years of age) made during the period 1983-2000. Pb was measured in PM_{10} samples collected in a 200 meter by 200 meter grid that encompassed the city. Pb in surface soil (0-10 cm) was measured at 145 locations in the city. Air and soil Pb concentrations were assigned to each participant by spatial interpolation from the sampling grid data to each home residence. The 5th-95th percentile ranges were 0.025-0.465 µg Pb/m^3 for air and 72-877 mg Pb/kg for soil. The results of multivariate regression analyses were reported in terms of the relative increase (the geometric mean blood Pb ratio, GMR) for an increase in air or soil Pb from the 5th to 95th percentile value. In a multivariate linear regression model (R^2 = 0.586) that included air and soil Pb in the same model and adjusted for covariates, the GMR values were: 2.55 per 0.44 µg/m^3 increase in air Pb (95% CI: 2.40, 2.71, R^2=0.484, p <0.001) and 1.30 per 800 mg/kg soil Pb (95% CI: 1.19, 1.43, R^2 = 0.017, p <0.001). Based on the values for R^2, the regression model accounted for approximately 59% of the total variance in blood Pb and, of this, 83% was attributed to air Pb. Values for GMR for soil

Pb varied depending on the sampling data and ranged from 1.41 to 2.89, with most recent data (from the year 2000) yielding a value of 1.63 per 800 mg/kg increase in soil Pb. The GMR values can be converted to regression slopes (slope = [starting blood Pb×ln(GMR)]/[95th − 5th percentile air or soil Pb]) for calculating equivalent air:blood Pb ratios. The model predicts an increase of 3.2 µg/dL blood Pb per 1 µg/m^3 increase in air Pb at the median air Pb concentration for the study (0.1 µg/m^3) and assuming a background blood Pb concentration of 1.5 µg/dL. Based on the GMR estimate of 1.63 for soil Pb, a 1,000 mg/kg increase in soil Pb would be associated with an increase in blood Pb of 0.9 µg/dL per mg/kg soil at the median soil Pb concentration of 206 mg/kg and assuming a background blood Pb concentration of 1.5 µg/dL. The degree of confounding of the GMR and estimates resulting from the air and soil Pb correlation was not reported, although the correlation coefficient for the two variables was 0.136 for the whole data set and 0.703 when data collected in 1983 was omitted. Because the model also included Pb levels in soil, the blood Pb-air Pb ratio may be underestimated since some of the Pb in soil was likely derived from air. The blood Pb-air Pb slope does not include the portion of the soil/dust Pb ingestion pathway that derives from air Pb, such as recently airborne Pb deposited to soil and dust which remains available for inhalation and ingestion. To estimate the blood Pb-air Pb ratio that included all air-related pathways, data for geometric mean of blood Pb and air Pb among the cohort of children studied were extracted from Figure 1 in Ranft et al. (2008) for each of the five study years. The extracted values of the geometric mean of blood Pb and air Pb were used in regressions employing linear and log-log fits. The linear model obtained was: PbB = (13.65×PbA) + 2.96 (R^2 = 0.92); i.e., the linear regression produced a constant slope of 14 µg/dL per µg/m^3. The log-log model was: ln(PbB) = (0.48×ln(PbA) + 2.61 (R^2 = 0.91), resulting in an inverse curve for dPbB/dPbA vs. PbA with a slope of 22 µg/dL per µg/m^3 at PbA = 0.1 µg/m^3.

Schnaas et al. (2004) analyzed data on blood Pb and air Pb concentrations during and after the phase out of leaded gasoline use in Mexico (1986-1997) in children as part of a prospective study conducted in Mexico City. The sample included 321 children born during the period 1987 through 1992. Repeated blood Pb measurements were made on each child at 6-month intervals up to age 10 years. Air Pb measurements in PM_{10} (annual average of quarterly means) were derived from three area monitors which represented distinct study zones. Children were assigned to study zones based on their current address and were assigned the corresponding annual average air Pb concentrations for their year of birth and appropriate air monitoring zones. Associations between lifetime (across the first 10 years of life) blood Pb concentration, air Pb concentration for year of birth and other variables (e.g., age, year of birth, family use of glazed pottery) were evaluated using multivariate regression models. The largest slope occurred in the cohort born in 1987, who experienced the largest decline in air Pb (from 2.8 to <0.1 µg/m^3); the

predicted slope for this group of children was 0.213 (95% CI: 0.114-0.312) ln [µg/dL blood] per ln[µg/m^3 air]. This slope corresponds to an increase of 2.2 µg/dL blood Pb per µg/m^3 at the median annual air Pb concentration of 0.4 µg/m^3 estimated over the years of the study. Slopes for other birth cohorts ranged from -0.003 (1992) to 0.166 (1988) with a median of 0.153 for all six cohorts. This median slope corresponds to an increase of 1.7 µg/dL blood Pb per µg/m^3 at the median annual air Pb concentration of 0.4 µg/m^3 estimated over the years of the study. Considering all cohorts simultaneously, data for annual geometric mean of blood Pb and air Pb were extracted from Figure 1 in Schnaas et al. (2004). However, in employing this approach, blood Pb is confounded by age and year because in the early years of the study, only younger children were available and in the later years of the study, only older children contributed data. The extracted values of the geometric mean of blood Pb and mean air Pb were used in regressions employing linear and log-log models for comparison to other studies and a log-linear model as employeed by the authors. The linear model obtained was: PbB = (2.50×PbA) + 5.61 (R^2 = 0.84), i.e., the linear model produced a constant slope of 2.50 µg/dL per µg/m^3. However, inspection of the graph (not shown here) suggested a bi-linear fit. Regression of the data over the interval 0.1-0.4 µg/m^3 produced a slope of 9.0 µg/dL per µg/m^3 (R^2 = 0.83), and regression of the data over the interval 0.4-2.8 µg/m^3 produced a slope of 1.52 µg/dL per µg/m^3 (R^2 = 0.83). The log-log model was: ln(PbB) = (0.26×ln(PbA)) + 2.20 (R^2 = 0.94), resulting in an inverse curve for dPbB/dPbA vs. PbA, with a slope of 4.5 µg/dL per µg/m^3 at PbA = 0.4 µg/m^3. The log-linear model as employed by the authors was: ln(PbB) = (0.32×PbA) + 1.73 (R^2 = 0.77); and described the data least well. The log-linear model produced an exponential curve of dPbB/dPbA vs. PbA, with a slope of 2.04 µg/dL per µg/m^3 at PbA = 0.4 µg/m^3.

Schwartz and Pitcher (1989) reported a multivariate regression analysis of associations between U.S. gasoline Pb consumption (i.e., sales) and blood Pb concentrations in the U.S. population during the period 1976-1980 when use of Pb in gasoline was being phased out. Although this analysis did not directly derive a slope for the air Pb-blood Pb relationships, other analyses have shown a strong correlation between U.S. gasoline Pb consumption and ambient air Pb levels during this same period (U.S. EPA, 1986a). Therefore, it is possible to infer an air Pb-blood Pb relationship from these data. Two sources of blood Pb data were used in Schwartz and Pitcher (1989): NHANES II provided measurements for U.S. children 6 months to 74 years of age (n = 9,996) during 1976-1980, and the City of Chicago blood Pb screening program provided approximately 7,000 blood Pb measurements in black children during 1976-1980. Gasoline Pb consumption was estimated as the product of monthly gasoline sales in the U.S. and quarterly estimates of Pb concentrations in gasoline reported to U.S. EPA. Based on the NHANES blood Pb data for white children, the regression coefficient was 2.14 µg/dL blood per 100 metric tons of gasoline Pb/day (SE=0.19, p=0.0000); results for black

children were essentially identical. Based on the Chicago blood Pb data the regression coefficient was 16.12 (µg/dL per 1,000 metric tons gasoline Pb/quarter (SE=1.37, p=0.0001), which is roughly equivalent to 1.79 µg/dL blood per 100 metric tons of gasoline Pb/day (the value cited in Schwartz and Pitcher (1989) is 1.97 µg/dL blood per 100 metric tons of gasoline Pb/day). U.S. EPA (1986a) reported data on gasoline Pb consumption (sales) and ambient Pb levels in the U.S. during the period 1976-1984 (Table 4-13). Based on these data, air Pb concentrations decreased in association with gasoline Pb consumption. The linear regression coefficient for the air Pb decrease was 0.23 µg/m^3 per 100 metric tons gasoline Pb/day (SE = 0.02, R^2 = 0.95, p <0.0001). If this regression coefficient is used to convert the blood Pb slopes from Schwartz and Pitcher (1989), the corresponding air Pb-blood Pb slopes would be 9.3 and 8.6 µg/dL per µg/m^3, based on the NHANES and Chicago data, respectively (e.g., 2.14/0.23 = 9.3 and 1.97/0.23=8.6).

Table 4-13 U.S. gasoline Pb consumption and air Pb levels

Date	Total Gasoline Pb (103 metric tons/yr)	Total Gasoline Pb (102 metric tons/day)a	Air Pb (µg/m^3)
1976	171.4	4.70	1.22
1977	168.9	4.63	1.20
1978	153	4.19	1.13
1979	129	3.53	0.74
1980	78.8	2.16	0.66
1981	60.7	1.66	0.51
1982	59.9	1.64	0.53
1983	52.3	1.43	0.40
1984	46	1.26	0.36

The linear regression coefficient is 0.23 µg/m^3 air per 100 metric tons/day (SE= 0.020, R^2 = 0.95, p <0.0001).
[a]Conversion factor is 10/365 days/year.

Source: U.S. EPA (1986a).

Tripathi et al. (2001) reported child blood Pb and air Pb trends for the city and suburbs of Mumbai, India over the period 1984-1996. Blood Pb data were obtained from children 6-10 years of age (n = 544) who lived in 13 locations within the Mumbai area. Air Pb concentrations were measured from high volume PM samplers (with the majority of Pb in the respirable size range) placed at a height of 1.6 meters that operated 24 hours. Data on Pb concentrations in air, residential soil, interior dust, and blood for three sampling periods are summarized in Table 4-14. Based on these data, blood Pb increased 3.6 µg/dL per 1 µg/m^3 air Pb (based on linear regression with air or soil Pb as the sole independent variable). Several uncertainties apply to these estimates, including potential exposure misclassification since the mean air Pb concentration was used for each suburb over the entire study period. The regression estimates were based on group mean blood Pb

estimates for the 13 sampling locations, rather than on the individual blood Pb estimates, which included repeated measures on an unreported fraction of the sample.

Table 4-14 Air Pb levels and blood Pb levels in children in Mumbai, India

	Blood Pb (µg/dL)			Air Pb (µg/m^3)		
Location	**N**	**GM**	**GSD**	**N**	**GM**	**GSD**
Borivilli	12	10.4	1.67	10	0.32	1.51
Byculla	117	11.0	1.99	30	0.99	1.73
Deonar	46	9.5	2.29	93	0.11	3.21
Goregaon	21	9.1	1.30	24	0.35	1.77
Govandi	20	8.9	1.42	10	0.10	1.52
Jogeshwari	20	8.6	1.32	24	0.11	2.47
Khar	17	9.0	1.53	22	0.18	3.15
Parel	168	10.4	1.91	37	0.44	1.48

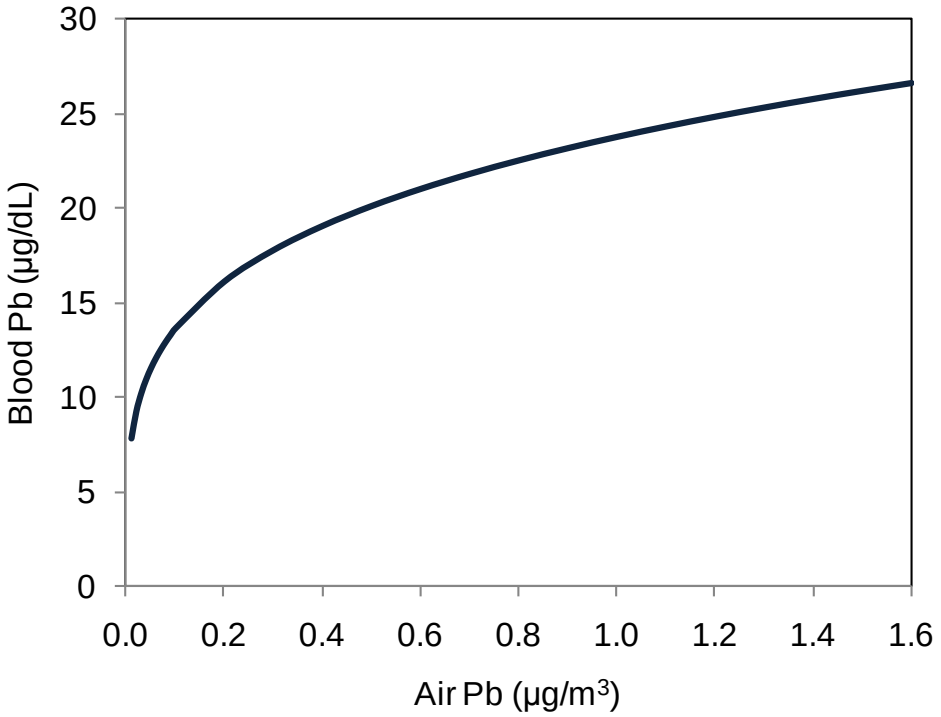
Colaba	12	9.2	1.86	9	0.14	1.63
Vakola	21	14.4	1.64	7	1.12	1.12

The linear regression coefficient is 3.62 µg/dL blood per µg/m^3 air (SE= 0.61, R^2= 0.76, p <0.001).
GM, geometric mean; GSD, geometric standard deviation; N, number of subjects.

Source: Data are from Tripathi et al. (2001).

Hayes et al. (1994) analyzed data collected as part of the Chicago, IL blood Pb screening program for the period 1974-1988, following the phase-out of leaded gasoline. The data included 9,604 blood Pb measurements in children (age: 6 months to 6 years) and quarterly average air Pb concentrations measured at 12 monitoring stations in Cook County, IL. Quarterly median blood Pb levels declined in association with quarterly mean air Pb concentrations. The regression model predicted a slope of 0.24 ln [µg/dL blood] per ln[µg/m^3 air], as illustrated in Figure 4-23. This slope corresponds to an increase of 8.2 µg/dL blood Pb per µg/m^3 at the average annual mean air Pb concentration of 0.62 µg/m^3.



Modified from Hayes et al. (1994).

Note: The regression model is: (ln[µg/dL blood Pb] = 0.24·ln[µg/m^3 air Pb] + 3.17).

Figure 4-23 Predicted relationship between air Pb and blood Pb based on data from Chicago, IL in children age 0-5 y (1974–1988).

4.5.1.2 Adults

Rodrigues et al. (2010) examined factors contributing to variability in blood Pb concentration in New England bridge painters, who regularly use electric grinders to prepare surfaces for painting. The study included 84 adults (1 female) who were observed during a 2-week period in 1994 or 1995. Subjects wore personal inhalable PM samplers designed to capture PM smaller than 100 µm, while performing various job-related tasks. The geometric mean air Pb concentration for the 2-week period was 58 µg/m^3 (GSD 2.8), with a maximum daily value of 210 µg/m^3. These Pb concentrations were reported to have been corrected by the National Institute for Occupational Safety and Health (NIOSH) respirator protection factors, which were not reported by the authors. Hand wipe samples were collected at the mid-shift break and at the end of the shift (after the subjects had reportedly cleaned up for the day; GM = 793 µg, GSD 3.7). Blood Pb samples were collected at the beginning of the 2-week period (GM = 16.1 µg/dL, GSD 1.7). Associations between exposure variables and blood Pb concentrations were explored with multivariate regression models (Table 4-15). When the model excluded

hand-wipe data (not all participants who wore the personal air samplers agreed to provide hand-wipes), the regression coefficient for the relationship between ln[blood Pb concentration (µg/dL)] and ln[air Pb (µg/m^3)] was 0.11 (SE = 0.05, p = 0.03). This slope corresponds to a 1.3-fold increase in blood Pb concentration for a 10-fold increase in air Pb concentration and a slope of 0.009 µg/dL per µg/m^3, at the average occupational air Pb concentration for the study (58 µg/m^3); non-occupational exposures were not included in the slope calculation. A second regression model included hand wipe Pb (n = 54) and yielded a regression coefficient of 0.05 (SE = 0.07, p = 0.45), which corresponds to a 1.12-fold increase in blood Pb concentration per 10-fold increase in air Pb concentration and a slope of 0.02 µg/dL per µg/m^3, at the average occupational air Pb concentration for the study (58 µg/m^3).

4.5.2 Environmental Lead-Blood Lead Relationships

Empirically-based relationships between blood Pb levels and Pb intakes and/or Pb concentrations in environmental media have provided the basis for what has become known as slope factor models. Slope factor models are highly simplified representations of empirically based regression models in which the slope parameter represents the change in blood Pb concentration projected to occur in association with a change in Pb intake or uptake. The slope parameter is factored by exposure parameters (e.g., exposure concentrations, environmental media intake rates) that relate exposure to blood Pb concentration (Maddaloni et al., 2005; U.S. EPA, 2003c; Abadin and Wheeler, 1997; Stern, 1996; Bowers et al., 1994; Stern, 1994; Carlisle and Wade, 1992). In slope factor models, Pb biokinetics are represented as a linear function between the blood Pb concentration and either Pb uptake (uptake slope factor, USF) or Pb intake (intake slope factor, ISF). The models take the general mathematical forms:

$$\mathbf{PbB} = \mathbf{E} \times \mathbf{ISF}$$

Equation 4-2

$$\mathbf{PbB} = \mathbf{E} \times \mathbf{AF} \times \mathbf{USF}$$

Equation 4-3

where PbB is the blood Pb concentration, E is an expression for exposure (e.g., soil intake × soil Pb concentration) and AF is the absorption fraction for Pb in the specific exposure medium of interest. Intake slope factors are based on ingested rather than absorbed Pb and, therefore, integrate both absorption and biokinetics into a single slope factor, whereas models that utilize an uptake slope factor include a separate absorption parameter. In contrast to mechanistic models, slope factor models predict quasi-steady state blood Pb concentrations that correspond to time-averaged daily Pb intakes (or uptakes) that occur over sufficiently long periods to produce a quasi-steady state (i.e., >75 days, ~3 times the $t_{1/2}$ for elimination of Pb in blood).

The U.S. EPA Adult Lead Methodology (ALM) is an example of a slope factor model that has had extensive regulatory use in the EPA Superfund program for assessing health risks to adults associated with non-residential exposures to Pb in contaminated soils (Maddaloni et al., 2005; U.S. EPA, 1996a). The model was developed to predict maternal and fetal blood Pb concentrations that might occur in relation to maternal exposures to contaminated soils. The model assumes an uptake slope factor of 0.4 µg/dL blood per µg/day Pb uptake. Additional discussion of slope factor models that have been used or proposed for regulatory use can be found in the 2006 Pb AQCD (U.S. EPA, 2006b).

Previous studies included in the 2006 Pb AQCD (U.S. EPA, 2006b) explored the relationship between blood Pb in children and environmental Pb concentrations. In a pooled analysis of 12 epidemiologic studies, interior dust Pb loading, exterior soil/dust Pb, age, mouthing behavior, and race were all statistically significant variables included in the regression model for blood Pb concentration (Lanphear et al., 1998). Significant interactions were found for age and dust Pb loading, mouthing behavior and exterior soil/dust level, and SES and water Pb level. In a meta-analysis of 11 epidemiologic studies, among children the most common exposure pathway influencing blood Pb concentration in structural equation modeling was exterior soil, operating through its effect on interior dust Pb and hand Pb (Succop et al., 1998). Similar to Lanphear et al. (1998), in the linear regression model, interior dust Pb loading had the strongest relationships with blood Pb concentration. Individual studies conducted in Rochester, NY, Cincinnati, OH, and Baltimore, MD report similar relationships between children's blood Pb and interior dust concentrations (Lanphear and Roghmann, 1997; U.S. EPA, 1996b; Bornschein et al., 1985).

Dixon et al. (2009) reported a multivariate analysis of associations between environmental Pb concentrations and blood Pb concentrations, based on data collected in the NHANES (1999-2004). The analyses included 2,155 children, age 12-60 months. The population-weighted geometric mean blood Pb concentration was 2.03 µg/dL (GSD 1.03). A linear model applied to these data yielded an R^2 of 40% (Table 4-16). The regression coefficient for the relationship between ln[blood Pb concentration (µg/dL)] and ln[floor dust Pb concentration (µg/ft^2)] was 0.386 (SE 0.089) for "not smooth and cleanable" surfaces (e.g., high-pile carpets) and 0.205 (SE 0.032) for "smooth and cleanable" surfaces (e.g., uncarpeted or low-pile carpets). These coefficients correspond to a 2.4-fold or 1.6-fold increase in blood Pb concentration, respectively, for a 10-fold increase in floor dust Pb concentration.

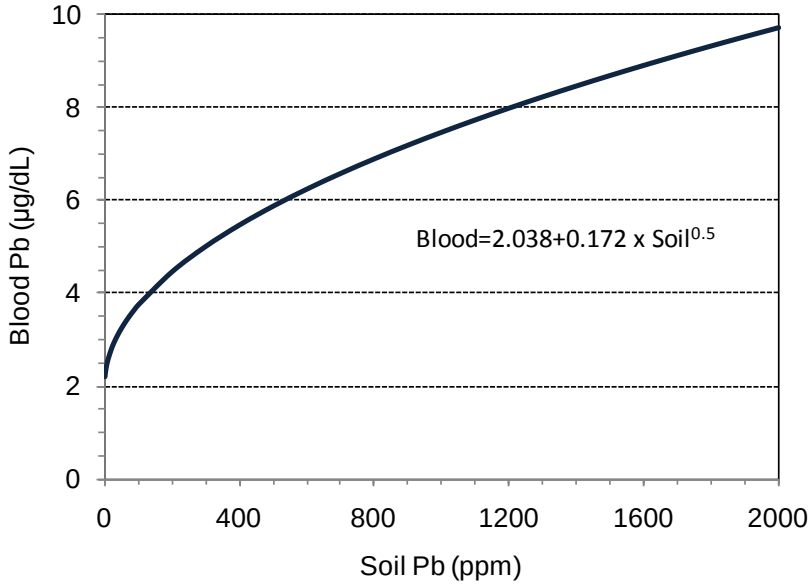
Mielke et al. (2007a) analyzed blood Pb and soil Pb concentration data collected as part of a blood Pb screening program in New Orleans (2000-2005). The data set included 55,551 blood Pb measurements for children 0-6 years of age and 5,467 soil Pb measurements. Blood Pb and soil Pb concentrations were matched at the level of census tracts. The association between blood Pb concentration and soil Pb concentration was evaluated using non-parametric permutation methods. The resulting best-fit model (R^2=0.528) was:

$$\mathbf{PbB} = \mathbf{2.038} + (\mathbf{0.172} \times \mathbf{PbS}^{\mathbf{0.5}})$$

Equation 4-4

where PbB is the median blood Pb concentration and PbS is the median soil Pb concentration. The resulting curvilinear relationship predicts a twofold increase in blood Pb concentration for an increase in soil Pb concentration from 100 to 1,000 ppm (Figure 4-24).



Note: The data set included 55,551 blood Pb measurements for children 0-6 years of age and 5,467 soil Pb measurements. Blood Pb and soil Pb concentrations were matched at the level of census tracts (Mielke et al., 2007a).

Figure 4-24 Predicted relationship between soil Pb concentration and blood Pb concentration in children based on data collected in the New

In a subsequent re-analysis of the New Orleans (2000-2005) data, individual child blood Pb observations were matched to census tract soil concentrations (Zahran et al., 2011). This analysis confirmed the association between blood Pb and both soil Pb and age reported in Mielke et al. (2007a). Regression coefficients for soil Pb (random effects generalized least squares regression) ranged from 0.217 to 0.214 (per soil $Pb^{0.5}$), which is equivalent to approximately a 2-fold increase in blood Pb concentration for an increase in soil Pb concentration from 100 to 1,000 ppm.

Several studies have linked elevated blood Pb levels to residential soil exposures for populations living nearby industrial or mining facilities. Gulson et al. (2009) studied the

blood Pb and isotopic Pb ratios of children younger than 5 years old and adults older than 18 years old living in the vicinity of a mine producing Magellan Pb ore in western Australia. They observed a median blood Pb level of 6.6 µg/dL for the children, with isotopic ratios indicating contributions from the mine ranging from 27 to 93%. A weak but significant linear association between blood Pb level and percent Magellan Pb was observed ($R^2 = 0.12$, $p = 0.018$). Among children with blood Pb levels over 9 µg/dL and among adults, the isotopic ratios revealed Pb exposures from a variety of sources. Garavan et al. (2008) measured soil Pb and blood Pb levels among children aged 1 month to 17.7 years old in an Irish town near a coal mine. The blood Pb measurements were instituted as part of a screening and community education program given that the presence of Pb had been documented in the environment. Garavan et al. (2008) found that over 3 years of the screening period, median blood Pb levels reduced by roughly 22% from 2.7 to 2.1 µg/dL.

An extensive discussion of the relationships between environmental Pb levels and blood Pb concentrations in children at the Bunker Hill Superfund Site, a former Pb mining and smelting site, was provided in the 2006 Pb AQCD. In the most recent analysis (TerraGraphics Environmental Engineering, 2004) of the data on environmental Pb levels and child blood Pb concentrations (1988-2002), blood Pb concentrations (annual GM) ranged from 2.6 to 9.9 µg/dL. Environmental Pb levels (e.g., dust, soil, paint Pb levels) data were collected at ~3,000 residences, with interior dust Pb concentrations (annual GM) ranging from ~400 to 4,200 mg/kg and yard soil Pb concentration (annual GM) ranging from ~150 to 2,300 mg/kg. Several multivariate regression models relating environmental Pb levels and blood Pb concentration were explored; the model having the highest R^2 (0.26) is shown in Table 4-17. The model predicts significant associations between blood Pb concentration, age, interior dust, yard soil, neighborhood soil (geometric mean soil Pb concentration for areas within 200 ft of the residence), and community soil Pb concentration (community GM). Based on the standardized regression coefficients, the community soil Pb concentration had the largest effect on blood Pb concentration, followed by neighborhood soil Pb concentration, interior dust Pb concentration, and yard soil Pb concentration (Table 4-17). The model predicted a 1.8 µg/dL decrease in blood Pb concentration in association with a decrease in community soil Pb concentration from 2,000 to 1,000 mg/kg. The same decrease in neighborhood soil Pb concentration, interior dust Pb concentration, or yard soil Pb concentration was predicted to result in a 0.8, 0.5, or 0.2 µg/dL decrease in blood Pb concentration, respectively. Note that the soil Pb component of the model was similar to that derived by Lewin et al. (1999), in which a model of blood Pb as a function of soil Pb among 0-6 y old children living near one of four industrial sites was given as PbB = 0.2438ln(PbS} + 0.2758.

Table 4-17 General linear model relating blood Pb concentration in children and environmental Pb levels—Bunker Hill Superfund Site

Malcoe et al. (2002) analyzed 1997 data on blood Pb and environmental Pb concentrations in a representative sample of Native American and white children (n = 224, age 1-6 years) who resided in a former Pb mining region in Ottawa County, OK. The data set included measurements of blood Pb, yard soil Pb, residential interior dust Pb loading, first-draw water Pb, paint Pb assessment and other behavioral (i.e., hand-to-mouth activity, hygiene rating) and demographic variables (i.e., hand-to-mouth activity, hygiene rating, poverty level, caregiver education). A multivariate regression model accounted for 34% of the observed variability in blood Pb. Yard soil Pb and interior dust Pb loading accounted for 10% and 3% of the blood Pb variability, respectfully. The regression model predicted a slope of 0.74 µg/dL blood Pb per ln[µg/g soil Pb] and a slope of 0.45 µg/dL blood Pb per ln[µg/ft^2] dust Pb loading.

4.6 Biokinetic Models of Lead Exposure-Blood Lead Relationships

An alternative to regression models are mechanistic models, which attempt to specify all parameters needed to describe the mechanisms (or processes) of transfer of Pb from the environment to human tissues. Such mechanistic models are more complex than regression models; this added complexity introduces challenges in terms of their mathematical solution and empirical verification. However, by incorporating parameters that can be expected to vary spatially or temporally, or across individuals or populations, mechanistic models can be extrapolated to a wide range of exposure scenarios, including those that may be outside of the domain of paired predictor-outcome data used to develop the model. Exposure-intake models, a type of mechanistic models, are highly simplified

mathematical representations of relationships between levels of Pb in environmental media and human Pb intakes (e.g., µg Pb ingested per day). These models include parameters representing processes of Pb transfer between environmental media (e.g., air to surface dust) and to humans, including rates of human contact with the media and intakes of the media (e.g., g soil ingested per day). Intake-biokinetic models provide the analogous mathematical representation of relationships between Pb intakes and Pb levels in body tissues (e.g., blood Pb concentration). Biokinetic models include parameters that represent processes of Pb transfer (a) from portals of entry into the body and (b) from blood to tissues and excreta. Linked together, exposure-intake and intake-biokinetics models (i.e., integrated exposure-intake-biokinetics models) provide an approach for predicting blood Pb concentrations (or Pb concentrations in other tissues) that corresponds to a specified exposure (medium, concentration, and duration). Detailed information on exposure and internal dose can be obtained from controlled experiments, but almost never from epidemiological observations or from public health monitoring programs. Exposure intake-biokinetics models can provide these predictions in the absence of complete information on the exposure history and blood Pb concentrations for an individual (or population) of interest. Therefore, these models are critical to applying epidemiologic-based information on blood Pb-response relationships to the quantification and characterization of human health risk. They are also critical for assessing the potential impacts of public health programs directed at mitigation of Pb exposure or of remediation of contaminated sites.

However, they are not without their limitations. Human exposure-biokinetics models include large numbers of parameters, which are required to describe the many processes that contribute to Pb intake, absorption, distribution, and elimination. The large number of parameters complicates the assessment of confidence in parameter values, many of which cannot be directly measured. Statistical procedures can be used to evaluate the degree to which model outputs conform to “real-world” observations and values of influential parameters can be statistically estimated to achieve good agreement with observations. Still, large uncertainty can be expected to remain about many, or even most, parameters in complex exposure-biokinetic models. Such uncertainties need to be identified and their impacts on model predictions quantified (i.e., sensitivity analysis or probabilistic methods).

Modeling of human Pb exposures and biokinetics has advanced considerably during the past several decades, although there have been relatively few developments since the 2006 Pb AQCD was published. Still in use is the *Integrated Exposure Uptake Biokinetic (IEUBK) Model for Lead in Childre*n (U.S. EPA, 1994) and models that simulate Pb biokinetics in humans from birth through adulthood (O'Flaherty, 1995; Leggett, 1993;

O'Flaherty, 1993). The EPA AALM is still in development. A complete and extensive discussion of these models can be found in the 2006 Pb AQCD (U.S. EPA, 2006b).

4.7 Summary and Conclusions

4.7.1 Exposure

Exposure data considered in this assessment build upon the conclusions of the 2006 Pb AQCD (2006b), which found air Pb concentrations in the U.S. and associated biomarkers of exposure to Pb have decreased substantially following the ban on Pb in gasoline, house-hold paints, and solder. Pb exposure is difficult to assess because Pb has multiple sources in the environment and passes through various media. The atmosphere is the main environmental transport pathway for Pb, and, on a global scale, atmospheric Pb is primarily associated with fine particulate matter, which can deposit to soil and water. In addition to primary emission of particle-bearing or gaseous Pb to the atmosphere, Pb can be suspended to the air from soil or dust. Air-related pathways of Pb exposure are the focus of this assessment. In addition to inhalation of Pb from ambient air, air-related Pb exposure pathways include inhalation and ingestion of Pb from indoor dust and/or outdoor soil that originated from recent or historic ambient air (e.g., air Pb that has penetrated into the residence either via the air or tracking of soil). Non-air-related Pb exposures may include occupational exposures, hand-to-mouth contact with Pb-containing consumer goods, hand-to-mouth contact with dust or chips of peeling Pb-containing paint, or ingestion of Pb in drinking water conveyed through Pb pipes. Pb can cycle through multiple media prior to human exposure. Given the multitude of possible air-related exposure scenarios and the related difficulty of constructing Pb exposure histories, most studies of Pb exposure through air, water, and soil can be informative to this review. Other exposures, such as occupational exposures, contact with consumer goods in which Pb has been used, or ingestion of Pb in drinking water conveyed through Pb pipes may also contribute to Pb body burden.

A number of monitoring and modeling techniques have been employed for ambient Pb exposure assessment. Environmental Pb concentration data can be collected from ambient air Pb monitors, soil Pb samples, dust Pb samples, and dietary Pb samples to estimate human exposure. Exposure estimation error depends in part on the collection efficiency of these methods; collection efficiency for ambient air Pb FRM samplers is described in Section 3.4. Additionally, high spatial variability of the Pb concentrations in various media also can contribute to exposure error, as described in the 2009 PM ISA (U.S. EPA, 2009). Models, such as the Integrated Exposure Uptake Biokinetic (IEUBK)

model, simulate human exposure to Pb from multiple sources and through various routes including inhalation, ingestion, and dermal exposure. IEUBK model inputs include soil Pb concentration, air Pb concentration, dietary Pb intake including drinking water, Pb dust ingestion, human activity, and biokinetic factors. Measurements and/or assumptions can be utilized when formulating the model inputs; errors in measurements and assumptions thus have the potential to propagate through the exposure models.

Section 4.1 presents data illustrating potential exposure pathways. Soil can act as a reservoir for deposited Pb emissions, and exposure to soil contaminated with deposited Pb can occur through resuspended PM as well as shoe tracking and hand-to-mouth contact, which is the main pathway of childhood exposure to Pb. In general, soil Pb concentrations tended to be higher within inner-city communities compared with neighborhoods surrounding the city. Recent data by Yamamoto et al. (2006) have shown that the size distribution of particles collected on children's hands have a mode around 40 µm with the upper tail of the distribution extending to 200-300 µm. Infiltration of Pb dust into indoor environments has been demonstrated, and Pb dust has been shown to persist in indoor environments even after repeated cleanings. Measurements of particle-bound Pb exposures reported in this assessment have shown that personal exposure measurements for Pb concentration are typically higher than indoor or outdoor ambient Pb concentrations. These findings may be related to local resuspension with body movement.

4.7.2 Toxicokinetics

The majority of Pb in the body is found in bone (roughly 90% in adults, 70% in children); only about 1% of Pb is found in the blood. Pb in blood is primarily (~99%) bound to red blood cells (RBCs). It has been suggested that the small fraction of Pb in plasma (<1%) may be the more biologically labile and toxicologically active fraction of the circulating Pb. The relationship between Pb in blood and plasma is pseudo-linear at relatively low daily Pb intakes (i.e., <10 µg/day/kg) and at blood Pb concentrations <25 µg/dL, and becomes curvilinear at higher blood Pb concentrations due to saturable binding to RBC proteins. As blood Pb level increases and the higher affinity binding sites for Pb in RBCs become saturated, a larger fraction of the blood Pb is available in plasma to distribute to brain and other Pb-responsive tissues.

The burden of Pb in the body may be viewed as divided between a dominant slow (i.e., uptake and elimination) compartment (bone) and smaller fast compartment(s) (soft tissues). Pb uptake and elimination in soft tissues is much faster than in bone. Pb accumulates in bone regions undergoing the most active calcification at the time of

exposure. During infancy and childhood, bone calcification is most active in trabecular bone (e.g., patella); whereas, in adulthood, calcification occurs at sites of remodeling in cortical (e.g., tibia) and trabecular bone (Aufderheide and Wittmers, 1992). A high bone formation rate in early childhood results in the rapid uptake of circulating Pb into mineralizing bone; however, in early childhood bone Pb is also recycled to other tissue compartments or excreted in accordance with a high bone resorption rate (O'Flaherty, 1995). Thus, much of the Pb acquired early in life is not permanently fixed in the bone.

The exchange of Pb from plasma to the bone surface is a relatively rapid process. Pb in bone becomes distributed in trabecular and the more dense cortical bone. The proportion of cortical to trabecular bone in the human body varies by age, but on average is about 80% cortical to 20% trabecular. Of the bone types, trabecular bone is more reflective of recent exposures than is cortical bone due to the slow turnover rate and lower blood perfusion of cortical bone. Some Pb diffuses to deeper bone regions where it is relatively inert, particularly in adults. These bone compartments are much more labile in infants and children than in adults as reflected by half-times for movement of Pb from bone into to the plasma (e.g., cortical half-time = 0.23 years at birth, 3.7 years at 15 years of age, and 23 years in adults; trabecular half-time = 0.23 years at birth, 2.0 years at 15 years of age, and 3.8 years in adults) (Leggett, 1993).

Evidence for maternal-to-fetal transfer of Pb in humans is derived from cord blood to maternal blood Pb ratios. Group mean ratios range from about 0.7 to 1.0 at the time of delivery for mean maternal blood Pb levels ranging from 1.7 to 8.6 µg/dL. Transplacental transfer of Pb may be facilitated by an increase in the plasma/blood Pb concentration ratio during pregnancy. Maternal-to-fetal transfer of Pb appears to be related partly to the mobilization of Pb from the maternal skeleton.

The dominant elimination phase of Pb kinetics in the blood, exhibited shortly after a change in exposure occurs, has a half-life of ~20-30 days. An abrupt change in Pb uptake gives rise to a relatively rapid change in blood Pb, to a new quasi-steady state, achieved in ~75-100 days (i.e., 3-4 times the blood elimination half-life). A slower phase of Pb clearance from the blood may become evident with longer observation periods following a decrease in exposure due to the gradual redistribution of Pb among bone and other compartments.

4.7.3 Lead Biomarkers

Overall, trends in blood Pb levels have been decreasing among U.S. children and adults over the past 20 years (Section 4.4). The median blood Pb level for the entire U.S. population is 1.2 µg/dL and the 95th percentile blood Pb level was 3.7 µg/dL, based on

the 2007-2008 NHANES data (NCHS, 2010). Among children aged 1-5 years, the median and 95th percentiles were slightly higher at 1.4 μg/dL and 4.1 μg/dL, respectively.

Blood Pb is dependent on both the recent exposure history of the individual, as well as the long-term exposure history that determines body burden and Pb in bone. The contribution of bone Pb to blood Pb changes depending on the duration and intensity of the exposure, age, and various other physiological stressors that may affect bone remodeling (e.g., nutritional status, pregnancy, menopause, extended bed rest, hyperparathyroidism) beyond that which normally and continuously occurs. In children, largely due to faster exchange of Pb to and from bone, blood Pb is both an index of recent exposure and potentially an index of body burden. In adults and children, where exposure to Pb has effectively ceased or greatly decreased, a slow decline in blood Pb concentrations over the period of years is most likely due to the gradual release of Pb from bone. Bone Pb is an index of cumulative exposure and body burden. Even bone compartments should be recognized as reflective of differing exposure periods with Pb in trabecular bone exchanging more rapidly than Pb in cortical bone with the blood. This difference in the compartments makes Pb in cortical bone a better marker of cumulative exposure and Pb in trabecular bone more likely to be correlated with blood Pb, even in adults.

Sampling frequency is an important consideration when evaluating blood Pb and bone Pb levels in epidemiologic studies, particularly when the exposure is not well characterized. It is difficult to determine what blood Pb is reflecting in cross-sectional studies that sample blood Pb once, whether recent exposure or movement of Pb from bone into blood from historical exposures. In contrast, cross-sectional studies of bone Pb and longitudinal samples of blood Pb concentrations over time provide more of an index of cumulative exposure and are more reflective of average Pb body burdens over time. The degree to which repeated sampling will reflect the actual long-term time-weighted average blood Pb concentration depends on the sampling frequency in relation to variability in exposure. High variability in Pb exposures can produce episodic (or periodic) oscillations in blood Pb concentration that may not be captured with low sampling frequencies. Furthermore, similar blood Pb concentrations in two individuals (or populations), regardless of their age, do not necessarily translate to similar body burdens or similar exposure histories.

The concentration of Pb in urine follows blood Pb concentration, in that it mainly reflects the exposure history of the previous few months and therefore, is likely a relatively poor index of Pb body burden. There is added complexity with Pb in urine because concentration is also dependent upon urine flow rate, which requires timed urine samples

that is often not feasible in epidemiologic studies. Other biomarkers have been utilized to a lesser extent (e.g., Pb in teeth).

4.7.4 Air Lead-Blood Lead Relationships

The 1986 Pb AQCD described epidemiological studies of relationships between air Pb and blood Pb. Much of the pertinent earlier literature described in the 1986 Pb AQCD was drawn from a meta-analysis by Brunekreef (1984). Based on the studies available at that time that considered multiple air-related Pb exposure pathways in the aggregate, the 1986 Pb AQCD concluded that "the blood Pb versus air Pb slope β is much smaller at high blood and air levels." This is to say that the slope β was much smaller for occupational exposures where high blood Pb levels (>40 μg/dL) and high air Pb levels (much greater than 10 $\mu g/m^3$) prevailed relative to lower environmental exposures which showed lower blood Pb and air Pb concentrations (<30 μg/dL and <3 $\mu g/m^3$). For those environmental exposures, it was concluded that the relationship between blood Pb and air Pb "…for direct inhalation appears to be approximately linear in the range of normal ambient exposures (0.1-2.0 $\mu g/m^3$)" (pp 1-98 of the 1986 Pb AQCD). In addition to the meta-analysis of Brunekreef (1984), more recent studies have provided data from which estimates of the blood Pb-air Pb slope can be derived for children (Table 2-7). The range of estimates from these studies is 2-9 μg/dL per $\mu g/m^3$, which encompasses the estimate from the Brunekreef (1984) meta-analysis of (3-6 μg/dL per $\mu g/m^3$). Most studies have described the blood Pb-air Pb relationship as either log-log (Schnaas et al., 2004; Hayes et al., 1994; Brunekreef, 1984), which predicts an increase in the blood Pb-air Pb slope with decreasing air Pb concentration or linear (Hilts, 2003; Tripathi et al., 2001; Schwartz and Pitcher, 1989), which predicts a constant blood Pb-air Pb slope across all air Pb concentrations. These differences may simply reflect model selection by the investigators; alternative models are not reported in these studies. The blood Pb-air Pb slope may also be affected in some studies by the inclusion of parameters (e.g., soil Pb) that may account for some of the variance in blood Pb attributable to air Pb. Other factors that likely contribute to the derived blood Pb-air Pb slope include differences in the populations examined and Pb sources, which varied among individual studies.

CHAPTER 5 INTEGRATED HEALTH EFFECTS OF LEAD EXPOSURE

5.1 Introduction

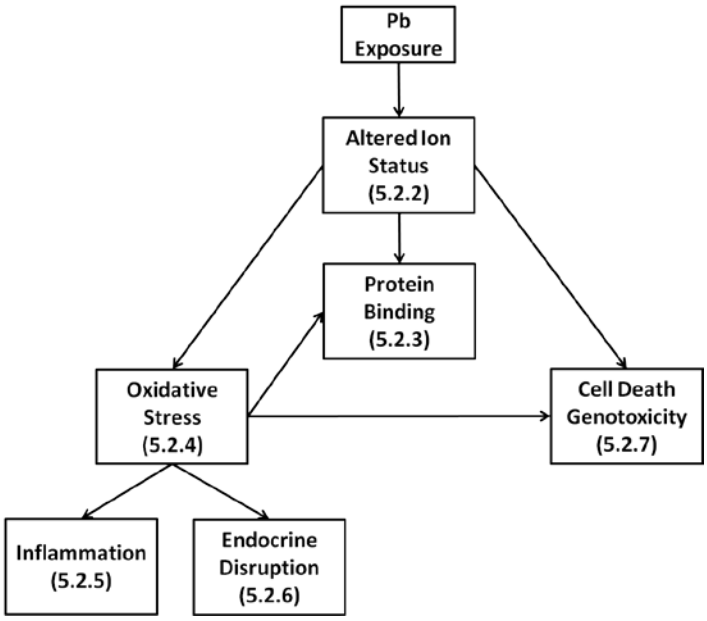
This chapter reviews, summarizes, and integrates the evidence for the broad spectrum of health effects associated with exposure to Pb. The chapter begins (Section 5.2) with a discussion of the evidence for the modes of action that mediate the health effects of Pb, including those modes of action that are shared by all of the health effects evaluated in this ISA and those modes of action that are specific for particular endpoints. Subsequent sections comprise evaluations of the epidemiologic and toxicological evidence for the health effects of Pb exposure on major outcome categories such as nervous system effects (Section 5.3), cardiovascular effects (Section 5.4), renal effects (Section 5.5), immune effects (Section 5.6), effects on heme synthesis and red blood cell function (Section 5.7), and reproductive and developmental effects (Section 5.8). Section 5.9 provides reviews of the evidence for the effects of Pb on other noncancer health outcomes, for which the cumulative bodies of evidence are smaller, including those related to the hepatic system (Section 5.9.1), gastrointestinal system (Section 5.9.2), endocrine system (Section 5.9.3), bone and teeth (Section 5.9.4), ocular health (Section 5.9.5), and respiratory system (Section 5.9.6). Chapter 5 concludes with a discussion of the evidence for Pb effects on cancer (Section 5.10).

Individual sections for major outcome categories (e.g., nervous system, cardiovascular, renal) begin with a brief summary of conclusions from the 2006 Pb AQCD followed by an evaluation of recent evidence that is intended to build upon evidence from previous reviews. Within each of these sections, results are organized by endpoint (e.g., cognitive function, behavior, neurodegenerative diseases) then by specific scientific discipline (i.e., epidemiology, toxicology). Sections for each of the major outcome categories (e.g., nervous system, cardiovascular, renal effects) conclude with an integrated summary of the evaluation of evidence and a conclusion regarding causality. Based upon the framework (described in the Preamble), a determination of causality was made for a broad outcome category (i.e., nervous system effects) by evaluating the coherence of evidence across disciplines and across a spectrum of related endpoints. Each discussion leading up to the causal determination characterizes the evidence on which the causal judgment was based, including the strength of evidence for the individual endpoints within the major outcome category.

5.2 Modes of Action

5.2.1 Introduction

The diverse health effects of Pb are dependent on multiple factors, including the concentration and duration of exposure, the particular Pb compounds constituting the exposure, and which tissues are affected. A mode of action (MOA) is the common set of biochemical, physiological, or behavioral responses (i.e., empirically observable precursor steps) that can cumulatively result in the formation of negative health outcomes. Although the effects of Pb appear to be mediated through multiple modes of action, alteration of cellular ion status (including disruption of calcium homeostasis, altered ion transport mechanisms, and perturbed protein function through displacement of metal cofactors) seems to be the major unifying mode of action underlying all subsequent modes of action (Figure 5-1). This section draws information from all of the subsequent health effects sections in Chapter 5, and identifies the major modes of action operating at the molecular, cellular, and tissue/organ level. In turn, the individual health effect sections bridge these effects to those observed on the organismal level. Each of the individual health effect sections includes a more detailed description of the mechanisms specific to the individual health effect. Accordingly, this section differs in structure and content from other health effects sections as it does not primarily focus on the literature published since the 2006 Pb AQCD, but rather incorporates recent information with older studies (which represent the current state of the science) on the possible modes of action of Pb.



Note: The subsections where these MOAs are discussed are indicated in parentheses.

Figure 5-1 Schematic representation of the relationships between the various MOAs by which Pb exerts its health effects.

5.2.2 Altered Ion Status

Physiologically-relevant metal ions (e.g., Ca, Mg, Zn, Fe) are known to have a multitude of functions in biological systems, including roles as charge carriers, intermediates in enzymatically-catalyzed reactions, and as structural elements in the proper maintenance of tertiary protein conformations (Garza et al., 2006). It is through disruption of these biological functions that Pb effects its negative actions, ultimately interfering with such tightly regulated processes as cell signaling, intracellular ion homeostasis, ion transport, energy metabolism, and enzymatic function.

5.2.2.1 Disruption of Ca^{2+} Homeostasis

Calcium (Ca^{2+}) is one of the most important carriers of cell signals and regulates virtually all aspects of cell function, including energy metabolism, signal transduction, hormonal regulation, cellular motility, and apoptosis (Carafoli, 2005). Ca^{2+} homeostasis is maintained through a tightly regulated balance of cellular transport and intracellular storage (Pentyala et al., 2010). Disruption of Ca^{2+} homeostasis by Pb has been observed in a number of different cell types and cell-free environments, indicating that this is a major mode of action for Pb-induced toxicity on a cellular level.

Ca^{2+} homeostasis is particularly important in bone cells, as the skeletal system serves as the major dynamic reservoir of Ca^{2+} in the body (Wiemann et al., 1999; Long et al., 1992). Bone cells also are unique in that they can exist in a microenvironment that is high in both Ca^{2+} and Pb concentrations, potentially increasing their relative susceptibility to Pb-induced toxicity (Long et al., 1992). A series of studies from the laboratory of Long, Dowd, and Rosen have indicated that exposure of cultured osteoblastic bone cells to Pb disrupts intracellular Ca^{2+} levels ($[Ca^{2+}]_i$). Exposure of osteoblasts to 1, 5, or 25 µM Pb for 40-300 minutes resulted in prolonged increases in $[Ca^{2+}]_i$ of 36, 50 and 120% over baseline, respectively (Schanne et al., 1997; Schanne et al., 1989). Long et al. (1992) observed that exposure of osteoblasts to either 400 ng parathyroid hormone (PTH)/mL culture for 1 hour or 25 µM Pb for 20 hours increased $[Ca^{2+}]_i$. Pretreatment of Pb-exposed cells with PTH increased $[Ca^{2+}]_i$ above concentrations observed in either single exposure, indicating that Pb may disrupt the ability of bone cells to respond to normal hormonal control. A similar additive increase in $[Ca^{2+}]_i$ was also observed when bone cells were co-treated with epidermal growth factor (EGF) plus Pb, versus Pb alone (Long and Rosen, 1992). Pb-induced increases in $[Ca^{2+}]_i$ were blocked by a protein kinase C (PKC) inhibitor, indicating that PKC activation may serve as the mechanism by which Pb perturbs $[Ca^{2+}]_i$ (Schanne et al., 1997). Schirrmacher et al. (1998) also observed alterations in Ca^{2+} homeostasis in osteoblasts exposed to 5 µM Pb for 50 minutes due to potential disruption of Ca^{2+}-ATPases. However, Wiemann et al. (1999) demonstrated that exposure to 5 or 12.5 µM Pb inhibited the Ca^{2+}-release-activated calcium influx of Ca^{2+} independently of any inhibitory effect on Ca^{2+}-ATPases.

Ca^{2+} homeostasis has also been shown to be disturbed in erythrocytes exposed to Pb (Quintanar-Escorza et al., 2010; Quintanar-Escorza et al., 2007; Shin et al., 2007). In blood samples taken from Pb-exposed workers (mean [SD] blood Pb level: 74.4 [21.9] µg/dL), the $[Ca^{2+}]_i$ was approximately 2.5-fold higher than that seen in nonexposed workers (mean [SD] blood Pb level: 9.9 [2] µg/dL) (Quintanar-Escorza et al., 2007). The increase in $[Ca^{2+}]_i$ was associated with higher osmotic fragility and modifications in erythrocyte shape. In a separate investigation, erythrocytes from 10 healthy volunteers were exposed to Pb at concentrations of 0.2 to 6.0 µM for 24 or 120 hours, concentration-related increases in $[Ca^{2+}]_i$ were observed across all concentrations for both durations of exposure (Quintanar-Escorza et al., 2010). Subsequent exposures of erythrocytes to either 0.4 or 4.0 µM Pb [corresponding to 10 or 80 µg/dL in exposed workers (Quintanar-Escorza et al., 2007)] for 12-120 hours resulted in duration-related increases with durations >12 hours. Osmotic fragility (measured as percent hemolysis) was increased in erythrocytes exposed to 0.4 µM Pb for 24 hours. Co-incubation with a vitamin E analog mitigated these effects, indicating that the increase in $[Ca^{2+}]_i$ is dependent on the oxidative state of the erythrocytes. Shin et al. (2007) observed that incubation of human erythrocytes with 5 µM Pb for 1 hour resulted in a 30-fold increase in $[Ca^{2+}]_i$ in vitro,

inducing the pro-coagulant activity of exposed erythrocytes. Induction of pro-coagulant activity in erythrocytes could lead to thrombus formation and negatively contribute to overall cardiovascular health, whereas increased osmotic fragility could substantially reduce erythrocyte life span and ultimately lead to anemic conditions.

Similar to effects seen in erythrocytes, Pb has been observed to interfere with Ca^{2+} homeostasis in platelets and white blood cells. Dowd and Gupta (1991) observed that 1 µM Pb (for 3.5 hours) was the lowest exposure concentration to result in increases in $[Ca^{2+}]_i$ in human platelets. The observed increase in Ca^{2+} levels was attributed to the increased influx of external Ca^{2+}, possibly through receptor-operated Ca^{2+} channels. In mouse splenic lymphocytes, 1 µM Pb was the lowest exposure concentration found to increase $[Ca^{2+}]_{i,}$ with incubation periods of 10 minutes or greater (Li et al., 2008c). These increases in Ca^{2+} appeared to be reversible as $[Ca^{2+}]_i$ returned to baseline after one hour. Pretreatment with a calmodulin antagonist slightly mitigated the effects of Pb exposure, indicating a role for calmodulin in disruption of Ca^{2+} homeostasis in lymphocytes. In rat tail arteries exposed to 1.2 µM Pb-acetate for 1 hour, intracellular stores of Ca^{2+} increased over controls, possibly through increased transmembrane influx of Ca^{2+} (Piccinini et al., 1977).

Exposure of the microsomal fraction of rat brain cells to as little as 0.25 µM Pb for 2 minutes resulted in increased release of Ca^{2+} into the media (Pentyala et al., 2010). Further, Pb exposure also decreased the activity of the microsomal Ca^{2+}-ATPase, thus decreasing the sequestration of Ca^{2+} into microsomes. The results of this study suggest that disruption of microsomal release and re-uptake of Ca^{2+} may alter Ca^{2+} homeostasis, ultimately leading to altered signal transduction and neuronal dysfunction. However, Ferguson et al. (2000) observed that $[Ca^{2+}]_i$ was decreased in rat hippocampal neurons in response to exposure to 0.1 µM Pb for 1-48 hours, although the observed decreases were not time-dependent. The decrease in $[Ca^{2+}]_i$ was shown to be due to increased efflux of Ca^{2+} out of the neuron via a calmodulin-regulated mechanism, possibly through stimulated Ca^{2+} efflux via Ca^{2+}-ATPase.

5.2.2.2 Disruption of Ion Transport Mechanisms

As described above, deregulation of Ca^{2+} homeostasis results in negative effects in multiple organ systems. Under normal conditions in the life cycle of most cells, cytosolic concentrations of free Ca^{2+} fluctuate around 100-200 nM and Ca^{2+} that has entered the cell must be removed in order to maintain normal homeostatic concentrations (Carafoli, 2005) . An important component of the maintenance of Ca^{2+} homeostasis is transmembrane transport of Ca ions via Ca^{2+}-ATPase and voltage-sensitive gates

(Carafoli, 2005). Pb has been shown to disrupt the normal movement of Ca^{2+} ions, as well as other physiologically important ions through interactions with these transport mechanisms.

Multiple studies have reported the effects of Pb exposure on Na^{+}-K^{+}-ATPase, Ca^{2+}-ATPase, and Mg^{2+}-ATPases in animal models. Decreases in the activity of all three ATPases were observed in the kidneys and livers of rats exposed to 750 ppm Pb in drinking water for 11 weeks (mean [SD] blood Pb level: 55.6 [6.3] µg/dL) (Kharoubi et al., 2008a) and in erythrocytes of rats exposed to 0.2% Pb in drinking water for 5 weeks (mean [SD] blood Pb level: 97.56 [11.8] µg/dL) (Sivaprasad et al., 2003). Increases in lipid peroxidation were seen in both studies, and the decrements in ATPase activities may be explained by generation of free radicals in Pb-exposed animals. A decrease in the activity of Na^{+}-K^{+}-ATPase was observed in rabbit kidney membranes exposed to 0.01 to 10 µM Pb, possibly due to Pb inhibiting the hydrolytic cleavage of phosphorylated intermediates in the K-related branch of the pump (Gramigni et al., 2009). Similar decreases in Na^{+}-K^{+}-ATPase activity were observed in synaptosomes isolated from rats exposed to 200 ppm Pb in drinking water for 3 months (blood Pb level: 37.8 µg/dL) (Rafalowska et al., 1996) or 15 mg/kg Pb injected (i.p.) for 7 days (blood Pb level: 112.5 µg/dL) (Struzynska et al., 1997a). Inhibition of Na^{+}-K^{+}-ATPase activity was also observed in primary cerebellar granule neuronal cultures obtained from rats pre- and postnatally exposed to Pb (0.1 % Pb-acetate in dams drinking water, resulting in blood Pb level of 4 µg/dL) (Baranowska-Bosiacka et al., 2011a). The activity of Ca^{2+}-ATPase in the sarcoplasmic reticulum of rabbits exposed to 0.01 µM Pb was similarly decreased (Hechtenberg and Beyersmann, 1991). The inhibitory effect of Pb was diminished in the presence of high MgATP concentrations. The activity of generic ATPase was reported to be altered in the testes of rats exposed to 300 ppm Pb-acetate gestationally, and in drinking water after weaning to the age of 6, 8, 10, or 12 weeks (Liu et al., 2008). In pregnant rats fed a Pb-depleted (20 ± 5 µg/kg) or control (1 mg/kg) diet during gestation and lactation, no difference was observed in the activity of Na^{+}-K^{+}-ATPase and Ca^{2+}-Mg^{2+}-ATPase in the parental generation (Eder et al., 1990). However, the offspring (exposed via placental and lactational transfer of Pb) of Pb-depleted rats displayed decreased activities in both enzymes compared with offspring of rats with higher Pb exposures. A similar increase in the Na^{+}-K^{+}-ATPase activity was observed in rats exposed (i.p.) to 20 mg/kg Pb for 14 consecutive days (Jehan and Motlag, 1995). Co-exposure of Pb with zinc and copper greatly attenuated the increase in ATPase activity. Although the precise mechanism was not investigated, Navarro-Moreno et al. (2009) reported that Ca^{2+} uptake was diminished in proximal renal tubule cells in rats chronically exposed to 500 ppm Pb in drinking water for 7 months (mean [SD] blood Pb level: 43.0 [7.6] µg/dL).

In vitro studies of ATPase activities in human erythrocyte ghosts have also shown that Pb affects the transport of metal ions across membranes. Calderon-Salinas et al. (1999b) observed that 1-5x10^4 µM Pb and Ca^{2+} were capable of inhibiting the passive transport of each other in human erythrocyte ghosts incubated with both cations. Subsequent inhibition experiments indicated that both cations share the same electrogenic transport pathway (Sakuma et al., 1984). Further study by this group (Calderon-Salinas et al., 1999a) demonstrated that Pb can noncompetitively block the transport of Ca^{2+} by inhibiting the activity of Ca^{2+}-Mg^{2+}-ATPase at concentrations of 1-5x10^3 µM. Mas-Oliva (1989) demonstrated that the activity of Ca^{2+}-Mg^{2+}-ATPase in human erythrocyte ghosts was inhibited by incubation with 0.1-100 µM Pb. The inhibitory action was most likely due to direct reaction with sulfhydryl groups on the ATPase at Pb concentrations greater than 1 µM, but due to the action of Pb on calmodulin at lower concentrations. Grabowska and Guminska (1996) observed that 10 µg/dL Pb was the lowest concentration to decrease the activity of Na^+-K^+-ATPase in erythrocyte ghosts; activity of Ca^{2+}- Mg^{2+}-ATPase was less sensitive to Pb exposure, and Mg^{2+}-ATPase activity was not affected.

In a study investigating ATPase activities in occupationally-exposed workers in Nigeria, Abam et al. (2008) observed that the activity of erythrocyte membrane-bound Ca^{2+}-Mg^{2+}-ATPase was decreased by roughly 50% in all occupational groups (range of mean [SD] blood Pb level across nine occupational groups: 28.75 [11.31] - 42.07 [12.01] µg/dL) compared to nonexposed controls (mean [SD] blood Pb level: 12.34 [2.44] in males and 16.85 [6.01] µg/dL in females). Higher membrane concentrations of Ca^{2+} and magnesium were also observed, indicating that Pb prevented the efflux of those cations from the cell, most likely by substituting for those metals in the active site of the ATPase. In a study of 247 mother-newborn pairs, Campagna et al. (2000) observed that newborn (cord) blood Pb (geometric mean [5th, 95th percentile]: 4.8 [2.8-9.2] µg/dL) was negatively and significantly associated with maternal blood Ca^{2+} pump activities; however, newborn (cord) blood Pb was not significantly associated with cord blood Ca^{2+} pump activities. Newborn hair Pb (geometric mean [5th, 95th percentile]: 1.1 [0.1-8.0] µg/g) was negatively and significantly associated with both maternal and cord blood Ca^{2+} pump activities. In a population of 81 newborns, Huel et al. (2008) found that newborn hair and cord blood Pb levels (mean [SD] newborn hair Pb and blood Pb levels: 1.22 [1.41] µg/g and 3.54 [1.72] µg/dL) were negatively associated with Ca^{2+}-ATPase activity in plasma membranes of erythrocytes isolated from cord blood; newborn hair Pb levels were more strongly associated with cord Ca^{2+} pump activity than were cord blood Pb levels.

Pb has also been shown to disrupt cation transport mechanisms through direct action on voltage-sensitive cation channels. Audesirk and Audesirk (1993, 1991) demonstrated that extracellular free Pb inhibits the action of multiple voltage-sensitive Ca^{2+} channels, with free Pb IC_{50} (half maximal inhibitory concentration) values of 0.7 µM for L-type

channels and 1.3 µM for T-type channels in neuroblastoma cells, and IC_{50} values as low as 0.03 µM for L-type channels in cultured hippocampal neurons. Sun and Suszkiw (1995) corroborated the inhibitory action of extracellular Pb on Ca^{2+} channels, demonstrating an IC_{50} value of 0.3 µM in adrenal chromaffin cells. The observed disruption of the Ca^{2+} channels most likely reflects competition between Pb and Ca^{2+} for the extracellular Ca^{2+} binding domain of the channel. Research by other laboratories supported these findings: Pb inhibited the action of multiple Ca^{2+} channels in human embryonic kidney cells transfected with L-, N-, and R-type channels (IC_{50} values of 0.38 µM, 1.31 µM, and 0.10 µM, respectively) (Peng et al., 2002) and P-type channels in cultured hippocampal neurons at concentrations up to 3 µM (Ujihara et al., 1995). However, intracellular Pb was observed to enhance Ca^{2+} currents through attenuation of the Ca^{2+} dependent deactivation of Ca^{2+} channels at an EC_{50} value of 200 µM, possibly through blocking the intracellular Ca^{2+} binding domain, or through Ca^{2+} dependent dephosphorylation of the channel (Sun and Suszkiw, 1995). Recently, Pb has also been shown to enter cells (HEK293, HeLa, and PC12 cell lines) through store-operated Ca^{2+} channels (Chiu et al., 2009; Chang et al., 2008b). In particular, the Orai1-STIM1 complex was shown to be critical in the entry of Pb ions into cells, and increased Pb permeation was directly related to decreased $[Ca^{2+}]_i$ concentrations at exposure concentrations as low as 0.1 µM.

Pb also disrupts the action of Ca^{2+}-dependent potassium channels. Alvarez et al. (1986) observed that Pb promoted the efflux of potassium from inside-out erythrocyte vesicles in a concentration-dependent manner at concentrations of 1-300 µM, either through action on a Mg modulatory site or through direct interaction with the Ca^{2+} binding site. Fehlau et al. (1989) also demonstrated Pb-induced activation of the potassium channel in erythrocytes. However, Pb only activated the potassium channels at concentrations below 10 µM; higher concentrations of Pb completely inhibited channel activity, indicating the modulation of potassium permeability is due to alterations in channel gating. Silken et al. (2001) observed that Pb activated potassium channels in erythrocytes from the marine teleost *Scorpaena porcus* in a concentration-dependent manner after a 20-minute incubation; minor loss of potassium was seen at Pb concentrations of 1-2 µM, whereas exposure to 20-50 µM Pb resulted in approximately 70% potassium loss. Competitive and inhibitory binding assays suggest that Pb directly activates potassium channels in *S. porcus*.

Disruption of Neurotransmitter Release

Pb has been shown to inhibit the evoked release of neurotransmitters by inhibiting Ca^{2+} transport through voltage-sensitive channels in in vitro experiments (Cooper and Manalis, 1984; Suszkiw et al., 1984). However, in these same experiments, concentrations of Pb as

5 µM and higher were also observed to actually increase the spontaneous release of neurotransmitters. Subsequent research by other groups affirmed that Pb demonstrates Ca^{2+}-mimetic properties in enhancing neurotransmitter release from cells in the absence of Ca^{2+} and Ca^{2+}-induced depolarization. Tomsig and Suszkiw (1995, 1993) reported that Pb exposure induced the release of norepinephrine (NE) from bovine adrenal chromaffin cells, and was considerably more potent at doing so than was Ca^{2+} ($K_{0.5}$ of $4.6x10^3$ µM for Pb versus 2.4 µM for Ca^{2+}). Activation of PKC was observed to enhance the Pb-induced release of NE. Westerrink and Vijverberg (2002) observed that Pb acted as a high affinity substitute for Ca^{2+}, and triggered enhanced catecholamine release from PC12 cells at 10 µM in intact cells and $3x10^4$ µM in permeabilized cells. The suppression of Ca^{2+}-induced evoked release of neurotransmitters combined with the ability of Pb to enhance spontaneous releases could result in higher noise in the synaptic transmission of nerve impulses in Pb-exposed animals. In rats exposed to Pb at concentrations of 0.1-1.0% in drinking water beginning at gestational day (GD)15-16 and continuing to 120 days postnatal, decreases in total potassium-stimulated hippocampal GABA release were seen at exposure levels of 0.1-0.5% (range of mean [SD] blood Pb levels: 26.8 [1.3] - 61.8 [2.9] µg/dL) (Lasley and Gilbert, 2002). Maximal effects were observed at 0.2% Pb in drinking water, but effects were less evident at 0.5%, and were absent at 1.0%. In the absence of Ca^{2+}, potassium-induced GABA release was increased with the two highest exposure concentrations, suggesting a Pb-induced enhancement of evoked release of GABA. The authors suggest that this pattern of response indicates that Pb is a potent suppressor of evoked release at low concentrations, but a Ca^{2+} mimic in regard to independently evoking exocytosis and release at higher concentrations (Lasley and Gilbert, 2002). Suszkiw (2004) reports that augmentation of spontaneous release of neurotransmitters may involve Pb-induced activation of CaMKII-dependent phosphorylation of synapsin I or direct activation of synaptotagmin I. Further, Suszkiw (2004) suggests that unlike the intracellularly mediated effects of Pb on spontaneous release of neurotransmitters, Pb-induced inhibition of evoked transmitter releases is largely due to extracellular blockage of the voltage-sensitive Ca^{2+} channels.

5.2.2.3 Displacement of Metal Ions and Perturbed Protein Function

The binding of metal ions to proteins causes specific changes in protein shape, and the specific cellular function of many proteins may be altered by conformational changes (Kirberger and Yang, 2008). Metal binding sites on proteins are generally ion-specific and are influenced by multiple factors, including binding geometries, ligand preferences, ionic radius, and metal coordination numbers (Kirberger and Yang, 2008; Garza et al., 2006). The coordination chemistry that normally regulates metal-protein binding makes

many proteins particularly susceptible to perturbation from Pb, as it is able to function with flexible coordination numbers and can bind multiple ligands (Kirberger and Yang, 2008; Garza et al., 2006). However, due to differences in its physical properties, Pb induces abnormal conformational changes when it binds to proteins (Kirberger and Yang, 2008; Bitto et al., 2006; Garza et al., 2006; Magyar et al., 2005), and these structural changes elicit altered protein function. It is known that $[Ca^{2+}]_i$ is an important second messenger in cell signaling pathways, and operates by binding directly to and activating proteins such as calmodulin and PKC (Goldstein, 1993). Alterations in the functions of both of these proteins due to direct interaction with Pb have been well documented in the literature.

PKC is a family of serine/threonine protein kinases critical for cell signaling and important for cellular processes, including growth and differentiation (Goldstein, 1993). PKC contains a C2 Ca^{2+}-binding domain and requires the cation, as well as diacylglycerol and phospholipids, for proper cellular activity (Garza et al., 2006). Markovac and Goldstein (1988b) observed that, in the absence of Ca^{2+}, exposure to picomolar concentrations of Pb for 5 minutes directly activated PKC purified from rat brains. The activation of PKC by Pb was more potent than was Ca^{2+}-dependent activation by five orders of magnitude. Long et al. (1994) affirmed these findings, reporting that Pb had a K_{act} 4,800 times smaller than that of Ca^{2+} ($5.5x10^{-5}$ µM versus 25 µM, following a 3 minute exposure). However, Ca^{2+} had a higher maximal activation of PKC than did Pb. This possibly indicates the presence of multiple Ca^{2+}-binding sites on the protein, and that Pb may bind the first site more efficiently than does Ca^{2+}, but not subsequent sites. Tomsig and Suszkiw (1995) further demonstrated the ability of Pb to activate PKC at picomolar concentrations in adrenal chromaffin cells incubated with Pb for 10 minutes but also reported that activation of PKC by Pb was only partial (approximately 40% of the maximum activity induced by Ca^{2+}) and tended to decrease at concentrations greater than one nanomolar.

Contrary to the above findings, Markovac and Goldstein (1988a) observed that Pb and Ca^{2+} activated PKC at equivalent concentrations and efficacies when broken cell preparations of rat brain microvessels were incubated with either cation for 45 minutes. However, when PKC activation was investigated in whole vessel preparations, no activation was observed, but PKC did become redistributed from the cytosolic to the particulate fraction. This suggests that Pb redistributes PKC at micromolar concentrations, but does not activate the protein in brain microvessels. In human erythrocytes exposed to Pb-acetate for 60 minutes, the amount of PKC found in erythrocyte membranes and total PKC activity was increased at concentrations greater than 0.1 µM (Belloni-Olivi et al., 1996). The observation that neither Ca^{2+} nor diacylglycerol was increased due to exposure indicates that Pb-induced activation of PKC

is due to direct interaction with the protein. Pb-induced alterations in PKC have also been observed in other tissues, including increased activity in rabbit mesenteric arteries at picomolar concentrations of Pb (Watts et al., 1995; Chai and Webb, 1988) and human erythrocytes from Pb-exposed workers (range of blood Pb levels: 5.4 to 69.3 µg/dL) (Hwang et al., 2002), and decreased activity in mouse macrophages and the rat brain cortex at micromolar concentrations (Murakami et al., 1993; Lison et al., 1990).

Calmodulin is another important protein essential for proper Ca^{2+}-dependent cell signaling. Calmodulin contains an "EF-hand" Ca^{2+} binding domain, and is dependent on the cation for proper activity (Garza et al., 2006). Calmodulin regulates events as diverse as cellular structural integrity, gene expression, and maintenance of membrane potential (Vetter and Leclerc, 2003; Saimi and Kung, 2002). Habermann et al. (1983) observed that exposure to Pb altered numerous cellular functions of calmodulin, including activation of calmodulin-dependent phosphodiesterase activity after 10 minutes incubation (minimal activation at 0.1 µM, EC_{50} = 0.5-1.0 µM), stimulation of brain membrane phosphorylation at Pb concentrations greater than 0.4 µM after 1 minute incubation, and increased binding of calmodulin to brain membranes at Pb concentrations greater than 1 µM after 10 minutes incubation. Habermann et al. (1983) reported that the affinity of Pb for Ca^{2+}-binding sites on calmodulin was approximate to that of Ca^{2+} itself (K_d ~ 20 µM), whereas Richardt et al. (1986) observed that Pb was slightly more potent than was Ca^{2+} at binding calmodulin (IC_{50} = 11 and 26 µM, respectively). Both studies indicated that Pb was much more effective at binding calmodulin than was any other metal cation investigated (e.g., mercury, cadmium, iron). Kern et al. (2000) observed that Pb was more potent in binding to, and affecting conformational changes in, calmodulin compared to Ca^{2+} (EC_{50} values of 4-5.5x10^{-4} µM (threshold = 1x10^{-4} µM) and 0.45-0.5 µM (threshold = 0.1 µM), respectively). Pb, in the absence of Ca^{2+}, was also observed to activate calmodulin-dependent cyclic nucleotide phosphodiesterase activity at much lower concentrations compared to Ca^{2+} (EC_{50} value 4.3x10^{-4} µM [threshold = 3x10^{-4} µM versus EC_{50} 1.2x10^{-3} µM (threshold = 0.2 µM; 50 minute incubation]). When incubated with physiological concentrations of Ca^{2+}, Pb induced phosphodiesterase activity at concentrations as low as 5x10^{-5} µM. Pb activated calcineurin, a phosphatase with widespread distribution in the brain and immune system, at threshold concentrations as low as 2x10^{-5} µM in the presence of Ca^{2+} (incubation time = 30 minutes), but inhibited its activity at concentrations greater than 2x10^{-4} µM (Kern and Audesirk, 2000). Thus, picomolar concentrations of intracellular Pb appear to amplify the activity of calmodulin and thus can be expected to alter intracellular Ca^{2+} signaling in exposed cells (Kern et al., 2000). Mas-Oliva (1989) observed that low-exposure (<1 µM, 20 minute incubation) stimulatory effects of Pb exposure on the activity of Ca^{2+}-Mg^{2+}-ATPase was due to Pb binding to calmodulin and subsequent activation of the ion pore. Ferguson et al. (2000)

observed that exposure of rat hippocampal neurons to Pb for 1 to 48 hours resulted in increased activation of a calmodulin-dependent Ca^{2+} extrusion mechanism.

Pb has also been observed to alter the activity of other proteins that rely on Ca^{2+} binding for normal cellular function. Osteocalcin is a matrix protein important in bone resorption, osteoclast differentiation, and bone growth and has three Ca^{2+}-binding sites (Dowd et al., 2001). Incubation of osteocalcin in solution with Ca^{2+} and Pb resulted in the competitive displacement of Ca^{2+} by Pb (Dowd et al., 1994). Pb was found to bind to osteocalcin more than 1000-times more tightly than was Ca^{2+} ($K_d = 1.6x10^{-2}$ µM versus 7 µM, respectively), and analysis with nuclear magnetic resonance (NMR) indicated that Pb induced similar, though slightly different, secondary structures in osteocalcin, compared to Ca^{2+}. The authors hypothesized that the observed difference in Pb-bound osteocalcin structure may explain previous findings in the literature that Pb exposure reduced osteocalcin adsorption to hydroxyapatite (Dowd et al., 1994). Further research by this group also found that Pb bound osteocalcin approximately 10,000-times more tightly than did Ca^{2+} ($K_d = 0.085$ µM versus 1.25×10^3 µM, respectively) (Dowd et al., 2001). However, the authors reported that Pb exposure actually caused increased hydroxyapatite adsorption at concentrations 2-3 orders of magnitude lower than that seen with Ca^{2+}. Additionally, Pb can displace Ca^{2+} in numerous other Ca^{2+}-binding proteins important in muscle contractions, renal Ca^{2+} transport and neurotransmission, including troponin C, parvalbumin, CaBP I and II, phospholipase A_2, and synaptotagmin I, at concentrations as low as the nanomolar range (Bouton et al., 2001; Osterode and Ulberth, 2000; Richardt et al., 1986).

Pb can displace metal cations other than Ca^{2+} that are requisite for protein function. One of the most researched targets for molecular toxicity of Pb is the second enzyme in the heme synthetic pathway, aminolevulinic acid dehydratase (ALAD). ALAD contains four zinc-binding sites and all four need to be occupied to confer full enzymatic activity (Simons, 1995). ALAD has been identified as the major protein binding target for Pb in human erythrocytes (Bergdahl et al., 1997a), and exposure to Pb results in inhibition of the enzyme in the erythrocytes of Pb-exposed workers and adolescents (blood Pb levels >10 µg/dL) (Ahamed et al., 2006; Ademuyiwa et al., 2005b), in human erythrocytes exposed to Pb for 60 minutes ($K_i = 7x10^4$ µM) (Simons, 1995), and in rats exposed to 25 mg/kg Pb once a week for 4 weeks (mean [SD] blood Pb level: 6.56 [0.98] µg/dL) (Lee et al., 2005). Additional experiments indicated that lower concentrations of zinc result in greater inhibition of enzyme activity by Pb, suggesting a competitive inhibition between zinc and Pb at a single site (Simons, 1995).

Zinc-binding domains are also found in transcription factors and proteins necessary for gene expression, including GATA proteins and transcription factors TFIIIA, Sp1, and

Erg-1 (Ghering et al., 2005; Huang et al., 2004; Reddy and Zawia, 2000; Hanas et al., 1999; Zawia et al., 1998). Pb was found to form tight complexes with the cysteine residues in GATA proteins (Pb stability constant (β^{Pb}) = 6.4×10^{9} M^{-1} for single zinc fingers and $\beta_2^{Pb2} = 6.4 \times 10^{19}$ M^{-2}), and was able to displace bound zinc from the protein under physiologically relevant conditions (Ghering et al., 2005). Once Pb was bound to GATA proteins, they displayed decreased ability to bind to DNA (Pb concentrations ≥ 1.25 µM) and activate transcription (Pb concentration = $1x10^{6}$ µM). Pb at a minimum concentration of 10 µM also binds to the zinc domain of TFIIIA, inhibiting its ability to bind DNA at concentrations (Huang et al., 2004; Hanas et al., 1999). Huang et al. (2004) also reported that exposure to Pb caused the dissociation of TFIIIA-DNA adducts and using NMR spectroscopy, found that altered TFIIIA activity was the result of a Pb-induced abnormal protein conformation.

Pb exposure modulated the DNA-binding profiles of the transcription factors Sp1 and Erg-1 in rat pups exposed to 0.2% Pb-acetate via lactation, resulting in a shift in DNA-binding toward early development (i.e., the first week following birth) (Reddy and Zawia, 2000; Zawia et al., 1998). The shifts in Sp1 DNA-binding profiles were shown to be associated with abnormal expression of genes related to myelin formation (Section 5.2.7.5). Further mechanistic research utilizing a synthetic peptide containing a zinc finger motif demonstrated that Pb can bind the histidine and cysteine residues of the zinc finger motif, thus displacing zinc and resulting in an increase in the DNA-binding efficiency of the synthetic peptide (Razmiafshari et al., 2001; Razmiafshari and Zawia, 2000). However, in DNA-binding assays utilizing recombinant Sp1 (which has three zinc finger motifs, opposed to only one in the synthetic peptide), 37 µM Pb was the lowest concentration observed to abolish the DNA-binding capabilities of Sp1 (Razmiafshari and Zawia, 2000).

Pb has also been reported to competitively inhibit Mg binding and thus inhibit the activities of adenine and hypoxanthine/guanine phosphoribosyltransferase in erythrocyte lysates of rats exposed to 0.1% Pb in drinking water for 9 months (mean [SD] blood Pb level: 7.01 [1.64] µg/dL) and in human erythrocyte lysates exposed to 0.1 µM Pb for as little as 5 minutes (Baranowska-Bosiacka et al., 2009), and cGMP phosphodiesterase at picomolar concentrations in homogenized bovine retinas (Srivastava et al., 1995). Pb was also reported to inhibit pyrimidine 5'-nucleotidase through competitive inhibition of magnesium binding, resulting in conformational changes and improper amino acid positioning in the active site (Bitto et al., 2006).

In summary, Pb has the ability to displace metal cations from the active sites of multiple enzymes and proteins, and thus to alter the functions of those proteins in occupationally exposed humans with blood Pb levels of 5.4-69.3 µg/dL, in adult rodents with blood Pb

levels of 6.5 µg/dL (exposure 4 weeks), in suckling rats exposed to 0.2% Pb via lactation, and in cell-free and cellular in vitro experiments conducted at exposure concentrations ranging from micromoles to picomoles. These alterations in protein function have implications for numerous cellular and physiological processes, including cell signaling, growth and differentiation, gene expression, energy metabolism, and biosynthetic pathways. Table 5-1 provides a list of enzymes and proteins whose function may be perturbed by Pb exposure.

Table 5-1 Enzymes and proteins potentially affected by exposure to Pb and the metal cation cofactors necessary for their proper physiological activity

	Metalloprotein/Enzyme	Direction of Action[a]	Metal Cation; Reference
Enzymes	Aminolevulinic acid dehydratase	↓	Zn; Simons (1995)
	Ferrochelatase	↓	Fe (2Fe-2S Cluster); Crooks et al. (2010)
	Superoxide dismutase	↓↑	Mn, Cu, Zn, Fe; Antonyuk et al. (2009), Borgstahl et al. (1992)
	Catalase	↓↑	Fe (Heme); Putnam et al. (2000)
	Glutathione peroxidase	↓↑	Se; Rotruck et al. (1973)
	Guanylate cyclase	↓	Fe (Heme); Boerrigter and Burnett (2009)
	cGMP phosphodiesterase	↓	Mg, Zn; Ke (2004)
	NAD synthase	↓	Mg; Hara et al. (2003)
	NAD(P)H oxidase	↑	Ca; Leseney et al. (1999)
	Pyrimidine 5'-nucleotidase	↓	Mg, Ca; Bitto et al. (2006), Amici et al. (1997), Paglia and Valentine (1975)
	Erythrocyte phosphoribosyltransferase	↓	Mg (Mn, Ca, Co, Ni, Zn); Deng et al. (2010), Arnold and Kelley (1978)
Ion Channels/ Transport	ATPase	↓↑	Ca, Mg, Na-K; Technische Universitat Braunschweig (2011)
	Mitochondrial transmembrane pore	↑	Ca; He et al. (2000)
	Calcium-dependent potassium channel	↑	Ca; Silkin et al. (2001), Alvarez et al. (1986)
Signal Transduction	Protein kinase C	↓↑	Ca; Garza et al. (2006)
	Calmodulin	↑	Ca; Garza et al. (2006)
Pb Binding	Metallothionein	↑	Zn, Cu; Yu et al. (2009)
DNA Binding	GATA transcriptional factors	↓	Zn; Hanas et al. (1999), Huang et al. (2004)

[a]↑ indicates increased activity; ↓ indicates decreased activity; ↓↑ indicates activity can be alternatively increased or decreased.

5.2.2.4 Mitochondrial Abnormality

Alterations in mitochondrial function, including disruptions in ion transport, ultrastructural changes, altered energy metabolism, and perturbed enzyme activities due to Pb intoxication are well documented in the scientific literature. Exposure of rats to Pb in feed (1% Pb for 4, 6, 8, 10, 12, or 20 weeks) or drinking water (300 ppm for 8 weeks, 500 ppm for 7 months, or 1% for 9 months) resulted in gross ultrastructural changes in renal tubules and epididymal mitochondria characterized as a general swollen appearance with frequent rupture of the outer membrane, distorted cristae, loss of cristae, frequent inner compartment vacuolization, observation of small inclusion bodies, and fusion with adjacent mitochondria (Wang et al., 2010d; Marchlewicz et al., 2009; Navarro-Moreno et al., 2009; Goyer, 1968; Goyer et al., 1968).

Transmembrane mitochondrial ion transport mechanisms are perturbed by exposure to Pb. Pb inhibits the uptake of Ca^{2+} into mitochondria (Parr and Harris, 1976), while simultaneously stimulating the efflux of Ca^{2+} out of the organelle (Simons, 1993a), thus disrupting intracellular/mitochondrial Ca^{2+} homeostasis. Pb exposure has also been shown to decrease the mitochondrial transmembrane potential in primary cerebellar granule neuronal cultures from rats exposed to 0.1% Pb in drinking water throughout gestation and lactation (Baranowska-Bosiacka et al., 2011a), astroglia incubated with 0.1 or 1.0 µM Pb for 14 days (Legare et al., 1993), proximal tubule cells exposed to 0.25, 0.5, and 1.0 µM for 12 hours (Wang et al., 2009c), and retinal rod photoreceptor cells incubated with 0.01 to 10 µM for 15 minutes (He et al., 2000). Further research indicated that Pb-induced mitochondrial swelling and decreased membrane potential is the result of the opening of a mitochondrial transmembrane pore (MTP), possibly by directly binding to the metal (Ca^{2+})-binding site on the matrix side of the pore (Bragadin et al., 2007; He et al., 2000). Opening of the MTP is the first step of the mitochondrial-regulated apoptotic cascade pathway in many cells (Rana, 2008; Lidsky and Schneider, 2003). He et al. (2000) additionally observed cytochrome c release from mitochondria, and caspase-9 and -3 activation following exposure of rod cells to Pb. Induction of mitochondrially-regulated apoptosis via stimulation of the caspase cascade following exposure to Pb has also been observed in rat oval cells (Agarwal et al., 2009).

Altered Energy Metabolism

Pb has been reported to alter normal cellular bioenergetics. In mitochondria isolated from the kidneys of rats exposed to 1% Pb in feed for 6 weeks, the rate of oxygen uptake during ADP-activated (state 3) respiration was lower compared to controls (Goyer et al., 1968). The rate of ATP formation in exposed mitochondria was observed to be approximately 50% that of control mitochondria. A decrease in state 3 respiration and

respiratory control ratios (state 3/state 4 [succinate or pyruvate/malate-activated]) was also observed in kidney mitochondria from rats exposed continuously from conception to six or nine months of age (i.e., gestationally, lactationally, and via drinking water after weaning) to 50 or 250 ppm Pb (Fowler et al., 1980). Pb-induced decreases in ATP and adenylate energy charge (AEC) were observed concurrently with increases in ADP, AMP, and adenosine in rats exposed to 1% Pb in drinking water for 9 months (Marchlewicz et al., 2009). Similarly, ATP and AEC were decreased, and AMP increased, in primary cerebellar granule neuronal cultures from rats exposed to 0.1% Pb in drinking water throughout gestation and lactation (Baranowska-Bosiacka et al., 2011a). One µM Pb (48 hours) was the lowest concentration observed to decrease cellular ATP levels in differentiated PC-12 cells, and these changes were correlated with a Pb-induced decrease in the expression of the voltage-dependent anion channel, which maintains cellular ATP levels in neurons (Prins et al., 2010). Dowd et al. (1990) reported that oxidative phosphorylation was decreased up to 74% after exposure of osteoblasts to 10 µM Pb. Parr and Harris (1976) reported that Pb inhibited coupled and uncoupled respiratory oxygen use in mitochondria, and that Pb prevented pyruvate, but not malate, uptake. Mitochondrial levels of ATP were diminished after exposure, and the authors compared the effects of Pb on the energy supply to the actions of classic respiratory inhibitors, low temperature, and chemical uncouplers. Bragadin et al. (1998) supported this view by demonstrating that alkylated Pb compounds acted as a chemical uncoupler of respiration by abolishing the proton gradient necessary for oxidative phosphorylation. Further, the enzymatic activities of complex I and IV of the respiratory chain have been shown to be decreased in the *peroneous longus* muscle of rats exposed to 250 ppm Pb or 5 ppm thallium in drinking water for 90 days (Méndez-Armenta et al., 2011). Contrary to the above findings, Rafalowska et al. (1996) reported that, although ATP levels did decrease, chronic exposure to Pb did not inhibit oxidative phosphorylation in the synaptosomes of rats exposed to 200 ppm Pb in water for 3 months. Similar effects with regard to the activity of the mitochondrial oxidative chain were observed in rats injected with 15 mg/kg Pb i.p. daily for seven days, as reported by Struzynksa et al. (1997a), although ATP levels were reported to increase after exposure to Pb.

Pb has also been shown to decrease glycolysis in osteoblasts exposed to 10 µM Pb and in human erythrocytes exposed to 30 µg/dL Pb (Grabowska and Guminska, 1996; Dowd et al., 1990). Contrary to these findings, Antonowicz et al. (1990) observed higher levels of glycolytic enzymes in erythrocytes obtained from Pb workers directly exposed to Pb, compared to controls exposed to lower concentrations of Pb (blood Pb levels: 82.1 versus 39.9 µg/dL), and suggested that Pb activated anaerobic glycolysis. In vitro exposure of human umbilical cord erythrocytes to 100-200 µg/dL Pb for 20 hours was observed to lower the cellular pools of adenine and guanine nucleotide pools, including NAD and NADPH (Baranowska-Bosiacka and Hlynczak, 2003). These decreases in nucleotide

pools were accompanied by an increase in purine degradation products (adenosine, etc.). Similar decreases in cellular nucleotide pools were observed when rats were exposed to 1% Pb in drinking water for four weeks (Baranowska-Bosiacka and Hlynczak, 2004). In erythrocytes, nucleotides are synthesized via salvage pathways such as the adenine pathway, which requires adenine phosphoribosyltransferase. The activity of this enzyme is inhibited by exposure to Pb in human and rat erythrocytes (see above for concentration and duration) (Baranowska-Bosiacka et al., 2009).

Disruptions in erythrocyte energy metabolism have been observed in workers occupationally exposed to Pb. Nikolova and Kavaldzhieva (1991) reported higher ratios of ATP/ADP in Pb-exposed workers with an average duration of exposure of 8.4 years (blood Pb not reported). Morita et al. (1997) evaluated the effect of Pb on NAD synthetase in the erythrocytes of Pb-exposed workers (mean [SD] blood Pb level: 34.6 [20.7] µg/dL) and observed an apparent concentration-dependent decrease in NAD synthetase activity with increased blood Pb level. The blood Pb level associated with 50% inhibition of NAD synthetase, which requires a magnesium cation for activity (Hara et al., 2003), was 43 µg/dL.

Altered Heme Synthesis

Exposure to Pb is known to inhibit two key steps in the synthesis of heme: porphobilinogen synthase (i.e., δ-aminolevulinic acid dehydratase), a cytoplasmic enzyme requiring zinc for enzymatic activity that condenses two molecules of aminolevulinic acid into porphobilinogen, and ferrochelatase, a mitochondrial iron-sulfur containing enzyme that incorporates Fe^{2+} into protoporphyrin IX to create heme. Farant and Wigfield (1990, 1987) observed that Pb inhibits the activity of porphobilinogen synthase in rabbit and human erythrocytes, and that the effect on the enzyme was dependent on the affinity for thiol groups at its active site. Taketani et al. (1985) examined the activity of Pb on ferrochelatase in rat liver mitochondria and observed that 10 µM Pb (30 minute incubation) reduced NAD(P)H-dependent heme synthesis by half when ferric, but not ferrous, iron was used. Pb inhibits the insertion of Fe^{2+} into the protoporphyrin ring and instead, Zn is inserted into the ring creating zinc protoporphyrin (ZPP). While not directly measuring the activity of ferrochelatase, numerous studies have shown that blood Pb levels are associated with increased erythrocyte ZPP levels in humans (average blood Pb levels ranging from 21.92 to 53.63 µg/dL) (Mohammad et al., 2008; Counter et al., 2007; Patil et al., 2006b; Ademuyiwa et al., 2005b) and animals (blood Pb level: 24.7 µg/dL) (Rendón-Ramirez et al., 2007).

5.2.3 Protein Binding

Evidence indicates that Pb binds to proteins within cells through interactions with side group moieties (e.g., thiol residues) and can potentially disrupt cellular function (Sections 5.2.2.3 and 5.2.2.4). However, some proteins are also able to bind Pb and protect against its negative effects through sequestration. The ability of Pb to bind proteins was first reported by Blackman (1936): Pb intoxication in children autopsy cases was observed to induce the formation of intranuclear inclusion bodies in the liver and kidney. Since that time, further research has been conducted into characterizing the composition of intranuclear inclusion bodies and identifying specific Pb-binding proteins.

5.2.3.1 Intranuclear and Cytoplasmic Inclusion Bodies

Goyer (1968) and Goyer et al. (1968) observed the formation of intranuclear inclusion bodies in the renal tubules of rats fed 1% Pb in food for up to 20 weeks. The observation of inclusion bodies was accompanied by altered mitochondrial structure and reduced rates of oxidative phosphorylation. Pb has further been observed to form cytoplasmic inclusion bodies preceding the formation of the intranuclear bodies, and to be concentrated within the subsequently induced intranuclear inclusion bodies following i.p. injection, drinking water, and dietary exposures (Navarro-Moreno et al., 2009; Oskarsson and Fowler, 1985; Fowler et al., 1980; McLachlin et al., 1980; Choie and Richter, 1972; Goyer et al., 1970a; Goyer et al., 1970b). Inclusion bodies have also been observed in the mitochondria of kidneys and the perinuclear space in the neurons of rats exposed to 500 ppm Pb-acetate in drinking water for 60 days or 7 months (Navarro-Moreno et al., 2009; Deveci, 2006). Intranuclear and cytoplasmic inclusions have also been found in organs other than the kidney, including liver, lung, and glial cells (Singh et al., 1999; Goyer and Rhyne, 1973). Pb found within nuclei has also been shown to bind to the nuclear membrane and histone fractions (Sabbioni and Marafante, 1976).

Upon denaturing intranuclear inclusion bodies with strong denaturing agents, Moore et al. (1973) observed that proteins included in the bodies were rich in aspartic and glutamic acid, glycine, and cysteine. Further work by Moore and Goyer (1974) characterized the protein as a 27.5 kDa protein that migrates as a single band on acrylamide gel electrophoresis. In contrast with the findings of Moore and Goyer, Shelton and Egle (1982) identified a 32 kDa protein with an isoelectric point of 6.3 from the kidneys of rats exposed to 1% Pb-acetate in feed or 0.75% in drinking water. This protein, dubbed p32/6.3, was not found in control rats, indicating that the protein was induced by Pb exposure. This finding was in agreement with studies that indicated formation of intranuclear inclusion bodies required protein synthesis (McLachlin et al., 1980; Choie et

al., 1975). In addition to its presence in kidneys of Pb-exposed animals, p32/6.3 has been observed to be present and highly conserved in the brains of rats, mice, dogs, chickens, and humans (Egle and Shelton, 1986). Exposure of neuroblastoma cells to 50 or 100 µM Pb glutamate for 1 or 3 days increased the abundance of p32/6.3 (Klann and Shelton, 1989). Shelton et al. (1990) determined that p32/6.3 was enriched in the basal ganglia, diencephalon, hippocampus, cerebellum, brainstem, spinal cord, and cerebral cortex, and that it contained a high percentage of glycine, aspartic, and glutamic acid residues. Selvin-Testa et al. (1991) and Harry et al. (1996) reported that pre- and post-natal exposure of rats to 0.2-1.0% Pb in drinking water increased the levels of another brain protein, glial fibrillary acidic protein, in developing astrocytes and that this increase may be indicative of a demand for astrocytes to sequester Pb.

5.2.3.2 Cytosolic Lead Binding Proteins

Numerous studies have also identified cytosolic Pb-binding proteins. Two binding proteins, with molecular weights of 11.5 and 63 kDa, were identified by (Oskarsson et al., 1982) in the kidney postmitochondrial cytosolic fraction after injection with 50 mg Pb. The two proteins were also found in the brain, but not the liver or lung. Mistry et al. (1985) identified three proteins (MW = 11.5, 63, and >200 kDa) in rat kidney cytosol, two of which, the 11.5 and 63 kDa proteins, were able to translocate into the nucleus. The 11.5 kDa kidney protein was also able to reverse Pb binding to ALAD through chelation of Pb and donation of a zinc cation to ALAD (Goering and Fowler, 1985, 1984). Cadmium and zinc, but not Ca^{2+} or Fe, prevented the binding of Pb to the 63 and 11.5 kDa cytosolic proteins, which agrees with previous observations that cadmium is able to reduce total kidney Pb and prevent the formation of intranuclear inclusion bodies (Mistry et al., 1986; Mahaffey et al., 1981; Mahaffey and Fowler, 1977). Additional cytosolic Pb-binding proteins have been identified in the kidneys of Pb-exposed rats and humans, including the cleavage product of α2-microglobulin, acyl-CoA binding protein (MW = 9 kDa), and thymosin β4 (MW = 5 kDa) (Smith et al., 1998; Fowler and DuVal, 1991).

Cytosolic Pb-binding proteins distinct from kidney proteins have also been identified in the brain of exposed rats and human brain homogenates exposed in vitro (Quintanilla-Vega et al., 1995; DuVal and Fowler, 1989; Goering et al., 1986). One protein (MW = 12 kDa) was shown to alleviate hepatic ALAD inhibition due to Pb exposure through competitive binding with Pb and donation of zinc to ALAD. Cytosolic Pb-binding proteins have been shown to be high in glutamic acid, aspartic acid, and cysteine residues (Fowler et al., 1993; DuVal and Fowler, 1989). Some evidence exists that cytosolic Pb-binding proteins directly target Pb and compartmentalize intracellular Pb as a protective measure against toxicity (Qian et al., 2005; Qian et al., 2000).

5.2.3.3 Erythrocytic Lead Binding Proteins

The majority (94%) of Pb in whole blood is found in erythrocytes (Ong and Lee, 1980a). Originally, the major Pb-binding protein in erythrocytes was identified as hemoglobin (Cohen et al., 2000; Lolin and O'Gorman, 1988; Ong and Lee, 1980a, b; Raghavan and Gonick, 1977). However, Bergdahl et al. (1997b) observed the principal Pb-binding protein to be 240 kDa and identified it as ALAD. Two smaller Pb-binding proteins were observed, but not identified (MW = 45 and <10 kDa). ALAD levels are inducible by Pb exposure; the total concentration of the enzyme, but not the activity, increases after exposure in both exposed humans (blood Pb = 30-75 µg/dL) and rats (Pb exposure = 25 mM in drinking water) (Boudene et al., 1984; Fujita et al., 1982; Fujita et al., 1981).

ALAD is a polymorphic gene with three isoforms: ALAD 1-1, ALAD 1-2, or ALAD 2-2. Carriers of the ALAD-2 allele have been shown to have higher blood Pb levels than carriers of the homozygous ALAD-1 allele (Scinicariello et al., 2007; Zhao et al., 2007; Kim et al., 2004; Pérez-Bravo et al., 2004; Smith et al., 1995a; Wetmur, 1994; Wetmur et al., 1991a; Astrin et al., 1987). Some newer studies, however, either observed lower blood Pb levels in carriers of the ALAD-2 allele or no difference in Pb levels among the different allele carriers (Scinicariello et al., 2010; Krieg et al., 2009; Chen et al., 2008c; Chia et al., 2007; Chia et al., 2006; Wananukul et al., 2006).

The ALAD-2 protein binds Pb more tightly than the ALAD-1form: in workers carrying the ALAD-2 gene, 84% of blood Pb was bound to ALAD versus 81% in carriers of the ALAD-1 gene ($p = 0.03$) (Bergdahl et al., 1997a). This higher affinity for Pb in ALAD-2 carriers may sequester Pb and prevent its bioavailability for reaction with other enzymes or cellular components. This is supported by the observation that carriers of the ALAD-2 gene have higher levels of hemoglobin (Scinicariello et al., 2007), decreased plasma levulinic acid (Schwartz et al., 1997b), decreased levels of zinc protoporphyrin (Scinicariello et al., 2007; Kim et al., 2004), lower cortical bone Pb (Smith et al., 1995b), and lower amounts of DMSA-chelatable Pb (Scinicariello et al., 2007; Schwartz et al., 2000a; Schwartz et al., 1997a). However, the findings that ALAD-2 polymorphisms reduced the bioavailability of Pb are somewhat equivocal. Wu et al. (2003a) observed that ALAD-2 carriers had lower blood Pb level (5.8 ± 4.2 µg/dL) than carriers of the ALAD-1 gene (blood Pb level = 6.2 ± 4.1 µg/dL), and that ALAD-2 carriers demonstrated decreased renal function at lower patellar Pb concentrations than those observed to decrease renal function in ALAD-1 carriers. This potentially indicates that ALAD-2 carriers have enhanced Pb bioavailability. Weaver et al. (2003b) observed that ALAD-2 polymorphisms were associated with higher DMSA-chelatable Pb concentrations, when normalized to creatinine levels. Further, Montenegro et al. (2006) observed among individuals with ALAD 1-1 or ALAD 1-2/2-2 genotypes a significant

increase in the amount of Pb found in the plasma (0.44 µg/L versus 0.89 µg/L, respectively) and in the % plasma/blood ratio (0.48% versus 1.45%, respectively). This potentially suggests that individuals with the ALAD 1-2/2-2 genotype are at increased risk of Pb-induced health effects due to lower amounts of Pb sequestration by erythrocyte ALAD, although this study did not specifically investigate the clinical implications of ALAD polymorphisms.

ALAD has the estimated capacity to bind Pb at 85 µg/dL in erythrocytes and 40 µg/dL in whole blood (Bergdahl et al., 1998). The 45 kiloDalton (kDa) and <10 kDa Pb-binding proteins bound approximately 12-26% and <1% of the blood Pb, respectively. At blood Pb concentrations greater than 40 µg/dL, greater binding to these components likely would be observed. Bergdahl et al. (1998) tentatively identified the 45 kDa protein as pyrimidine-5'-nucleotidase and the <10 kDa protein as acyl-CoA binding protein. Smith et al. (1998) previously identified acyl-CoA binding protein as a Pb-binding protein found in the kidney.

Studies also observed the presence of an inducible, low-molecular weight (approximately 10 kDa) Pb-binding protein in workers occupationally exposed to Pb (Gonick et al., 1985; Raghavan et al., 1981, 1980; Raghavan and Gonick, 1977). The presence of this low molecular weight protein seemed to have a protective effect as workers that exhibited toxicity at low blood Pb concentrations were observed to have lowered expression of this protein or low levels of Pb bound to it (Raghavan et al., 1981, 1980). The presence of low molecular weight Pb-binding proteins in exposed workers was confirmed by Lolin and O'Gorman (1988) and Church et al. (1993a, b). Further Lolin and O'Gorman (1988) reported that the observed protein was only present when blood Pb levels were greater than 39 µg/dL, in agreement with the Pb-binding capacity of ALAD, identified by Bergdahl et al. (1998). Xie et al. (1998) confirmed this, observing the presence of a second low molecular weight protein with greater affinity than ALAD only at higher blood Pb levels. Church et al. (1993a, b) observed the presence of a 6-7 kDa protein in the blood of 2 Pb workers (blood Pb >160 µg/dL); approximately 67% of Pb was bound to the protein in the blood of the asymptomatic worker, whereas only 22% of the Pb was bound to it in the symptomatic worker. The reported protein was rich in cysteine residues and tentatively identified as metallothionein.

5.2.3.4 Metallothionein

Metallothionein is a low-molecular weight metal-binding protein, most often zinc or copper, which is rich in cysteine residues and plays an important role in the protection against heavy metal toxicity, trace element homeostasis, and scavenging free radicals (Yu

et al., 2009). Exposure to Pb-acetate induces the production of Pb- and Zn-metallothionein in mice exposed via i.p. or intravenous (i.v.) injection at 30 mg/kg (Maitani et al., 1986), in mice exposed via i.p. injection at 300 µmol/kg (Yu et al., 2009), or in rats exposed via i.p. injection at 24 µmol/100g (Ikebuchi et al., 1986). The induced Pb-metallothionein consisted of 28% half-cysteine and reacted with an antibody for Zn-metallothionein II (Ikebuchi et al., 1986). In contrast, exposure of rats to Pb via drinking water (200 or 300 ppm) failed to induce metallothionein in the kidneys or intestines (Wang et al., 2009b; Jamieson et al., 2007). Goering and Fowler (1987a, b) observed that pretreatment of rats with zinc before injection with Pb resulted in Pb and zinc co-eluting with zinc-thionein, and that zinc-thionein I and II were able to bind Pb in vitro (Goering and Fowler, 1987a, b). Further, Goering and Fowler (1987a) found that kidney and liver zinc-thionein decreased binding of Pb to liver ALAD and was able to donate zinc to ALAD, thus attenuating the inhibition of ALAD due to Pb exposure. These findings are in agreement with Goering et al. (1986) and DuVal and Fowler (1989) who demonstrated that rat brain Pb-binding proteins attenuated Pb-induced inhibition of ALAD.

Metallothionein has been reported to be important in the amelioration of Pb-induced toxicity effects. Liu et al. (1991) reported that zinc-metallothionein reduced Pb-induced membrane leakage and loss of potassium in cultured hepatocytes incubated with 600-3,600 µM Pb. Metallothionein-null mice exposed to 1,000, 2,000, or 4,000 ppm Pb for 20 weeks suffered renal toxicity described as nephromegaly and decreased renal function compared to Pb-treated wild-type mice (Qu et al., 2002). Interestingly, metallothionein-null mice were unable to form intranuclear inclusion bodies and accumulated less renal Pb than did the wild-type mice (Qu et al., 2002). Metallothionein levels were induced by Pb exposure in non-null mice. Exposure to Pb (1,000, 2,000, or 4,000 ppm), both for 104 weeks as adults and from GD8 to early adulthood, resulted in increased preneoplastic lesions and carcinogenicity in the testes, bladder, and kidneys of metallothionein-null rats compared to wild type mice (Tokar et al., 2010; Waalkes et al., 2004). Inclusion bodies were not observed in null mice. The authors concluded that metallothionein is important in the formation of inclusion bodies and mitigation of Pb-induced toxic effects, and that those with polymorphisms in metallothionein coding genes may be at greater susceptibility to Pb. In support of this theory, Chen et al. (2010a) observed that Pb-exposed workers with a mutant metallothionein allele had higher blood Pb levels than did carriers of the normal allele (24.17 and 21.27 versus 17.03 µg/dL), and were more susceptible to the effects of Pb on systolic BP and serum renal function parameters.

5.2.4 Oxidative Stress

Oxidative stress occurs when free radicals or reactive oxygen species (ROS) exceed the capacity of antioxidant defense mechanisms. This oxidative imbalance results in uncontained ROS, such as superoxide (O_2^-), hydroxyl radical ($OH^\bullet$), and hydrogen peroxide (H_2O_2), which can attack and denature functional/structural molecules and, thereby, promote tissue damage, cytotoxicity, and dysfunction. Pb has been shown to cause oxidative damage to the heart, liver, kidney, reproductive organs, brain, and erythrocytes, which may be responsible for a number of Pb-induced health effects (Salawu et al., 2009; Shan et al., 2009; Vaziri, 2008b; Gonick et al., 1997; Sandhir and Gill, 1995; Khalil-Manesh et al., 1994; Khalil-Manesh et al., 1992b). The origin of ROS produced after Pb exposure is likely a multipathway process, resulting from oxidation of δ-aminolevulinic acid (ALA), membrane and lipid oxidation, nicotinamide adenine dinucleotide phosphate (NAD(P)H) oxidase activation, and antioxidant enzyme depletion, as discussed below. Some of these processes result from the disruption of functional metal ions within oxidative stress proteins, such as superoxide dismutase (SOD), catalase (CAT), and glutathione peroxidase (GPx). Interestingly, Pb exposure in many species of plants, invertebrates, and vertebrates discussed in the Ecological Effects of Pb results in upregulation of antioxidant enzymes and increased lipid peroxidation (Chapter 7). Oxidative stress is a common mode of action for a number of other metals (e.g., Cd, Mn, As, Co, Cr) that are often found with Pb and by which possible interactions with Pb have been suggested to occur (Jomova and Valko, 2011; Jomova et al., 2011; Matović et al., 2011; HaMai and Bondy, 2004). Not all of these co-occurring metals directly produce ROS or redox cycle, but instead may suppress the free radical scavenging ability of the organism thus leading to oxidative stress.

5.2.4.1 δ-ALA Oxidation

The majority of Pb present in the blood accumulates in erythrocytes where it enters through passive carrier-mediated mechanisms including a vanadate-sensitive Ca^{2+} pump. Once Pb enters erythrocytes, it is predominantly found in the protein-bound form, with hemoglobin and δ-ALAD both identified as targets (Bergdahl et al., 1997a). Through its sulfhydryl and metal ion disrupting properties, Pb incorporates with and inhibits a number of enzymes in the heme biosynthetic process, including δ-ALA synthetase, δ-ALAD, and ferrochelatase. Pb has been shown to be able to disrupt the zinc ions requisite for the activity of δ-ALAD, the rate limiting step in heme synthesis, leading to enzyme inhibition at picomolar concentrations (Simons, 1995). Additionally, low blood Pb levels (mean: 7 µg/dL) have been found to inhibit the activity of δ-ALAD in humans, and the lowest blood Pb level observed to be associated with lower δ-ALAD activity in these

studies was 5 µg/dL (Ahamed et al., 2005; Sakai and Morita, 1996). A significant negative correlation (r = -0.6) was found between blood Pb levels in adolescents (range of blood Pb levels: 4-20 µg/dL) and blood δ-ALAD activity in adolescents (Ahamed et al., 2006). This inhibition of δ-ALAD results in the accumulation of δ-ALA in blood and urine, where δ-ALA undergoes tautomerization and autoxidation. Oxidized δ-ALA generates ROS through reduction of ferricytochrome *c* and electron transfer from oxyHb, metHb, and other ferric and ferrous complexes (Hermes-Lima et al., 1991; Monteiro et al., 1991). The autoxidation of δ-ALA produces O_2^-, OH•, H_2O_2, and an ALA radical (Monteiro et al., 1989; Monteiro et al., 1986).

5.2.4.2 Membrane and Lipid Peroxidation

A large number of studies in humans and experimental animals have found that exposure to Pb can lead to membrane and lipid peroxidation. It is possible that ROS produced from δ-ALA oxidation, as described above, interacts with and disrupts membrane lipids (Oteiza et al., 1995; Bechara et al., 1993). Additionally, Pb has the capacity to stimulate ferrous ion initiated membrane lipid peroxidation serving as a catalyst for these events (Adonaylo and Oteiza, 1999; Quinlan et al., 1988). The extent of peroxidation of lipids varies based on the number of double bonds present in unsaturated fatty acids, since double bonds weaken the C-H bonds on the adjacent carbon, making H removal easier (Yiin and Lin, 1995). After Pb exposure (4-12 µg/dL in vitro, 24 hours), the production of malondialdehyde (MDA), a marker of oxidative stress and lipid oxidation end product, increased relative to the number of double bonds of the fatty acid. In the absence of Fe^{2+}, Pb has not been shown to promote lipid peroxidation; however, it may accelerate peroxidation by H_2O_2 (Quinlan et al., 1988). This could be due to altering membrane structure, restricting phospholipid movement, and facilitating the propagation of peroxidation.

Pb induces changes in the fatty acid composition of a membrane, which could lead to oxidative damage. Exposure to Pb (>62.5 ppm in drinking water, 3 weeks) in chicks promoted an increase in arachidonic acid (AA, 20:4) as a percentage of total fatty acids, and decreased the relative proportion of shorter chain fatty acids (linoleic acid, 18:2) (Lawton and Donaldson, 1991). It is possible that Pb depressed the desaturation of saturated fatty acids to the corresponding monoenoic fatty acids, while stimulating elongation and desaturation of linoleic acid to AA. Since fatty acid chain length and unsaturation are related to the oxidative potential, changes in fatty acid membrane composition may result in enhanced lipid peroxidation. In addition, changes in fatty acids, thus membrane composition, can result in altered membrane fluidity (Donaldson and Knowles, 1993). Changes in membrane fluidity will disturb the conformation of the

active sites of membrane associated enzymes, disrupt metabolic regulation, and alter membrane permeability and function.

A number of recent studies report increased measures of lipid peroxidation in various organs, tissues, and species. Occupational Pb exposure resulting in elevated blood Pb levels (means >8 µg/dL) in various countries provides evidence of lipid peroxidation, including increased plasma MDA levels (Ergurhan-Ilhan et al., 2008; Khan et al., 2008; Mohammad et al., 2008; Quintanar-Escorza et al., 2007; Patil et al., 2006a; Patil et al., 2006b). One study found a correlation between the MDA levels and blood Pb levels even in the unexposed workers, although they had blood Pb levels higher than the mean blood Pb level of the current U.S. population (i.e., <12 µg/dL) (Quintanar-Escorza et al., 2007). Other studies found evidence of increased lipid peroxidation among the general population, including children, with elevated blood Pb levels (means >10 µg/dL) (Ahamed et al., 2008; Ahamed et al., 2006; Jin et al., 2006). In adolescents, Ahamed et al. (2006) found a blood MDA levels to be positively correlated (r = 0.7) with blood Pb levels ranging between 4-20 µg/dL. Similar results have been shown after Pb exposure in animal studies (Abdel Moneim et al., 2011b; Pandya et al., 2010; Dogru et al., 2008; Yu et al., 2008; Adegbesan and Adenuga, 2007; Lee et al., 2005). Enhanced lipid peroxidation has been found in Pb treated (50 µg, 1-4 hours) rat brain homogenates (Rehman et al., 1995), rat proximal tubular cells (0.5-1 µM, 12 hours) (Wang et al., 2011b), and in specific brain regions, hippocampus and cerebellum, after Pb exposure (500 ppm, 8 weeks) to rats (Bennet et al., 2007). Overall, there was a correlation between the blood Pb level and measures of lipid peroxidation often measured by MDA levels.

Interestingly, many species of plants, invertebrates, and vertebrates exhibit increased lipid peroxidation with Pb exposure (Sections 7.2.4, 7.3.5, and 7.3.12). The increase in lipid peroxidation following Pb exposure observed across species and kingdoms demonstrate an evolutionarily conserved oxidative response following Pb exposure.

5.2.4.3 NAD(P)H Oxidase Activation

NAD(P)H oxidase is a membrane bound enzyme that requires Ca^{2+} in order to catalyze the production of O_2^- from NAD(P)H and molecular oxygen (Leseney et al., 1999). Two studies provide evidence for increased activation of NAD(P)H oxidase that may contribute to the production of ROS after Pb exposure (Ni et al., 2004; Vaziri et al., 2003). Vaziri et al. (2003) found increased protein expression of the NAD(P)H subunit gp^{91}phox in the brain, heart, and renal cortex of Pb treated rats (100 ppm in drinking water, 12 weeks). This upregulation was present in Pb-treated (1-10 ppm) human coronary artery endothelial cells, but not vascular smooth muscle cells (VSMC), which

do not express the protein (Ni et al., 2004). It is possible that NAD(P)H oxidase serves as a potential source of ROS in cells that express this protein.

5.2.4.4 Antioxidant Enzyme Disruption

Oxidative stress can result not only from the increased production of ROS, but also from the decreased activity of antioxidant defense enzymes. Pb has been shown to alter the function of several antioxidant enzymes, including SOD, CAT, glucose-6-phosphate dehydrogenase (G6PD), and the enzymes involved in glutathione metabolism, GPx, glutathione-S-transferase (GST), and glutathione reductase (GR). These changes in the antioxidant defense system could be due to the high affinity of Pb for sulfhydryl groups contained within proteins and its metal ion mimicry. However changes could also be a consequence of increased oxidative damage by Pb.

Studies of the effects of Pb on the activities of SOD and CAT give divergent results. These metalloprotein enzymes require various essential trace elements for proper structure and function, making them a target for Pb toxicity. CAT is a heme containing protein that requires iron ions to function (Putnam et al., 2000). SOD exists in multiple isoforms that require copper and zinc (SOD1 and SOD3) (Antonyuk et al., 2009) or manganese (SOD2) (Borgstahl et al., 1992). A number of studies have found decreased activity of these enzymes (Pandya et al., 2010; Ergurhan-Ilhan et al., 2008; Mohammad et al., 2008; Yu et al., 2008; Patil et al., 2006a; Patil et al., 2006b; Conterato et al., In Press), whereas others have observed increased activity following Pb exposure (Ahamed et al., 2008; Lee et al., 2005). Pb exposure (500 ppm, 1, 4, and 8 weeks) in rats showed that organ SOD and CAT responded differently depending on the dose and tissue investigated. Activity of SOD and CAT varied based on the brain region analyzed and time of exposure (Bennet et al., 2007). Another study found that the brain had consistently decreased SOD activity, irrespective of dose in prenatally exposed animals (0.3 and 3.0 ppm, blood Pb level 20.4 and 24.5 µg/dL); however hepatic SOD activity increased at low level Pb administration and decreased after high level exposure (Uzbekov et al., 2007). It is possible that the increased SOD and CAT protein is due to activation by ROS, while decreased enzyme activity is the result of metal ion substitution by Pb causing enzyme inactivation.

Glutathione is a tripeptide antioxidant containing a cysteine with a reactive thiol group that can act nonenzymatically as a direct antioxidant or as a cofactor in enzymatic detoxification reactions by GST. Glutathione will donate an electron while in its reduced state (GSH), which leads to conversion to the oxidized form, glutathione disulfide (GSSG). Pb binds to the thiol and can both interfere with the antioxidant capacity of and

decrease levels of GSH. Short-term administration of Pb in vitro (0.1 µM) and biomarkers of Pb exposure in humans (18 µg/dL mean blood Pb level) have been associated with decreased blood and organ GSH and cysteine content, which may be due to increased GSH efflux from tissues (Pandya et al., 2010; Pillai et al., 2010; Ahamed et al., 2009; Ahamed et al., 2008; Flora et al., 2007; Ahamed et al., 2005; Chetty et al., 2005; Nakagawa, 1991, 1989). Long-term Pb exposure elicits a compensatory upregulation in the biosynthesis of GSH in the attempt to overcome Pb toxicity, thus often manifesting as an increase in Pb-induced GSH (Daggett et al., 1998; Corongiu and Milia, 1982; Hsu, 1981; Conterato et al., In Press). However, other studies have found that long-term Pb exposure resulting in mean blood Pb levels between 6.6 and 22 µg/dL, causes the depletion of GSH (Mohammad et al., 2008; Lee et al., 2005; Ercal et al., 1996). Thus, the time of exposure is important to consider when measuring GSH levels.

Glutathione reductase is able to reduce GSSG back to GSH. Therefore, an increased GSSG/GSH ratio is considered to be indicative of oxidative stress. Epidemiologic studies have found higher blood Pb levels to be associated with increases in the GSSG/GSH ratio (Mohammad et al., 2008; Ercal et al., 1996; Sandhir and Gill, 1995). In one study, this association was observed in a population of children with a mean blood Pb level below 10 µg/dL (Diouf et al., 2006). Studies have found mixed effects on GR activation. GR possesses a disulfide at its active site that is a target for inhibition by Pb. Studies in animals and cells have reported decreased (Bokara et al., 2009; Sandhir and Gill, 1995; Sandhir et al., 1994), increased (Sobekova et al., 2009; Howard, 1974), and no change (Hsu, 1981) in GR activity after Pb exposure. This could be because the effect of Pb on GR varies depending on sex (Sobekova et al., 2009) and organ or organ region (Bokara et al., 2009).

GSH is used as a cofactor for peroxide reduction and detoxification of xenobiotics by the enzymes GPx and GST. GPx requires selenium for peroxide decomposition (Rotruck et al., 1973), whereas GST functions via a sulfhydryl group. By reducing the uptake of selenium, depleting cellular GSH, and disrupting protein thiols, evidence indicates that Pb decreases the activity of GPx and GST (Pillai et al., 2010; Yu et al., 2008; Lee et al., 2005; Nakagawa, 1991; Schrauzer, 1987). Similar to other antioxidant enzymes, compensatory upregulation of these enzymes is described after Pb exposure in animals and in Pb-exposed workers (painters with a mean blood Pb level of 5.4 µg/dL) (Bokara et al., 2009; Ergurhan-Ilhan et al., 2008; Conterato et al., 2007; Daggett et al., 1998; Conterato et al., In Press). However, in another study, these enzymes were not able to compensate for the increased Pb-induced ROS, further contributing to the oxidative environment (Farmand et al., 2005).

Recently, γ-glutamyltransferase (GGT) within its normal range has been regarded as an early and sensitive marker of oxidative stress. This may be because cellular GGT metabolizes extracellular GSH to be used in intracellular GSH synthesis. Thus, cellular GGT acts as an antioxidant enzyme by increasing the intracellular GSH pool. However, the reasons for the association between GGT and oxidative stress have not been fully realized (Lee et al., 2004). In one study, occupational Pb exposure (mean blood Pb level of 29.1 µg/dL) was associated with increased serum GGT levels (Khan et al., 2008). Interestingly, higher blood Pb level was similarly associated with higher serum GGT levels in a sample of the U.S. adult population (NHANES III) with lower blood Pb levels (Lee et al., 2006a). In this study of nonoccupationally-exposed individuals, a concentration-dependent relationship was observed at blood Pb levels <7 µg/dL.

5.2.4.5 Nitric Oxide Signaling

$^{\bullet}$NO, also known as endothelium-derived relaxing factor, is a potent endogenous signaling molecule involved in vasodilation. Short- and long-term Pb exposure in animals decreases the biologically active $^{\bullet}$NO, not through reduction in $^{\bullet}$NO-production capacity (Vaziri and Ding, 2001; Vaziri et al., 1999b), but as a result of inactivation and sequestration of $^{\bullet}$NO by ROS (Malvezzi et al., 2001; Vaziri et al., 1999a). Endogenous $^{\bullet}$NO can interact with ROS, specifically O_2^-, produced following exposure to Pb to form the highly cytotoxic reactive nitrogen species, peroxynitrite ($ONOO^-$). This reactive compound can damage cellular DNA and proteins, resulting in the formation of nitrotyrosine among other products. Overabundance of nitrotyrosine in plasma and tissues is present after exposure to Pb (Vaziri et al., 1999a). $^{\bullet}$NO is also produced by macrophages in the defense against certain infectious agents, including bacteria. Studies have indicated that Pb exposure can significantly reduce production of $^{\bullet}$NO in immune cells (Pineda-Zavaleta et al., 2004; Lee et al., 2001b; Tian and Lawrence, 1995), possibly leading to reduced host resistance (Tian and Lawrence, 1996).

Production of $^{\bullet}$NO is catalyzed by a family of enzymes called nitric oxide synthases (NOS), including endothelial NOS (eNOS), neuronal NOS (nNOS), and inducible NOS (iNOS), which require a heme prosthetic group and a zinc cation for enzymatic activity (Messerschmidt et al., 2001). Paradoxically, the reduction in $^{\bullet}$NO availability in vascular tissue following Pb exposure is accompanied by statistically significant upregulation in NOS isotypes (Vaziri and Ding, 2001; Vaziri et al., 1999b; Gonick et al., 1997). A direct inhibitory action of Pb on NOS enzymatic activity has been rejected (Vaziri et al., 1999b). Instead, the upregulation of NOS occurs as compensation for the decreased $^{\bullet}$NO resulting from ROS inactivation (Vaziri et al., 2005; Vaziri and Ding, 2001; Vaziri and Wang, 1999).

Soluble Guanylate Synthase

Many biological actions of •NO, such as vasorelaxation, are mediated by cyclic guanosine monophosphate (cGMP), which is produced by soluble guanylate cyclase (sGC) from the substrate guanosine triphosphate. Soluble guanylate cyclase is a heterodimer requiring one molecule of heme for enzymatic activity (Boerrigter and Burnett, 2009). In VSMC, sGC serves as the •NO receptor. Marked reduction in plasma concentrations and urinary excretion of cGMP is observed after Pb exposure to rats (5 ppm for 30 days and 100 ppm for 12 months [resulting in a mean blood Pb level of 29.4 µg/dL]) (Marques et al., 2001; Khalil-Manesh et al., 1993b). In addition, Pb exposure downregulated the protein abundance of sGC in vascular tissue (Farmand et al., 2005; Courtois et al., 2003; Marques et al., 2001). This downregulation in sGC was prevented by antioxidant therapy (ascorbic acid) suggesting that oxidative stress also plays a role in Pb-induced downregulation of sGC (no change in blood Pb level was observed after ascorbic acid treatment) (Marques et al., 2001).

5.2.5 Inflammation

Misregulated inflammation represents one of the major hallmarks of Pb-induced immune effects. It is important to note that this can manifest in any tissue where immune cell mobilization and tissue insult occurs. Enhanced inflammation and tissue damage occurs through the modulation of inflammatory cell function and production of pro-inflammatory cytokines and metabolites. Overproduction of ROS and an apparent depletion of antioxidant protective enzymes and factors (e.g., selenium) accompany this immunomodulation (Chetty et al., 2005).

Traditional immune-mediated inflammation can be seen with bronchial hyperresponsiveness, asthma, and respiratory infections associated with exposure to Pb. But it is important to recognize that any tissue or organ can be affected by immune-mediated inflammatory dysfunction given the distribution of immune cells as both permanent residents and infiltrating cell populations (Mudipalli, 2007; Carmignani et al., 2000). Pb spheres implanted in the brains of rats produced neutrophil-driven inflammation with apoptosis and indications of neurodegeneration (Kibayashi et al., 2010). Pb also induces renal tubulointerstitial inflammation (mean blood Pb level of 18 µg/dL or 100 ppm exposure for 14 weeks) (Rodriguez-Iturbe et al., 2005; Ramesh et al., 2001), which has been coupled with activation of the redox sensitive nuclear transcription factor kappa B (NFκB) and lymphocyte and macrophage infiltration in rats (100 ppm for 14 weeks resulting in mean blood Pb levels ranging 23-27 µg/dL,) (Bravo et al., 2007). These events could be in response to the oxidative environment arising from

Pb exposure, since Pb-induced inflammation and NFκB activation can be ameliorated by antioxidant therapy (Rodriguez-Iturbe et al., 2004).

Inflammation can be mediated by the production of chemical messengers such as prostaglandins (PG). Pb exposure has been reported to increase arachidonic acid (AA) metabolism, thus elevating the production of PGE_2, PGF_2, and thromboxane in occupationally-exposed humans (mean blood Pb level 48 µg/dL) (Cardenas et al., 1993) and animal and cell models (e.g., 0.01 µM, 48 h) (Chetty et al., 2005; Flohe et al., 2002; Knowles and Donaldson, 1997; Lee and Battles, 1994). Dietary Pb supplementation of animals (500 ppm, 19 days) can increase the percentage of cell membrane AA, the precursor of cyclooxygenase and lipoxygenase metabolism to PGs and leukotrienes (Knowles and Donaldson, 1990). Additionally, Pb (1 µM) may promote the release of AA via activation of phospholipase A_2, as shown in isolated VSMC (Dorman and Freeman, 2002).

Inflammation may be the result of increased pro-inflammatory signaling or may stimulate these signaling pathways. Pb can elevate the expression of the pro-inflammatory transcription factors NFκB and activator protein-1 (AP-1), as well as the AP-1 component c-Jun (Korashy and El-Kadi, 2008; Korashy and Ei-Kadi, 2008; Bravo et al., 2007; Ramesh et al., 1999; Pyatt et al., 1996). Pb exposure (25 µM) to dendritic cells stimulated phosphorylation of the Erk/MAPK pathway, but not p38, STAT3 or 5, or CREB (Gao et al., 2007)

5.2.5.1 Cytokine Production

There are three modes by which Pb affects immune cytokine production. First, Pb can act on macrophages to elevate the production of pro-inflammatory cytokines such as TNF-α and interleukin (IL)-6 (Cheng et al., 2006; Chen et al., 1999; Dentener et al., 1989). This can result in local tissue damage during the course of immune responses affecting such targets as the liver. Second, when Pb acts on dendritic cells, it skews the ratio of IL-12/IL-10 such that T-derived lymphocyte helper (Th)1 responses are suppressed and Th2 responses are promoted (Chen et al., 2004; Miller et al., 1998). Third, when acquired immune responses occur following exposure to Pb, Th1 lymphocyte production of cytokines is suppressed (e.g., IFN-γ) (Lynes et al., 2006; Heo et al., 1996). In contrast, Th2 cytokines such as IL-4, IL-5, and IL-6 are elevated (Gao et al., 2007; Kim and Lawrence, 2000). The combination of these three modes of cytokine changes induced by Pb creates a hyperinflammatory state among innate immune cells and acquired immunity is skewed toward Th2 responses.

Iavicoli et al. (2006a) reported that low blood Pb concentrations produced significant changes in cytokine levels in mice. At a low dietary Pb concentration (0.11 ppm, blood Pb level of 1.6 µg/dL), IL-2 and IFN-γ were decreased compared to the controls (0.02 ppm, 0.8 µg/dL), indicating a suppressed Th1 response. As the dietary and blood Pb concentrations increased (resulting in blood Pb levels 12-61 µg/dL), a Th2 phenotype was observed with suppressed IFN-γ and IL-2 and elevated IL-4 production. These findings support the notion that the immune system is remarkably sensitive to Pb-induced functional alterations and that nonlinear effects may occur at low Pb exposures. TGF-β production is also altered by Pb exposure to cells (1 µM, 3 days) (Zuscik et al., 2007). IL-2 is one of the more variable cytokines with respect to Pb-induced changes. Depending upon the protocol it can be slightly elevated in production or unchanged. Recently, Gao et al. (2007) found that Pb-treated dendritic cells (25 µM) promoted a slight but statistically significant increase in IL-2 production among lymphocytes. Proinflammatory cytokines have been measured in other organs and cell types after Pb exposure. Elevation of IL-1β and TNF-α were observed in the hippocampus after Pb exposure (15 ppm, i.p., daily for 2 weeks, blood Pb level of 30.8 µg/dL) and increased IL-6 was found in the forebrain (Struzynska et al., 2007).

Consistent with animal studies, epidemiologic studies also found higher concurrent blood Pb levels in children and occupationally-exposed adults to be associated with a shift toward production of Th2 cytokines relative to Th1 cytokines. The evidence in children was based on comparisons of serum cytokine levels among groups with different blood Pb levels without consideration of potential confounding factors. Among children ages 9 months to 6 years in Missouri, Lutz et al. (1999) found that children with concurrent blood Pb levels 15-19 µg/dL had higher serum levels of IL-4 and IgE (Section 5.6.3) than did children with lower blood Pb levels. These results were consistent with the mode of action for IL-4 to activate B cells to induce B cell class switching to IgE. In another study of children in grades 5 and 6 in Taiwan, investigators did not group children by blood Pb levels but by potential for Pb exposures due to age of home and location of residence (Hsiao et al., 2011). Concurrent blood Pb levels did not differ by residence in old versus new homes or by urban versus rural residence (means: 3.2-3.8 µg/dL) but were higher among children living near an oil refinery, in particular, among children with known respiratory allergies (mean: 8.8 µg/dL). This latter group of children also had the lowest serum levels of IFN-γ and highest levels of IL-4. There was no direct comparison of cytokine levels between blood Pb level groups in the population overall; however, cytokine levels were similar between healthy and allergy groups in the other Pb source groups that had similar blood Pb levels. Thus, the differences in cytokine levels between healthy and allergic children living near the oil refinery may have been influenced by differences in their blood Pb levels.

Evidence of association between blood Pb levels and cytokine levels in nonoccupationally-exposed adults was equivocal. Among adult university students in Incheon, Korea, Kim et al. (2007) found associations of concurrent blood Pb level with serum levels of TNF-α and IL-6 that were larger among male students with blood Pb levels 2.51-10.47 µg/dL. Notably, the relative contributions of lower recent versus higher past Pb exposures to these effects is not known. In models that adjusted for age, sex, BMI, and smoking status, a 1 µg/dL increase in blood Pb level was associated with a 23% increase (95% CI: 4, 55%) in log of TNF-α and a 26% increase in log of IL-6 (95% CI: 0, 55%). The association between levels of blood Pb and plasma TNF-α was greater among men who were GSTM1 null or had the TNF-α GG genotype. For the association between blood Pb level and plasma IL-6, the effect estimate was slightly elevated in TNF-α GG genotype but not elevated in the GSTM1 positive group. The effects of Pb on several physiological systems have been hypothesized to be mediated by the generation of ROS (Daggett et al., 1998). Thus, the null variant of GSTM1, which is associated with reduced elimination of ROS, may increase the risk of Pb-associated immune effects. The results for the TNF-α polymorphism were difficult to interpret. The GG genotype is associated with lower expression of TNF-α, and the literature is mixed with respect to which variant increases risk of inflammation-related conditions. Among adults in Italy, blood Pb levels were not correlated with either Th2 or Th1 cytokine levels in men (Boscolo et al., 1999) or women (Boscolo et al., 2000)

Results from studies of occupationally-exposed adults also suggested that Pb exposure may be associated with decreases in Th1 cytokines and increases in Th2 cytokines; however, analyses were mostly limited to comparisons of levels among different occupational groups with different mean blood Pb levels (Di Lorenzo et al., 2007; Valentino et al., 2007; Yucesoy et al., 1997a). The exception was a study of male foundry workers, pottery workers, and unexposed workers by Valentino et al. (2007). Multiple regression analyses were performed with age, BMI, smoking, and alcohol consumption included as covariates. Although information on concentration-response relationships was not provided, higher blood Pb level was associated with higher IL-10 and TNF-α. Levels of IL-2, IL-6, and IL-10 also increased from the lowest to highest blood Pb group. In contrast with most other studies, both exposed worker groups had lower IL-4 levels compared with controls. In a similar analysis, DiLorenzo et al. (2007) separated exposed workers into intermediate (9.1-29.4 µg/dL) and high (29.4-81.1 µg/dL) blood Pb level groups, with unexposed workers comprising the low exposure group (blood Pb levels 1-11 µg/dL). Mean TNF-α levels showed a monotonic increase from the low to high blood Pb group. Levels of granulocyte colony-stimulating factor (G-CSF) did not differ between the intermediate and high blood Pb groups among the Pb recyclers; however, G-CSF levels were higher in the Pb recyclers than in the unexposed controls. Furthermore, among all subjects, blood Pb showed a strong, positive correlation with G-CSF. Yucesoy

et al. (1997a) found lower serum levels of the Th1 cytokines, IL-1β and IFN-γ, in workers (mean blood Pb level of 59.4 µg/dL) compared with controls (mean blood Pb level of 4.8 µg/dL); however levels of the Th2 cytokines, IL-2 and TNF-α levels, were similar between groups. As most occupationally-exposed cohorts represent populations highly exposed to Pb, with mean blood Pb levels >22 µg/dL, effects observed within these cohorts may not be generalizable to the population as a whole. However, animal, general population, and occupational studies suggest that exposure to Pb increases the production of pro-inflammatory cytokines, skews the ratio of Th1 and Th2 cytokines to favor Th2 responses, and suppresses lymphocyte cytokine production.

5.2.6 Endocrine Disruption

5.2.6.1 Hypothalamic-Pituitary-Gonadal Axis

Pb is a potent endocrine disrupting chemical found to be associated with reproductive and developmental effects in both male and female animal models. Pb may act both at multiple points along the hypothalamic-pituitary-gonadal (HPG) axis and directly at gonadal sites. The HPG axis functions in a closely regulated manner to produce circulating sex steroids and growth factors required for normal growth and development. Long-term Pb exposure in animals has been shown to reduce serum levels of follicle-stimulating hormone (FSH), luteinizing hormone (LH), testosterone, and estradiol (Biswas and Ghosh, 2006; Rubio et al., 2006). Similar changes in serum HPG hormones have been observed after high-level Pb exposure in animals, resulting in blood Pb levels > 20 µg/dL (Dearth et al., 2002; Ronis et al., 1998b; Foster, 1992; Sokol and Berman, 1991). Increases in LH and FSH have been associated with increasing concurrent blood Pb levels in adult women from the NHANES cohort (Krieg, 2007). The change in HPG hormones likely occurs through the inhibition of LH secretion and the reduction in the expression of the steroidogenic acute regulatory protein (StAR) (Huang and Liu, 2004; Srivastava et al., 2004; Huang et al., 2002; Ronis et al., 1996). StAR expression is the rate-limiting step essential in maintaining gonadotropin-stimulated steroidogenesis, which results in the formation of testosterone and estradiol. Prenatal Pb exposure (resulting in 3 µg/dL blood Pb) was found to decrease basal StAR synthesis, but not gonadotropin-stimulated StAR synthesis, suggesting that Pb may not directly affect ovarian responsiveness to gonadotropin stimulation (Srivastava et al., 2004). Instead, Pb may act at the hypothalamic-pituitary level to alter LH secretion, which is necessary to drive StAR production and subsequent sex hormone synthesis. Release of LH and FSH from the pituitary is controlled by gonadotropin-releasing hormone (GnRH). Pb exposure (10 µM, 90 min) in rat brain median eminence cells can block GnRH release (Bratton et

al., 1994). Pb may also interfere with release of pituitary hormones through interference with cation-dependent secondary messenger systems, which mediate hormone release and storage.

Endocrine disruption may also be a result of altered hormone binding to endocrine receptors. Prenatal and postnatal Pb exposure (20 ppm) to rats was able to decrease the number of estrogen, LH, and FSH receptors found in the uterus or ovaries and receptor binding affinity (Wiebe et al., 1988; Wiebe and Barr, 1988). Altered hormone binding ability may be due to the ion binding properties of Pb, resulting in changes in receptor tertiary structure that will disrupt ligand binding. In addition, Pb-induced changes in hormone levels that act as inducing agents for receptor synthesis may affect the number of hormone receptors produced.

Some of these endocrine disrupting effects of Pb have been related to the generation of ROS. Treatment with antioxidants is able to counteract a number of the endocrine disrupting effects of Pb, including apoptosis and decreased sperm motility and production (Salawu et al., 2009; Shan et al., 2009; Madhavi et al., 2007; Rubio et al., 2006; Wang et al., 2006a; Hsu et al., 1998a). Direct generation of ROS in epididymal spermatozoa was observed after Pb exposure in rats (i.p. 20 or 50 ppm, 6 weeks) (Hsu et al., 1998b). In addition, lipid peroxidation has been observed in Pb-exposed rats (i.p. 0.025 ppm, 15 days) (Pandya et al., In Press). Lipid peroxidation in the seminal plasma was significantly increased in a group of Pb-exposed workers with high blood Pb levels (>40 µg/dL) (Kasperczyk et al., 2008).

The liver is often associated with the HPG axis due in part to its production of insulin-like growth factor 1 (IGF-1). Children with increased blood Pb levels (>4 µg/dL) (Huseman et al., 1992) and Pb-exposed animals (blood Pb level of 14 µg/dL) (Pine et al., 2006; Dearth et al., 2002) and gonadal cells (50 ppm Pb exposure) (Kolesarova et al., 2010) show a decrease in plasma IGF-1, which may be the result of decreased translation or secretion of IGF-1 (Dearth et al., 2002). IGF-1 also induces LH-releasing hormone release, such that IGF-1 decrements may explain decreased LH and estradiol levels. IGF-1 production is stimulated by growth hormone (GH) secreted from the pituitary gland and could be the result of GH depletion.

A number of studies have revealed that Pb exposure affects the dynamics of growth. Decreased growth after Pb exposure could be the result of Pb-induced decreased GH levels (Berry et al., 2002; Camoratto et al., 1993; Huseman et al., 1992; Huseman et al., 1987). This decrease in GH could be a result of decreased release of GH releasing hormone (GHRH) from the hypothalamus or disrupted GHRH binding to its receptor, which has been reported in vitro after Pb treatment (IC_{50} free Pb in solution $5.2x10^{-5}$ µM,

30 minutes) (Lau et al., 1991). GH secretion may also be altered from decreased testosterone, a result of Pb exposure.

5.2.6.2 Hypothalamic-Pituitary-Thyroid Axis

The effects of Pb on the hypothalamic-pituitary-thyroid (HPT) axis are mixed. Pb exposure impacts a variety of players in the thyroid hormone system. A number of human studies (blood Pb levels >7.3 µg/dL) have shown that elevated blood Pb are associated with lower thyroxine (T_4) and free T_4 levels without alteration in triiodothyronine (T_3), suggesting that long-term Pb exposure may depress thyroid function in workers (Dundar et al., 2006; Tuppurainen et al., 1988; Robins et al., 1983). However, animal studies on thyroid hormones have shown mixed results. Pb-exposed cows (blood Pb levels >51 µg/dL) were reported to have an increase in plasma T_3 and T_4 levels (Swarup et al., 2007), whereas mice and chickens manifested decreased serum T_3 concentrations after Pb exposure accompanied by increased lipid peroxidation (Chaurasia et al., 1998; Chaurasia and Kar, 1997). Decreased serum T_3 and increased lipid peroxidation were both restored by vitamin E treatment, suggesting the disruption of thyroid hormone homeostasis could be a result of altered membrane architecture and oxidative stress; however, no data were provided to exclude changes in Pb kinetics as the mechanism of protection (Chaurasia and Kar, 1997).

Decreased T_4 and T_3 may be the result of altered pituitary release of thyroid stimulating hormone (TSH). However, several studies have reported higher TSH levels in high-level Pb-exposed workers (blood Pb levels >39 µg/dL) (Lopez et al., 2000; Singh et al., 2000; Gustafson et al., 1989), which would result in increased T_4 levels. Overall, results on the effects of Pb on the HPT axis are inconclusive.

5.2.7 Cell Death and Genotoxicity

A number of studies have attempted to characterize the genotoxicity of inorganic Pb in human populations, laboratory animals, and cell cultures. Endpoints investigated include DNA damage (single- and double-strand breaks, DNA-adduct formation), mutagenicity, clastogenicity (sister chromatid exchange, micronucleus formation, chromosomal aberrations), and epigenetic changes (changes in gene expression, mitogenesis). It is important to note that numerous studies have utilized exposure to Pb chromate to investigate genotoxicity endpoints; some studies have specifically attributed the observed increases in DNA damage and clastogenicity to the chromate ion while others have not. Due to the uncertainty regarding whether observed genotoxic effects are due to chromate

or Pb in studies using this form of inorganic Pb, only studies utilizing other forms of inorganic Pb (e.g., Pb nitrate, acetate) are discussed below.

5.2.7.1 DNA Damage

A number of studies in human populations have observed associations between Pb exposure and increased DNA damage, as measured as DNA strand breaks. Most of these associations have been observed in occupationally-exposed populations (Grover et al., 2010; Minozzo et al., 2010; Shaik and Jamil, 2009; Danadevi et al., 2003; Hengstler et al., 2003; Palus et al., 2003; Fracasso et al., 2002; de Restrepo et al., 2000). It is important to note that occupationally-exposed adults have very high blood Pb levels, and in one study (de Restrepo et al., 2000) the association between blood Pb level and DNA damage was observed only in workers with blood Pb levels greater than 120 µg/dL. Also, the studies were equivocal in regard to how blood Pb levels correlated with DNA damage: Fracasso et al. (2002) observed that DNA damage increased with increasing blood Pb levels (blood Pb levels, <25, 25-35, and >35 µg/dL), whereas Palus et al. (2003) (mean blood Pb level: 50.4 µg/dL [range: 28.2-65.5 µg/dL]) and Minozzo et al. (2010) (mean [SD]: 59.43 µg/dL [28.34]) observed no correlation. Lastly, Pb-exposed workers are also potentially exposed to other genotoxic materials, making it difficult to rule out confounding co-exposures. However, Hengstler et al. (2003) examined workers exposed to Pb, cadmium, and cobalt and observed that neither blood (mean: 4.4 [IQR: 2.84-13.6] µg/dL) nor air Pb levels (mean: 3.0 [IQR: 1.6-50.0] µg/m^3) were associated with DNA damage when examined alone, but that blood Pb influenced the occurrence of single strand DNA breaks when included in a multiple regression model along with cadmium in air and blood and cobalt in air indicating lack of confounding. Two studies were found that investigated Pb-induced DNA damage resulting from nonoccupational exposures. Mendez-Gomez (2008) observed that children living at close and intermediate distances to a Pb smelter had mean (range) blood Pb levels of 19.5 (11.3-49.2) and 28.6 (11.4-47.5) µg/dL, respectively, compared to blood Pb level of 4.6 (0.1-8.7) µg/dL for children living distant to the smelter. DNA damage was increased in children living nearest to the smelter, compared to the children at the intermediate distance, but was not different from children living farthest away from the smelter. Multivariate analysis (which considered children urinary As levels, highest in children farthest from the smelter), revealed no statistically significant associations between DNA damage and blood Pb level. Further, DNA repair ability was also observed to be unrelated to blood Pb levels. Alternatively, Yanez et al. (2003) observed that children living close to a mining complex (mean [range] blood Pb level: 11.6 [3.0 to 19.5] µg/dL) did have higher levels

of DNA damage compared to control children who lived further away from the mining facility (mean [range] blood Pb level: 8.3 [3.0-25.0] µg/dL).

In mice given 0.7 to 89.6 mg/kg Pb nitrate by gavage for 24, 48, or 72 hours, or 1 or 2 weeks, single strand DNA breaks in white blood cells were observed but did not increase with increasing concentration (Devi et al., 2000). The three highest concentrations had responses which were similar in magnitude and were actually lower than the responses to lower concentrations tested. In mice exposed to Pb (blood Pb level of 0.68 µg/dL) via inhalation for up to 4 weeks, differential levels of DNA damage were observed in different organ systems, with only the lung and the liver demonstrating statistically greater DNA damage compared to the respective organ controls after acute exposure (Valverde et al., 2002). Statistically elevated levels of DNA damage were observed in the kidneys, lungs, liver, brain, nasal cavity, bone marrow, and leukocytes of mice exposed over a period of 4 weeks, although variability was high in all groups. The magnitude of the DNA damage was characterized as weak and did not increase with increasing durations of exposure. Xu et al. (2008) exposed mice to 10-100 mg/kg Pb-acetate via gavage for four weeks and observed a concentration-dependent increase in DNA single strand breaks in white blood cells that was statistically significant at 50 and 100 mg/kg. The authors characterized the observed DNA damage as severe. Pb nitrate induced DNA damage in primary spermatozoa in Pb-exposed rats (blood Pb levels of 19.5 and 21.9 µg/dL) compared to control rats (Nava-Hernandez et al., 2009). The level of DNA damage was not concentration dependent and was comparable in both exposure groups. Narayana and Al-Bader (2011) observed no increase in DNA damage in the livers of rats exposed to 0.5 or 1% Pb nitrate in drinking water for 60 days. Interestingly, although the results were not statistically significant and highly variable within exposure groups, DNA fragmentation appeared to be lower in the exposed animals.

Studies investigating Pb-induced DNA damage in human cell cultures were contradictory. Pb-acetate did not induce DNA strand breaks in human HeLa cells when exposed to 500 µM Pb-acetate for 20-25 hours or 100 µM for 0.5-4 hours (Hartwig et al., 1990; Snyder and Lachmann, 1989). Pb nitrate, administered to lymphoma cells at 1000-10,000 µM for 6 hours, did not result in any DNA-protein crosslinks (Costa et al., 1996). Pb-acetate was observed by Woźniak and Blasiak (2003) to result in DNA single and double strand breaks in primary human lymphocytes exposed to 1-100 µM for 1 hour, although the pattern of damage was peculiar. DNA damage was greater in cells exposed to 1 or 10 µM, compared to those exposed to 100 µM. DNA-protein crosslinks were only observed in the 100 µM exposure group, suggesting that the decreased strand breaks observed in the high exposure group may be a result of increased crosslinking in this group. Pasha Shaik et al. (2006) also observed DNA damage in human lymphocytes exposed to 2,100-3,300 µM Pb nitrate for 2 hours. Although there was a concentration-

dependent increase in DNA damage from 2,100-3,300 µM, no statistics were reported and no unexposed control group was included making it difficult to interpret these results. Gastaldo et al. (2007) observed that exposure of human endothelial cells to 1-1,000 µM Pb nitrate for 24 hours resulted in a concentration-dependent increase in DNA double strand breaks.

Studies in animal cell lines were equally as ambiguous as those using human cell lines. Zelikoff et al. (1988) and Roy and Rossman (1992) reported that Pb-acetate (concentration not stated and 1,000 µM, respectively) did not induce single or double DNA strand breaks or DNA-protein or DNA-DNA crosslinks in CHV79 cells. However, both Xu et al. (2006) and Kermani et al. (2008) reported Pb-acetate-induced DNA damage in PC12 cells exposed to 0.1, 1, or 10 µM for 24 hours and in bone marrow mesenchymal stem cells exposed to 60 µM for 48 hours, respectively. Wedrychowski et al. (1986) reported that DNA-protein crosslinks were induced in a concentration-dependent manner in hepatoma cells exposed to 50-5,000 µM Pb nitrate for 4 hours. Pb-acetate and Pb nitrate increased the incidence of nick translation in CHV79 cells when a bacterial DNA polymerase was added.

Pb-acetate did not induce single strand DNA breaks in HeLa cells exposed to 500 µM for 20-25 hours (Hartwig et al., 1990). However, exposure to both Pb-acetate and UV light resulted in increased persistence of UV-induced strand breaks, compared to exposure to UV light alone. Similar effects were seen in hamster V79 cells: UV-induced mutation rates and SCE frequency was exacerbated by co-incubation with Pb-acetate. Taken together, these data suggest that Pb-acetate interferes with normal DNA repair mechanisms triggered by UV exposure alone. Pb nitrate was observed to affect different DNA double strand break repair pathways in human endothelial cells exposed to 100 µM for 24 hours. Exposure to Pb inhibited nonhomologous end joining repair, but increased two other repair pathways, MRE11-dependent and Rad51-related repair (Gastaldo et al., 2007). Interestingly, in contrast to the above studies, exposure of lung carcinoma cells to 100, 300, or 500 µM Pb-acetate for 24 hours resulted in an increase in nucleotide excision repair efficiency (Li et al., 2008a). Roy and Rossman (1992) observed an increase in UV-induced mutagenicity when CHV79 cells were co-exposed to 400 µM Pb-acetate (a nonmutagenic concentration of Pb-acetate), indicating an inhibition of DNA repair. Treatment of Chinese hamster ovary cells to 0.5-500 µM Pb-acetate resulted in a concentration-dependent accumulation of apurinic/apyrimidinic site incision activity, indicating that DNA repair was diminished (McNeill et al., 2007).

5.2.7.2 Mutagenicity

Only one human study was found that investigated Pb-induced mutagenicity. Van Larebeke et al. (2004) investigated the frequency of mutations in the hypoxanthine phosphoribosyltransferase (HPRT) gene in Flemish women without occupational exposures to Pb or a number of other heavy metals and organic contaminants. Higher blood Pb level (range 1.6-5.2 µg/dL) was associated with greater HPRT mutation frequency in the total population. Also, women with high blood Pb levels (i.e., greater than the population median, not reported) demonstrated a greater mutation frequency compared to women with lower blood Pb levels.

Pb-induced mutagenicity was investigated in four studies using human cell cultures. Ye (1993) exposed human keratinocytes to 0.1-100 µM/mL Pb-acetate for 2-24 hours. This study did not measure HPRT mutations directly, but rather measured the amount of tritium incorporated into DNA as an indicator of mutation. In the presence of 6-thioguanine, tritium incorporation was increased in exposed cells, indicating weak mutagenicity. Hwua and Yang (1998) reported that Pb-acetate was not mutagenic in human foreskin fibroblasts exposed to 500-2,000 µM for 24 hours. Pb-acetate remained nonmutagenic in the presence of 3-aminotriazole, a catalase inhibitor, indicating that oxidative metabolism did not play a part in potential mutagenicity of Pb. Exposure to Pb-acetate alone did not induce mutagenicity in lung carcinoma cells (100-500 µM for 24 hours) or fibroblasts (300-500 µM for 24 hours) (Li et al., 2008a; Wang et al., 2008c). However, pretreatment with PKC inhibitors before Pb treatment did result in statistically significant increases in mutagenicity in both cell lines.

Results from investigations into Pb-induced mutagenicity using animal cell lines were as equivocal as were the findings from human cell line studies, although the mixed findings may be reflective of specific Pb compounds used. Pb-acetate was observed to be nonmutagenic (HPRT assay) in Chinese hamster V79 cells exposed to 1-25 µM of the compound for 24 hours (Hartwig et al., 1990), but elicited a mutagenic response in CHV79 cells (gpt assay) exposed to 1,700 µM for 5 days (Roy and Rossman, 1992). Pb-acetate was observed to be nonmutagenic (HPRT assay) in Chinese hamster ovary cells exposed to 5 µM for 6 hours (McNeill et al., 2007). The observation of mutagenicity in the second study is complicated by the concurrent observation of severe cytotoxicity at the same concentration. Pb nitrate was alternatively found to be nonmutagenic in CHV79 cells (gpt assay) exposed to 0.5-2,000 µM for 5 days (Roy and Rossman, 1992), but mutagenic in the same cell line (HPRT assay) exposed to 50-5,000 µM for 5 days (Zelikoff et al., 1988). However, mutagenicity was only observed at 500 µM, and was higher than that observed at higher concentrations. Pb sulfate was also observed to be mutagenic in CHV79 cells (HPRT assay) exposed to 100-1,000 µM for 24 hours, but as

with Pb nitrate, it was not concentration-dependent (Zelikoff et al., 1988). Pb chloride was the only Pb compound tested in animal cell lines that was consistently mutagenic: three studies from the same laboratory observed concentration-dependent mutagenicity in the gpt assay in Chinese hamster ovary cells exposed to 0.1-1 µM Pb chloride for one hour (Ariza and Williams, 1999; Ariza et al., 1998; Ariza and Williams, 1996).

5.2.7.3 Clastogenicity

Clastogenicity is the ability of a compound to induce chromosomal damage, and is commonly observed as sister chromatid exchange, micronuclei formation, or incidence of chromosomal aberrations (i.e., breaks or gaps in chromosomes). The potential for Pb to be clastogenic has been investigated in numerous studies as described below.

Sister Chromatid Exchange

An association between blood Pb levels (means: 10.48 - 86.9 µg/dL) and sister chromatid exchange (SCE) was observed in a number of occupational studies (Wiwanitkit et al., 2008; Duydu et al., 2005; Palus et al., 2003; Duydu et al., 2001; Pinto et al., 2000; Bilban, 1998; Anwar and Kamal, 1988; Huang et al., 1988). However, there are numerous methodological issues that limit firm conclusions from being drawn. Most notably, occupational co-exposures to other genotoxic materials were possible, although some studies excluded workers with exposures to known mutagens (Pinto et al., 2000; Huang et al., 1988). In most studies that attempted to investigate the concentration-response relationship in workers, no association was observed between increasing blood Pb levels and the number of SCE (Palus et al., 2003; Duydu et al., 2001; Pinto et al., 2000). However, Huang et al. (1988) did observe increased SCE in exposed workers in the two highest blood Pb groups (52.1 and 86.9 µg/dL), with a statistically significant association observed in the 86.9 µg/dL group. Pinto et al. (2000) did report an association with duration of exposure (range of years exposed: 1.6-40). Two studies reported no correlation between occupational exposure to Pb and number of SCE (Rajah and Ahuja, 1996; Rajah and Ahuja, 1995). However, these two studies may have suffered from limited statistical power to observe an effect as they included very small numbers of Pb-exposed workers. Mielzynska et al. (2006) found no association between blood Pb level and SCEs in children in Poland. Children had an average blood Pb level of 7.69 µg/dL and 7.87 SCEs/cell.

Pb exposure has been observed to induce SCEs in multiple laboratory animal studies. In mice exposed to up to 100 mg/kg Pb-acetate i.p., Pb induced SCEs with 50 and 100 mg/kg (Fahmy, 1999). Pb nitrate, also administered i.p. and induced the formation of

SCEs in a concentration-dependent manner (10-40 mg/kg) in the bone marrow of exposed mice (Dhir et al., 1993). Nayak et al. (1989b) exposed pregnant mice to 100-200 mg/kg Pb nitrate via i.v. injection and observed an increase in SCEs in dams at 150 and 200 mg/kg; no SCEs were observed in the fetuses. Tapisso et al. (2009) exposed rats to 21.5 mg/kg Pb-acetate (1/10th the LD_{50}) via i.p. injection on alternating days for 11 or 21 days, for a total of 5 or 10 exposures. Induction of SCEs in the bone marrow of exposed rats was increased over controls in a statistically significant duration-dependent manner. It is important to note that all three of these studies utilized an injection route of exposure that may not be relevant to routes of exposure in the general population (e.g., air, drinking water exposure).

Few studies were found that investigated SCE formation in human cell lines due to Pb exposure. Statistically significant, concentration-dependent increases in SCEs were observed in human lymphocytes obtained from a single donor when incubated with 1, 5, 10, or 50 µM Pb nitrate (Ustundag and Duydu, 2007). Melatonin and N-acetylcysteine were reported to ameliorate these effects, indicating Pb may induce SCEs through increased oxidative stress. Pb chloride was also observed to increase SCE levels in human lymphocytes exposed to 3 or 5 ppm (Turkez et al., In Press).

Studies investigating SCE in rodent cells were more equivocal than those in human cells. Pb sulfate, acetate, and nitrate were found not to induce SCE in Chinese hamster V79 cells (Hartwig et al., 1990; Zelikoff et al., 1988). Both of these studies only examined 25-30 cells per concentration, reducing their power to detect Pb-induced SCEs. Cai and Arenaz (1998), on the other hand, used 100 cells per treatment and observed that exposure to 0.05-1 µM Pb nitrate for 3-12 hours resulted in a weak, concentration-dependent increase in SCEs in Chinese hamster ovary cells. Lin et al. (1994) also observed a concentration-dependent increase in SCEs in Chinese hamster cells exposed to 3-30 µM Pb nitrate for 2 hours.

Micronucleus Formation

Pb-induced micronucleus formation was observed in numerous occupational studies (Grover et al., 2010; Khan et al., 2010b; Minozzo et al., 2010; Shaik and Jamil, 2009; Minozzo et al., 2004; Palus et al., 2003; Vaglenov et al., 2001; Pinto et al., 2000; Bilban, 1998; Vaglenov et al., 1998). The workers in the occupational studies generally had high blood Pb levels (>20 µg/dL) making comparisons to the general population difficult, although Pinto et al. (2000) observed increased micronuclei in exposed workers with an average blood Pb level of 10.48 µg/dL compared with unexposed controls. In studies investigating the correlation between blood Pb levels and micronucleus formation, no association was observed (Minozzo et al., 2010; Minozzo et al., 2004; Palus et al., 2003;

Pinto et al., 2000), although Pinto et al. (2000), Grover et al. (2010), and Minozzo et al. (2010) did report an association between micronuclei formation and duration of exposure. Only one study was found that investigated micronucleus formation in a nonworker population; Mielzynska et al. (2006) reported a statistically significant positive correlation between blood Pb levels and micronuclei frequency in children in Poland. Children, with an average blood Pb level of 7.69 µg/dL, were observed to have 4.44 micronucleated cells per 1,000 cells analyzed. Children with blood Pb levels greater than 10 µg/dL had significantly more micronucleated cells than did children with blood Pb levels less than 10 µg/dL.

Micronucleus formation in response to Pb exposure has been observed in rodent animal studies. Celik et al. (2005) observed that exposure of female rats to 140, 250, or 500 g/kg Pb-acetate once per week for 10 weeks resulted in statistically significantly increased numbers of micronucleated polychromatic erythrocytes (PCEs) compared to controls. Similarly, Alghazal et al. (2008b) exposed rats to 100 ppm Pb-acetate daily for 125 days and observed statistically significant increases in micronucleated PCEs in both sexes. Tapisso et al. (2009) exposed rats to 21.5 mg/kg Pb-acetate (1/10th the LD_{50}) via i.p. injection on alternating days for 11 or 21 days, for a total of 5 or 10 exposures. Formation of micronuclei in the bone marrow of exposed rats was increased over that in controls in a significant duration-dependent manner. Two further studies investigated formation of micronuclei in the bone marrow of exposed mice: Roy et al. (1992) exposed mice to 10 or 20 mg/kg Pb nitrate i.p. and observed a concentration-dependent increase in micronuclei, whereas Jagetia and Aruna (1998) observed an increase in micronuclei in mice exposed to 0.625-80 mg/kg Pb nitrate i.p., though the increase was not concentration-dependent. Mice exposed to 1 g/L Pb-acetate via drinking water, a more environmentally relevant route of exposure, for 90 days had statistically significant increases in micronucleated PCEs (Marques et al., 2006).

A few studies were found that reported increased micronucleus formation in human cell lines treated with Pb. Concentration-dependent micronucleus formation was observed in human lymphocytes when exposed to either 1, 5, 10, or 50 µM Pb nitrate or 3 or 5 ppm Pb chloride (Ustundag and Duydu, 2007; Turkez et al., In Press). Gastaldo et al. (2007) also observed a dose-dependent increase in micronuclei in human endothelial cells exposed to 1-1,000 µM Pb nitrate for 24 hours. Two animal cell culture studies investigating micronuclei formation produced contrasting results. One study observed that micronuclei were not induced in Chinese hamster cells exposed to 3-30 µM Pb nitrate for 2 hours (Lin et al., 1994), whereas the other observed that Pb-acetate induced a concentration-dependent increase in Chinese hamster cells when administered at 0.03-10 µM for 18 hours (Bonacker et al., 2005).

Chromosomal Aberrations

Chromosomal aberrations (e.g., chromosome breaks, nucleoplasmic bridges, di- and a-centric chromosomes, and rings) were examined in a number of occupational studies (Grover et al., 2010; Shaik and Jamil, 2009; Pinto et al., 2000; Bilban, 1998; De et al., 1995; Huang et al., 1988). Methodological limitations outlined in previous sections, including potential for occupational co-exposure to genotoxic substances and generally high blood Pb levels (>20 µg/dL) that limit the relevance of findings to the general population, also pertain to the present findings. No correlation was observed between increasing blood Pb level and the number of chromosomal aberrations, although an association was observed between duration of exposure and chromosomal damage (Grover et al., 2010; Pinto et al., 2000). Other studies reported no association between occupational exposure to Pb and chromosomal aberrations (Anwar and Kamal, 1988; Andreae, 1983). Smejkalova (1990) observed greater chromosomal damage and aberrations in children living in a heavily Pb-contaminated area of Czechoslovakia compared with children living in an area with less contamination, although the difference between the two areas was not statistically significant. Although blood Pb levels were statistically significantly higher in children living in the Pb-contaminated area than in children living in the less contaminated area, they were generally comparable (low 30s versus high 20s µg/dL, respectively), indicating there may not be enough of a dose contrast to detect a significant difference in aberration rates.

The majority of animal studies investigating Pb-induced genotoxicity focused on the capacity of Pb to produce chromosomal damage. Fahmy (1999) exposed mice to 25-400 mg/kg Pb-acetate i.p., either as a single exposure or repeatedly for 3, 5, or 7 days. Chromosomal damage was observed to increase in bone marrow cells (100-400 mg/kg) and spermatocytes (50-400 mg/kg) in a concentration-dependent manner after both exposure regimens. Pb nitrate was also observed to produce concentration-dependent chromosomal damage in mice exposed i.p. to a single exposure of 5, 10, or 20 mg/kg (Dhir et al., 1992b). In a similar experiment, Dhir et al. (1990) exposed mice to 10, 20, or 40 mg/kg Pb nitrate and saw an increase in chromosomal aberrations, although there was no concentration-dependent response as the response was similar in all concentrations tested. Nayak et al. (1989b) exposed pregnant mice to 100-200 mg/kg Pb nitrate via i.v. injection and observed no chromosomal gaps or breaks in dams or fetuses, but did report some karyotypic chromosomal damage and weak aneuploidy at the low exposure. In a similar experiment, low levels of chromosomal aberrations were observed in dams and fetuses injected with 12.5-75 mg/kg Pb nitrate, but there was no concentration-dependent response reported and few cells were analyzed (Nayak et al., 1989a). In rats given 2.5 mg/100 g Pb-acetate i.p. daily for 5-15 days or 10-20 mg/100 g once and analyzed after 15 days, Pb-induced chromosomal aberrations were observed (Chakraborty et al.,

1987). The above studies all suffer from the use of a route of exposure that may not be relevant to human environmental exposures. However, studies utilizing drinking water or dietary exposures also observed increases in chromosomal damage. Aboul-Ela (2002) exposed mice to 200 or 400 mg/kg Pb-acetate by gavage for 5 days and reported that chromosomal damage was present in the bone marrow cells and spermatocytes of animals exposed to both exposure concentrations. Dhir et al. (1992a) also observed a concentration-dependent increase in chromosomal damage in mice exposed via gavage, albeit at much lower concentrations: either 5 or 10 mg/kg. Nehez et al. (2000) observed a Pb-induced increase in aneuploidy and percent of cells with damage after exposure to 10 mg/kg administered by gavage 5 days a week for 4 weeks. In the only study that investigated dietary exposure, El-Ashmawy et al. (2006) exposed mice to 0.5% Pb-acetate in feed, and observed an increase in abnormal cells and frequency of chromosomal damage.

In the few studies that investigated the capacity of Pb to induce chromosomal damage in human cell lines, Pb exposure did not induce chromosomal damage. Wise et al. (2005; 2004) observed that Pb glutamate was not mutagenic in human lung cells exposed to 250-2,000 µM for 24 hours. Pasha Shaik et al. (2006) observed that Pb nitrate did not increase chromosomal aberrations in primary lymphocytes (obtained from healthy volunteers) when incubated with 1,200 or 2,000 µM for 2 hours. Studies utilizing animal cell lines generally supported the finding of no Pb-induced chromosomal damage in human cell lines. Pb nitrate was found to induce no chromosomal damage in Chinese hamster ovary cells exposed to 500-2,000 µM for 24 hours (Wise et al., 1994), 3-30 µM for 2 hours (Lin et al., 1994), or 0.05-1 µM for 3-12 hours (Cai and Arenaz, 1998). Wise et al. (1994) did observe increased chromosomal damage in Chinese hamster ovary cells exposed to 1,000 µM Pb glutamate for 24 hours, but did not see any damage in cells exposed to higher concentrations (up to 2,000 µM).

5.2.7.4 Epigenetic Effects

Epigenetic effects are heritable changes in gene expression resulting without changes in the underlying DNA sequence. A prime example of an epigenetic effect is the abnormal methylation of DNA, which could lead to altered gene expression and cell proliferation and differentiation.

DNA Methylation

A single i.v. injection of 75 µmol/kg Pb nitrate resulted in global hypomethylation of hepatic DNA in rats (Kanduc et al., 1991). The observed hypomethylation in the liver

was associated with an increase in cell proliferation. A few additional studies in humans observed that higher bone Pb levels were associated with lower DNA methylation patterns in adults and cord blood of newborns (Wright et al., 2010; Pilsner et al., 2009). Changes in DNA methylation patterns could potentially lead to dysregulation of gene expression and altered tissue differentiation.

Mitogenesis

Conflicting results have been reported regarding Pb-induced effects on mitogenesis, with both increased and decreased cell growth and mitogenesis. A discernable pattern of effects is difficult to detect when analyzing effects across human, in vivo animal, and in vitro studies. Only a few studies have investigated the potential epigenetic effects of Pb exposure in human populations indirectly by examining mitogenesis or the induction of cell proliferation, which can be a consequence of epigenetic changes. These studies (Minozzo et al., 2010; Minozzo et al., 2004; Rajah and Ahuja, 1995) reported that Pb reduced mitogenesis in Pb-exposed workers (mean blood Pb levels: 35.4 µg/dL, 59.4 µg/dL, and not reported, respectively). The observation of decreased cell division in exposed workers may indicate that cells suffered DNA damage and died during division, or that division was delayed to allow for DNA repair to occur. It is also possible that Pb exerts an aneugenic effect and arrests the cell cycle.

Many studies have investigated the ability of Pb to induce mitogenesis in animal models, and have consistently shown that Pb nitrate can stimulate DNA synthesis and cell proliferation in the liver of animals exposed to 100 µM/kg via i.v. injection (Nakajima et al., 1995; Coni et al., 1992; Ledda-Columbano et al., 1992; Columbano et al., 1990; Columbano et al., 1987). Shinozuka et al. (1996) observed that Pb-induced hepatocellular proliferation was similar in magnitude to that induced by TNF-α at 100 µM/kg, and Pb was observed to induce TNF-α in glial and nerve cells and NF-κB, TNF-α, and iNOS in liver cells in exposed animals at 12.5 mg/kg and 100 µM/kg, respectively (Cheng et al., 2002; Menegazzi et al., 1997). In the only study that examined Pb exposure via inhalation, exposure to 10,000 µM Pb-acetate for 4 weeks resulted in increased cellular proliferation in the lungs (Fortoul et al., 2005).

A great amount of research has been conducted investigating the potential effects of Pb on mitogenesis in human and animal cell cultures. In human cell cultures, Pb-acetate inhibited cell growth in hepatoma cells (0.1-100 µM for 2-6 days) (Heiman and Tonner, 1995) and primary oligodendrocyte progenitor cells (1 µM for 24 hours) (Deng and Poretz, 2002) but had no observable effects on growth in glioma cells (0.01-10 µM for 12-72 hours) (Liu et al., 2000). Pb glutamate had no effect on cell growth in human lung cells, but did increase the mitotic index (250-1,000 µM for 24 hours) (Wise et al., 2005).

The increase in the mitotic index was attributed to an arrest of the cell cycle at M-phase, and was not attributed to an actual increase of cell growth and proliferation. Gastaldo et al. (2007) also reported S and G2 cell cycle arrests in human endothelial cells following exposure to 100 µM Pb nitrate for 24 hours. Conflicting results with regard to DNA synthesis were reported, with a concentration-dependent inhibition of DNA synthesis reported in hepatoma cells (1-100 µM for 72 hours) (Heiman and Tonner, 1995), but an induction of synthesis observed in astrocytoma cells (1-50 µM for 24 hours) (Lu et al., 2002).

In rat fibroblasts and epithelial cells, Pb-acetate, chloride, oxide, and sulfate were all observed to inhibit cell growth (10-1,000 µM for 1-7 days and 0.078-320 µM for 48 hours, respectively) (Iavicoli et al., 2001; Apostoli et al., 2000). Iavicoli et al. (2001) observed that in addition to inhibiting cell growth in rat fibroblasts, Pb-acetate caused GS/M and S-phase arrest. Pb-acetate decreased cell proliferation in mouse mesenchymal stem cells when administered at 20-100 µM for 48 hours (Kermani et al., 2008). Pb nitrate was alternatively reported to increase (Lin et al., 1994) and decrease (Cai and Arenaz, 1998) the mitotic index in Chinese hamster ovary cells exposed to 1 µM Pb nitrate. Lin et al. (1994) did not consider cell cycle arrest when measuring the mitotic index and did not observe a decrease at higher concentrations; in fact, the highest concentration tested, 30 µM, had a mitotic index equal to that in the untreated control cells.

5.2.7.5 Gene Expression

Two animal studies have investigated the ability of Pb to alter gene expression in regard to phase I and II metabolizing enzymes. Suzuki et al. (1996) exposed rats to 100 µg/kg Pb-acetate or nitrate via i.p. injection and observed an induction of GST-P with both Pb compounds. The induction of GST-P by Pb was observed to occur on the transcriptional level and to be dependent on the direct activation of the cis-element GPEI enhancer. Degawa et al. (1993) reported that i.v. exposure to 20, 50, or 100 µmol/kg Pb nitrate selectively inhibited CYP1A2 levels. Pb was shown not to inhibit CYP1A2 by direct enzyme inhibition, but rather to decrease the amount of CYP1A2 mRNA. In contrast, Korashy and El Kadi (2004) observed that exposure of murine hepatoma cells to 10-100 µM Pb nitrate for 24 hours increased the amount of CYP1A1 mRNA while not influencing the activity of the enzyme. NAD(P)H:quinone oxidoreductase and GST Ya activities and mRNA levels were increased after exposure to Pb. Incubation of primary human bronchial epithelial cells with 500 µg/L Pb-acetate for 72 hours resulted in the up-regulation of multiple genes associated with cytochrome P450 activity, glutathione

metabolism, the pentose phosphate pathway, and amino acid metabolism (Glahn et al., 2008).

Additional animal studies provide further evidence that exposure to Pb compounds can perturb gene expression. Zawia and Harry (1995) investigated whether the observed Pb-induced disruption of myelin formation in rat pups exposed postnatally was due to altered gene expression. In pups exposed to 0.2% Pb-acetate via lactation from postnatal day (PND)1-20, the expression of proteolipid protein, a major structural constituent of myelin, was statistically significantly elevated at PND20, compared to controls. The expression of another structural element of myelin, myelin basic protein, was similarly elevated in exposed animals, although not significantly so. The expression of both genes returned to control levels 5 days following the termination of exposure. These data suggest that altered gene expression in structural myelin proteins due to Pb exposure may be responsible for observed alterations in abnormal conduction of nerve impulses. Long et al. (2011) investigated the Pb-induced induction of ABCC5, an ATP-binding cassette transporter, in embryonic and adult zebrafish. In the initial in vitro portion of the study, exposure of zebrafish fibroblasts to 20 µM Pb nitrate for 24 hours significantly increased the induction of ABBC5 mRNA 2.68-fold over controls. Similar levels of induction were observed when embryonic zebrafish were exposed to 5 µM 24 to 96 hours; specifically, induction of ABCC5 was seen in the livers of developing embryos. In adult fish, induction of ABCC5 was observed in the brains, intestines, and kidneys of exposed fish, but decreased in their livers. Induction of ABCC5 was observed to attenuate the toxicity of Cd, but not Hg or As, in developing embryos, the attenuation of Pb-induced toxicity was not investigated. However, these findings indicate that increased expression of ABCC5 due to heavy metal exposure may play a part in cellular defense mechanisms.

5.2.7.6 Apoptosis

Occupational exposure to Pb and induction of apoptosis was investigated in a few studies. One study directly reported that exposure to Pb increased apoptosis compared to nonexposed controls (Minozzo et al., 2010), whereas the others reported that two early indicators of apoptosis, karyorrhexis and karyolysis, were elevated in exposed workers (Grover et al., 2010; Khan et al., 2010b). Pb nitrate was also observed to induce apoptosis in the liver of exposed animals (Columbano et al., 1996; Nakajima et al., 1995). Apoptosis was observed in rat fibroblasts exposed to Pb-acetate and rat alveolar macrophages exposed to Pb nitrate (Iavicoli et al., 2001; Shabani and Rabbani, 2000). Observation of Pb-induced apoptosis may represent the dysregulation of genetically-controlled cell processes and tissue homeostasis.

5.2.8 Summary

The diverse health effects of Pb are mediated through multiple, interconnected modes of action. Each of the modes of action discussed has the potential to contribute to the development of a number of Pb-induced health effects (Table 5-2). While this section draws from older literature as well as newer lines of evidence, the inclusion of new evidence does not qualitatively change the conclusions regarding individual modes of action. However, the new evidence strengthens the conclusions. Evidence for the majority of these modes of action is observed at low blood Pb levels in humans, between 2 and 17 µg/dL, with supporting evidence from in vitro assays. As many of these studies are examining adults with likely higher past than current Pb exposures, uncertainty exists as to the Pb exposure level, duration, and timing leading to these blood Pb levels associated with these modes of action. These observable effect levels are reflective of the data and methods available and do not imply that these modes of action are not acting at lower Pb exposure or blood Pb levels or that these concentrations represent the threshold of the effect. The observable effect levels in humans, reported in Table 5-2, are drawn from the available data; and, do not imply that theses modes of action are not acting at lower exposure levels or that these doses represent the threshold of the effect. Also, the data presented in this table does not inform regarding the exposure frequency and duration required to elicit a particular MOA.

Table 5-2 MOAs, their related health effects, and information on concentrations eliciting the MOAs

Mode of Action [Related Health Effects (ISA section)]	Concentrations or doses (Conditions)[a]	
	Blood Pb	Dose
Altered Ion Status [All Health Effects of Pb]	3.5 µg/dL (mean in cord blood; association with cord blood Ca^{2+}-ATPase pump activity) Huel et al. (2008)	0.00005 µM free Pb^{2+} (In vitro; 30 minutes; calmodulin activation assay) Kern et al. (2000)
Protein Binding [Renal (5.5), Heme Synthesis and RBC Function (5.7)]	17.0 µg/dL (concurrent mean in adult workers with wildtype metallothionein expression; increased BP susceptibility) Chen et al. (2010a)	50 µM Pb glutamate (In vitro; 24 hours; increased nuclear protein in neurological cell) Klann and Shelton (1989)
Oxidative Stress [All Heath Effects of Pb]	5.4 µg/dL (concurrent mean in adult male workers; decreased CAT activity in blood) Conterato et al. (In Press)	0.1 µM Pb-acetate (In vitro; 48 hours; decreased cellular GSH in neuroblastoma cells) Chetty et al. (2005)
Inflammation [Nervous System (5.3), Cardiovascular (5.4), Renal (5.5), Immune (5.6), Respiratory (5.6.4), Hepatic (5.9.1)]	2.5 µg/dL (concurrent minimum in adult males; increased serum TNF-α and blood WBC count) Kim et al. (2007)	0.01 µM Pb-acetate (In vitro; 48 hours; increased cellular PGE_2 in neuroblastoma cells) Chetty et al. (2005)
Endocrine Disruption [Reproductive and Developmental Effects (5.8), Endocrine System 5.9.3), Bone and Teeth (5.9.4)]	1.7 µg/dL (concurrent minimum in women with both ovaries removed; increased serum FSH) Krieg (2007)	10 µM Pb nitrate (In vitro; 30 minutes; displaced GHRH binding to rat pituitary receptors) Lau et al. (1991)
Cell Death/Genotoxicity [Cancer (5.10), Reproductive and Developmental Effects (5.8), Bone and Teeth (5.9.4)]	3.3 µg/dL (concurrent median in adult women; increased rate of HPRT mutation frequency) Van Larebeke et al. (2004)	0.03 µM Pb-acetate (In vitro; 18 hours; increased formation of micronuclei) Bonacker et al. (2005)

[a]This table provides examples of studies that report effects with low doses or concentration; they are not the full body of evidence used to characterize the weight of the evidence. In addition, the levels cited are reflective of the data and methods available and do not imply that these modes of action are not acting at lower Pb exposure or blood Pb levels or that these doses represent the threshold of the effect. Additionally, the blood concentrations and doses (indicating Pb exposure concentrations from in vitro systems) refer to the concentrations and doses at which these modes of action were observed. While the individual modes of action are related back to specific health effects sections (e.g., Nervous System, Cardiovascular), the concentrations and doses given should not be interpreted as levels at which those specific health effects occur.

The alteration of cellular ion status (including disruption of Ca^{2+} homeostasis, altered ion transport mechanisms, and perturbed protein function through displacement of metal cofactors) appears to be the major unifying mode of action underlying all subsequent modes of action (Figure 5-1). Pb will interfere with endogenous Ca^{2+} homeostasis, necessary as a cell signal carrier mediating normal cellular functions. $[Ca^{2+}]_i$ has been shown to increase after Pb exposure in a number of cell types including bone, erythrocytes, brain cells, and white blood cells, due to the increased flux of extracellular Ca^{2+} into the cell. This disruption of ion transport is due in part to the alteration of the activity of transport channels and proteins, such as Na^+-K^+ ATPase and voltage-sensitive Ca^{2+} channels. Pb can interfere with these proteins through direct competition between Pb and the native metals present in the protein metal binding domain or through disruption of proteins important in Ca^{2+}-dependent cell signaling, such as PKC or calmodulin.

Disruption of ion transport not only leads to altered Ca^{2+} homeostasis, it can also result in perturbed neurotransmitter function. Pb has been shown to be able to displace metal ions, such as Zn, Mg, and Ca^{2+}, from proteins due to the flexible coordination number of Pb and multiple ligand binding ability, leading to abnormal conformational changes to proteins and altered protein function. Evidence for this metal ion displacement and protein perturbation has been shown at picomolar concentrations of Pb. Additional effects of altered cellular ion status are the inhibition of heme synthesis and decreased cellular energy production due to perturbation of mitochondrial function.

Although Pb will bind to proteins within cells through interactions with side group moieties, thus potentially disrupting cellular function, protein binding of Pb may represent a mechanism by which cells protect themselves against the toxic effects of Pb. Intranuclear and intracytosolic inclusion body formation has been observed in the kidney, liver, lung, and brain following Pb exposure. A number of unique Pb binding proteins have been detected, constituting the observed inclusion bodies. The major Pb binding protein in blood is ALAD with carriers of the ALAD-2 allele potentially exhibiting higher Pb binding affinity. Additionally, metallothionein is an important protein in the formation of inclusion bodies and mitigation of the toxic effects of Pb.

A second major mode of action of Pb is the development of oxidative stress, due in many instances to the antagonism of normal metal ion functions. The origin of oxidative stress produced after Pb exposure is likely a multipathway process, resulting from oxidation of δ-ALA, NAD(P)H oxidase activation, membrane and lipid peroxidation, and antioxidant enzyme depletion. Through the inhibition of δ-ALAD due to displacement of Zn, accumulated δ-ALA goes through an auto-oxidation process to produce ROS. Additionally, Pb can induce the production of ROS through the activation of NAD(P)H oxidase. Pb-induced ROS can interact with membrane lipids to cause a membrane and lipid peroxidation cascade. Enhanced lipid peroxidation can also result from Pb potentiation of Fe^{2+} initiated lipid peroxidation and alteration of membrane composition after Pb exposure. Increased Pb-induced ROS will also sequester and inactivate biologically active ·NO, leading to the increased production of the toxic product nitrotyrosine, increased compensatory NOS, and decreased sGC protein. Pb-induced oxidative stress not only results from increased ROS production but also through the alteration and reduction in activity of the antioxidant defense enzymes. The biological actions of a number of these enzymes are antagonized due to the displacement of the protein functional metal ions by Pb.

In a number of organ systems Pb-induced oxidative stress is accompanied by misregulated inflammation. Pb exposure will modulate inflammatory cell function, production of pro-inflammatory cytokines and metabolites, inflammatory chemical

messengers, and pro-inflammatory signaling cascades. Cytokine production is skewed toward the production of pro-inflammatory cytokines like TNF-α and IL-6 as well as toward the promotion of a Th2 response and suppression of a Th1 response accompanied by decreased production of related cytokines.

Evidence indicates that Pb is a potent endocrine disrupting chemical. Pb will disrupt the HPG axis evidenced by a decrease in serum hormone levels, such as FSH, LH, testosterone, and estradiol. Pb interacts with the hypothalamic-pituitary level hormone control causing a decrease in pituitary hormones, altered growth dynamics, inhibition of LH secretion, and reduction in StAR protein. Pb has also been shown to alter hormone receptor binding likely due to interference of metal cations in secondary messenger systems and receptor ligand binding and through generation of ROS. Pb also may disrupt the HPT axis by alteration of a number of thyroid hormones, possibly due to oxidative stress. However, the results of these studies investigating HPT are mixed and require further investigation.

The association of Pb with increased genotoxicity and cell death has been investigated in humans, animals, and cell models. Occupational Pb exposure in humans has been associated with increased DNA damage, however lower blood Pb and exposure levels have been associated with these effects in experimental animals and cells. Results vary on the effect of Pb on DNA repair activity, however a number of studies reported decreased repair processes following Pb exposure. There is evidence of mutagenesis and clastogenicity in highly-exposed humans, however weak evidence has been shown in animals and cell based systems. Human occupational studies provide limited evidence for micronucleus formation (blood Pb levels >10 µg/dL), supported by Pb-induced effects in both animal and cell studies at higher exposure levels. Animal studies have also provided evidence for Pb-induced chromosomal aberrations. The observed increases in clastogenicity may be the result of increased oxidative damage to DNA due to Pb exposure, as co-exposures with antioxidants ameliorate the observed toxicities. Limited evidence of epigenetic effects is available, including DNA methylation, mitogenesis, and gene expression. Pb may alter gene expression by displacing Zn from multiple transcriptional factors, thus perturbing their normal cellular activities. Consistently positive results have provided evidence of increased apoptosis following Pb exposure.

Similar to Pb, other polyvalent metal ions (e.g., Cd, Cr, Be, Ba, Se, Sr, As, Al, Cu) have demonstrated molecular mimicry and displacement of biological cation (Garza et al., 2006). In this manner, these metal ions share with Pb a common central mode of action of disruption of ion status. Specifically, these metals have been shown to disrupt cellular processes as diverse as Ca^{2+} homeostasis, cell signaling, neurotransmitter release, cation membrane channel function, protein-DNA binding, and cellular membrane structure

(Pentyala et al., 2010; Huang et al., 2004; Atchison, 2003; Jehan and Motlag, 1995; Richardt et al., 1986; Cooper and Manalis, 1984; Habermann et al., 1983). Additionally, presumably through their shared central mode of action, some of these metal ions also display corresponding downstream modes of actions such as oxidative stress, apoptosis, and genotoxicity (Jomova and Valko, 2011; Jomova et al., 2011; Matović et al., 2011; Agarwal et al., 2009; Méndez-Gómez et al., 2008; Rana, 2008; Hengstler et al., 2003).

Overall, Pb-induced health effects can occur through a number of interconnected modes of action that generally originate with the alteration of ion status.

5.3 Nervous System Effects

5.3.1 Introduction

The 2006 Pb AQCD concluded that the "overall weight of the available evidence provides clear substantiation of neurocognitive decrements being associated in young children with blood-Pb concentrations…" (U.S. EPA, 2006b). This conclusion was based on evidence from several prospective and cross-sectional studies conducted in diverse populations and after adjusting for potential confounding by socioeconomic status (SES), parental intelligence, and caregiving environment. This association was substantiated in a pooled analysis of children, 5 to 10 years of age, participating in seven prospective studies (Boston, MA; Cincinnati, OH; Rochester, NY; Cleveland, OH; Mexico City, Mexico; Port Pirie, Australia; and Kosovo, Yugoslavia) (Lanphear et al., 2005). Associations between blood Pb levels and decrements in intelligence quotient (IQ), mental development, memory, and other specific indices of cognitive function in children ages 6 months to 17 years were most strongly indicated in children with population mean blood Pb levels (measured at various lifestages) in the range of 5-10 µg/dL; however, several results indicated associations in groups of children (ages 2-10 years) with mean blood Pb levels in the range of 3-5 µg/dL (Bellinger, 2008; Canfield, 2008; Hornung, 2008; Rojo-Tellez, 2008). Based on fewer available studies, the 2006 Pb AQCD described consistent associations of blood Pb levels with behavioral outcomes, including inattention, and antisocial and delinquent behavior assessed in children ages 6 to 13 years (U.S. EPA, 2006b).

Toxicological studies provided coherence with similarly consistent findings for Pb-induced impairments in learning and behavior in rodents and monkeys (U.S. EPA, 2006b). In contrast with studies in children, Pb exposure was not found consistently to affect memory of animals. Effects on learning were largely demonstrated as poorer performance on Morris water maze and discrimination reversal tasks, and effects on

behavior were largely demonstrated as distractibility, impulsivity, and insensitivity to changes in reinforcement. These effects in animals were predominantly found with Pb exposures that resulted in blood Pb levels between 20-50 µg/dL; however, some studies observed learning and behavioral impairments in animals with steady-state blood Pb levels of 10-15 µg/dL (Cory-Slechta, 1994; Altmann et al., 1993; Rice and Karpinski, 1988; Gilbert and Rice, 1987). Toxicological studies also provided biological plausibility by characterizing modes of action for Pb-induced nervous system effects. In particular, toxicological evidence for Pb exposure interfering with neuronal metabolism at the cellular and histological level (e.g., synaptic architecture during development, neurotransmitter release, glia, neurite outgrowth, the blood brain barrier, and oxidative stress), provided biological plausibility for blood Pb levels in children being causally associated with deficits in multiple functional domains such as cognitive function, motor function, memory, mood, and behavior. Additional biological plausibility was provided by associations observed of childhood blood Pb levels with changes indicative of neuronal damage and altered brain physiology assessed in young adults using magnetic resonance imaging techniques (Yuan et al., 2006; Cecil et al., 2005; Meng et al., 2005; Trope et al., 2001).

A common finding across several epidemiologic studies of children was a supralinear concentration-response relationship between blood Pb level and neurocognitive deficits, i.e., a larger decrement in neurocognitive function per unit increase in blood Pb levels in children in the lower range of the population blood Pb level distribution (Kordas et al., 2006; Schnaas et al., 2006; Tellez-Rojo et al., 2006; Lanphear et al., 2005; Rothenberg and Rothenberg, 2005; Bellinger and Needleman, 2003; Canfield et al., 2003a). Most of these epidemiologic results were based on the analysis of concurrent blood Pb levels and a cut-point of 10 µg/dL to define lower and higher blood Pb levels. These findings were corroborated by findings from analyses of the pooled cohort data indicating that a nonlinear relationship fit the data better than a linear relationship did (Lanphear et al., 2005; Rothenberg and Rothenberg, 2005). Consistent with epidemiologic findings, toxicological studies observed nonlinear Pb concentration-response relationships for outcomes such as neuronal activation (Lewis and Pitts, 2004), neurogenesis (Gilbert et al., 2005), and retinal responses (Fox et al., 1991; Fox and Farber, 1988; Fox and Chu, 1988).

Another area of focus included the comparison of various lifestages of Pb exposure in terms of risk of neurodevelopmental deficits. Toxicological studies clearly demonstrated that in utero with or without early postnatal exposure to Pb was an especially sensitive window for Pb-induced neurodevelopmental effects. Nonetheless, not all endpoints in animal toxicology studies had a single defined window of sensitivity but instead were shown to be affected by exposures at multiple periods during the lifespan of the

organism. Epidemiologic studies observed cognitive deficits in children ranging from 2 to 10 years of age in association with prenatal, peak childhood, cumulative childhood, and concurrent blood Pb levels. Although examined in few studies, tooth or bone Pb levels were associated with cognitive and behavioral deficits in children and adolescents (Wasserman et al., 2003; Greene and Ernhart, 1993; Bellinger et al., 1991; Needleman et al., 1979), also pointing to an effect of cumulative childhood Pb exposure. Among studies of children (ages 2-10 years) that examined blood Pb levels measured at multiple lifestages, several found that concurrent blood Pb was associated with an equal or larger decrement in IQ (Chen et al., 2005; Lanphear et al., 2005; Wasserman et al., 1994; Dietrich et al., 1993b; Bellinger et al., 1992). A common limitation of epidemiologic studies of children was the high correlation among blood Pb levels at different ages, making it difficult to ascertain which developmental periods of Pb exposure were associated with the greatest risk of neurodevelopmental decrements (Lanphear et al., 2005). The issue of persistence of the neurodevelopmental effects of Pb exposure also was considered, with some evidence suggesting that the associations of biomarkers of early childhood Pb exposure (e.g., deciduous tooth, blood at age 2 or 6 years) with neurodevelopmental outcomes persisted into adolescence and young adulthood (Ris et al., 2004; Tong et al., 1996; Needleman et al., 1990). Some studies in rats and monkeys also demonstrated that the effects of in utero and early postnatal Pb exposures on neurodevelopmental outcomes persisted into adulthood (Cory-Slechta, 1994; Altmann et al., 1993; Rice and Karpinski, 1988; Gilbert and Rice, 1987).

In epidemiologic studies of adults, a range of nervous system effects (e.g., impaired memory, attention, reaction time, visuomotor tasks and reasoning, alterations in visual or brainstem evoked potentials, postural sway) were mostly clearly indicated in Pb-exposed workers with blood Pb levels in the range of 14 to 40 μg/dL (Iwata et al., 2005; Bleecker et al., 1997; Baker et al., 1979; Cantarow and Trumper, 1944). In the limited literature examining nonoccupationally-exposed adults, the weight of evidence supported associations of bone Pb levels with cognitive function (Weisskopf et al., 2004; Wright et al., 2003b) but not concurrent blood Pb levels (Krieg et al., 2005; Nordberg et al., 2000; Payton et al., 1998; Muldoon et al., 1996). These findings suggested that rather than recent exposures, past or cumulative Pb exposures contributed to cognitive deficits in nonoccupationally-exposed adults. With regards to neurodegenerative diseases, whereas a few toxicological studies demonstrated Pb-induced amyloid plaques commonly associated with Alzheimer's disease pathophysiology (Basha et al., 2005; Zawia and Basha, 2005), epidemiologic studies did not indicate that Pb exposure was associated with Alzheimer's Disease in adults. Pb biomarker (blood or bone) levels were inconsistently associated with amyotrophic lateral sclerosis (ALS) in adults in the general population; however, some case-control studies found that history of occupational Pb exposure was more prevalent among ALS cases than controls (Kamel et al., 2002;

Chancellor et al., 1993). Associations were reported for essential tremor and symptoms of anxiety and depression, but each was examined in only a few studies.

As discussed throughout this section, recent epidemiologic and toxicological studies continued to demonstrate associations of Pb exposure and biomarkers of Pb exposure with nervous system effects. The weight of evidence continued to be derived from associations observed of Pb exposure and blood Pb levels in young animals and children, respectively, with cognitive function decrements, inattention, and impulsivity. Expanding upon the previous body of evidence, several recent studies in children found similar associations with lower population mean (or quantile) blood Pb levels (1-5 µg/dL). Whereas previous evidence was inconsistent, several new studies in children reported associations between concurrent blood Pb levels and attention deficit hyperactivity disorder (ADHD). Recent studies in adults focused primarily on cognitive function decrements but also provided additional evidence for Pb-associated mood disorders, ALS, Parkinson's Disease, and essential tremor. New toxicological studies expanded evidence for the effects of prenatal and postnatal Pb exposure on learning, memory, and attention and provided insight into the contribution of social stress to this paradigm. New or expanded areas of toxicological research related to Pb exposure included mood disorders, neurofibrillary tangle formation, and adult dementia after early life Pb exposures. Historically important areas of toxicological research were further expanded with recent findings for Pb-induced effects on neurotransmitters, synapses, glia, neurite outgrowth, the blood brain barrier, and oxidative stress. The data detailed in the subsequent sections continue to enhance the understanding of nervous system effects associated with Pb exposure.

5.3.2 Cognitive Function and Learning

5.3.2.1 Epidemiologic Studies of Cognitive Function in Children

Epidemiologic studies have assessed global cognitive function most frequently by full-scale IQ (FSIQ) and its verbal and performance subscale components in children ages 3 to 17 years and by the Bayley Scales of Infant Development in children ages 6 months to 3 years. These indices have strong psychometric properties and are among the most rigorously standardized measures. A large body of evidence also comprises associations of blood Pb levels with specific cognitive abilities, including memory and learning, executive function, language, and visuospatial processing. These specific indices of cognitive function are reflected in global measures of intelligence and also are more comparable to tests of learning and memory in animals. Fewer studies have examined

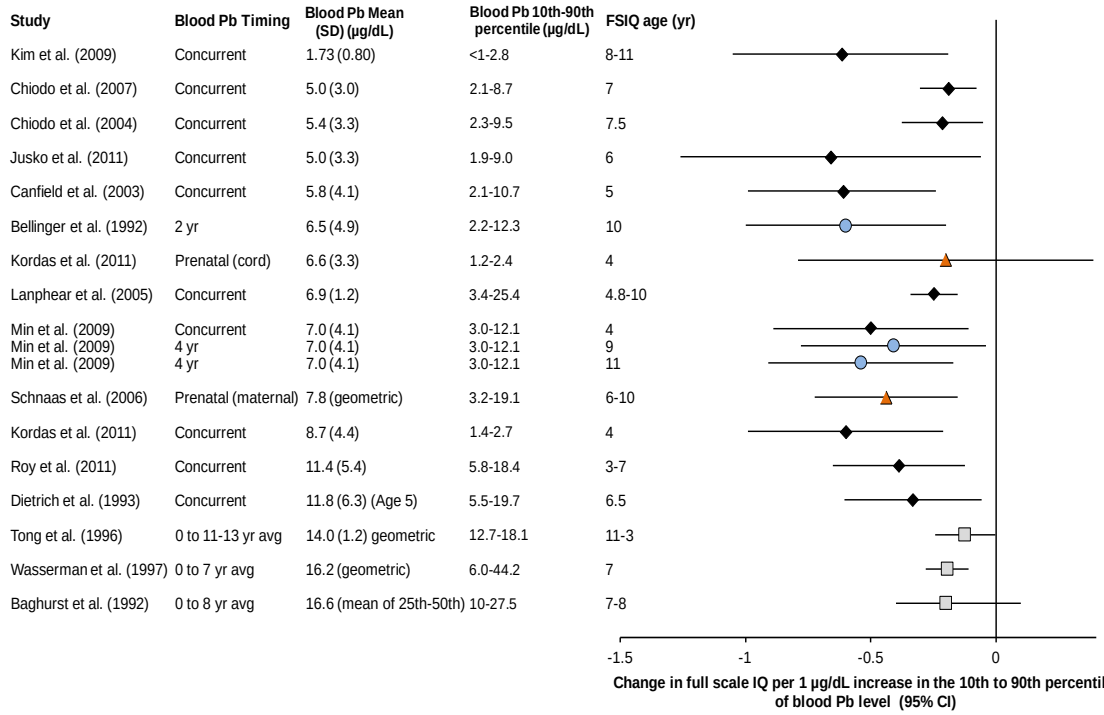
academic performance and achievement; however, these outcomes may provide information on the impact of Pb exposure on life success. The epidemiologic evidence for each of these categories of outcomes was evaluated separately in order of increasing weight of evidence. Emphasis was placed on prospective studies with repeated assessments of blood Pb levels and cognitive function and on studies examining blood Pb levels similar to those measured in contemporary U.S children (i.e., less than 5 µg/dL), and younger children whose blood Pb levels are less influenced by higher past Pb exposures.

Many factors have been shown to influence the intellectual abilities of children, including parental SES, parental education, parental IQ, quality and stability of the caregiving environment, nutritional status, and birth weight (Nation and Gleaves, 2001; Wasserman and Factor-Litvak, 2001). These and other influences on neurodevelopment often are correlated with blood Pb levels. Thus, due to their association with both blood Pb level and outcome, these other risk factors may potentially confound (i.e., bias due to an association with blood Pb level and causal association with the outcome) the associations observed between blood Pb level and indices of cognitive function. In the evaluation of the effect of Pb independent from the effects of the other variables, greater weight was given to studies that accounted for potential confounding in the study design or in statistical analyses. A detailed discussion of the collective weight of evidence for the independent associations between Pb exposure and nervous system effects in relation to the adequacy of control for confounding by other risk factors is located in Section 5.3.11.

Full-scale IQ in Children

Several longitudinal cohort studies were initiated in the 1980s in order to address limitations of cross-sectional studies, including establishing a temporal association between blood Pb levels and cognitive outcomes, examining the persistence of cognitive deficits to older ages, and comparing risk estimates among blood Pb levels measured at different lifestages. Moreover, cooperation among investigators to adopt similar assessment protocols facilitated pooled and meta-analyses and comparison of results across populations that differed in the range of blood Pb levels, race/ethnicity, and SES. Individual cohort studies in diverse populations were consistent in demonstrating associations between higher blood Pb and lower FSIQ in populations of school-aged children with mean blood Pb levels in the range of 5 to 10 µg/dL (Schnaas et al., 2006; Bellinger and Needleman, 2003; Canfield et al., 2003a; Wasserman et al., 1997; Dietrich et al., 1993a; Baghurst et al., 1992; Bellinger et al., 1987) (Figure 5-2 and Table 5-3). In analyses restricted to children in the lower range of the blood Pb distribution (e.g., < 10 µg/dL), associations were observed in groups of children with mean blood Pb levels 3-4 µg/dL (Bellinger, 2008; Canfield, 2008; Hornung, 2008). Across cohort studies,

associations were observed with concurrent, prenatal, early childhood (e.g., age 2 years), and childhood average blood Pb levels (e.g., 0-8 year average) (Figure 5-2 and Table 5-3). These findings were substantiated in a pooled analysis of seven prospective studies (Boston, MA; Cincinnati, OH; Rochester, NY; Cleveland, OH; Mexico City, Mexico; Port Pirie, Australia; and Kosovo, Yugoslavia) by Lanphear et al. (2005) as well as multiple meta-analyses that included both prospective and cross-sectional studies (Pocock et al., 1994; Schwartz, 1994; Needleman and Gatsonis, 1990).



Note: Studies generally are presented in ascending order of mean blood Pb level. To facilitate comparisons among effect estimates across studies with different distributions of blood Pb levels and model structures (e.g., linear, log-linear), effect estimates are standardized to a 1 µg/dL increase in blood Pb level within the 10th to 90th percentile interval. The percentiles are estimated using various methods and are only approximate values. Effect estimates are assumed to be linear within the 10th to 90th percentile interval of blood Pb level. The various tests used to measure FSIQ are scored on a similar scale (approximately 40-160). Black diamonds, blue circles, orange triangle, and gray squares represent associations with concurrent, earlier childhood, prenatal, and lifetime average blood Pb levels, respectively.

Figure 5-2 Associations of blood Pb levels with full-scale IQ (FSIQ) among children.

Table 5-3 Additional characteristics and quantitative results for studies represented in Figure 5-2

Study	Population/ Location	Blood Pb Data (µg/dL)	Statistical Analysis	FSIQ Assessment[a]	Effect Estimate (95% CI)[b,c]
Kim et al. (2009a)	279 children in Seoul, Seongnam, Ulsan, and Yeoncheon, Korea, ages 8-11 yr in April-December 2007	Concurrent Mean (SD): 1.73 (0.80) 10th-90th: < 1-2.8	Log linear regression model adjusted for age, sex, maternal education, paternal education, yearly income, maternal smoking during pregnancy, indirect smoking after birth, birth weight, maternal age	KEDI-WISC at ages 8-11 yr	-0.62 (-1.05, -0.19)
Chiodo et al. (2007)	506 African-American children in Detroit, MI area followed from birth (1989-1991) to age 7 yr. Large proportions of children with prenatal exposure to cocaine or marijuana	Concurrent Mean (SD): 5.0 (3.0) 10th-90th: 2.1-8.7	Regression model adjusted for prenatal alcohol and drug use, SES, Symptom Checklist (component of HOME score), maternal IQ	WISC-III at age 7 yr	-0.19 (-0.30, -0.08)[b]
Chiodo et al. (2004)	246 African-American children in Detroit, MI area followed from birth (not reported) to age 7.5 yr. Large proportions of children with prenatal exposure to cocaine or marijuana	Concurrent Mean (SD): 5.4 (3.3) 10th-90th: 2.3-9.5	Log linear regression model adjusted for SES, education, number of children <18 yr, HOME score, maternal vocabulary test score, sex, parity, family environment scale	WISC-III at age 7.5 yr	-0.22 (-0.38, -0.05)[b]
Jusko et al. (2011)	194 children in Rochester, NY followed from age 6 mo (1994-1995) to age 6 yr.	Concurrent Mean (SD): 5.0 (3.3) 10th-90th: 1.9-9.0	Linear regression model adjusted for sex, birth weight, transferrin saturation, maternal race, maternal IQ, maternal education, HOME score, family income, and maternal prenatal smoking	WPPSI-R at age 6 yr	-0.66 (-1.26, -0.06)
Canfield et al. (2003a)	172 children in Rochester, NY born 1994-1995 followed from age 6 mo to age 5 yr.	Concurrent Mean (SD): 5.8 (4.1) 10th-90th: 2.1-10.7	Linear regression model adjusted for sex, maternal race, prenatal smoking, maternal education, child iron status, household income, maternal IQ, HOME score, birth weight	Stanford-Binet at age 5 yr	-0.61 (-0.99, -0.24)
Bellinger et al. (1992)	148 children in the Boston, MA area followed from birth (1979-1981) to age 15-17 yr.	Early childhood (age 2 yr) Mean (SD): 6.5 (4.9) 10th-90th: 2.2-12.3	Linear regression model adjusted for HOME score (age 10 and 5 yr), child stress, race, maternal IQ, SES, sex, birth order, marital status	WISC-R at age 10 yr	-0.58 (-0.99, -0.18)
Lanphear et al. (2005)	1,333 children pooled from Boston, Cincinnati, Cleveland, Mexico City, Port Pirie, Rochester, and Yugoslavia cohorts	Concurrent Mean (SD): 6.9 (1.2) 10th-90th: 3.4-25.4	Log linear regression model adjusted for HOME score, birth weight, maternal IQ, maternal education	FSIQ measured at ages 5-10 yr	-0.25 (-0.34, -0.15)
Min et al. (2009)	267 primarily African-American children in the Cleveland, OH area followed from birth (1994-1996) to age 11 yr. Children were exposed prenatally to multiple drugs.	Age 4 yr Mean (range): 7.0 (1.3-23.8) 10th-90th: 3.0-12.1	Linear regression model adjusted for HOME score, caregiver's vocabulary test, sex, parity, maternal marital status, head circumference at birth	WISC-R at age 4 yr (concurrent) WISC-R at age 9 yr WISC-R at age 11 yr	-0.50 (-0.89, -0.11) -0.41 (-0.78, -0.04) -0.54 (-0.91, -0.17)
Schnaas et al. (2006)	150 children in Mexico City, Mexico followed from birth (1987-1992) to age 10 yr.	Prenatal (maternal 28-36 weeks) Geometric mean (95% CI): 7.8 (2.5-24.5) 10th-90th: 3.2-19.1	Log linear mixed effects regression model adjusted for sex, SES, maternal IQ, HOME score, birth weight, postnatal blood Pb, random slope for subject	McCarthy GCI at ages 6-10 yr	-0.44 (-0.73, -0.15)

Study	Population/ Location	Blood Pb Data (µg/dL)	Statistical Analysis	FSIQ Assessment[a]	Effect Estimate (95% CI)[b,c]
Kordas et al. (2011)	186 children in Mexico City, Mexico followed from birth (1994-1995) to age 4 yr	Prenatal (cord) Mean (SD): 6.6 (3.3) 10th-90th: 1.2-2.4 Concurrent Mean (SD): 8.7 (4.4) 10th-90th: 1.4-2.7	Linear regression model adjusted for sex, birth weight, gestational age, maternal age, years of schooling, IQ, smoking status, marital status, crowding in home, type of floor in home	McCarthy GCI at age 4 yr Prenatal Concurrent	 -0.20 (-0.79, 0.39) -0.60 (-0.99, -0.21)
Roy et al. (2011)	717 children in Chennai, India ages 3-7 yr	Concurrent Mean (SD): 11.4 (5.4) 10th-90th: 5.8-18.4	Log linear model adjusted for mid-arm circumference, age, sex, family income, parental education, parental IQ, family size	Binet-Kamat at ages 3-7 yr	-0.39 (-0.65, -0.13)
Dietrich et al. (1993a)	253 children in Cincinnati, OH followed from birth (1979-1985) to age 20-23 yr.	Concurrent NR Age 5 yr Mean (SD): 11.8 (6.3) 10th-90th: 5.5-19.7	Linear regression model adjusted for HOME score, maternal IQ, birth weight, birth length, child sex, maternal cigarette consumption during pregnancy	WISC-R at age 6.5 yr	-0.33 (-0.60, -0.06)
Tong et al. (1996)	375 children in Port Pirie, Australia followed from birth (1979-1982) to age 11-13 yr.	Lifetime avg Geometric mean (GSD): 14.0 (1.2) 10th-90th: 12.7-18.1	Regression model adjusted for sex, age, school grade, parental occupational prestige, HOME score, maternal IQ, family functioning score, parental smoking, marital status, parental education, maternal age, birth weight, birth order, feeding method, breastfeeding duration, family size, life events, prolonged absences from school	WISC-R at age 11-13 yr	-0.12 (-0.24, -0.003)
Wasserman et al. (1997)	290 children in Kosovo, Yugoslavia followed from birth (1985-1986) to age 10-12 yr.	Lifetime avg Geometric mean: 16.2 10th-90th: 6.0-44.2	Generalized estimating equations with log-transformed blood Pb adjusted for age, sex, sibship size, birth weight, language spoken in home, HOME score, maternal age, maternal education, maternal Raven score	WISC-III at ages 10-12 yr	-0.20 (-0.28, -0.11)
Baghurst et al. (1992)	494 children in Port Pirie, Australia followed from birth (1979-1982) to age 11-13 yr.	Lifetime avg Mean of 25-50th: 16.6 10th-90th: 10-27.5	Log linear regression model adjusted for sex, birth weight, birth order, feeding method, breastfeeding duration, parental education, maternal age, parental smoking, SES, quality of home environment, maternal IQ, parents living together	WISC-R at age 7-8 yr	-0.20 (-0.40, 0.10)

[a]WISC = Wechsler Intelligence Scale for Children, WPPSI = Wechsler Preschool and Primary Scale of Intelligence, GCI = General Cognitive Index
[b]Effect estimates are standardized to a 1 µg/dL increase in blood Pb level within the 10th to 90th percentile interval. Effect estimates are assumed to be linear within the 10th to 90th percentile interval of blood Pb level. The percentiles are estimated using various methods and are only approximate values.
[c]95% CI was constructed using a standard error that was estimated for a p-value of 0.01. Authors specified a p-value of <0.01.

The analysis pooling data from seven prospective studies included 1,333 children ages 5-10 years of age with a median (5th-95th percentile) concurrent blood Pb level of 9.7 µg/dL (2.5-33.2 µg/dL) (Lanphear et al., 2005). In multivariate models that adjusted for study site, maternal IQ, Home Observation for the Measurement of Environment (HOME) inventory (assessment of physical environment, parental responsivity, learning stimulation, emotional climate, and family interactions), birth weight, and maternal education, higher concurrent, peak, average lifetime, and early childhood blood Pb levels were associated with lower FSIQ measured at age 5-10 years, with the largest decrement in FSIQ estimated for concurrent blood Pb level (-0.25 points [95% CI: -0.34, -0.15] per 1 µg/dL increase in blood Pb level in the 10th to 90th percentile interval [2.2-12.3 µg/dL]

of blood Pb level)[1]. Various models were investigated to characterize the shape of the blood Pb concentration-response relationship. Consistent with findings from several individual cohort studies, Lanphear et al. (2005) found that a log-linear model best fit the data, with a greater decrease in FSIQ estimated for an increase in concurrent blood Pb from 2.4-10 µg/dL (3.9 points [95% CI: 5.3, 2.4]) than an increase from 10 to 20 µg/dL (1.9 points [95% CI: 2.6, 1.2]). Among children with concurrent blood Pb less than 10 µg/dL, the median blood Pb level was 4.2 µg/dL (Hornung, 2008).

A key additional strength of the pooled analysis by Lanphear et al. (2005) was the extensive examination of the potential for confounding by several factors related to SES and the caregiving environment. Variables such as HOME score, birth weight, maternal IQ, and maternal education were statistically significantly associated with FSIQ and were included in the final model with blood Pb level. While a smaller decrement in FSIQ was estimated for concurrent blood Pb level in this adjusted model than in the unadjusted model (-0.43 points [95% CI: -0.53, -0.33] per 1 µg/dL increase in blood Pb level in the 10th to 90th percentile interval of blood Pb level), the adjusted blood Pb effect estimate was nonetheless statistically significant. HOME score was not available in the Rochester study; however, exclusion of data from that cohort resulted in a 3% less negative effect estimate, indicating the lack of a strong influence of HOME score alone on blood Pb level-IQ associations. Other variables such as child sex, tobacco exposure during pregnancy, alcohol use during pregnancy, maternal age at delivery, marital status, and birth order were not statistically significantly associated with FSIQ and did not alter the effect estimate for concurrent blood Pb level. The individual study populations represented a wide range of SES, maternal education, and cultural backgrounds. Sensitivity analyses, in which one study was successively excluded, revealed that no single study was responsible for driving the results. Per 1 µg/dL increase in blood Pb level in the 10th to 90th percentile interval of blood Pb level, effect estimates excluding one study at a time ranged between -0.22 and -0.27, indicating the robustness of the concurrent blood Pb level effect estimate despite between-study variability in the distributions of potential confounding factors.

The small number of studies published since the 2006 Pb AQCD continued to demonstrate associations between higher blood Pb level (primarily concurrent) and lower FSIQ in children between ages 3 and 11 years (Figure 5-2 and Table 5-3). Similar to studies reviewed in the 2006 Pb AQCD, most recent studies demonstrated associations between blood Pb level and lower FSIQ in populations with mean blood Pb level between 5 to 10 µg/dL. New results from the prospective cohorts were limited. Mazumdar et al.

[1]To facilitate comparisons among effect estimates across studies with different distributions of blood Pb levels and model structures (e.g., linear, log-linear), effect estimates are standardized to a 1 µg/dL increase in blood Pb level within the estimated 10th to 90th percentile interval. Effect estimates are assumed to be linear within the 10th to 90th percentile interval of blood Pb level.

(2011) reported on the follow-up of the Boston cohort to age 28-30 years (55 out of the original 249 enrolled at birth). Blood Pb levels measured at age 6 months, 4 years, 10 years, and levels averaged over childhood were associated with decrements in FSIQ in adults. The effect estimates were similar in magnitude for all childhood blood Pb measures, except for 6 month blood Pb level, which was associated with a smaller FSIQ decrement. These findings indicated that the effect of childhood Pb exposures may persist to adulthood.

Jusko et al. (2011; 2008) affirmed the findings in the Rochester cohort previously reported by Canfield et al. (2003a), who examined the cohort at age 5 years (Figure 5-2 and Table 5-3). Jusko et al. (2011) examined the Rochester cohort at age 6 years and, similar to Canfield et al. (2003a), found that a 1 µg/dL increase in concurrent blood Pb level was associated with a 0.66-point decrease (95% CI: -1.26, -0.06) in FSIQ. Model covariates were the same as those analyzed by Canfield et al. (2003a): sex, race, family income, maternal education, race, prenatal smoking, birth weight, transferrin saturation, maternal IQ, and HOME score. At both age 5 and 6 years, higher peak and lifetime average blood Pb levels also were associated with lower FSIQ, and incremental increases in blood Pb levels tended to be associated with larger FSIQ decrements in analyses restricted to children with blood Pb levels less than 10 µg/dL (Jusko et al., 2008; Canfield et al., 2003a). Canfield et al. (2003a) provided additional information on the extent of confounding by SES- and caregiving-related variables. The effect estimate in the covariate-adjusted model was 40% smaller than it was in the model with concurrent blood Pb level alone; however, the association with concurrent blood Pb level remained statistically significant.

Additional evidence recently was provided for children in Mexico City, albeit in a separate cohort of children born later with lower blood Pb levels at corresponding ages. Among children born 1987-1992, Schnaas et al. (2006) previously reported larger Pb-associated decrements in FSIQ for prenatal maternal (28-36 weeks) blood Pb levels than for concurrent blood Pb levels between ages 1 and 10 years. In contrast, Kordas et al. (2011) found that concurrent blood Pb level was associated with a larger decrement in FSIQ at age 4 years than was cord blood Pb level. Children in the latter study were born between 1994 and 1995 and at age 4 years had a mean (SD) blood Pb level of 8.7 (4.4) µg/dL. In Schnaas et al. (2006), the geometric mean (95% CI) blood Pb level at age 4 years was 10.3 (4.2, 20.5) µg/dL. It is not clear whether different temporal patterns of Pb exposure may have contributed to the contrasting associations for prenatal and concurrent blood Pb levels in the two studies.

Surkan et al. (2007) examined children from urban Boston, Massachusetts and rural Farmington, Maine participating in a trial designed to assess the effect of amalgam dental

fillings on child neurodevelopment. Prior to placement of amalgam fillings, blood Pb levels were measured, and children were administered an extensive battery of neuropsychological tests including tests of memory, learning, visual-motor ability, reading, reaction time. A strength of the study was that the range of concurrent blood Pb level in this study, 1-10 µg/dL, was lower than that examined in previous studies. Thus, it provided information on associations between blood Pb level and IQ decrements within a lower range of blood Pb levels. However, consistent with several previous studies, Surkan et al. (2007) found lower FSIQ in the group of children with concurrent blood Pb levels of 5 to 10 µg/dL. For example, adjusting for age, race/ethnicity, birth weight, SES, and primary caregiver IQ, children with blood Pb levels 5-10 µg/dL had lower FSIQ scores (-6.04 points [95% CI: -10.7, -1.36]) compared with children who had levels 1-2 µg/dL (referent group). Children with blood Pb levels 2-5 µg/dL did not have FSIQ scores (-0.12 [95% CI: -3.30, 3.06]) that differed from children with blood Pb levels 1-2 µg/dL. Another strength of this study was the analysis of potential confounding by a larger list of variables than that included in the final models. Although HOME score was not examined, several variables such as SES, caregiver education, parenting stress, marital status of caregiver, and maternal utilization of prenatal or annual health care were not significantly ($p > 0.20$) associated with child IQ either independently or in a model with blood Pb level (Surkan et al., 2007).

Other recent studies found blood Pb-associated lower FSIQ in populations of children in Asia with lower blood Pb levels (Kim et al., 2009b; Zailina et al., 2008) than were previously examined. Kim et al. (2009b) examined children ages 8 to 11 years in Korea (born mid- to late-1990s) with a mean (range) concurrent blood Pb level of 1.73 (0.42-4.91) µg/dL. Children were tested using the Korean Educational Development Institute-WISC, which assesses vocabulary, arithmetic, picture arrangement, and block design. In a log-linear regression analysis adjusted for age, sex, maternal and paternal education, yearly income, prenatal smoking, postnatal environmental tobacco smoke exposure, birth weight, and maternal age at birth, a 1 µg/dL higher concurrent blood Pb level was associated with a 0.64-point lower (95% CI: -1.05, -0.19) FSIQ within the 10th-90th percentile interval of blood Pb level (< 1 to 2.8 µg/dL). The potential confounders examined in this study were not found to have a strong influence on the findings as a similar magnitude of effect was estimated in a model that included only blood Pb level (-0.73 points [95% CI: -1.19, -0.27] per 1 µg/dL increase in blood Pb level in the 10th to 90th percentile interval). Although several important SES-related confounders were considered, there was no direct assessment of the home environment and the primary caregiver IQ in this study, which are notable limitations.

Kim et al. (2009b) also examined effect modification of the blood Pb-FSIQ relationship by concurrent blood manganese (Mn) levels. The mean (range) blood Mn level was

14.3 (5.3-29.02) µg/dL. Blood Pb and Mn levels were not correlated (r = 0.03, p = 0.64). To examine effect modification, children were divided into two groups: blood Mn level above and below the median (14 µg/dL). Multivariate linear regression models predicting FSIQ and verbal IQ (VIQ) used concurrent blood Pb level as the predictor variable in the low and high Mn groups. As illustrated in Figure 5-3, the associations of concurrent blood Pb level with FSIQ and VIQ was larger in magnitude and statistically significant for children in the high Mn group compared with children in the low Mn group (-0.65 points [95% CI: -1.26, -0.05] in high Mn group versus -0.50 points [95% CI: -1.23, 0.22] in low Mn group per 1 µg/dL increase in blood Pb level in the 10th to 90th percentile interval). However, higher blood Pb level was associated with lower FSIQ in children in the low Mn group.

Note: High and low Mn refer to levels above and below the median of 14 µg/dL, respectively.

Figure 5-3 Effect modification of the association between concurrent blood Pb level and FSIQ by blood Mn level.

Higher concurrent blood Pb level also was associated with a lower IQ score (as assessed by the McCarthy General Cognitive Index) among children ages 6-8 years in Malaysia with a mean blood Pb level of 3.69 µg/dL (Zailina et al., 2008). The concentration-response function was not reported; however, in a multivariate model, blood Pb level and not potential confounding factors such as paternal education, maternal education, household income, number of siblings, and birth order was reported to be significantly associated with FSIQ. As with Kim et al. (2009b), a notable limitation was the lack of consideration of confounding by the caregiving environment.

Pb has long been known to impact dopaminergic neurons, inhibit depolarization-evoked neurotransmitter release, and stimulate spontaneous neurotransmitter release (Section 5.3.8.8). Further, dopaminergic activity is a key process in regulating cognitive function. Thus, variants in dopamine-related genes have the potential to act as effect modifiers of Pb-associated neurodevelopmental effects. Recent studies in children that examined effect modification by variants in dopamine genes produced contrasting results. In a study of children at ages 2 and 4 years, Kordas et al. (2011) did not find differences in association between concurrent blood Pb level and FSIQ by the Taq A1/A1 dopamine receptor 2 (DRD2) genotype, which is associated with reduced dopamine receptor density. Roy et al. (2011) examined children of similar age (3-7 years) in Chennai, India and found that among children with the Taq A1/A1 genotype, a 1 µg/dL higher blood Pb level was associated with a 0.84-point lower (95% CI: -1.66, -0.01) FSIQ within the 10th-90th percentile interval of blood Pb level (5.8-18.3 µg/dL). The same increment in blood Pb level was associated with a 0.36-point lower (95% CI: -0.76, -0.04) FSIQ in children with the Taq A2/A2 higher receptor density genotype. Concurrent blood Pb level was associated with FSIQ in both studies in analyses including all subjects. However, there were many differences between study populations that may have contributed to differences in effect modification by the DRD2 variant. Compared with the group in India, the group in Mexico had a lower mean blood Pb level and lower mean FSIQ score. Additionally, children in the Mexico City group with the Taq A1/A1 genotype had a higher mean FSIQ score, whereas FSIQ scores were similar between Taq genotypes in the children in India.

Other recent studies examined children in the U.S.; however, in these studies, there were high proportions of children with prenatal exposure to alcohol, tobacco, marijuana, or cocaine that may limit the generalizability of findings. Chiodo et al. (2007) examined a population of African American children (age 7 years, born 1989-1991) in the Detroit, MI area with relatively low blood Pb level (mean [SD]: 5.0 [3.0]) but high prevalence of prenatal exposure to cocaine (38%) or marijuana (35%). In a detailed analysis of potential confounding factors, investigators found that cocaine exposure did not meet the criterion for inclusion in the model (i.e., $p > 0.10$ for association with FSIQ). Prenatal marijuana

exposure was associated with FSIQ ($p < 0.10$) and was included in a multivariate model along with caretaker education, SES, HOME score, symptom checklist, number of children in the home, maternal IQ, sex, and prenatal cigarette smoking. In this multivariate model, higher blood Pb level was associated with lower FSIQ (Figure 5-2 and Table 5-3). These findings supported an independent association of blood Pb level despite the high prevalence of prenatal drug exposure in the study population.

Min and colleagues (2009) followed children in Cleveland, OH from age 4 to 11 years who were exposed prenatally to alcohol (77%), cigarette smoking (61%), marijuana (31%), or cocaine (51%). The study population was primarily African-American (86%) and of low SES (98%); 39% of mothers had not finished high school, and 86% were unmarried at the time of enrollment. The mean (range) blood Pb level, measured at age 4 years, was 7.0 µg/dL (1.3-23.8). Several lines of evidence indicated that prenatal drug exposure did not heavily influence the association between blood Pb level and FSIQ. Prenatal alcohol exposure was correlated with blood Pb level but was not statistically significantly associated with IQ ($p > 0.10$) and did not change the blood Pb level effect estimate by more than 10%. Prenatal cocaine exposure was associated with FSIQ at age 9 years; however, blood Pb level at age 4 years remained associated with a decrement in FSIQ at age 9 years after adjusting for cocaine exposure and several SES-related factors (Table 5-3). Based on the examination of interaction terms, associations between blood Pb level and FSIQ were not statistically significantly different between drug-exposed and -unexposed children.

Similar to previous studies with repeated assessments of cognitive function over time, Min et al. (2009) found that the association between blood Pb level at age 4 years and FSIQ persisted to older ages. Higher blood Pb level at age 4 years was associated with similar magnitudes of decrements in FSIQ at ages 4, 9 and 11 years (Figure 5-2 and Table 5-3). Researchers also examined the shape of the concentration-response function using a restricted cubic spline function. Although the cubic spline term did not attain statistical significance ($p = 0.19$), qualitative analysis indicated that the association between blood Pb level and FSIQ decrements persisted and was greater at lower levels blood Pb (< 7 µg/dL). These findings were consistent with those from the pooled analysis (Lanphear et al., 2005) and other individual studies (Tellez-Rojo et al., 2006).

Bayley Scales of Infant Development

The Bayley Scales of Infant Development are the most widely used tests of infant intelligence. The Mental Development Index (MDI) is statistically analogous to IQ, i.e., both scores have a population-standardized mean of 100 and standard deviation of 15. While MDI assesses general cognitive function in infants, it is important to note that

MDI scores are not necessarily correlated with IQ scores measured later in childhood. Associations between blood Pb levels and MDI scores were found in most of the prospective cohort studies in children between age 6 months and 3 years and mean blood Pb levels 5-10 µg/dL (Table 5-4). Recent studies examined children who were born in the mid-1990s to mid-2000s and continued to demonstrate associations between higher cord and concurrent blood Pb level and lower MDI scores (Table 5-4). Studies that found associations with concurrent blood Pb levels also tended to find associations with prenatal cord or maternal blood Pb levels. Recent studies provided new information on effect modification by nutritional status, maternal self-esteem, co-exposure to Mn, and genetic variants. While studies adjusted for multiple SES-related variables including maternal IQ and education, most did not consider confounding by the caregiving environment. Concurrent and cord blood Pb levels were associated with MDI, adjusting for HOME score in diverse cohorts (Solon et al., 2008; Wasserman et al., 1992; Bellinger et al., 1987). In the Cleveland cohort, associations of cord and postnatal blood Pb levels with MDI at ages 6 months to 2 years became null after adjusting for covariates including HOME score (Ernhart et al., 1988; Ernhart et al., 1987). In the analysis of the Cincinnati cohort, HOME score was not significantly associated with blood Pb level or MDI and thus, did not meet the criteria for model inclusion (Dietrich et al., 1987a). Collectively, evidence does not indicate that Pb-associated MDI decrements are driven by confounding by quality of the caregiving environment.

Table 5-4 Associations of blood Pb level with Bayley MDI in children ages 6 months to 3 years[a]

Study	Population/ Location	Blood Pb Levels (µg/dL)	Statistical Analysis	Cognitive Index	Effect Estimate (95% CI)[b]
Jedrychowski et al. MDI = Mental Development Index, MTHFR = methylenetetrahydrofolate reductase
[a]Studies are presented in order of increasing population mean blood Pb level.
[b]Except where noted, effect estimates are standardized to a 1 µg/dL increase in blood Pb level within the 10th to 90th percentile interval of blood Pb level.

In a population of children in Krakow, Poland with lower cord blood Pb levels (median 1.23 µg/dL, 95% CI: 1.24, 1.34 µg/dL) than those previously examined, increasing cord blood Pb level was associated with similar magnitudes of decrease in MDI at ages 12, 24, and 36 months (Jedrychowski et al., 2009b) (Table 5-4). Consistent with the hypothesis that the developing male central nervous system may be more vulnerable than that of females to environmental insults resulting in later behavioral problems (Moffitt et al., 2001), investigators estimated a larger in MDI per unit increase in cord blood Pb level among the 233 males than among the 223 females (Figure 5-4). Although mean cord blood Pb levels were similar between males (1.35 µg/dL) and females (1.41 µg/dL), the mean 36-month MDI score was lower among males than among females (101 and 105, respectively, $p = 0.0001$).

Figure 5-4 Regression of fitted MDI score at 36 months on log-transformed cord blood Pb level by sex.

Solon et al. (2008) examined children in the Philippines, ages 6 to 35 months. A key strength of this study was the adjustment for HOME score as well as maternal education, maternal smoking, premature birth, region of residence, and years of schooling of child. Not only did investigators find an association between higher concurrent blood Pb level and lower MDI score (Table 5-4), but they also found effect modification by red blood cell folate levels. Among children with folate levels less than or equal to 230 µg/mL, blood Pb level had a marginal association with lowering MDI scores in the range of 0.80 to 2.44 points. Among children with higher folate levels, blood Pb level was not estimated to have a negative marginal impact. These findings from Solon et al. (2008) indicated that children with folate deficiencies may be at increased risk of Pb-associated decreases in cognitive function. The results were consistent with observations that higher folate level is associated with lower blood Pb level since folate improves Pb excretion by inhibiting the binding of Pb to blood elements.

Multiple studies in different Mexico City mother-child pair cohorts recently reported associations between blood Pb levels (e.g., maternal, cord blood, or child postnatal) and decrements in Bayley MDI in children between age 12 and 36 months (Claus Henn et al.; Pilsner et al., 2010; Surkan et al., 2008; Hu et al., 2006; Tellez-Rojo et al., 2006). Recent studies extended findings from Tellez-Rojo et al. (2006) with follow-up of the same

cohort to age 3 years and observations of effect modification by maternal self-esteem (Surkan et al., 2008) and blood Mn levels (Claus Henn et al.).

Claus Henn et al. examined interactions between blood Mn and Pb levels. Investigators selected mid-range (2.0-2.8 µg/dL) blood Mn levels as the reference group based on previous observations that MDI scores were least affected by increases in blood Mn level in this group. Among subjects with age 12-month blood Mn levels less than 2.0 µg/dL, a 1 µg/dL higher age 12-month blood Pb level was associated with a 3.0-point (95% CI: -5.2, -0.78) lower MDI. Among subjects with blood Mn levels greater than 2.8 µg/dL, a 1 µg/dL higher age 12-month blood Pb level was associated with a 2.2-point (-4.4, 0) lower MDI. Interactions were not found using age 24-month blood Mn and Pb levels. Effects estimates were similar in magnitude before and after adjustment for sex, gestational age, hemoglobin, maternal IQ, maternal education, and visit. Findings in this Mexico City cohort added to those from Kim et al. (2009b) in older children that associations between blood Pb level and cognitive function may be influenced by Mn co-exposure, and results from both studies indicated that blood Pb level was associated with decrements in cognitive function with both lower and higher levels of blood Mn. Biological plausibility for the interactive effects of Pb and Mn exposure is provided by observations that Mn has similar modes of action and cellular targets as does Pb, i.e., altering Ca^{+2} metabolism, inducing oxidative damage to neuronal cells, diminishing dopamine transmission. Claus Henn et al. also indicated that Pb-Mn co-exposure may affect cognitive function in children as young as 12 to 36 months of age.

Surkan et al. (2008) stratified data by the level of maternal self-esteem as reported by mothers. Higher age 24-month blood Pb level was associated with lower MDI score among children with mothers in the lowest three quartiles of self-esteem but not among children with mothers in the highest quartile of self-esteem (Table 5-4). Model covariates included cohort, sex, maternal IQ, maternal age, maternal education, parity, maternal smoking, maternal alcohol consumption, and maternal self-esteem. While HOME score was not examined, maternal self-esteem may incorporate many of the same aspects as HOME score, including mother-child interactions, educational interactions, and dietary practices. These findings indicated that higher maternal psychosocial functioning (e.g., lower stress, anxiety, and depression and higher self-esteem) may contribute to better caregiving, which in turn may improve neuropsychological functioning of the child. The biological plausibility of these findings in children is well-supported by observations in animals unrelated to Pb that environmental enrichment reverses the effects of early stress experiences on reactions such as depressed behavior, HPA activation, and immunosuppressant (Laviola et al., 2008; Laviola et al., 2004; Moreley-Fletcher et al., 2003; Francis et al., 2002). With specific regards to Pb exposure, social isolation or enrichment has been found to exacerbate or protect against, respectively, Pb

exposure-induced learning impairments in animals (Section 5.3.2.2). It is worth mentioning in this context that the potential programming effects of stress on childhood health outcomes may occur at an even more fundamental level, i.e., through epigenetic programming (Dolinoy and Jirtle, 2008).

Hu et al. (2006) compared associations among prenatal blood Pb levels measured at different stages of gestation among 146 mother-child pairs meeting the following criteria: born at 37 weeks or greater gestational age, at least one valid Pb measurement during pregnancy, complete information on maternal age and IQ, and measurement of child blood Pb level at 24 months when the 24-month MDI was ascertained. Among blood Pb levels measured at various lifestages, 1st trimester maternal blood Pb level (whole or plasma Pb) was associated with larger decreases in subsequent 24-month MDI scores compared with maternal 3rd trimester, cord, and child concurrent blood Pb (Table 5-4). These results were adjusted for sex, 24-month blood Pb level, height-for-age Z score, weight, maternal age, and maternal IQ. HOME score was not included in the final model; however, investigators examined the potential for confounding by a larger list of unspecified variables. Prenatal Pb exposure effects also were indicated in a study conducted in Mexico City that examined FSIQ repeatedly during ages 6-10 years (Schnaas et al., 2006). Third trimester (weeks 28-36) maternal blood Pb level, was associated with larger decreases in FSIQ than were maternal blood Pb level at 12-20 weeks, maternal blood Pb level at delivery, or concurrent child blood Pb levels measured between ages 6 and 10 years.

In another recent study in Mexico City, Mexico, investigators found higher cord blood Pb level to be associated with a lower MDI score in children at age 24 months (-0.73 points [95% CI: -1.2, -0.23] in score per 1 µg/dL increase in cord blood Pb level in the 10th-90th percentile interval [3.5-10.5 µg/dL]) (Pilsner et al., 2010). Investigators additionally examined effect modification by variants in the methylenetetrahydrofolate reductase (MTHFR) gene. The MTHFR enzyme is involved in folate metabolism, which, in turn, is involved in homocysteine methylation to the amino acid methionine. The transfer of methyl groups that results from folate metabolism is important for biological processes including Phase II detoxification reactions and epigenetic regulation of gene expression. The MTHFR gene has common functional variants, including the C677T SNP, which produces an enzyme with lower metabolic activity and is associated with lower serum folate levels (Kordas et al., 2009). Lower folate levels have been associated with higher blood Pb levels. Although Pilsner et al. (2010) found that both cord blood Pb levels and the MTHFR C677T allele were associated with lower child MDI score at age 24 months, they did not find a statistically significant interaction between blood Pb level and the MTHFR 677T allele. Results from stratified analyses were not reported, thus differences in the magnitude of association between genotypes could not be compared.

Specific Indices of Cognitive Function in Children

In addition to indices of global cognitive function, blood Pb levels also have been associated with specific cognitive abilities, including memory, learning, visuospatial processing, and other executive functions such as planning and problem solving in children and adolescents (Kordas et al., 2006; Tellez-Rojo et al., 2006; Chiodo et al., 2004; Ris et al., 2004; Canfield et al., 2003b; Lanphear et al., 2000; Bellinger and Stiles, 1993; Dietrich et al., 1992; Bellinger et al., 1991; Dietrich et al., 1991; Needleman et al., 1979) (Figure 5-5 and Table 5-5). Studies often found associations with multiple indices of cognitive function, and because several tests are interrelated, it is difficult to attribute the effects of Pb exposure to a specific domain of cognitive function. Evidence that blood Pb levels are associated with a spectrum of cognitive indices provides coherence for the associations observed between blood Pb levels and FSIQ, a global measure of cognitive function. Furthermore, these tests of learning and memory in humans are homologous to tests in animals, and compared with that for FSIQ, evidence for these specific indices may improve understanding of the coherence between findings in humans and animals (Rice, 1996). These complex cognitive functions have been described to be mediated by the actions of neurotransmitters dopamine and glutamate in the hippocampus, prefrontal cortex, and ventral striatum of the brain. In toxicological studies, Pb exposure has been shown to disrupt the function of these systems, which provides biological plausibility for associations observed between blood Pb levels and deficits in a range of executive functions in children.

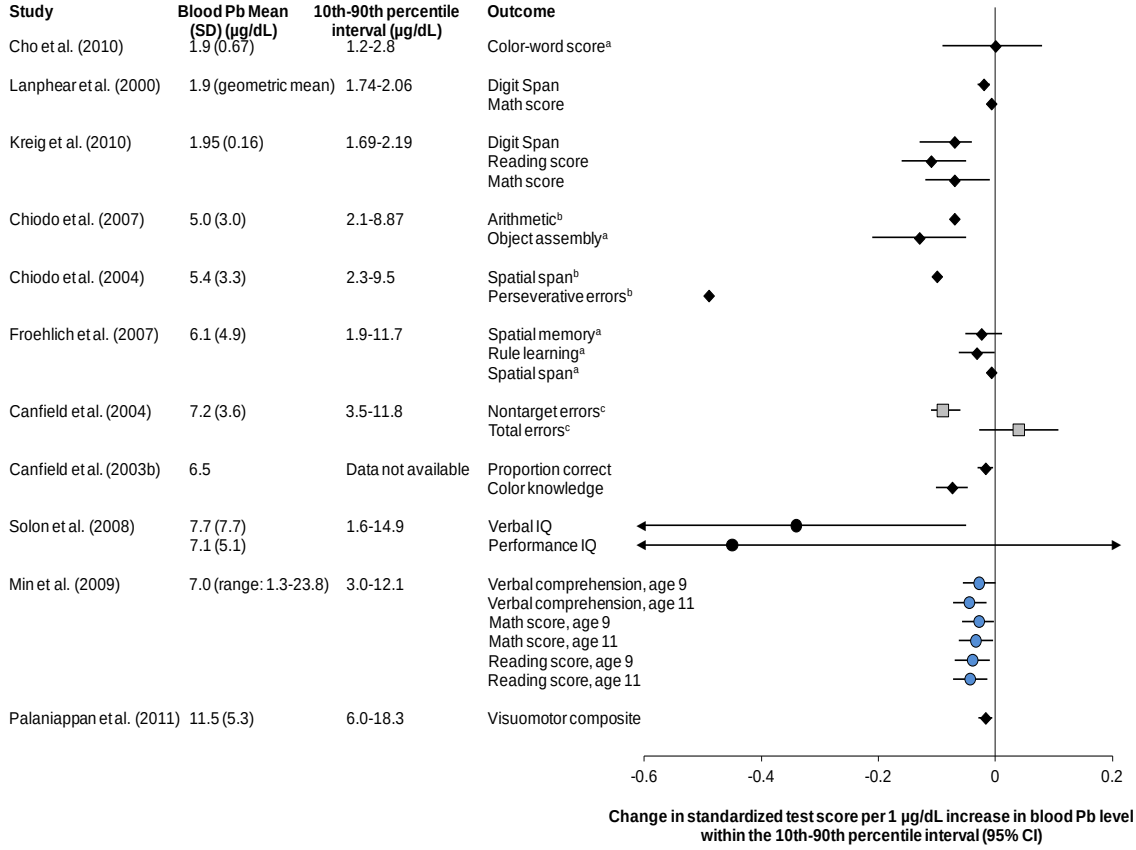
Studies published since the 2006 Pb AQCD added to the evidence for associations between higher blood Pb level (concurrent most frequently examined) and lower performance in specific indices of cognitive function (Figure 5-5 and Table 5-5). The weight of evidence indicated that decrements in specific cognitive indices were associated with concurrent blood Pb level and in populations with mean blood Pb levels between 5-10 µg/dL. Most studies considered potential confounding by multiple SES-related variables, and many found blood Pb-associated decrements in cognitive function in both unadjusted and covariate-adjusted models (Palaniappan et al., 2011; Chiodo et al., 2007; Froehlich et al., 2007). Many studies did not examine potential confounding by HOME score. However, studies that did (Min et al., 2009; Solon et al., 2008; Froehlich et al., 2007; Canfield et al., 2004; Canfield et al., 2003b) and did not adjust for HOME score (Krieg et al., 2010; Jedrychowski et al., 2008; Surkan et al., 2007; Lanphear et al., 2000) both found associations between blood Pb level and decrements in specific cognitive indices.. Several studies found associations after adjusting for different potential confounding factors, including parental IQ or education and HOME score. The set of covariates varied among the specific cognitive endpoints, and HOME score was not associated with every cognitive index. For example, only household income remained

significantly associated with total errors in the spatial working memory task and was included in the final model (Froehlich et al., 2007). Solon et al. (2008) found that in a multivariable model with blood Pb level and several potential confounders, HOME score remained significantly associated with verbal IQ in 5 year-old children, whereas maternal education, maternal smoking, and premature birth did not. Combined, these findings support the independent association of blood Pb level with specific cognitive indices and indicate that the potential confounding variables vary among endpoints and study populations.

Several analyses of the Rochester cohort at ages 4 and 5 years indicated associations of blood Pb level with various indices of cognitive function, including visual and working memory, planning, and problem solving (Froehlich et al., 2007; Canfield et al., 2004; Canfield et al., 2003b). In particular, the associations observed with tests of memory and rule learning and reversal provided strong coherence with observations of Pb-induced impaired performance in animals in homologous tests of the Morris Water Maze, the delayed spatial alternation, and discrimination reversal learning (Section 5.3.2.2). Compared with other prospective cohort studies, findings from the Rochester cohort demonstrated associations between blood Pb level and decrements in executive functions in younger children with a lower mean blood Pb level (6.5 and 6.0 µg/dL at ages 4 and 5 years, respectively). An additional strength of these studies was the detailed analysis of potential confounding by various demographic and SES-related variables (including HOME score) and other environmental exposures. Covariates were selected for specific models based on their association with a particular test ($p \leq 0.20$), and several models adjusted for maternal IQ, maternal education, and HOME score.

Canfield et al. (2003b) reported associations of concurrent blood Pb level with various parameters of the Shape School tasks, which test the ability of children to recall correctly shapes and colors that are attributed to specific cartoon characters. Concurrent blood Pb level was associated with color knowledge, shape knowledge, and number of correct responses at age 4 years (Figure 5-5 and Table 5-5). At age 5 years, higher lifetime average blood Pb level (area under the curve calculation using repeat measurements between age 6 months and 5 years) was associated with poorer performance on multiple tasks related to learning, working and spatial memory, and planning as assessed by the Cambridge Neuropsychological Testing Automated Battery (CANTAB) in both unadjusted and covariate-adjusted analyses (Canfield et al., 2004). These memory tests in children share homology with the Morris water maze test in animals in that both test the ability of subjects to use efficient search strategies to identify target locations, retain spatial information, and access remembered items in working memory. Both measure the time to complete the task and the number of errors made. At age 4 and 5 years, associations of concurrent blood Pb level with several indices of executive function were

robust to additional adjustment for attentiveness and child FSIQ, indicating that higher blood Pb level is associated with specific aspects of associative learning that are not represented by attentiveness and general knowledge base.



[a]Standard error was estimated from p-value.

[b]Sufficient data were not provided to calculate 95% CIs.

[c]Direction of effect estimate was changed to indicate that a negative estimate represents poorer performance and a positive estimate represents improved performance. Black diamonds, gray squares, and blue circles represent associations with concurrent, lifetime average, and earlier childhood blood Pb levels

Note: Regression coefficients were standardized to their standard deviation to facilitate comparisons among tests with different scales. Studies generally are presented in order of increasing mean blood Pb level. Effect estimates are standardized to a 1 µg/dL increase in blood Pb level within the 10th-90th percentile interval. The percentiles are estimated using various methods and are only approximate values. Effect estimates are assumed to be linear within the 10th to 90th percentile interval of blood Pb level.

Figure 5-5 Standardized regression coefficients describing the associations of blood Pb levels with specific indices of cognitive function in children.

[a]Effect estimates are transformed to a z-score and standardized to a 1 µg/dL increase in blood Pb level in the 10th-90th percentile interval.
[b]95% CI was constructed using a standard error that was estimated from a p-value.
[c]Sufficient data were not provided to calculate 95% CI.
[d]The direction of the effect estimate was changed such that a negative estimate represents poorer performance and a positive estimate represents better performance.
[e]Effect estimates compare test performance of children in higher blood Pb groups to children in lowest blood Pb group.

A recent analysis of the Rochester cohort age 5 years extended previous findings with observations that higher concurrent blood Pb level also was associated with lower performance on many of the same tests executive function as assessed by CANTAB (Froehlich et al., 2007) (Figure 5-5 and Table 5-5). In addition to spatial memory, Froehlich et al. (2007) found associations with rule learning and reversal tasks. Pb exposure of animals consistently has been found to induce impairments in homologous tests of cognitive flexibility, including delayed spatial alternation tests (Section 5.3.2.2). Both of these tests assess the ability of children and animals to complete a task according to a change in rules or reinforcement. Impaired performance in both children and animals is indicated by increased response errors, decreased percent of correct responses, and perseverance (i.e., animals repeatedly pressing the same lever without moving between the two locations or children repeatedly selecting the wrong target despite a change in rules or reinforcement. Some effect estimates describing the blood Pb-cognitive function association were attenuated after adjustment for covariates (e.g., spatial span and planning tasks), whereas others were magnified (e.g., total trials in rule learning, total errors in spatial working memory) (Froehlich et al., 2007). Further, despite attenuation, several associations did not change in statistical significance (Figure 5-5 and Table 5-5).

Froehlich et al. (2007) also added to previous findings in the Rochester cohort by indicating that associations were modified by sex and dopamine receptor (DRD4) genetic variants. An increase in blood Pb level was associated with larger decrements in rule

learning and reversal and spatial memory in children with the DRD4 exon III 7-repeat microsatellite (assessed using a blood Pb-DRD4-7 interaction term, p = 0.042). The biological plausibility for these findings is provided by observations that the DRD4-7 variant is associated with reduced dopamine-induced signaling in downstream pathways (e.g., cyclic AMP), that Pb exposure is found to impact dopaminergic activity (Section 5.3.8.8), and that dopamine is a key neurotransmitter that regulates cognitive processes. Associations of concurrent blood Pb level with rule learning and reversal also were greater in boys. Additional support for these observed interactions was provided by observations with children with the DRD4-7 variant and boys had poorer performance on rule learning and reversal tasks.

Several other studies found associations between higher blood Pb level and poorer performance on rule learning and reversal tasks in children and young adults (Surkan et al., 2007; Kordas et al., 2006; Chiodo et al., 2004; Bellinger et al., 1994a; Bellinger and Stiles, 1993). Across studies, the age range of subjects was 6 to 20 years, and most studies examined concurrent blood Pb levels. In the Boston cohort, age 4.5 year blood Pb levels were associated with poorer cognitive flexibility at age 10 years (Bellinger and Stiles, 1993), and deciduous tooth Pb (measured at ages 6-7 years) was associated with poorer cognitive flexibility at ages 19-20 years (Bellinger et al., 1994a).

Blood Pb-associated decrements in executive function in children with mean blood Pb levels < 5 were not as clearly demonstrated. Among children in five Korean studies, ages 8-11 years, blood Pb level was not associated with performance a color-word association test. In the study of children (ages 6-10 years) participating in NECAT, Surkan et al. (2007) provided information on the blood Pb-cognitive function concentration-response relationship. Children with concurrent blood Pb levels 3-4 µg/dL had lower scores compared with children with blood Pb levels 1-2 µg/dL; however, only a few associations were statistically significant (e.g., digit span, memory, motor speed). In analyses adjusted for caregiver IQ, age, SES, race, and birth weight, children with concurrent blood Pb levels of 5 to 10 µg/dL had lower performance in a number of executive functioning domains such as working memory, visuospatial skills, cognitive flexibility, and ability to formulate, test, and adapt hypotheses (Figure 5-5 and Table 5-5). Compared with children with blood Pb levels of 1-2 µg/dL, children with blood Pb levels 5-10 µg/dL had lower scores on the reading (5.2 points [95% CI: 0.95, 9.45]) and math (4.0 points [95% CI: 0.43, 7.6]) composites of the Wechsler Individual Achievement Test. These decrements were robust to adjustment for child FSIQ. Thus, these findings combined with those from the Rochester cohort (Canfield et al., 2004; Canfield et al., 2003b) provide evidence that higher blood Pb level is associated with decrements in specific cognitive functions that may not be represented by FSIQ, a test of global function.

In other studies of populations with mean concurrent or cord blood Pb level < 3 µg/dL, the contributions of likely higher past Pb exposures cannot be excluded. Also, these studies did not have as extensive consideration for potential confounding. In infants in Krakow, Poland with a mean cord blood Pb level of 1.42 µg/dL, higher cord blood Pb level was associated with a lower score on a visual recognition memory test (Jedrychowski et al., 2008) (Table 5-5). The cord blood Pb levels may have been influenced by past Pb exposures of the mother mobilized from bone stores to the blood. While investigators adjusted for maternal education, parity, and sex, they did not adjust for other SES-related variables such as maternal IQ or HOME score.

The influence of past Pb exposures also is uncertain in the NHANES analyses, which included adolescent subjects born in the 1970s. Krieg et al. (2010) examined an older subset of children (ages 12-16 years) from NHANES III (1988-1994) who were previously examined in Lanphear et al. (2000). Among all ages and older adolescents, higher concurrent blood Pb level was associated with lower scores on block design, digit span, reading score, and arithmetic tests (Figure 5-5 and Table 5-5) (Krieg et al., 2010; Lanphear et al., 2000). In analyses of quartiles of blood Pb level Lanphear et al. (2000) additionally found a monotonic decrease in math and reading scores across increasing quartiles in covariate-adjusted models. Per unit increase in blood Pb level, the decrease in arithmetic and reading scores were larger among children with blood Pb levels less than 2.5 µg/dL than among all subjects, with statistically significant associations found for children with blood Pb levels less than 5 µg/dL. While the NHANES results were adjusted for sex, race/ethnicity, test language, and multiple SES-related variables such as family income and caregiver education, information on HOME score was unavailable.

Krieg et al. (2010) provided additional information on effect modification by vitamin D receptor (VDR) variants. Although there were not differences in blood Pb levels among the various haplotypes of VDR, various polymorphisms and haplotypes modified the association between blood Pb level and a range of neurocognitive tests. The VDR regulates calcium absorption and metabolism, and effect modification by VDR variants is consistent with the well-established mode of action of Pb in mimicking calcium in shared transport and metabolic pathways. However, several inconsistencies were observed by Krieg et al. (2010) in that a particular variant was associated with a lower Pb-associated decrement in some indices but a greater Pb-associated decrement in other indices. For example, among children ages 12-16 years, the VDR rs2239185 CC genotype was associated with the largest blood Pb-associated decrease in digit span score and reading score. The decreases in digit span score (95% CI) per 1 µg/dL increase in concurrent blood Pb level were -1.5 points (-2.2, -0.71) for the CC genotype and -0.26 points (-0.99, 0.46) for the TT genotype. Conversely, the TT genotype was associated with the greatest Pb-associated decrease in arithmetic score. The decreases (95% CIs) in math score per

1 µg/dL increase in concurrent blood Pb level were -8.4 points (-11.5, -5.2) for the TT genotype and -2.7 points (-10.1, 4.6) for the CC genotype. Effect modification by VDR rs731236 was more consistent across cognitive tests, with larger blood Pb-associated decrements in cognitive performance found in children with the CC genotype. It is important to recognize that not all of these VDR variants have been linked to functional changes.

Other recent studies conducted in diverse populations of children also found associations between higher blood Pb level and decrements in learning, memory, and visuospatial skills; however, they had limited or no consideration of potential confounding by SES-related variables, which limits the implications of their findings (Nelson and Espy, 2009; Counter et al., 2008; Min et al., 2007; Vega-Dienstmaier et al., 2006).

Academic Performance in Children

As described in the preceding sections, a preponderance of evidence demonstrates Pb-associated deficits in FSIQ and specific indices of cognitive function, including math, reading, and vocabulary skills. Deficits in global cognitive function and the aforementioned skills can lead to poorer academic achievement and school performance, which may be more objective measures of abilities and skills and have important implications for success later in life. Aptitude tests are used to predict future performance of an individual on a task or test. Achievement tests and school performance, in comparison, assess the actual knowledge of an individual in subject areas the individual has studied and measure the acquired knowledge of that subject. Studies reviewed in the 2006 Pb AQCD consistently demonstrated associations of Pb biomarkers with measures of academic achievement and performance including scores on math or vocabulary tests, class rank, teacher assessment of academic functioning, and high school completion. Several studies found that blood or dentin Pb levels measured at an early age (ages 2-8 years) were associated with academic performance at older ages (ages 8-18 years), suggesting the effect of early exposure to Pb may be persistent (Leviton et al., 1993; Bellinger et al., 1992; Needleman et al., 1990). Several studies found associations with concurrent blood Pb levels (Kordas et al., 2006; Wang et al., 2002a; Al-Saleh et al., 2001; Lanphear et al., 2000). Among recent studies, academic performance was examined less frequently; however, findings were consistent with the extant body of evidence.

The longitudinal study by Bellinger et al. (1992) was particularly noteworthy for examining associations of blood Pb level at several ages from the prenatal period to age 10 years with Kaufman Test of Educational Achievement (KTEA) scores at age 10 years in the Boston cohort. While blood Pb levels at several ages were associated with lower academic achievement scores when in a model alone, only blood Pb level at age 2 years

showed a statistically significant association with lower predicted academic achievement after adjusting for HOME score, child stress, maternal age, race, maternal IQ, SES, sex, birth order, marital status, and number of residence changes. These covariates were selected because they were associated with blood Pb level and KTEA score, changed the blood Pb effect estimate by more than 10%, or because they were recognized to be important predictors of cognitive development (e.g., maternal IQ, birth order, sex). Age 2 year blood Pb level was associated with a similar magnitude of decrease in the KTEA battery composite score in univariate and multivariate models. Additionally, the association was robust to adjustment for FSIQ, indicating that blood Pb levels may be associated with poorer performance on academic tasks not reflected in FSIQ.

Miranda et al. (2007b) and (2009) linked blood Pb surveillance data collected between ages 0 and 5 years with end-of-grade (EOG) testing data for 8,600 fourth grade children in seven of the largest counties in North Carolina and 57,678 children in the entire state, respectively. A key strength of these analyses was the availability of individual-level data on blood Pb level and achievement score on a large number of children representative of the North Carolina fourth grade population, which provided large numbers of children with lower blood Pb levels (2-5 µg/dL). Thus, in this study, there was greater power to discern differences in achievement scores among children in the lower range of blood Pb levels. However, due to the records-based research design, investigators had a smaller set of available potential confounding variables than those typically considered in analyses of neurodevelopmental outcomes. In addition to adjusting for sex, race, school-type, school district, and age of blood Pb measurement, investigators adjusted for participation in a free or reduced lunch program as a measure of SES, and parental education as a measure of parental IQ. Miranda et al. (2007b) additionally adjusted for daily use of a computer as a measure of a stimulating home environment. Higher early childhood blood Pb levels were associated with lower reading and math EOG scores (Figure 5-6 and 5-7), and in both analyses, children with a blood Pb level of 2 µg/dL had lower EOG scores ($p \leq 0.05$) compared with children with a blood Pb level of 1 µg/dL. Further, across deciles of blood Pb level, the decrease in EOG score generally was monotonic (Figure 5-6). In the statewide dataset, compared with children with an earlier (measured at some point between birth and age 5 years) blood Pb level of 1 µg/dL, children with an earlier blood Pb level of 2 µg/dL had a 0.30-point lower (95% CI: -0.58, -0.01) reading EOG score (Miranda et al., 2009).

Note: These results illustrate the decrease from a baseline score of 262.6 for a hypothetical referent white female, screened at 2 years of age, living in Wake County, NC, with parents with a high school education, not enrolled in the school lunch program, and who does not use a computer every day (i.e., model covariates = zero).

Figure 5-6 Associations between childhood blood Pb levels and fourth grade End-of-Grade (EOG) math scores.

While the linear regression analyses indicated fractional-point decreases in EOG scores per 1 µg/dL increases in blood Pb level, Miranda et al. (2009) additionally used quantile regression to discern differential effects in various segments of the EOG distribution (i.e., what is the 10th percentile of EOG scores conditioned on early childhood blood Pb levels). Compared with linear regression, quantile regression is more robust in response to outliers and predicts outcomes at the top and bottom tails of the outcome distribution rather than at the mean. With increasing blood Pb level, the lower tail of the EOG distribution was stretched out more so than were the middle or upper portions of the distribution. For example, an increase in blood Pb level from 1 to 5 µg/dL was associated with a greater decrease in EOG score among children in the 5th percentile of EOG than in children in the 95th percentile of EOG score (Figure 5-7). These findings indicated that children residing at the lowest performance regions of the EOG score distribution may be more affected by Pb exposure. Similarly, using quantile regression, Miranda et al. (2009) showed that while cumulative social risk (lower parental education, being enrolled in a school lunch program) had a greater negative association with academic achievement in these children, blood Pb level was independently associated with EOG score decrements that were as large as 1 to 2 points.

Note: Baseline score calculated for a hypothetical referent individual with a blood Pb level of 1 µg/dL, parents completed college, and not enrolled in the school lunch program (i.e., model covariates = zero).

Figure 5-7 Greater reduction in EOG achievement test scores with increasing blood Pb level in lower percentiles of the test score distribution.

Similar to Miranda et al. (2009), Chandramouli et al. (2009) observed associations between early childhood blood Pb levels (age 30 months) and later academic performance (Standard Assessment Tests [SAT] at age 7 years) among participants of the Avon Longitudinal Study of Parents and Children conducted in the U.K. However, in this study, decrements in SAT score were most clearly indicated in children with blood Pb levels of 5 to 10 µg/dL. Compared with children with blood Pb levels 0-2 µg/dL, children with blood Pb levels 5-10 µg/dL scored 0.51 points lower (95% CI: -0.82, -0.32) on the reading test and 0.49 points lower (95% CI: -0.78, -0.31) on the math test, adjusting for maternal education, home ownership, maternal smoking, home facilities score, parental SES, family adversity index, and parenting attitudes. Children with blood Pb levels 2-5 µg/dL did not consistently have lower scores compared with children with blood Pb levels 0-2 µg/dL. While these aforementioned recent studies found associations for early childhood blood Pb levels, unlike the longitudinal assessment by Bellinger et al. (1992), they did not have blood Pb measurements available at other lifestages. Therefore, recent studies could not provide information on associations with blood Pb levels at other lifestages.

5.3.2.2 Toxicological Studies of Cognition, Memory and Learning

As described in Section 5.3.2.1, epidemiologic studies in children have consistently demonstrated associations between blood Pb levels and decrements in a range of executive functions related to memory, reasoning, problem solving, and verbal skills. Studies in animals also demonstrate Pb-induced decrements in various indices of executive function, and several tests conducted in animals share homology with tests conducted in humans.

Data on neurocognition and learning as well as other nervous system endpoints with concentration-response data are shown in Figure 5-8 and accompanying Table 5-6. These data demonstrate that numerous studies in animal models have demonstrated that Pb exposure produces a spectrum of changes in the central nervous system, including deficits in CNS development and plasticity and altered homeostasis of mediators of cognitive function that manifest with deficits in memory, learning, and cognition. It is thought that early life Pb exposure can permanently alter CNS development and other pathways that contribute to these aforementioned memory and learning deficits, but the animal toxicology data show that multiple sensitive developmental windows for Pb exposure exist (Rice and Gilbert, 1990). As illustrated in Figure 5-8 and Table 5-6, Pb-induced impairments in learning primarily previously were observed in animals with blood Pb levels > 30 µg/dL. Several new studies added to the evidence for impaired learning and memory in animals with lower blood Pb levels, 8-17 µg/dL (Cory-Slechta et al., 2010; Li et al., 2009c; Niu et al., 2009; Virgolini et al., 2008a; Stangle et al., 2007). In these studies of animals with lower blood Pb levels, Pb exposures began early, during the gestational or lactation period.

Study ID in Figure 5-8	Reference	Blood Pb Level (µg/dL)	Outcome
1	Beaudin et al. (2007)	13 & 31	Behavior, neonate: Lactational Pb exposure, offspring deficient in Reward Omission testing.
			Physical development; Postnatal Pb exposure (birth to 4 weeks of age): Pb-dependent development of over-reactivity to reward omission and errors is reversible with chelation treatment.
2	Grant et al. (Grant et al., 1980)	57	Behavior, neonate: chronic Pb exposure (drinking water) to dams and pups, Changed behavior, males.
3	Kishi et al. (1983)	59 & 186	Behavior, neonate: Pb exposure (oral gavage of pups) during lactational period, Changed emotional behavior, males and females.
			Motor function, neonate: Pb exposure (oral gavage of pups) during lactational period, motor function (rotarod performance) impaired, both sexes.
			Physical development; Pb exposure during lactation (oral gavage): Delayed development of righting reflex in male rats.
4	Overmann (1977)	33, 174 & 226	Behavior-Pb exposure (oral gavage of pups) during lactation: aversive conditioning affected by Pb exposure, male and females.
			Cognition-Pb exposure (oral gavage of pups) during lactation: Response inhibition impaired, both sexes.
			Motor function- Pb exposure (oral gavage of pups) during lactation: Increased motor activity and impaired motor coordination (rotarod), male and females.
5	Stangle et al. (2007)	13 & 31	Cognition; Developmental Pb exposure (PND1-PND30): Impaired learning with visual discrimination task, heightened response to errors, both sexes.
			Motor function; Developmental Pb exposure (PND1-PND30): Alcove latency and response latency significantly affected by Pb exposure, both sexes.
6	Gong & Evans (1997)	38 & 85	Cognition-Adult male 21 day Pb exposure: Hyperactivity with Habituation to new cage environment.
			Morphology; 21 day Pb exposure to adult males: Marker of neuronal injury-elevated hippocampal glial fibrillary acidic protein (GFAP).
			Physical development; Adult male rats (21 day Pb exposure): Neurotoxicity measured with brain glial fibrillary acidic protein (GFAP).
7	Rice (1990)	32 & 36	Cognition-Chronic Pb exposure from birth: Spatial discrimination reversal task impairment, both sexes.
8	Li et al. (2009c)	80 & 100	Cognition-Gestational & lactational Pb exposure: Morris water maze performance impaired.
			Morphology; Gestational & lactational Pb exposure: Increased levels of inflammatory cytokines & exocytosis related proteins in brains of pups at weaning, both sexes.
			Oxidative stress-gestational and lactational Pb exposure: Elevated hippocampal TNF levels in offspring, males and females.
9	Li et al. (2010b)	80 & 102	Cognition- Gestational & lactational Pb exposure: Morris water maze performance impaired.
			Morphology: Increased levels of Alzheimer disease-associated proteins in mice with gestational and lactational Pb exposure, both sexes.
			Proliferation/diff/survival, gestational & lactational Pb exposure: Increased hippocampal expression of P-tau and amyloid beta in male and female pups.
10	Cory-Slechta et al. (2010)	10 & 13	Corticosterone: Lifetime Pb +/- stress: Correlation between 9-month old's corticosterone level and frontal cortex dopamine levels in behaviorally tested female offspring.
			Stress: Corticosterone-Lifetime Pb plus stress: Affects FI performance, dopamine and serotonin levels in female offspring.
			Stress: Corticosterone-neurotransmitter-Lifetime Pb exposure in female rats plus stress: Dopamine homeostasis affected.
11	Virgolini, Rossi-George, Weston et al. (2008b)	25	Corticosterone: Maternal Pb plus stress: Elevated corticosterone in male offspring with prenatal stress + offspring stress was further enhanced with Pb exposure.
			Stress: Corticosterone-Maternal Pb plus stress: Affects FI performance.
			Neurotransmitter; Gestational and lactational Pb exposure: Induced DA and 5HT changes in rat offspring.

Study ID in Figure 5-8	Reference	Blood Pb Level (µg/dL)	Outcome
			Stress induced neurotransmitter effects, Maternal Pb plus stress: 5-HT and 5-HIAA (5-HT metabolite), and dopamine turnover were significantly affected in males.
12	Virgolini et al. (2005)	15 & 27	Corticosterone: Chronic Pb exposure from weaning: Pb exposure alone decreased basal plasma corticosterone levels at 5 months of age, males.
			Motor function: Chronic Pb exposure from weaning: Locomotor activity significantly decreased FI response rates & increased post-reinforcement pause period in a concentration-dependent manner, males.
			Stress: Corticosterone-Chronic Pb plus stress: Affects neurotransmitters & FI performance
13	Virgolini, Rossi-George, Lisek et al. (2008a)	31	Corticosterone: Maternal Pb exposure (gestation and lactation) +/- stress: Differential basal corticosterone levels between behavioral and non-behavioral tested rats, females.
		11 &/or 31	Stress: Corticosterone-Maternal Pb plus stress: Affects FI performance, dopamine, serotonin, and NE levels.
			Motor function: Maternal Pb +/- stress: Increased locomotor activity (run rate) with Pb and stress exposure.
		31	Neurotransmitter; Gestational and lactational Pb exposure: Induced NE aberrations in adult rat offspring (both sexes).
			Stress induced motor function: Maternal Pb +/- stress: Increased locomotor activity (run rate) with Pb and stress exposure.
			Stress induced neurotransmitter; Gestational and lactational Pb exposure + stress: Induced HVA (monoamine neurotransmitter metabolite) and NE aberrations in female adult rat offspring.
14	Hu et al. (2008b)	4 & 12	Morphology; Gestational Pb exposure: Neurite outgrowth marker PSA-NCAM decreased in rat pups, both sexes.
			Neurophysiology; gestation Pb exposure: decreased hippocampal sialyltransferase activity, both sexes.
			Physical development; t-Gestational Pb exposure: Early brain synapse development impaired (hippocampal PSA-NCAM).
15	Wu et al. (2008a)	19 & 26	Morphology: Elevated expression of Alzheimer's disease-related genes and Tc factors in aged brains of female monkeys (exposed to Pb as infants).
			Oxidative stress: Elevated oxidative DNA damage in aged brains of female monkeys (exposed to Pb as infants).
16	Tavakoli-Nezhad et al. (2001)	18, 29, & 54	Morphology; 3 to 6 weeks of Postnatal (starting at PND22) Pb exposure in males: Decreased number of spontaneously active midbrain dopamine neurons.
17	Leasure et al. (2008)	10 & 42	Motor function; Mouse maternal (dam) Pb exposure: Induced decreased rotarod performance in offspring (1 year-old male offspring).
			Neurotransmitter; Mouse maternal (dam) Pb exposure: Affects 1 year old male offspring dopamine homeostasis, both sexes.
18	Fortune & Lurie (2009)	8 & 43	Neurotransmitter; Mouse maternal (dam) Pb exposure: Affects offspring superior olivary complex (auditory) neurotransmitters, both sexes.

Memory and Learning - Morris Water Maze

Blood Pb levels have been associated with decrements in both verbal (e.g., digit span) and spatial memory in children (e.g., spatial and visual memory span) (Figure 5-5 and Table 5-5). In the 2006 Pb AQCD, the results from different animal studies testing the effect of Pb on memory were mixed with impaired memory observed in animals with blood Pb levels 10-35 µg/dL but improved memory observed in other studies. Low-dose Pb was not found to affect short-term memory, i.e., recall of a learned task. Mixed results for memory also may be due to the fact that memory tests also test inattention. Memory tests may give incorrect results when opportunities exist for impaired attention to contribute to test results (U.S. EPA, 2006b). In animals, spatial memory is tested most

commonly using the Morris water maze. The 2006 Pb AQCD reported deficits in the Morris water maze performance with Pb exposure. New research continued to show Pb-induced impaired Morris water maze performance. The Morris water maze tests spatial memory and learning by having a mouse swim and locate or remember the location of a platform submerged in opaque water. The Morris water maze is homologous to the spatial memory components of the CANTAB and WISC-R, which test the ability of subjects to recall correctly a sequence of locations (Froehlich et al., 2007; Canfield et al., 2004; Chiodo et al., 2004).

Li et al. (2009c) examined Pb exposures from gestation through lactation. During this period, dams received Pb-acetate dissolved in drinking water (0.1%, 0.5%, and 1% with corresponding blood Pb levels of 4, 8 and 10 µg/dL at postnatal day [PND]21). Beginning at weaning, Pb-exposed pups were subjected to Morris water maze performance testing. Pb-exposed pups had statistically significant increases in escape latency and number of crossings of the platform area at 0.5% and 1% Pb-acetate exposure (blood Pb levels of 8 and 10 µg/dL, respectively), indicating impaired memory and learning (Li et al., 2009c). The pups in Li et al. (2009c) were not separated by sex. Cao et al. (2009) found that chronic administration of the supplement melatonin exacerbated Pb-induced impairments in spatial memory and long-term potentiation. Adult male Wistar rats that had been exposed to Pb-acetate (0.2%) from birth received melatonin (3 mg/kg) from weaning via gastric gavage for 60 days. At this point (PND81-90), animals performed in the Morris water maze, and LTP of the hippocampal dentate gyrus was measured.

Another study found that various dietary supplements or methioninecholine concomitant with Pb exposure in weanling males shortened the escape latency of Pb-exposed pups to resemble more closely the escape latency of control pups (Fan et al., 2010; Fan et al., 2009a). Zinc and methionine were effective dietary supplements in Fan et al. (2009a); glycine, taurine, vitamin C, vitamin B1, tyrosine had no effect on the Pb-associated Morris water maze results. These data on the effect of early life Pb exposure on learning and memory in the Morris water maze affirm earlier findings including those by Kuhlmann et al. (1997) who used maternal Pb diet exposure (gestation and lactation), continuous Pb exposure (gestation through adulthood) or post-weaning Pb exposure and only found only significant impairments in the maternal and continuous exposure groups.

Another component of memory is working memory, which is the ability to temporarily keep information in mind while using the information to perform a related or unrelated task. The Morris water maze measures working memory in addition to learning. The 2006 Pb AQCD reported that working memory as assessed by the Morris water maze was

significantly affected in chronic developmentally Pb-exposed (Pb-acetate in feed 10 days prior to mating through PND 21) female offspring at PND 21 (Jett et al., 1997).

Working memory also can be measured by testing delayed spatial alternation (DSA), which specifically tests spatial reversal learning. With DSA, an animal receives rewards based on alternating responses between two separate levers. In children, tests of spatial reversal learning includes the rule learning and reversal components of the CANTAB, Stroop Test, and WCST, and decrements in DSA have been associated with higher blood Pb levels in children (Figure 5-5 and Table 5-5). Studies detailed in earlier Pb AQCDs showed that Pb-exposed animals had deficits under DSA testing (Alber and Strupp, 1996; Rice and Gilbert, 1990; Rice and Karpinski, 1988; Levin et al., 1987; Levin and Bowman, 1986). Studies in nonhuman primates showed Pb-induced behavioral impairment on DSA tasks (Rice and Gilbert, 1990) across many exposure periods, including early-life and chronic Pb exposures. Specifically, there were multiple lifestages during which Pb exposure induced deficits in this task. As in children, deficits in DSA included increased response errors, decreased percent of correct responses, and perseverance at a task (i.e., repeatedly pressing the same lever without moving between the two locations). These observations have been consistently made in nonhuman primates with continuous Pb exposure or juvenile to adult exposure but less consistently made in rats with juvenile only or juvenile to adult exposure. In fact, some rodent studies showed increased accuracy in the delayed alternation trials (Cory-Slechta et al., 1991). Working memory is a subcategory of executive function or goal-oriented problem solving. Pb-induced deficits in working memory may be one of many factors that contribute to associations between blood Pb levels and inattention observed in humans (Min et al., 2007; Surkan et al., 2007; Chiodo et al., 2004; Schweitzer et al., 2000; Stiles and Bellinger, 1993).

Learning - Y Maze

A recent study using the three-branch radial Y-maze showed Pb-induced effects on learning in rat offspring exposed during lactation and into adulthood (Niu et al., 2009). The Y-maze has a light at the end of each branch. The branch with the illuminated light is a safe area whereas the other two branches are electrified and cause a mild electric shock when entered. The Y-maze test evaluates learning based on three criteria: 1) learning days or the number of days required to learn the maze (90% correctly); 2) the error number (EN) or the number of Y-maze runs required to learn the maze; and 3) the total reaction time (TRT) or the total amount of time spent in the maze per test day. Wistar Albino rat pups were exposed to Pb-acetate during lactation until the termination of the experiment at 12 weeks of age (dam drinking water 300 mg/L, blood Pb level: 17 µg/dL at 6 weeks of age. Rats were evaluated on the three Y-maze endpoints at 6, 8, 10 and

12 weeks of age.) Pb induced statistically significant impairments in learning, in particular, at 8, 10 and 12 weeks of age. EN and TRT were significantly affected only at 8 and 10 weeks, respectively. Hippocampal glutamate levels were also significantly attenuated in Pb-exposed animals, and this is discussed in more detail in Section 5.3.8.4.

Learning - Response Inhibition and Schedule-Controlled Behavior Testing

Response inhibition is another measure of executive function and is measured with multiple tests of premature responses, decreased pause time between two scheduled events, and increased perseverance. These tests include Differential Reinforcement of Low Rates of Responding (DRL), Fixed Interval (FI) testing (Table 5-7), FI with Extinction (FI-Ext) or Fixed Ratio (FR)-FI, and Signal Detection with Distraction. Multiple studies from the 2006 Pb AQCD as well as earlier literature showed that early life Pb exposure contributed to response inhibition across the spectrum of these aforementioned tests. Monkeys with moderate blood Pb levels (11-13 µg/dL) learned the DRL task more slowly but eventually acquired reinforcement rates equal to that in controls. Newer data from female rats exposed to Pb (Stangle et al., 2007) continued to show animals with premature responses after Pb exposure or response inhibition decrements. These findings in animals are consistent with observations in children that blood Pb levels are associated with poorer impulse control (Figure 5-14 and Table 5-9). In children, impulsivity is commonly assessed by having parents or teachers rate problem behaviors such as trouble waiting, interrupting others, and responding at inappropriate times. However, studies also have specifically tested response inhibition assessed using the continuous performance test, which similar to animal tests, measures reactions to a stop signal (Section 5.3.3.1).

The 2006 Pb AQCD discussed learning or cognition as measured with schedule-controlled behaviors including FI and FR operant conditioning and found that FI response rate was affected differentially with low-level (as low as 11 µg/dL) and high-level Pb (peak levels of 115 µg/dL) exposures increasing and decreasing FI response rate, respectively. This nonlinear response was since further explored in recent work, much of which also examined the interaction between stress and Pb exposure.

Table 5-7 Summary of effects of maternal and lifetime Pb exposure on FI performance

	Maternal Pb[b]		Lifetime Pb[c]	
Pb (ppm)	Overall rate[a]	PRP[a]	Overall rate[a]	PRP[a]
0 ppm:				
0-PS	No Significant Effect[d]	No Significant Effect	No Significant Effect	No Significant Effect
0-OS	No Significant Effect	*↓ -23%	No Significant Effect	No Significant Effect
50 ppm:				
50-NS	No Significant Effect	No Significant Effect	*↑ 95%	No Significant Effect
50-PS	No Significant Effect	No Significant Effect	*↑ 79.2%	*↓ -42%
50-OS	*↑ 64.9%	No Significant Effect	*↑ 74.7%	* ↓-39.3%
150 ppm:				
150-NS	*↑ 42.4%	*↓ -30.3%	No Significant Effect	No Significant Effect
150-PS	No Significant Effect	*↓ -25.7%	*↑ 90.7%	*↓ -44.7%
150-OS	*↑ 59.2%	No Significant Effect	*↑ 78.5%	No Significant Effect

Note: *Dam blood Pb levels ranged from 5-13 µg/dL over gestation and lactation; offspring blood Pb ranged from 7-13 µg/dL from early life time points out to ten months of age. Thus, this study demonstrates that lifetime Pb exposure with or without prenatal stress induced learning deficits in female mice. Mechanistically, these authors propose that associations of Pb and stress with learning deficits may be related to aberrations in corticosterone and dopamine.

[a]Based on calculation of group mean values across session block post-stress challenge for both maternal and lifetime Pb exposure studies. All calculations represent percent of 0-NS control values; ↑, represents increase; ↓, represents decrease. PRP = post-reinforcement pause.

Learning Ability with Stress

The combined paradigm of Pb exposure and stress experienced by a laboratory animal is now being studied by multiple investigators who are focusing on the common pathway of HPA axis alteration and altered brain neurotransmitter levels. These studies indicated greater impairments in learning with Pb when combined with stress. These findings provide support for the association between higher blood Pb level and lower MDI score observed in children with mothers with low self-esteem but not children with mothers with high self-esteem (Surkan et al., 2008) (Table 5-4). In children, maternal self-esteem has been linked with the ability to cope with stress and improved maternal-child interactions. As indicated in Figure 5-8 and Table 5-6, Pb exposure has been shown to increase corticosterone levels and exacerbate Pb-induced dopamine release and learning ability. Cory-Slechta and colleagues have conducted multiple investigations in this area. Most recently, they showed enhanced learning deficits in female rat offspring following lifetime Pb exposure combined with maternal restraint or prenatal stress (Cory-Slechta et al., 2010). This exposure paradigm used dams who were exposed to Pb for 2 weeks prior

to mating through lactation and pups from a mixed sex litter from their dams during the aforementioned period and then via drinking water Pb (50 ppm) through the remainder of their lifetime. The resultant blood Pb levels of dams and pups ranged from 5 to 13 µg/dL.

In a separate investigation, Pb plus stress-related outcomes were examined in female offspring of dams who were exposed to Pb from 2 months prior to mating through lactation, i.e., developmental Pb exposure (2 exposure groups: 50 or 150 ppb Pb-acetate in drinking water) (Virgolini et al., 2008a). Dams were subject to restraint stress at GD16-17. Compared with controls, marked increases in response rates on FI performance were found in the Pb plus stress female offspring, whose mean blood Pb level was 11 µg/dL (50 ppb Pb-acetate). Because these animals did not show effects with maternal stress or Pb exposure alone, the results indicated a potentiation of effects with Pb and stress co-exposures.

Similarly, lifetime Pb exposure (50 or 150 ppm, resulting in blood Pb levels of 11-16 and 25-33 µg/dL, respectively) plus stress (maternal or offspring) also induced FI aberrations at the post-reinforcement pause (PRP) period in female offspring (Rossi-George et al., 2011) (Table 5-7). Again, the results indicated a potentiation of effects. Within the FI schedule, the PRP represents timing capacity or proper temporal discrimination. Namely, the PRP is the period during which the animal must wait or pause before depressing the lever for a reward. In this case, Pb plus stress exposed animals started responding too early due to a decreased pause or PRP interval. Aberrant FI performance in infants and children has been used as a marker for impulsivity. Separately, overall FI response rate, a hyperactive behavior, was significantly increased with Pb exposure alone and with maternal or offspring stress at the 50 ppm exposure dose. At 150 ppm Pb, stress (maternal or offspring) increased FI response rate but Pb alone had no effect on FI. Biochemical analysis of possible mechanistic contributions to these aberrations revealed alterations in frontal cortex norepinephrine, reductions in dopamine homeostasis in the nucleus accumbens, and enhancement of the striatal monoamine system. This study on the effect of lifetime Pb exposure with or without stress on FI testing itself or during the PRP component of FI testing further affirms Pb-related learning deficits and provides possible mechanistic explanations.

Pb exposure over various developmental windows has been shown to affect corticosterone levels in rodents. These findings indicate that associations of Pb and stress with learning deficits (FI testing in females) may be related to aberrations in corticosterone and dopamine. Maternal Pb exposure (150 ppm drinking water from 2 months prior to mating through lactation with restraint stress as detailed above) induced increased basal corticosterone in female and male offspring at 9 months of age; no interactions of Pb and stress were observed in this model (Cory-Slechta et al., 2004). By

14 months of age, these offspring had reduced corticosterone concentrations versus control animals, indicating a possible acceleration of age-related decreases in basal corticosterone levels (Cory-Slechta et al., 2008). Pb-induced decreases in corticosterone were enhanced with maternal stress. Postnatal exposure of male rodents to Pb (PND 21-5 months of age) produced animals with significant decrements in baseline corticosterone; this effect produced a U-shaped concentration-response curve with significant decrements in basal corticosterone levels in the 50 ppm exposure group versus control (Virgolini et al., 2005). In summary, developmental (gestational and lactational) and post-weaning exposure to Pb induced changes in the HPA axis (corticosterone levels) in both sexes that were dynamic as the animal aged.

Mechanistic understanding of the cognitive deficits observed with Pb and/or stress exposure was explored in a recent study. HPA hypofunction following dam Pb exposure (pup gestational and lactational Pb exposure) with or without maternal stress was reported (Rossi-George et al., 2011; Virgolini et al., 2008a). This study used the same model of developmental Pb exposure as is detailed in the preceding paragraph. Outcomes were examined in both male and female offspring. At 2 months of age without stress, basal corticosterone in females was significantly increased with 150 ppm Pb (resulting in blood Pb level of 32 µg/dL at PND21) and 50 ppm Pb (resulting in blood Pb level of 19 µg/dL) (Figure 5-9). Pb plus stress attenuated the Pb-induced elevations in corticosterone to baseline levels (Figure 5-9). At age 10 months, Pb and stress accelerated the age-dependent decrease in corticosterone levels in females. In males, basal corticosterone levels were not affected significantly by Pb and/or stress at 2 or 10 months of age (Figure 5-9). These authors also explored the function of the glucocorticoid negative feedback loop using the dexamethasone suppression test and found that Pb and/or maternal stress significantly impacted this negative feedback by increasing nuclear glucocorticoid receptor levels. This negative feedback loop was impacted more at the lower dose (50 ppm versus 150 ppm Pb-acetate). As summarized in Table 5-7, the results indicate that lifetime Pb exposure when combined with stress can exacerbate impairments in learning. The interaction between Pb and stress may be mediated via effects on corticosterone and dopamine.

Figure 5-9 Mean basal corticosterone levels of female and male offspring exposed to lifetime Pb.

Another study examined the effects of Pb on the HPA axis but examined the interaction with an outside stress administered using control vehicle injections (Rossi-George et al., 2009). The corticosterone response to this vehicle injection stress was prolonged in a nonlinear concentration-dependent manner in both sexes with the most profound effects observed at the lower 50 ppm Pb dose. Maternal stress also prolonged the corticosterone stress response to vehicle injection and enhanced the Pb effect in males. To test the negative feedback of the HPA axis, exogenous dexamethasone (DEX) was administered to suppress endogenous corticosterone. The DEX test revealed HPA axis hypofunction. Specifically, Pb and Pb plus maternal stress initially reduced the ability of DEX to suppress corticosterone. With time, the effect of DEX in males induced prolonged corticosterone suppression or failure to return to baseline as was observed in control animals. In summary, dam Pb exposure induced HPA negative feedback hypofunction in both sexes of offspring with an inverse U concentration-response function.

These studies of lifetime exposure (2011; Rossi-George et al., 2009) reported different basal stress hormone levels with Pb exposure. Males with lifetime Pb exposure had no statistically significant corticosterone response to Pb exposure; whereas males with dam Pb exposure had statistically significant decreases in corticosterone at 5 months of age in

the 50 ppm exposure group only (not in 150 ppm Pb exposure group). On the other hand, females had concentration-dependent corticosterone responses to Pb exposure in both exposure models (lifetime Pb exposure and dam Pb exposure). Maternal stress alone also led to HPA axis negative feedback hypofunction. Pb plus maternal stress enhanced negative feedback in males and attenuated this effect in females. Pb exposure with or without maternal stress prolonged the effect of DEX-dependent corticosterone suppression in males. These data together show that HPA axis alterations could provide a link between the contribution of Pb and stress to health effects.

Schedule-controlled behavior is often measured using FI or FR testing. Because the FI animals are regularly handled by laboratory personnel and participate in tests of cognition, their baseline level of stress may be skewed from that of a laboratory animal that constantly remains in a cage without daily handling. Because effects on the HPA axis are of interest to Pb researchers, the baseline corticosterone levels of animals that have participated in behavior testing (FI) and those who have not (NFI) have been compared. Specifically, the corticosterone differences between FI and NFI animals after developmental Pb exposure (dam-only Pb exposure) have been measured. Virgolini et al. (2008b) found that basal corticosterone levels were significantly different between FI and NFI animals. Also, the combination of dam Pb exposure with maternal stress was explored in FI and NFI animals. At the baseline age of 4-5 months, NFI animals displayed significant differences from FI animals. Pb exposure with or without stress did not induce differences in corticosterone levels in FI females. The corticosterone level of male FIs was affected by Pb and stress exposure (Virgolini et al., 2008b). In the FI males, the 50 ppb Pb exposure group (50Pb) had decreased corticosterone versus control (no Pb exposure) and the 150 ppb Pb exposure group (150Pb) had elevated corticosterone versus control. Male NFI animals showed a U shaped concentration-response curve with 50Pb animals having significantly less corticosterone than did control or 150Pb animals. In the NFI males, stress did not affect corticosterone levels or interact with the effect of Pb. NFI females exposed to 150Pb had significantly elevated corticosterone versus control (no Pb exposure). These data demonstrate that behaviorally trained animals have altered HPA axis and response to Pb exposure versus animals that are housed under conditions without daily handling by caregivers.

Virgolini et al. (2008b) also expanded evidence for Pb exposure-stress interactions through the examination of the effects additional intermittent stress as an adult. The authors proposed that associations of Pb and stress with learning deficits (FI testing in females) may be related to aberrations in corticosterone and dopamine. Dam exposure to Pb (50 or 150 ppm Pb-acetate) followed by intermittent stress (cold, novelty or restraint) in offspring as adults induced statistically significant changes in FI response rate. Females were more sensitive to the adult intermittent stressors at the higher dose of Pb

(150 ppm) with statistically significant increases in FI response rate and decreased PRP, i.e., increased impulsivity (Figure 5-10). Males were more sensitive (decreased FI response rate due to decreased run rate) to the restraint stress at the lower Pb dose (50 ppm). At the higher dose of Pb, males were more sensitive to the cold stress (increased FI response rate and increased run rate) (Figure 5-11). Corticosterone levels were examined in this study and showed concentration-dependent correlations with FI outcomes in females but were independent of dose in males.

Another study examined female rats with lifetime Pb exposure combined with prenatal stress and found enhanced learning deficits (drinking water 50 ppm Pb-acetate, resulting in offspring blood Pb levels: 7-13 µg/dL) (Cory-Slechta et al., 2010). Learning was evaluated with multiple schedule of repeated learning (RL) and performance testing. RL was impaired, but performance was not affected with Pb exposure. The Pb-impaired RL was further enhanced with prenatal stress. There were statistically significant associations between Pb/stress and corticosterone concentration, dopamine from the frontal cortex, dopamine turnover in the nucleus accumbens, and total number of responses required to learn a sequence. Also, Pb-exposed offspring with and without maternal stress exposure had statistically significant decreases in hippocampal nerve growth factor (NGF) versus controls. Thus, this study demonstrated that lifetime Pb exposure with or without prenatal stress induced learning deficits in female mice.

Cognitive Flexibility

Cognitive flexibility is a component of executive function that measures the ability to reallocate mental resources when situations change (Monsell, 2003). This flexibility is assessed as the ability to alter behavioral responses according to the context of the situation and incorporates the function of attention, working memory, and visual processing. Discrimination reversal learning and concurrent random interval (RI-RI) scheduling are used to measure cognitive flexibility. The 2006 Pb AQCD reported discrimination reversal learning deficits in monkeys with blood Pb levels of 11-20 µg/dL. Rats also showed similar deficits but the authors attributed the changes to learning-related problems instead of cognitive flexibility (Garavan et al., 2000; Hilson and Strupp, 1997). Interestingly, recent work has shown that N-Methyl-D-aspartic acid or N-Methyl-D-aspartate (NMDA) receptors and D2-like receptors, two well-characterized targets of Pb, are involved in discrimination reversal learning (Herold, 2010). Another test of cognitive flexibility is called concurrent random interval (RI-RI) scheduling in which depression on two response levers is reinforced at different frequencies. The 2006 Pb AQCD reported monkeys with Pb-induced cognitive flexibility impairment under RI-RI (Newland et al., 1994). Coherence for these observations of Pb-induced deficits in cognitive flexibility is provided by consistent evidence in animals and children for associations of Pb with

individual tests of inattention, memory, and visual processing. Studies in children also demonstrate associations between blood Pb levels and decrements in specific tests of cognitive flexibility that are homologous to tests in animals such as discrimination reversal learning, the WCST, and Stoop test (Figure 5-5 and Table 5-5). While tests in animals measure the ability to complete a task according to changes in reinforcement, tests in humans assess the ability of subjects to complete a task according to changes in rules.

5.3.2.3 Toxicological Studies on the Effects of Chelation

Earlier work in the animal toxicological literature has shown that succimer or chelation treatment of Pb-exposed lab animals was able to normalize various aberrant Pb-induced behaviors including activity level, habituation (Gong and Evans, 1997) and forced-swim immobility (Stewart et al., 1996). A more recent study examined the effect of succimer treatment on various behavioral and cognitive outcomes in control and neonatally Pb-exposed female animals (PND 1-30 Pb-acetate exposure, 300 ppm dam through lactation and either 30 or 300 ppm pup water) by drinking water, generating a moderate Pb (m-Pb) exposure and a high Pb (h-Pb) exposure group. Pb blood levels at PND52 in the control, m-Pb, h-Pb, m-Pb+succimer, and h-Pb+succimer were 1.5; 12.6; 31; 2.8; and 8.5 µg/dL, respectively. Brain Pb levels at the same time for the same groups were 41 (control), 1,040 (m-Pb), 3,690 (h-Pb); and 196 (m-Pb+succimer) and 1,370 (h-Pb+succimer) ng/g dry weight. Succimer treatment significantly attenuated the m-Pb induced impaired learning ability. Effects on arousal that were significantly affected in h-Pb rats were significantly attenuated with succimer treatment. Succimer treatment in the h-Pb animals only slightly improved learning ability but did not improve the impaired inhibitory control (Stangle et al., 2007). These are important findings because they provide evidence that certain neurobehavioral or cognitive impairments associated with Pb exposure appear to be reversible with chelation therapy.

In another study, a 3-week course of Pb-acetate (PND 1-17, dam drinking water) plus or minus succimer/chelator (PND 31-52) treatment was given to determine if succimer could alleviate behavioral deficits in rats exposed to Pb for the first 4 weeks of life. Pb-exposed animals had altered reactivity and increased reward omission and errors. Pb-exposed animals receiving chelation treatment had normalized reactivity to reward omission and errors (Beaudin et al., 2007). Pb-induced behavioral abnormalities were attenuated with chelation therapy.

The interaction between Pb and methionine choline also has been examined (Fan et al., 2009a). Pb-exposed rats were supplemented with methionine choline to provide

information on its effect on Pb disposition in various tissues (blood, bone, brain) and its contributions to neurocognitive or neurobehavioral changes. As a sulfur source, methionine is a chelator and a free-radical scavenger. Choline is important for cell membranes and neurotransmitter synthesis (Zeisel and Blusztajn, 1994). In this model, methionine choline attenuated Pb-induced memory and learning deficits (Section 5.3.2.2). Exposure of weanling male rats to Pb-acetate in drinking water (300 mg/L) through PND60 produced a blood Pb level of 60 µg/dL, bone Pb level of 165 µg/g, and brain Pb level of 0.63 µg/g. Methionine choline supplementation significantly attenuated blood and bone Pb levels but produced a nonsignificant attenuation of brain Pb (0.51 µg/g) in rats that had significant improvements in learning and memory (Section 5.3.2.2). Also, in another study, the metal chelators DP-109 and DP-460 were neuroprotective for Pb-related effects in the ALS mouse neurodegenerative model or Tg(SOD1-G93A) model (Petri et al., 2007).

In summary, succimer or chelation treatment appears to be able to restore Pb-dependent impairments of learning and arousal and be neuroprotective in a concentration-dependent fashion. In these studies, succimer use was more efficacious at lower doses of Pb exposure. Chelation did not restore Pb-impaired inhibitory control. Chelation with the antioxidant supplement affected the disposition of Pb in various tissues, significantly attenuating blood and bone Pb levels and nonsignificantly attenuating brain Pb.

5.3.2.4 Integrated Summary of Cognitive Function in Children

Results from recent epidemiologic studies and animals studies expand the strong existing evidence base demonstrating that Pb exposure is associated with impaired cognitive function in children. A large epidemiologic evidence base demonstrates associations of higher blood Pb level with lower FSIQ in school-aged children, lower MDI scores in children ages 6 months to 3 years, and lower scores on tests of specific cognitive functions in children ages 6 months to age 16 years (Figure 5-2 and Figure 5-5; Table 5-3, Table 5-4, and Table 5-5). Blood Pb level has been associated with a range of cognitive indices, including memory, verbal and math skills, and cognitive flexibility. There was no clear indication that blood Pb level was more strongly associated with performance in a particular domain of cognitive function. Studies in animals clearly demonstrated impaired performance on Morris Water Maze, the delayed spatial alternation, and discrimination reversal learning with Pb exposure. These animal observations provided strong coherence with associations in children with homologous tests of spatial memory and rule learning and reversal (Figure 5-5 and Table 5-5). Several studies found that blood or dentin Pb levels measured at an early age (ages 2-8 years) were associated with poorer academic performance at older ages (ages 8-18 years),

suggesting the effect of early exposure to Pb may be persistent and have important implications for success later in life.

The weight of epidemiologic evidence for Pb-associated cognitive function decrements was provided by several prospective studies conducted in diverse populations that found associations with blood Pb levels measured during various lifestages (concurrently, prenatally (cord or maternal), earlier in childhood, and averaged over multiple years) and had extensive evaluation of potential confounding variables. The association with FSIQ was substantiated in a pooled analysis of children, 5 to 10 years of age, participating in seven prospective studies (Boston, MA; Cincinnati, OH; Rochester, NY; Cleveland, OH; Mexico City, Mexico; Port Pirie, Australia; and Kosovo, Yugoslavia) (Lanphear et al., 2005). Several new studies added evidence for associations of FSIQ with concurrent blood Pb level in populations with lower mean blood Pb levels. Previously, the weight of evidence supported these associations in populations with mean blood Pb levels in the range of 5-10 µg/dL. However, several new studies shifted the weight of evidence to lower blood Pb levels (primarily concurrent), with populations means in the range of 2-7 µg/dL (2011; Kim et al., 2009b; Min et al., 2009; Zailina et al., 2008; Chiodo et al., 2007). Studies of specific cognitive indices and academic performance did not consistently find decrements in performance in children with blood Pb levels < 5 µg/dL (Cho et al., 2010; Miranda et al., 2010; Chandramouli et al., 2009; Surkan et al., 2007). Several new toxicological studies added to the evidence for impaired learning and memory in animals with lower blood Pb levels, 8-17 µg/dL (Cory-Slechta et al., 2010; Li et al., 2009c; Niu et al., 2009; Virgolini et al., 2008a; Stangle et al., 2007). A large body of new evidence from Cory-Slechta and colleagues demonstrated that lifetime Pb exposure when combined with stress in animals exacerbated impairments in learning (2011; Cory-Slechta et al., 2010; Rossi-George et al., 2009; Virgolini et al., 2008a). Findings also indicated that these interactions potentially were mediated via effects on corticosterone and dopamine.

With regards to important lifestages of Pb exposure, the weight of toxicological evidence demonstrates impaired learning and memory in animals exposed to Pb gestationally with or without early postnatal exposure. In particular, impairments in learning and memory observed with lower blood Pb levels (8-17 µg/dL), were found with Pb exposures that began during the gestational or lactation period. The prospective epidemiologic studies found decrements in cognitive function of children in association with concurrent, prenatal (cord and maternal), early childhood, and cumulative average blood Pb levels. However, collectively, based on the frequency of examination, the weight of evidence demonstrates associations between cognitive function decrements and concurrent blood Pb levels in children ages 4-10 years. Among studies that examined MDI in children ages 6 months to 3 years, several found stronger associations of MDI with prenatal (maternal

or cord) blood Pb than with postnatal child blood Pb (Hu et al., 2006; Bellinger et al., 1987; Dietrich et al., 1987a; Vimpani et al., 1985). Child concurrent or lifetime average blood Pb levels also were associated with MDI scores (Claus Henn et al.; Solon et al., 2008; Surkan et al., 2007; Tellez-Rojo et al., 2006; Wasserman et al., 1992; Vimpani et al., 1985). Thus, both postnatal child and maternal Pb exposures may contribute to lower cognitive function in young children. It is important to note that in studies that examined maternal pregnancy or cord blood Pb levels, there is greater uncertainty regarding the relative contributions of maternal past and recent Pb exposures that contributed to associations. The influence of past or cumulative maternal Pb exposures was supported by observations that maternal patella Pb levels were associated with MDI among children at age 2 years in Mexico City (Gomaa et al., 2002). Nonetheless, results for prenatal blood Pb levels and concurrent child blood Pb levels measured during specific postnatal ages indicate that relatively short-duration Pb exposures (< 1 year) influence the cognitive development of children between birth and age 3 years. Short-duration Pb exposures may be especially important during early childhood because processes such as neurogenesis and synaptic pruning are highly active during the first few years of life (Rice and Barone, 2000; Landrigan et al., 1999).

Epidemiologic studies found independent associations of blood Pb level after adjusting for multiple potential confounding factors, including parental IQ, SES, household income, and HOME score. In most studies that provided unadjusted and adjusted effect estimates, blood Pb level was found to be associated with a smaller but statistically significant decrement in FSIQ after adjusting for potential confounding factors (Palaniappan et al., 2011; Kim et al., 2009b; Chiodo et al., 2007; Froehlich et al., 2007; Lanphear et al., 2005; Canfield et al., 2003a). Analyses of associations of covariates with blood Pb level and cognitive function indicated that the potential confounding variables may vary across populations and endpoints. HOME score was not associated with every cognitive index. Studies that adjusted for multiple SES-related factors but did not examine HOME score produced similar magnitudes of associations as did studies that adjusted for HOME score (Table 5-3, Table 5-4, toTable 5-5). Thus, confounding by HOME score may be minimized when other correlated variables are accounted for in analyses. Further, it is uncertain the extent to which HOME score alone may confound blood Pb-IQ associations as studies have not reported the magnitude of change in the blood Pb effect estimate with just the addition of HOME score in the model. Thus, while the caregiving environment can be an important confounder, the overall weight of evidence indicates that it does not mitigate the strong findings linking higher blood Pb levels with lower FSIQ in children. Prenatal drug exposure also was not found to have a large influence on the relationship between blood Pb level and FSIQ (Min et al., 2009; Chiodo et al., 2007). That Pb exposure induces impairments in tests of learning and memory in animals further that are directly homologous to tests conducted in children

further demonstrates that confounding by SES and HOME does not fully account for the associations between blood Pb levels and cognitive function observed in children.

The evidence from epidemiologic and toxicological studies linking Pb exposure with decrements in multiple cognitive functional domains is strengthened by the well-characterized toxicological evidence for Pb exposure interfering with development of the brain and activity of neurochemical processes that mediate cognitive function (Section 5.3.8). Pb has been shown to increase the permeability of the blood-brain barrier and deposit in the target central nervous system. Pb has been shown to impair neurogenesis, synaptic architecture, and neurite outgrowth. The high activity of these processes during fetal and infant development provides biological plausibility for young children being particularly at increased risk for Pb-associated impairments in cognitive function. Cognitive function is mediated by the cortical and subcortical structures of the brain that integrate function in the hippocampus, prefrontal cortex, and nucleus accumbens using dopamine and glutamate as primary neurotransmitters. Experimental studies have shown that Pb induces changes in dopamine release in these regions. Numerous studies also have shown Pb-induced changes in hippocampal function, including changes in glutamate release, receptor binding, and long-term potentiation. Thus, several lines of toxicological evidence establish a neuroanatomical and neurochemical basis for the effect of Pb on cognitive function

5.3.2.5 Epidemiologic Studies of Cognitive Function in Adults

Adults without Occupational Lead Exposures

As described in the preceding section, Pb exposure of animals that begins in gestation and lasts through the early postnatal period or for a lifetime has been shown to induce learning impairments in adult animals. Less well characterized are learning impairments in adult animals due to adult-only Pb exposures. In contrast, epidemiologic studies have examined cognitive performance in adults primarily in association with concurrently measured blood and bone Pb levels. For nonoccupationally-exposed adults, the 2006 Pb AQCD cited some evidence for associations of cognitive performance with bone Pb levels but not blood Pb levels (U.S. EPA, 2006b). Studies published since the 2006 Pb AQCD continued to indicate that bone Pb levels were associated more consistently with cognitive function in nonoccupationally-exposed adults (Table 5-8). Despite the large number of available publications, it is important to recognize that several studies are variants on analyses in the same population (e.g., NHANES or the Normative Aging Study [NAS]) and should not be considered as all independent assessments of the Pb-cognitive function relationship. Another point to consider is that although cross-sectional

and longitudinal studies have been conducted, most examine the associations between one measurement of cognitive function and one concurrent measurement of blood Pb level. Such a design has the inherent weakness that temporality cannot be determined, which limits the causal inference regarding the effects of Pb exposure. When bone Pb level is used as the exposure measure, this issue is mitigated somewhat because bone Pb is a biomarker that reflects many cumulative years of exposure. Additionally, with single measurements of both blood and bone Pb level, it is difficult to characterize the specific timing, duration, and level of Pb exposure that contributed to the associations observed with cognitive function. This uncertainty may apply particularly for assessments of blood Pb levels, which are influenced both by current exposures and cumulative Pb stores in bone that are mobilized during bone remodeling compared with occupationally-exposed adults (Sections 4.3 and 4.7.3).

Several analyses of the large prospective Baltimore Memory Study and NAS have contributed to greater understanding of the relationship between biomarkers of Pb and cognitive effects in adults. In both cohorts, subjects were evaluated periodically with in-person clinical assessments and self-administered questionnaires. Both studies were noted for comparisons of associations between bone and blood Pb levels within the same cohort and for their repeated assessments of Pb biomarker levels and cognitive function over time. In particular, the repeated assessments permitted the examination of associations of Pb biomarkers with changes in cognitive function over time, which allowed investigators to establish temporality between Pb biomarker levels and subsequent changes in cognitive function. The Baltimore Memory Study (BMS) included men and women, 50-70 years of age, residing in Baltimore, MD. A total of 1,140 out of 2,351 (48.5%) subjects participated from neighborhoods that represented a diversity of race and SES. Of particular note, this study was unique in that it included a large proportion of African-Americans (n=395). In comparison, the NAS involved only men (original n = 2,280) residing in the Greater Boston area. Subjects primarily were white and at enrollment were aged 21 to 80 years and had no current or past chronic medical conditions. Studies differed with respect to the potential confounding variables analyzed. The most notable difference was the inclusion of age, smoking and alcohol intake as covariates in the NAS analyses. Despite differences in study population characteristics and potential confounding variables considered, findings were similar between cohorts.

In the BMS, longitudinal analyses were conducted with repeat cognitive testing of study subjects at approximately 14-month intervals. Most subjects completed follow-up; 91% of the original cohort returned for a second round of testing and 83% for a third round each (Bandeen-Roche et al., 2009). An interquartile range higher tibia Pb level (12.7 μg/g) was associated with a 0.019 units per year decrease in eye-hand coordination z-score, adjusting for age, sex, interviewer, race and SES. Tibia Pb was associated with a

larger decrease among African Americans than among whites (Table 5-8). Tibia Pb levels were weakly associated with other time-related decreases in other indices of cognitive function (e.g., language, processing speed, executive function).

Cross-sectional analyses of the BMS included comparisons of the associations for blood and bone Pb level. The 991 adults in Shih et al. (2006) had a mean (SD) blood and tibia Pb levels of 3.46 (2.23) μg/dL and 18.7 (11.2) μg/g, respectively, Whereas higher concurrent blood and bone Pb level both were associated with poorer performance in the domains of language, processing speed, eye-hand coordination, executive function, verbal memory and learning, visual memory, and visuoconstruction, associations with tibia Pb level tended to be larger in magnitude (per SD increase) and statistically significant (Table 5-8). Tibia Pb levels were associated with worse performance on tests in all domains in models adjusted for age, sex, testing technician, and presence of the apolipoprotein (APO)E-ε4 allele (potential risk factor for Alzheimer's Disease). The magnitudes of associations were attenuated with additional adjustment for education, race, and SES. In these fully-adjusted models, higher tibia Pb levels were associated with poorer performance in domains except language and processing speed, with a borderline statistically significant association observed for visuoconstruction. In linear models, visuoconstruction scores were 0.0044 SDs (95% CI: -0.0091, 0.0003) lower per 1 μg/g bone higher tibia Pb level. Analysis of a quadratic term for tibia Pb indicated no evidence of nonlinearity.

Other cross-sectional analyses indicated effect modification by race and neighborhood psychosocial hazards. In contrast with the longitudinal results, race-stratified analyses of persistent effects in cross-sectional analyses indicated that tibia Pb levels were associated with greater decreases in performance on tests of eye-hand coordination, executive functioning, and verbal memory and learning among whites than among African Americans (Bandeen-Roche et al., 2009) (Table 5-8).

[a]Studies are presented by cohort then generally in the order of discussion in the text.

[b]Effect estimates have been standardized to the standard deviation of the cognitive test scores and standardized to an SD or IQR increase in blood or bone Pb level.

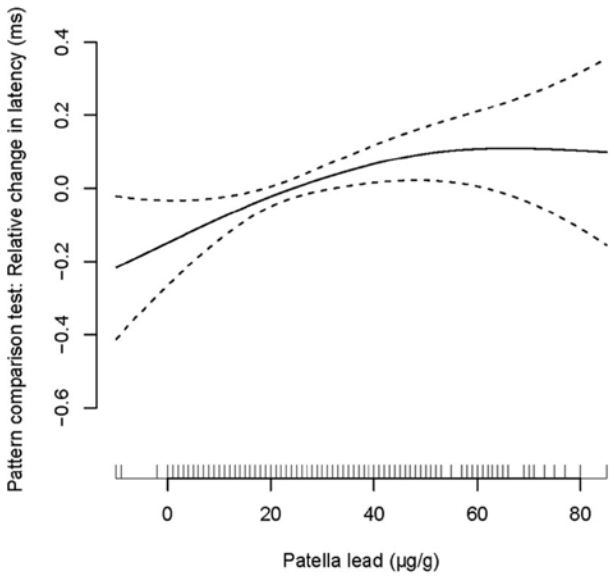
[c]Effect estimates indicate interactions between Pb and category of neighborhood psychosocial hazard (NPH), with the lowest tertile of NPH serving as the reference group.

[d]Effect estimates indicate interactions between Pb and ALAD genotype.

[e]The directions of effect estimates were changed to indicate a negative slope as a decrease in cognitive performance.

[f]Results refer to mean cognitive function scores among tertiles of bone Pb.

Similar to the BMS, in the NAS cohort, higher tibia Pb levels were associated with decreases in cognitive performance over time (Weisskopf et al., 2007a). Weisskopf et al. (2007a) expanded evidence by finding associations with patella Pb levels. Two measurements of cognitive function, collected approximately 3.5 years apart were available for 60-70% of participants. Longitudinal analyses were conducted with repeated measures plus a bone Pb-time interaction term in order to estimate the association between bone Pb level and decline in cognitive test score over time. Although bone Pb levels were associated with increased response latency on a pattern comparison test, they were associated with fewer errors on the same test. The authors proposed that this may be related to slowing reaction time to improve accuracy. When the nine men with the highest bone Pb levels were removed, the association with fewer errors was no longer statistically significant. However, the authors did not indicate whether the point estimate changed. In the analysis with patella Pb, Weisskopf et al. (2007a) found a nonlinear association, with latency times becoming worse over time (i.e., larger values or slower response time) up to approximately 60 µg/g patella Pb, but the change over time leveling off at higher levels (Figure 5-12). Below 60 µg/g, a 20 µg/g difference in patella Pb level was associated with an increase in latency of approximately 0.15 ms.



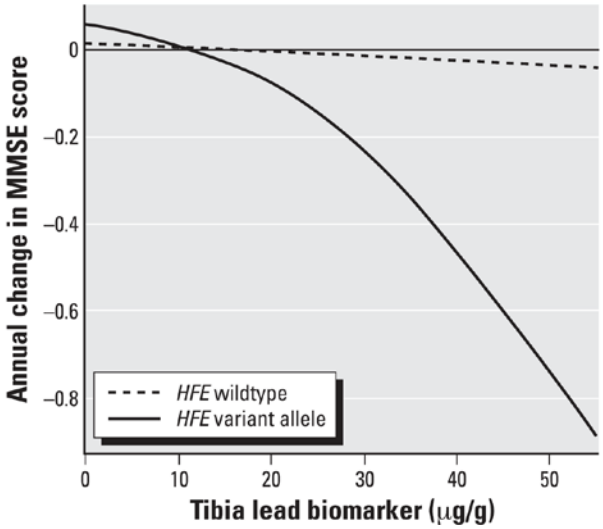
Source: Reprinted with permission of Williams & Wilkins, Weisskopf et al. (2007a).

Note: Models are adjusted for age, age squared, education, smoking, alcohol intake, years between bone Pb measurement and first cognitive test, and years between the cognitive tests. The 9 subjects with the highest patella Pb concentrations (>89 µg/g bone mineral) were removed. The estimate is indicated by the solid line and the 95% confidence interval by the dashed lines. Patella Pb concentrations of all individual subjects are indicated by short vertical lines on the abscissa. (reference = 0 at mean of patella Pb concentration).

Figure 5-12 Nonlinear association between patella Pb level and the relative change over time in response latency on the pattern comparison test.

Longitudinal analysis of the NAS cohort also indicated effect modification by hemochromatosis (HFE) gene variants (Wang et al., 2007a). In models adjusted for age, years of education, nonsmoker, former smoker, pack-years, nondrinker, alcohol consumption, English as first language, computer experience, and diabetes, an interquartile range higher tibia Pb level (15µg/g) was associated with a 0.22 point steeper annual decline (95% CI: -0.39, -0.05) in MMSE score among men with either the H63D and C282Y variant. The association was found to be nonlinear, with larger Pb-associated declines observed at higher tibia Pb levels (Figure 5-13). This difference was comparable to the difference in MMSE score between men who were 4 years apart in age in their study sample. Tibia Pb level was associated with a smaller decline in MMSE score in men with only HFE wildtype alleles (Figure 5-13). HFE variants, H63D and C282Y, are associated with hemochromatosis, a disease characterized by higher iron body burden. Higher iron body burden has been linked with lower Pb absorption, thus the apparent interaction could be related to altered Pb toxicokinetics rather than some other direct biological interaction. For example, the relation between tibia Pb level and Pb dose at the biologically relevant site(s) could be shifted to the left among for HFE variant allele carriers such that for the same tibia Pb level, Pb the dose at the relevant biological site(s)

may be higher leading to a greater annual decline in MMSE score as indicated in Figure 5-13 (solid curve). This implies that similar decreases in MMSE score would still be found in wildtype HFE carriers only at higher tibia Pb levels.



Source: Wang et al. (2007a).

Note: The lines indicate curvilinear trends estimated from the penalized spline method. Among HFE wild-types, the association between tibia Pb and annual cognitive decline was nearly linear, but among variant allele carriers, the association tended to deviate from linearity (p = 0.08). The model was adjusted for age, years of education, nonsmoker, former smoker, pack-years, nondrinker, alcohol consumption, English as first language, computer experience, and diabetes.

Figure 5-13 Exploration of nonlinear association of tibia Pb level with annual rate of cognitive decline, by hemochromatosis (HFE) gene variant.

The 2006 Pb AQCD described associations of blood and tibia Pb levels with poorer cognitive performance among 141 NAS men (Payton et al., 1998). Several new and larger cross-sectional NAS analyses corroborated previous findings for bone Pb but generally indicated weak associations with concurrent blood Pb levels and only in groups with specific genetic variants. In contrast with the longitudinal analyses, Weisskopf et al. (2007a) found that repeat measures of bone Pb levels were not consistently associated with cognitive function in cross-sectional analyses. In a study of Mini-Mental State Examination (MMSE) tests scores (test of general cognitive function) among 720 men 45 years of age and older, higher concurrent blood Pb levels were associated with lower MMSE scores among ALAD2 carriers (Weuve et al., 2006). A 3 µg/dL higher concurrent blood Pb level (the interquartile range) was associated with a 0.26 point lower mean MMSE score (95% CI: -0.54, -0.01) among ALAD2 carriers and a 0.04 point lower score (95% CI: -0.16, -0.07) among noncarriers. A subsequent study did not find a consistent

direction of modification of the association between blood or bone Pb levels and other tests of cognitive function by ALAD genotype (Rajan et al., 2008). Nonetheless, Rajan et al. (2008) found tibia Pb levels to be associated more strongly and consistently with poorer cognitive performance compared with concurrent blood or patella Pb levels (Table 5-8).

Effect modification by stress was examined in both the NAS and BMS cohorts. In the NAS cohort, higher bone Pb levels were associated with poorer cognitive function among individuals with higher individual-level perceived stress (Peters et al., 2007). Higher tibia Pb levels also were associated with larger decrements in cognitive performance among BMS subjects living in neighborhoods with a greater number psychosocial hazards (e.g., number of violent crimes, emergency calls, off-site liquor licenses) (Glass et al., 2009) (Table 5-8). These observation of effect modification by environmental stress in adult humans is supported by several observations of Pb-stress interactions in impaired learning and memory and adult animals with Pb exposures from gestation through post-weaning and lifetime Pb exposures (Section 5.3.2.2).

Weuve et al. (2009) studied the association of blood and bone Pb levels with cognitive function in a subset of 587 healthy women in the Boston, MA area participating in the Nurses' Health Study. Blood and bone Pb levels were measured between the ages of 47 and 74 years, and the mean (SD) blood Pb level in this group was 2.9 (1.9) µg/dL measured in samples collected an average of 5 years before cognitive testing. As in the aforementioned studies of adults, tibia and patella Pb levels were more consistently associated with cognitive performance than was blood Pb levels (Table 5-8). Contrary to expectation, higher patella and tibia Pb levels were associated with higher scores on the "f" naming test (naming words that begin with f). In separate models, the "f" naming test was omitted from a composite index of all cognitive tests, and a one SD (10 µg/g bone) higher tibia Pb level was associated with 0.051-point lower (95% CI: -0.010, -0.003) standardized composite score. A similar magnitude of decrease was estimated for an increase in age of 3 years in these women. The magnitude of association was slightly smaller for an SD unit increase in patella Pb level (-0.033 [95% CI: -0.080, 0.014).

Several studies analyzed data from the U.S.-representative NHANES III (1991-1994) population of men and women and investigated effect modification by age and genetic variants. Only blood Pb levels were available and were measured in samples collected concurrently with cognitive testing. Krieg and Butler (2009) did not find blood Pb level consistently to be associated with poorer performance on cognitive testing among 2,090 adults 20-59 years of age or among 1,796 adults 60 years of age and older. Because different types and numbers of tests were conducted in the two age groups, it is difficult to compare findings between age groups. In the subset of the population with genetic

analysis, blood Pb-cognitive function associations were not found to be modified by ALAD genetic variants in the same direction (Krieg et al., 2009). Among adults ages 20-59 years with the CC and CG ALAD genotype groups combined (i.e., ALAD2 carriers), reaction time improved (i.e., faster reaction time) by 38 ms per 10-fold increase in concurrent blood Pb level. In contrast, among ALAD2 carriers, higher blood Pb levels were associated with poorer performance on a symbol-digit substitution task. The potential direction of effect modification by the ALAD2 genotype is not immediately clear as the greater affinity of the ALAD2 enzyme subunit for Pb may increase susceptibility to Pb-associated health effects by increasing blood Pb levels or it may diminish Pb-associated health effects by decreasing Pb bioavailability by maintaining it in a sequestered state in the bloodstream. Krieg et al. (2010) did find differences in the association between concurrent blood Pb level and scores on a symbol-digit substitution test by the VDR variants, rs731236 and VDR rs2239185, and by the VDR haplotype. Similar to observations in adolescent NHANES participants (Section 5.3.2.1), results were not uniform across the various tests. However, blood Pb level generally was associated with greater decrements in cognitive performance among adults with the CC genotypes of VDR variants.

Other studies with smaller numbers of subjects generally produced results consistent with those from the larger studies above. A cross-sectional study of 188 rural Chinese men and women found a weak association between higher plasma Pb levels and a lower composite cognitive score based on a battery of in-person administered tests (Gao et al., 2008). It should be noted, though, that Pb in plasma makes up a very small fraction of all Pb in blood and is a different, and much less used, biomarker than Pb in whole blood. The relevance of this Pb fraction is not entirely clear. Pb in plasma is not bound to erythrocytes, as is about 99% of blood Pb. Thus, it has been postulated that plasma Pb may be more toxicologically active (Chuang et al., 2001; Hernandez-Avila et al., 1998). In another cross-sectional study of 47 men and women in Rochester, NY (55-67 years of age), subjects in the higher two tertiles of calcaneal bone (trabecular bone with higher turnover rate than tibia) Pb level performed worse on delayed matching-to-sample and paired associated learning tasks (Van Wijngaarden et al., 2009) (Table 5-8). In analyses of tibia Pb levels, subjects in the highest tertile of tibia Pb level did not consistently perform worse on cognitive tests (Table 5-8). The exact calcaneal and tibia Pb levels in tertiles were not reported.

Adults with Occupational Lead Exposures

The 2006 Pb AQCD concluded that in adults, blood Pb levels were associated with cognitive function most consistently among those with occupational Pb exposures. These findings were supported by results from a few recent studies of occupationally-exposed

adults. Dorsey et al. (2006) followed up on a cohort of Pb-exposed workers in Korea with a mean age of 43.4 years, on whom patella Pb measurements were made. This group represented a typically highly-exposed occupational group with an average blood Pb level of 30.9 μg/dL. In this cohort, both blood and tibia Pb levels previously were found to be associated with poorer performance on a battery of neurocognitive tests (Schwartz et al., 2005; Schwartz et al., 2001). Dorsey et al. (2006) found higher patella Pb levels to be associated with poorer manual dexterity, poorer sensory function, and greater depression symptoms. These associations for patella Pb levels were not as strong as the previously reported associations were with either blood or tibia Pb levels in this occupational cohort.

A follow-up study of the original 1982 Lead Occupational Study was conducted 2001-2004 with 83 of the original 288 Pb-exposed workers and 51 of the original 181 controls (Khalil et al., 2009b). Those originally in the exposed workers group had last worked in a job with Pb exposure from 0.02 to 16 years (median: 6) prior to follow-up testing. While the follow-up participation was somewhat low, participants did not differ from nonparticipants on most baseline cognitive tests except for performing slightly better on aspects of the grooved pegboard test and recall on a paired associates learning task. This suggests that the follow-up participation was not biased to poor performers. At follow-up, the former Pb-exposed workers performed worse than did the controls in total cognitive score and in the spatial and general intelligence domains ($p < 0.05$). They also performed worse in all other domains (e.g., motor, executive, and memory) although the differences were not as large. A similar pattern was observed in analyses using tibia Pb levels measured at the follow-up visit to represent exposure. Weaker associations were observed with concurrent blood Pb levels (median among the exposed: 12 μg/dL). Among the former Pb workers, higher tibia Pb levels were associated with a greater decrease in total score and scores for spatial and executive domains between baseline and follow-up. Tibia Pb level were associated inversely with poorer performance in other domains as well. As in nonoccupationally-exposed adults, the stronger findings for tibia Pb levels in former Pb-exposed workers indicate stronger effects of higher past Pb exposures than lower current exposures on cognitive function.

Additional studies aimed to characterize factors that either mediate or modify the association between Pb biomarkers and cognitive function. A study of 61 current Pb smelter workers with a mean age of 40 years and blood Pb level of 29.1 μg/dL found that both a working lifetime time-weighted integrated blood Pb level (an index of cumulative exposure) ($p = 0.09$) and tibia Pb level ($p = 0.08$) were associated with longer times to complete the grooved pegboard test (Bleecker et al., 2007a). Among 112 Pb smelter workers, working lifetime time-weighted integrated blood Pb level was associated with poorer performance on attention and digit symbol tasks among those with low cognitive

reserve (assessed by performance on the Wide Range Achievement Test-R for reading) (Bleecker et al., 2007b).

Apolipoprotein E is a transport protein for cholesterol and lipoproteins. The gene appears to regulate synapse formation (connections between neurons) and may be particularly critical in early childhood. A genetic variant, called the ApoE-ε4 allele is a haplotype between 2 exonic SNPs and is perhaps the most widely studied genetic variant with respect to increasing risk of neurologic disease. ApoE-ε4 carriers are at two-fold increased risk of developing Alzheimer's disease, although the majority of such individuals still do not develop the disease. Thus, it is biologically plausible that ApoE-ε4 carriers may be biologically susceptible to cognitive dysfunction. A study of occupationally-exposed adults found that among individuals with at least one ApoE-ε4 allele, blood Pb level was associated with poorer performance on digit symbol, pegboard assembly, and complex reaction time tests (Stewart et al., 2002).

Studies also indicated that Pb-exposed workers may be at increased risk of motor dysfunction. Among Pb smelter workers, working lifetime time-weighted integrated blood Pb level was associated with poorer motor performance ($p < 0.05$). Iwata et al. (2005) examined the cross-sectional association between blood Pb level and aspects of postural sway among 121 Pb-exposed workers in Japan with blood Pb levels between 6 and 89 μg/dL (mean: 40 μg/dL). In multiple regression analyses adjusted for age, height, and smoking and drinking status, higher blood Pb level was associated with greater sagittal sway with eyes open ($p < 0.05$) and eyes closed ($p < 0.01$) and transversal sway with eyes closed ($p < 0.05$). The authors calculated a benchmark dose level (Budtz-Jorgensen et al., 2001; NRC, 2000) of 14.3 μg/dL from a linear concentration-response model of their data. A supralinear concentration-response function was found to fit the data slightly better than was a linear function.

Summary of Cognitive Function in Adults

In summary, among nonoccupationally-exposed adults, there is weak evidence that cognitive function is associated with concurrently measured blood Pb levels. The strongest evidence was provided by NHANES analyses, in which concurrent blood Pb levels were associated with lower cognitive function in particular age and genetic variant subgroups (Krieg et al., 2010; Krieg and Butler, 2009; Krieg et al., 2009). These analyses did not have bone Pb measures for comparison. It is important to note that because bone Pb is a major contributor to blood Pb levels, blood Pb level also can reflect to a large extent longer term exposures, including higher past exposures, especially among adults without occupational exposures. Thus, in the NHANES analyses of adults, it is difficult to characterize the relative contributions of recent and past Pb exposures to the

associations observed between concurrent blood Pb level and cognitive function. Consistent with the conclusion of the 2006 Pb AQCD, several recent studies found associations between bone Pb levels and cognitive function in adults (Table 5-8). Much of the evidence was provided by analyses of two cohorts: BMS and NAS. Recent longitudinal analyses demonstrated that higher bone Pb levels measured at baseline were associated with subsequent declines in cognitive function over 2- to 4-year periods (Bandeen-Roche et al., 2009; Weisskopf et al., 2007a). These findings suggested that long-term Pb exposure may contribute to ongoing declines in cognitive function in adults. Recent studies that analyzed both blood and bone Pb levels generally found stronger associations for bone Pb levels, in particular tibia Pb levels, across the various cognitive tests that were performed (Table 5-8). The discrepant findings for blood and bone Pb levels indicate that cumulative Pb exposure that likely included higher past exposures, may be a better predictor of cognitive function in adults than is blood Pb level. Patella and tibia Pb levels were examined in the NAS and Nurses' Health Study; however, evidence did not consistently indicate that tibia Pb levels were more strongly associated with decreases in cognitive performance (Weuve et al., 2009; Weisskopf et al., 2007a). Additional support for the effects of cumulative or past Pb exposure is provided by analyses of the Boston prospective cohort as adults. Deciduous tooth Pb was associated with decrements in specific cognitive indices at ages 19-20 years (Bellinger et al., 1994a), and blood Pb levels measured at age 6 months, 4 years, 10 years, and levels averaged over childhood were associated with decrements in FSIQ at ages 28-30 years (Mazumdar et al., 2011).

Although based on limited examination, there is some indication that certain variants in HFE, ALAD, or VDR genes modify the association between Pb and cognitive function in nonoccupationally-exposed adults; however, results were uniform across the various cognitive tests performed. Aside from identifying populations potentially at increased risk and elucidating underlying modes of action, such effect modification also serves to strengthen the basic inference about associations between Pb biomarkers and cognitive function. Specifically, when effect modification is identified, potential confounding factors would have to vary by levels of the modifying factor, which is usually unlikely, particularly when considering genotype. It also is important to bear in mind that it is not always clear whether the observed effect modification reflects a change in the toxicokinetics of Pb and therefore a change in dose at the biological site of action or a direct biological interaction that increases the toxicity of Pb at a particular target organ or tissue.

In contrast with nonoccupationally-exposed adults, in adults with current occupational Pb exposures, cognitive function was associated with both blood and bone Pb levels. These findings indicate that among adults with occupational Pb exposures, both current and

cumulative exposures affect cognitive function. In the study of former Pb workers, blood Pb levels (median: 12 μg/dL) and findings were more similar to those from nonoccupationally-exposed adults. Among former Pb workers, tibia Pb levels were associated more strongly with cognitive performance than were blood Pb levels (Khalil et al., 2009b). Thus, in the absence of higher current Pb exposures, cumulative Pb exposures may have a greater effect on cognitive function in adults.

5.3.3 Behavioral Effects

5.3.3.1 Epidemiologic Studies of Behavioral Effects in Children

Noncognitive effects of Pb are more complex to study relative to IQ tests. There are fewer objective tests of behavior, and existing tests do not have as strong psychometric properties and are less rigorously standardized compared with IQ tests. In several studies, behaviors are assessed frequently using teacher and/or parent ratings and thus are subject to greater measurement error. However, domain-specific neuropsychological assessments are advantageous as they may provide greater insight into the underlying CNS damage that may be associated with exposures (e.g., structural, neural system, neurotransmitter) (White et al., 2009). Several epidemiologic studies reviewed in the 2006 Pb AQCD reported associations between blood Pb levels and a wide range of behavioral effects, with the weight of evidence supporting associations with inattention and hyperactivity and smaller bodies of evidence indicating associations with misconduct and delinquent behaviors and withdrawn and depressive behaviors (Bellinger and Rappaport, 2002; Needleman et al., 2002; Dietrich et al., 2001; Burns et al., 1999; Wasserman et al., 1998; Needleman et al., 1996; Bellinger et al., 1994a). Coherence was provided by similar findings of inattention, impulsivity, and changes in social behavior in Pb-exposed animals (Section 5.3.3.2). Epidemiologic studies found that blood Pb levels were associated with decrements in cognitive function and behavioral problems within the same population of children, which demonstrates the strong relationship between the two neurodevelopmental domains. The strong relationship between cognitive function and behavior in children also is demonstrated by the fact that the schedule controlled behavior tests in animals measure both memory and inattention. Thus, behavioral problems associated with Pb exposure may contribute to problems with learning, which may progress to antisocial and delinquent behavior later in life.

Most previous epidemiologic studies found that blood or dentin Pb levels measured at an early age (e.g., 2-6 years of age) were associated with behavioral problems later in childhood and early adulthood (e.g., 7-22 years of age). Most studies examined

associations with blood Pb levels assessed at a single time point; however, even the prospective studies with serial measurements of blood Pb levels, found a range of behavioral problems to be associated with both prenatal and early childhood blood Pb levels (Dietrich et al., 2001) and lifetime average blood Pb levels (Burns et al., 1999). Thus, evidence did not conclusively identify a single lifestage of Pb exposure that was associated with the greatest risk of behavioral problems and misconduct. Recent studies strengthened the evidence for associations of blood Pb levels with inattention and aggression (Figure 5-14 and Table 5-9). Based on a smaller number of studies, new evidence demonstrates associations of blood Pb levels with ADHD diagnosis and diagnostic indices as well as with conduct disorders (Table 5-10 and Table 5-11). As with cognitive function, the epidemiologic evidence for each category of outcomes was evaluated separately in order of increasing weight of evidence. Emphasis was placed on prospective studies with repeated assessments of blood Pb levels and behavior, studies assessing effects relevant to blood Pb levels in contemporary U.S. children (i.e., less than 5 µg/dL), and studies of younger children whose blood Pb levels are less influenced by higher past Pb exposures.

Similar to cognitive function, associations between blood Pb levels and behavioral outcomes may be potentially confounded by factors such as parental SES, parental education, parental IQ, quality and stability of the caregiving environment, and nutritional status. Accordingly, in assessing whether blood Pb-behavior associations were independent of the effects of the other variables, greater weight was given to studies that accounted for potential confounding in the study design or in statistical analyses.

Inattention and Hyperactivity in Children

Consistent with previous evidence, recent studies provided strong evidence that blood Pb level were associated with various endpoints related to inattention, hyperactivity, and impulsivity in children after adjusting for potential confounding by multiple SES-related variables and co-exposures (Figure 5-14 and Table 5-9). Evidence was equally consistent for inattention assessed using teacher and parent ratings and objective tests that measure sustained attention such as the continuous performance test (CPT). The associations observed with CPT, in particular, provide strong coherence with findings in animals for Pb-induced impairments in homologous tests of response inhibition in Schedule Controlled Behavior Tests (Section 5.3.3.2). Both tests measure reactions to stop signals, i.e., premature responses, reaction time. Most of the recent evidence is derived studies of non-U.S. children. Whereas previous studies primarily examined associations with blood Pb levels measured earlier in childhood, recent studies indicated associations with concurrent blood Pb levels. Further, many earlier studies of inattention and impulsivity included children with higher blood Pb levels than those observed in contemporary

children. Recent studies provided new evidence of blood Pb-associated inattention and impulsivity in populations of children with mean blood Pb levels ranging from 2 to 5 µg/dL (Cho et al., 2010; Plusquellec et al., 2010; Chiodo et al., 2007; Plusquellec et al., 2007).

Previous results from prospective studies indicated that early childhood Pb exposures were associated with attention deficits in adolescence and young adulthood (Ris et al., 2004; Bellinger et al., 1994a). Bellinger et al. (1994a) found that compared with young adults (ages 19-20 years) who had deciduous tooth Pb levels 2.9-5.9 ppm, adults with deciduous tooth Pb levels > 19.9 ppm committed more errors on the CPT and performed worse on Stroop and WCST, which measure the ability to shift focus and execute a different task. In the CLS cohort, Ris et al. (2004) found increases in attention as measured by CPT in association with prenatal maternal, 3-60 month average, and 78 month blood Pb levels in adolescents ages 15-17 years, adjusting for maternal IQ, SES, HOME, and adolescent marijuana use. Prenatal blood Pb level was associated with slightly larger increases in attention, and larger associations were estimates for males (Figure 5-14 and Table 5-9).

Studies in children in Korea with relatively low blood Pb levels (means < 3 µg/dL) both demonstrated associations with measures of inattention (Cho et al., 2010; Min et al., 2007). In a population of children ages 8-11 years, Cho et al. (2010) found relationships of concurrent blood Pb levels with ADHD symptoms (i.e., inattentiveness, hyperactivity, and total score) rated by teachers and parents, with the association with teacher ADHD rating attaining statistical significance. In addition to the low blood Pb levels in this study (mean: 1.9 µg/dL [range: 0.53-6.16]), a strength of this study was the comparison of effect estimates with and without adjustment for potential confounders such as age, sex, paternal education, maternal IQ, child IQ, city of residence, birth weight, and urinary cotinine. In multivariate models, effect estimates decreased by 2 to 14%; however, associations remained statistically significant. Mean ADHD ratings by teacher and parents were similar (both 9.1); however, parental ratings had greater variability (SD: 11.5 for parents and 8.6 for teachers), which may have contributed to differences in association. Although higher blood Pb levels were associated with more errors (responding to a nontarget) on the CPT test, they were not consistently associated other indicators of inattention on the CPT or Stroop test (Figure 5-14 and Table 5-9). Further, effect estimates lost statistical significance when urinary cotinine was included in models.

Cho et al. (2010) did not examine potential confounding by HOME score but they did examine parental history of neuropsychiatric disease (e.g., ADHD, learning disability, depression, obsessive-compulsive disorder). Mean blood Pb levels were similar in children with and without parental history of neuropsychiatric disease (1.80 and

1.93 µg/dL, respectively, p = 0.32). Thus, the relationship between blood Pb level and ADHD-related symptoms in the child was not likely confounded by parental neuropsychiatric disease. Results from this study also indicated that the relationship between blood Pb level and ADHD-related symptoms was independent of the relationship between blood Pb level and IQ. Min et al. (2007) examined a population of children (ages 7-16 years) in Korea with a mean concurrent blood Pb level of 2.9 µg/dL and adjusted for maternal score on attention tests. Investigators found that a 1 µg/dL increase in concurrent blood Pb level was associated with a 16.8 ms increase (95% CI: -1.08, 0.06) in reaction time, a test of attention. Although this study did not consider confounding by SES and caregiving environment, the findings was consistent with those from Cho et al. (2010).

Similar results were obtained in a study of children, ages 8-12 years, in Romania, except that concurrent blood Pb level was associated with similar magnitudes of increase in inattention, hyperactivity, and impulsivity as assessed by both parents and teachers (Nicolescu et al., 2010). Results for parent and teacher ratings were strengthened by observations that blood Pb levels also were associated with increased false-alarm rates in responses to stop signals (Figure 5-14 and Table 5-9). Blood Pb levels in this study also were relatively low (median: 3.7 [95% CI: 1.7, 11.1]), and removing five children with blood Pb levels at or above 10 µg/dL had minimal impact on observed associations. Exposures to aluminum and mercury, other neurotoxic metals, also were examined, and blood Pb level was associated with the largest, statistically significant increases in inattention, impulsivity, and hyperactivity.

The aforementioned studies did not consider confounding by the caregiving environment, i.e., HOME score. Studies that did adjust for HOME score, also found associations of blood Pb level with inattention and hyperactivity (Chandramouli et al., 2009; Chiodo et al., 2007). In their longitudinal study of children in the U.K., Chandramouli et al. (2009) found association of higher blood Pb level at age 30 months with hyperreactivity at ages 7 and 8 years; however, this association was observed primarily in children with blood Pb levels greater than 10 µg/dL (Table 5-9) and the strongest for ratings given by teachers. Children with elevated blood Pb levels did not consistently have elevated odds of inattention as assessed using stop signal tasks. Similar to Cho et al. (2010), this association was not influenced by the inclusion of child IQ in the model. Therefore, these findings add support for increasing blood Pb levels having effects on behavior independent of effects on cognitive function. Chiodo et al. (2007; 2004) found that concurrent blood Pb level was associated with inattention in 7 year-old children in Detroit, MI, as assessed using teacher ratings and CPT (Figure 5-14 and Table 5-9). Potential confounders were selected based on the association of each with a particular endpoint, thus model covariates varied among endpoints. HOME score was associated

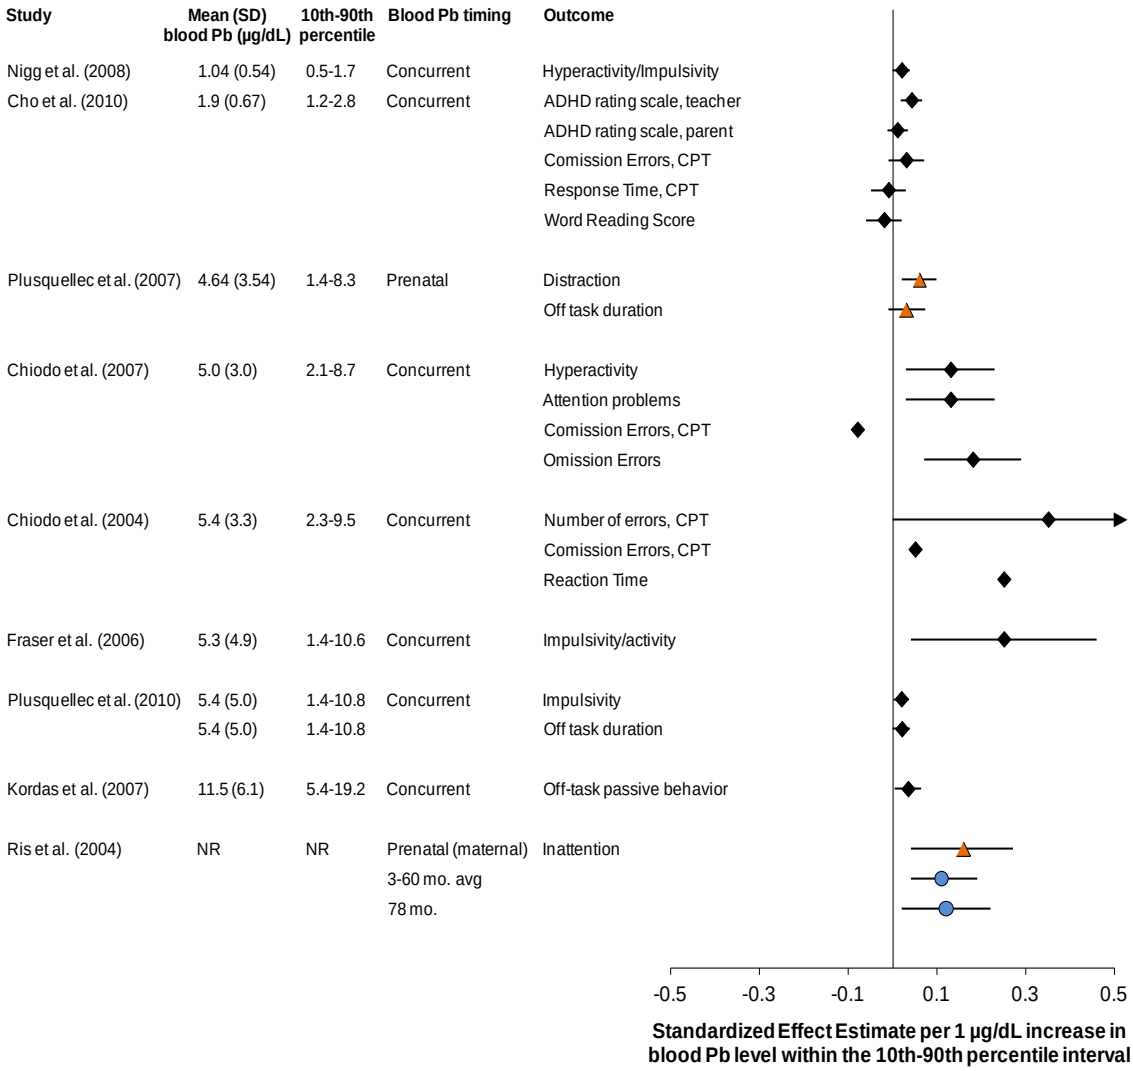
with inattention teacher ratings (Chiodo et al., 2007) but not with all CPT indices of inattention (2007; Chiodo et al., 2004). Blood Pb level was associated with inattention alone and adjusted for covariates. These findings indicated that HOME score did not account for all of the association between blood Pb level and behavioral outcomes. As was discussed in Section 5.3.2.1, this cohort comprised large proportions of children with prenatal exposure to alcohol and drugs. While this may limit the generalizability of findings, it is important to note that alcohol and drug use were not associated with every inattention index or in each study. Blood Pb level remained associated with inattention in a model that included alcohol and marijuana use along with other demographic and SES-related variables.

A series of studies conducted in Inuit children living in northern Quebec, Canada reported associations between blood Pb levels and measures of inattention after extensive consideration of potential confounding variables (Plusquellec et al., 2010; Plusquellec et al., 2007; Fraser et al., 2006). Plusquellec et al. (2007) found higher cord blood Pb level to be associated with higher ratings by investigators for distractibility in completing tasks, frenetic movement, and duration of off task behaviors at age 11 months (Figure 5-14 and Table 5-9). In the same cohort of children, concurrent blood Pb level but not cord blood Pb level was associated with impulsivity, irritability, and duration of off task behavior at ages 4-6 years (Plusquellec et al., 2010). Fraser et al. (2006) additionally indicated that at ages 4-6 years, the relationship between concurrent blood Pb level and motor function (i.e., transversal sway, reaction time) may be mediated by the effects of blood Pb level on an inattention/impulsivity index. These studies conducted in Inuit children evaluated confounding by examining associations of demographic, SES, and co-exposures with outcomes independently and with blood Pb level in models. HOME score was not associated with inattention or impulsivity. These findings further indicate that confounding by HOME score cannot fully account for the collective body of evidence for associations between blood Pb level and measures of inattention and impulsivity.

Consistent with findings in a group of children in Korea (Cho et al., 2010) and children in the U.K. (Chandramouli et al., 2009), Nigg et al. (2008) found that associations of blood Pb level with a hyperactivity/impulsivity index in a group of U.S. children, ages 8-17 years, were independent of associations with IQ. Whereas other studies assessed direct and indirect effects of blood Pb level on behavioral outcomes by including IQ in the model as a covariate, Nigg et al. (2008) specifically used regression-based path analysis, a more rigorous method to characterize the impact of one variable on the association of another in the model after controlling for other previous variables. After adjusting for sex and income, investigators found that concurrent blood Pb level had a direct association with hyperactivity/impulsivity that was not completely mediated by the blood Pb-IQ association. Instead, the association between blood Pb level and IQ was

found to be mediated via the association with hyperactivity/impulsivity. Based on associations between hyperactivity/impulsivity slower stop signal reaction time and response variability, the authors concluded that the association between blood Pb level and hyperactivity/impulsivity was mediated via poorer response on the stop task. It is important to note that other potential confounders including parental IQ and HOME score were not examined

Several other recent studies found associations between concurrent blood Pb levels and inattention; however, their results should be interpreted with caution due to their limited consideration of confounding by SES-related variables (Li et al., 2008d), their examination of children living near Pb sources who likely have limited applicability to contemporary children in the U.S. general population (Bao et al., 2009; Kordas et al., 2007), or both (Liu et al., 2011a).



Note: Test scores were standardized to their standard deviation to facilitate comparisons among tests with different scales. Studies generally are presented in order of increasing mean blood Pb level. Effect estimates are standardized to a 1 µg/dL increase in blood Pb level within the 10th-90th percentile interval. Black diamonds, orange triangles, and blue circles represent associations with concurrent, prenatal (maternal), and earlier childhood blood Pb levels, respectively.

Figure 5-14 Associations of blood Pb levels with behavioral indices of inattention, hyperactivity, and impulsivity.

Table 5-9 Additional characteristics and quantitative results for studies presented in Figure 5-14

Study	Population/Location	Blood Pb Levels (µg/dL)	Statistical Analysis	Outcome	Effect Estimate (95% CI)[a]

[c]Direction of effect estimate was changed to indicate an improvement in performance.

[d]Sufficent data were not provided to calculate 95% CIs.

[e]Odds in higher quantile of blood Pb level compared to that in lowest quantile of blood Pb level.

[f]Results represent the change in false alarm rate.

[g]Results represent the mean (SD) score in each quartile.

Attention Deficit Hyperactivity Disorder in Children

Studies of ADHD were included in the 2006 Pb AQCD; however, previous studies did not conclusively demonstrate that blood Pb level was associated with ADHD itself. Importantly, previously studies examining ADHD were fewer in number and limited by smaller sample sizes (Gittleman and Eskenazi, 1983; David et al., 1972). Recent studies consistently reported associations of blood Pb levels with ADHD in children. Coherence and biological plausibility for these associations are provided by the consistent body of epidemiologic and toxicological evidence indicating Pb-associated increases in inattention, hyperactivity, and impulsivity.

Several recent studies reported associations between concurrent blood Pb level and ADHD diagnosis or diagnostic indices in children between the ages of 8 and 17 years (Table 5-10). While none of the studies examined the potential for confounding by HOME score, they did evaluate confounding by several other demographic and SES-related variables, as well as parental history of psychopathology, including ADHD (Cho et al., 2010; Nicolescu et al., 2010). Recent studies also provided evidence of association between blood Pb level and ADHD in populations born in the mid- to late-1990s with relatively low concurrent blood Pb levels (means: 1.9 and 3.7 µg/dL) (Cho et al., 2010; Nicolescu et al., 2010). However, the temporal trends in Pb exposure in these non-U.S. populations may have differed from those in U.S. children of the same age.

Table 5-10 Associations between blood Pb level and ADHD diagnosis or diagnostic indices in children

Study	Population/Location	Blood Pb Levels (µg/dL)[a]	Statistical Analysis	Outcome	Effect Estimate (95% CI)[b]
Nigg et al. (2008)	150 children ages 8-17 yr. Year of birth and location NR	Concurrent Mean (SD) 8-11 yr: 1.04 (0.53) 12-17 yr: 1.03 (0.54) 10th-90th: 0.5-1.7	Three-group analysis of covariance with sex and income. **No parental IQ or education**	ADHD Dx by two licensed clinicians	F(2,145) = 6.08, p = 0.04
Braun et al. (2006)	4,704 children ages 4-15 yr born 1984-1998 U.S. NHANES 1999-2002	Concurrent 3rd quintile: 1.1-1.3	Logistic regression model adjusted for postnatal ETS, prenatal ETS, age, sex, race, childcare attendance, health insurance coverage, ferritin levels	ADHD Dx or medication use at age 4-15 yr	1.4 (0.4, 3.4) blood Pb 0.8-1.0 vs. <0.8 µg/dL[c] 2.1 (0.7, 6.8), blood Pb 1.1-1.3 vs. <0.8 µg/dL[c] 2.7 (0.9, 8.4), blood Pb 1.4-2.0 vs. <0.8 µg/dL[c] 4.1 (1.2, 14.0), blood Pb > 2.0 vs. <0.8 µg/dL[c]
Froehlich et al. (2007)	2,588 children, ages 8-15 yr born 1986-1996 U.S. NHANES 2001-2004	Concurrent 2nd quartile: 0.9-1.3	Logistic regression model adjusted for current household ETS exposure, sex, age, race/ethnicity, income, preschool attendance, maternal age, birth weight, and interaction terms for Pb and prenatal ETS interaction	ADHD Dx	8.1 (3.8, 18.7), blood Pb level > 2.0 µg/dL plus prenatal ETS exposure vs. blood Pb level <0.8 µg/dL and no prenatal ETS exposure[c]
Cho et al. (2010)	667 children ages 8-11 yr born 1997-2000 Five Korean cities	Concurrent Mean (SD): 1.9 (0.67) 10th-90th: 1.2-2.8	Log linear regression model adjusted for age, sex, parental education, maternal IQ, child IQ, city, birth weight, urinary cotinine	Total ADHD rating, teacher Total ADHD rating, parent using Korean ADHD Rating Scale IV at ages 8-11 yr.	0.042 (0.017, 0.067) 0.010 (-0.013, 0.033)
Nicolescu et al. (2010)	83 children ages 8-12 yr born 1995-1999 Bucharest and Pantelimon, Romania	Concurrent Median (IQR): 3.7 (2.6) 10th-90th: 1.8-7.1	Log linear regression model adjusted for city, sex, age, computer experience, handedness, eye problems, number of siblings, parental education, prenatal smoking, family psychopathology	ADHD score, parent ADHD score, teacher using German version of Conner's scales at ages 8-12 yr.	OR: 1.04 (1.00, 1.10) OR: 1.06 (1.00, 1.12)
Roy et al. (2009a)	756 children ages 3-7 yr tested 2005-2006 Chennai, India	Concurrent Mean (SD): 11.4 (5.3) 10th-90th: 5.8-18.3	Log linear regression model adjusted for age, sex, hemoglobin, average monthly income, parental education, number of other children, clustering in school and classroom	ADHD index z-score using Conners' ADHD/DSM-IV Scales at ages 3-7 yr.	0.002 (0, 0.033)
Chen et al. (2007)	780 children in TLC trial followed ages 2-7 yr Baltimore, MD; Cincinnati, OH; Newark, NJ; Philadelphia, PA Children underwent chelation therapy	Concurrent Mean (SD): 12.0 (5.2) 10th-90th: 6.5-18.7	Regression-based path analysis adjusted for city, race, sex, language, parental education, parental employment, single parent, age at blood Pb measurement, caregiver IQ	ADHD index Using Conners' Parent Rating Scale-Revised at age 7 yr.	0.54 (-1.22, 2.30) Direct 0.90 (0.35, 1.45) Indirect

[a]Studies are presented in order of increasing quantile or population mean blood Pb level.
[b]Except where noted, effect estimates represent regression coefficients. All effect estimates are standardized to a 1 µg/dL increase in blood Pb level within the 10th-90th percentile interval.
[c]Odds ratio in higher quantile of blood Pb level, with children in the lowest quantile of blood Pb level serving as the reference group.

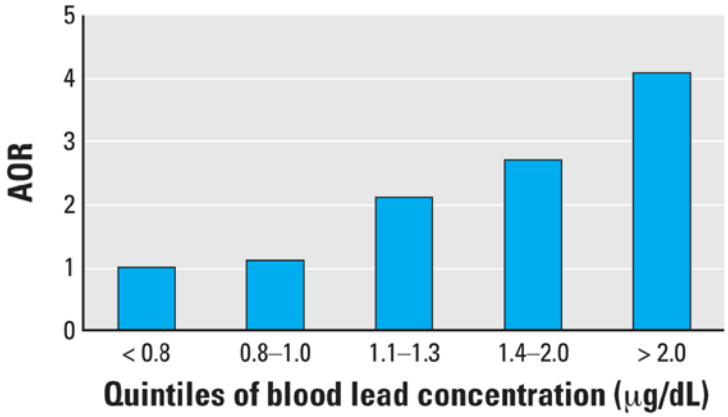
In addition to finding associations of concurrent blood Pb level with inattention and hyperactivity, Cho et al. (2010) found a statistically significant relationship with a total ADHD index as rated by teachers in population of children ages 8-11 years in Korea. In a

multivariate model that included age, sex, paternal education, maternal IQ, child IQ, city of residence, birth weight, and urinary cotinine, the effect estimate decreased by 12%; however, the association remained statistically significant (Table 5-10). Neuropsychiatric disease (e.g., ADHD, learning disability, depression, obsessive-compulsive disorder) in parents was not associated with child blood Pb level, and thus, likely did not confound the relationship between blood Pb level and ADHD index in the child. Results from this study also indicated that the relationship between blood Pb level and ADHD index was independent of the relationship between blood Pb level and IQ.

Similar to Cho et al. (2010), Nicolescu et al. (2010) found higher concurrent blood Pb levels to be associated with greater inattention, impulsivity, and total ADHD score among children in Romania, ages 8-12 years. As with individual symptoms, only concurrent blood Pb level, and not aluminum or mercury, was associated with a higher total ADHD rating (4% increase [95% CI: 0, 10] per 1 µg/dL increase in concurrent blood Pb level within the 10th-90th percentile interval [1.8-7.1 µg/dL]). The association did not change substantially in an analysis that excluded the 5 children with blood Pb levels at or above 10 µg/dL. Adjustment for potential confounding by city, sex, age, computer experience, handedness, eye problems, number of siblings, parental education, prenatal smoking exposure, prenatal alcohol exposure, and parental history of psychological or psychiatric problems resulted in a decrease in statistical significance for blood Pb level associations, although investigators did not report whether the magnitude of association changed. It is important to note that model covariates were selected a priori but not all were associated with both blood Pb level and behavioral endpoint. Only sex, number of siblings, and maternal education were reported to be significantly associated with both blood Pb level and total ADHD rating. Parental history of psychological or psychiatric problems was significantly correlated with parental but not teacher rating of ADHD total score; however, ORs were fairly similar for ADHD score rated by teachers and parents. Despite the potential for over-adjustment in this study, higher blood Pb level was associated with a higher ADHD total score rating.

A recent analysis of data from NHANES 1999-2002 found a relationship between higher blood Pb level and greater odds of ADHD (parent-report of a diagnosis of ADHD or use of stimulant medication) among children ages 4-15 years (Braun et al., 2006). Strengths of this study included the large sample representative of U.S. children (n = 4704) and the low concurrent blood Pb levels at which associations were observed. These authors reported a monotonic increase in ORs from the lowest to highest quintile of blood Pb level, adjusting for age, race, prenatal smoking exposure, smoker in the home, preschool/child care attendance, health insurance coverage, and ferritin levels (Figure 5-15). With children in the lowest quintile serving as the reference group (<0.8 µg/dL), children in the fifth quintile of concurrent blood Pb level (>2.0 µg/dL, maximum not

reported) had the highest prevalence of ADHD (OR: 4.1 [95% CI: 1.2, 14]). A similar OR was estimated when children with blood Pb levels > 5.0 µg/dL were excluded from the highest group. Children in the other three higher quintiles of blood Pb level (range: 0.8-2.0 µg/dL) also had a higher prevalence of ADHD relative to the reference group (Table 5-10).



Source: Braun et al. (2006)

Note: Adjusted for child age, gender, race/ethnicity, preschool attendance, serum ferritin, prenatal tobacco smoke exposure, smoker in the household, and insurance status (p for trend = 0.012). Data from ages 4-15 years from NHANES 1999-2002 by quintile of concurrent blood Pb level.

Figure 5-15 Adjusted odds ratios for Attention Deficit Hyperactivity Disorder (ADHD) among U.S. children.

In the NHANES 2001-2004 dataset restricted to children ages 8-15 years, Froehlich and colleagues (2009) found an interaction between prenatal tobacco smoke exposure (maternal report) and concurrent blood Pb levels. Investigators found ADHD to be independently associated with prenatal tobacco smoke exposure (OR: 2.4 [95% CI: 1.5, 3.7]) and concurrent blood Pb levels (OR: 2.3 [95% CI: 1.5, 3.8]) in children with blood Pb levels >1.3 µg/dL compared with children with blood Pb levels < 0.8 µg/dL. These results were adjusted for current household smoke exposure, sex, age, race/ethnicity, income, preschool attendance, maternal age, and birth weight. As in the younger NHANES dataset, a similar OR was estimated when children with blood Pb levels > 5.0 µg/dL were excluded from the highest tertile. The strongest association was observed in children with both high blood Pb level and prenatal tobacco smoke exposure. Compared to children in the lowest tertile of blood Pb levels with no exposure to prenatal tobacco smoke, children in the highest tertile of blood Pb level with exposure to prenatal tobacco smoke had the highest prevalence of ADHD (OR: 8.1 [95% CI: 3.5, 18.7]). Although ADHD was associated with low concurrent blood Pb levels (1.3-5 µg/dL), it is

important to acknowledge that the adolescents in both NHANES analyses were born in the late 1980s and may have had higher Pb exposures earlier in childhood that contributed to the observed associations.

Consistent with findings in the NHANES population, Nigg et al. (2008) found an association between concurrent blood Pb level and ADHD diagnosis among children 8-17 years. Concurrent blood Pb levels in this population also were low, ranging between 0.40 and 3.47 µg/dL. However, the examination of adolescents adds uncertainty regarding the relative contributions of higher past Pb exposures and current exposures to the observed associations. A key strength of this study over other studies was the verification of parental reports of ADHD by licensed clinicians using the same diagnostic criteria. Although the results were adjusted for household income, other potential confounders including parental IQ and HOME score were not examined.

Roy and colleagues (2009a) examined associations between concurrent blood Pb level and a range of behavioral problems in 756 children, ages 3-7 years, in Chennai, India. In this population, the mean blood Pb level was higher than that in most other studies (11.4 [SD: 5.3] µg/dL); however, this study demonstrated associations of concurrent blood Pb level with inattention, hyperactivity, and a total ADHD index (assessed by teachers using Conners' ADHD/Diagnostic and Statistical Manual for Mental Disorders) in younger children compared with other studies. In generalized estimating equations, higher blood Pb level was associated with a higher ADHD index score adjusting for age, sex, hemoglobin, average monthly income, parental education, number of other children, and clustering at school and classroom levels (Table 5-10). In analyses that did not adjust for potential confounding variables, mean ADHD scores were similar in the first three quartiles of blood Pb level and elevated in children with blood Pb levels > 18.71 µg/dL, suggesting that in this population, associations may have been driven by children with the highest blood Pb levels.

Whereas several studies indicated the direct effects of increasing blood Pb level on inattention and hyperactivity indices, Chen et al. (2007) found stronger indirect effects of blood Pb level on an ADHD index among children at age 5 years (Table 5-10). Important limitations of this study include the high blood Pb levels of children at ages 12 to 33 months (20-44 µg/dL) that made them eligible for a randomized controlled trial of chelation. Because this study only enrolled children with Pb poisoning, it is difficult to extend findings to children with lower blood Pb levels. Blood Pb levels of study subjects remained high at age 5 years (mean: 12.0 µg/dL) and out the range of the current U.S. general population of children.

In recent commentaries to studies reporting associations between blood Pb level and ADHD in children, Brondum (2011, 2007) asserted the need for studies to consider

confounding by parental history of ADHD. Given the highly heritable nature of ADHD, parental history of ADHD is a strong risk factor for ADHD in children (Faraone and Doyle, 2001). Therefore, the risk associated with parental history of ADHD may mask the smaller magnitudes of risk associated with environmental exposures, including Pb. However, little information is available on an association between ADHD in the parent and blood Pb level in the child, thus, it is uncertain whether parental ADHD confounds and fully accounts for the associations observed between blood Pb level and ADHD in children. It should be noted that for parental ADHD to be a confounder, parental Pb levels would have to be highly associated with ADHD in the parent and with blood Pb level in the child. Among children in Korea, Cho et al. (2010) found that parental history of psychopathology (ADHD or several other conditions) was not associated with child blood Pb level. Among children in Romania, parental history of psychopathology was associated with a higher ADHD rating in the child as assessed by parents but not teachers (Nicolescu et al., 2010). Higher blood Pb level was associated with higher ADHD ratings in children in models with blood Pb level alone and in models that adjusted for parental psychopathology plus other covariates. Further, associations of blood Pb level with ADHD rating assessed by parents and teachers were similar in magnitude (Table 5-10). While available data are limited, they do not provide strong evidence that parental psychopathology fully accounts for the associations observed between blood Pb level and ADHD in children.

Social Misconduct and Delinquent Behavior

The 2006 Pb AQCD described several studies in which higher levels of blood and bone Pb were associated with higher frequency or risk of misconduct in children or delinquent behavior in adolescents (U.S. EPA, 2006b). Previous studies primarily indicated associations with measures of cumulative Pb exposure, including early childhood average blood Pb level, lifetime average blood Pb level, or bone Pb level. Recent studies added to the collective body of evidence by demonstrating associations for concurrent blood Pb level and for a variety of conduct problems including aggression (Chiodo et al., 2007), conduct disorder (Braun et al., 2008), oppositional defiant disorder (Nigg et al., 2008) and more serious behaviors such as criminal arrests (Wright et al., 2008) (Table 5-11). Associations were found with early childhood and concurrent blood Pb levels and were demonstrated in populations with lower blood Pb levels (means: 1-8 µg/dL) than those examined in the 2006 Pb AQCD. Nonetheless, the weight of cumulative evidence supports associations in populations with mean blood Pb levels between 5 and 11 µg/dL. However, because some studies examined outcomes in adolescents and young adults born in the 1970s and 1908s, there is greater uncertainty regarding the level, timing, frequency, and duration of Pb exposure that contributed to the observed associations.

Several other studies examined children and adolescents born in the 1990s, who likely did not have as high historical Pb exposures earlier in childhood (Chandramouli et al., 2009; Braun et al., 2008; Chiodo et al., 2007).

Table 5-11 Associations between blood Pb level and misconduct and delinquent behavior in children and young adults[a]

Study	Population/Location	Blood Pb Levels (µg/dL)	Statistical Analysis	Outcome	Effect Estimate (95% CI)[b]
Blood Pb level as a continuous variable

Blood Pb level as a categorical variable					
Braun et al. (2008)	Children ages 8-15 yr U.S. NHANES 2001-2004	2nd quartile: 0.8-1.0	Logistic regression with sample weights applied to produce national estimates, adjusted for oversampling of minorities and young children and adjusted for age, poverty income ratio, maternal age, sex, race, prenatal ETS, cotinine, blood Pb levels	Conduct disorder Using Diagnostic Interview Schedule for Children-Caregiver Module at age 8-15 yr	OR: 7.24 (1.06, 49.47), blood Pb level 0.8-1.0 µg/dL vs. blood Pb <0.8 µg/dL[d] 12.37 (2.37, 64.56), blood Pb level 1.1-1.4 µg/dL vs. blood Pb <0.8 µg/dL[d] 8.64 (1.87, 40.04), blood Pb level 1.5-10 µg/dL vs. blood Pb <0.8 µg/dL[d]
Chandramouli et al. (2009)	488 children ages 7-8 yr born 1991-1992 Avon, UK	Age 30 mo Mean (SD): NR	Linear regression model adjusted for maternal education, home ownership, maternal smoking, HOME score, maternal SES, family adversity index, parenting attitudes at 6 mo.	Antisocial activities using Antisocial Behavior Interview at ages 7-8 yr	OR: 0.93 (0.47, 1.83)[d] blood Pb 2-5 vs. 0-2 µg/dL 1.44 (0.73, 2.84)[d] blood Pb 5-10 vs. 0-2 µg/dL 2.90 (1.05, 8.03)[d] blood Pb > 10 vs. 0-2 µg/dL

[a]Results with continuous blood Pb are presented first followed by results with categorical blood Pb. Within each group, studies generally are presented in order of increasing mean blood Pb level.
[b]Effect estimates are standardized to a 1 µg/dL increase in blood Pb level.
[c]95% CI was estimated from a reported p-value of 0.05.
[d]Odds in higher quantile of blood Pb level compared to that in lowest quantile of blood Pb level.

The consistency of association of Pb biomarker levels with social misconduct and delinquent behavior was corroborated in a recent meta-analysis (Marcus et al., 2010) that included 19 studies (those reviewed in the 2006 Pb AQCD plus several recent studies) with a total of 8,561 children and adolescents (mean ages ranging from 3.5 years to 18.4 years). Effect estimates were converted to Pearson correlation coefficients, and the combined effect estimate was r = 0.19 (95% CI: 0.14, 0.23). The key finding of this study was the robustness of associations to considerations of heterogeneity in study design, definition and assessment method of conduct problems, potential confounding variables examined, and blood Pb levels. The major source of heterogeneity in effect estimates was the biomarker of Pb examined. A larger magnitude of effect was estimated for hair Pb levels compared with bone or blood Pb levels; however, similar effect sizes were estimated for blood and bone Pb levels. Although the authors suggested that hair Pb may be a better indicator of cumulative Pb exposure compared to bone Pb levels, due to the high turnover of bone in throughout childhood and into adolescence, an empirical basis for interpreting hair Pb measurements in terms of body burden or exposure has not been firmly established (Section 4.3.4.2).

In the meta-analysis, effect sizes did not differ significantly between longitudinal and cross-sectional studies, among studies that examined different conduct problems (i.e., opposition defiance, delinquency, externalizing problems), or among studies that assessed conduct disorders using self-report, teachers report, or criminal records. Controlling for covariates such as SES, birth weight, parental IQ, and home environment did not attenuate the relationship between blood Pb level and conduct problems. In

addition to strengthening the evidence for the independent associations of Pb biomarker levels with conduct disorders, the results indicate that the lack of adjustment for any particular covariate, including HOME score, does not warrant limiting inferences from a particular study.

Studies of children ages 7-8 years found associations between blood Pb level and misconduct adjusting for HOME score and several other potential confounding variables. They examined different lifestages of blood Pb level and did not clearly indicate associations between blood Pb level and misconduct with blood Pb levels less than 5 µg/dL. In their longitudinal study of children in the U.K. who were born in the 1990s, Chandramouli et al. (2009) found associations of age 30 month blood Pb level not only with hyperreactivity but also with antisocial behavior at age 7-8 years. Results were adjusted for maternal education, home ownership, maternal smoking, HOME score, maternal SES, family adversity index, and parenting attitudes at 6 months. In analyses of blood Pb level as a categorical variable, greater antisocial activity was most clearly indicated in children with blood Pb levels greater than 10 µg/dL (Table 5-11). Chiodo et al. (2007) examined children, ages 7.5 years in Detroit, Michigan with a mean (SD) concurrent blood Pb level of 5.0 (3.0) µg/dL. Higher blood Pb was associated with higher teacher ratings of delinquent behaviors and inappropriate behaviors, adjusting for HOME score and other variables. The association with inappropriate behavior additionally adjusted for caregiver psychopathology. As with cognitive function and inattention outcomes, prenatal alcohol and drug exposure were not found to influence associations for blood Pb level. Blood Pb level was associated with behavioral problems in unadjusted and adjusted analyses, corroborating the independent associations for blood Pb level.

In the U.S. NHANES 2001-2004 dataset of children ages 8-15 years (born in the 1990s), Braun et al. (2008) analyzed blood Pb as a categorical variable and found higher prevalence of conduct disorder with concurrent blood Pb levels in the range of 0.8 to 1.0 µg/dL, the lowest level among all studies examined. Compared with children with blood Pb levels less than 0.8 µg/dL, the OR (95% CI) in children with blood Pb levels 0.8-1.0 µg/dL was 7.24 (1.06, 49.47). Odds ratios also were elevated in children with blood Pb levels higher than 1.0 µg/dL (Table 5-11). The wide 95% CIs likely were due to the small numbers of cases of conduct disorder, as assessed using DSM-IV criteria. For example, there were 22 cases of conduct disorder among children with blood Pb levels 0.8-1.0 µg/dL. Poisson regression models showed that children with blood Pb levels 0.8-1.0 µg/dL had 1.55 (95% CI: 1.09, 2.22) times as many conduct disorder symptoms as did children with blood Pb levels < 0.8 µg/dL. Investigators had data available on a limited set of potential confounders, and poverty income ratio was used to control for potential confounding by SES.

While other recent studies supported associations between biomarkers of Pb exposure and misconduct and delinquent behavior, they examined Pb levels in blood or tooth samples collected in the 1980s when Pb exposures were much higher (Fergusson et al., 2008; Wright et al., 2008). Although this evidence may be less informative as to the relationship between current blood Pb levels and misconduct and delinquent behavior in adolescents and young adults, it is important to note the consistency of findings among populations with widely varying blood Pb levels and historical Pb exposures.

In the CLS cohort, prenatal and postnatal blood Pb levels previously were reported to be associated with self- and parent-reported delinquent and social acts at ages 16-17 years (Dietrich et al., 2001). Wright et al. (2008) extended these findings to include associations of prenatal and postnatal blood Pb levels with criminal arrests (ascertained from county records) at ages 19-24 years. Mean blood Pb levels were 8.3 µg/dL (range 1-26) for the prenatal period (maternal blood), 13.4 µg/dL (range 4-37) for the average between birth and age 6 years, and 8.3 µg/dL (range 2-33) at age 6 years. In models that adjusted for maternal IQ, sex, SES score, and maternal education, the relative risks (RRs) for total arrests per 1 µg/dL increment in blood Pb level were 1.07 (95% CI: 1.01, 1.13) for prenatal blood Pb level, 1.01 (95% CI: 0.97, 1.05) for average childhood blood Pb level, and 1.05 (95% CI: 1.01, 1.09) for blood Pb level at age 6 years. Blood Pb levels measured during these lifestages also were associated with increased risk of violent criminal arrests (Table 5-11). Although interactions terms for blood Pb by sex were not statistically significant, the attributable risk for males was considerably higher for males (0.85 arrests/year [95% CI: 0.48, 1.47]) than for females (0.18 [95% CI: 0.09, 0.33]). Results from the two CLS studies suggest that in addition to the prenatal blood Pb levels, early childhood blood Pb levels may also predict criminal behavior in adulthood. However, it is important to note that in these CLS studies, concurrent blood Pb levels were not analyzed. Therefore, these studies do not provide information on the potential effects of more recent Pb exposures or differences in association between earlier and more recent blood Pb levels.

A strength of Wright et al. (2008) was the detailed examination of potential confounding by a large number of variables. All of the examined covariates were weakly correlated with blood Pb levels ($r = 0.24$-0.35), thereby minimizing the potential for confounding. Nonetheless, variables such as maternal IQ, maternal education, and SES were included in the model because they were associated with arrests in the full multivariate model or changed the blood Pb level by more than 10%. HOME score was similar between subjects with and without criminal arrest records and did meet the criteria for inclusion in the final model.

In the New Zealand cohort of children born in 1977, dentin Pb levels measured between ages 6 and 8 years were associated with self-reported and documented violent or property convictions at ages 14-21 years (Fergusson et al., 2008). Similar to those from the meta-analysis, these findings pointed to an effect of cumulative childhood Pb exposure. Analyses were adjusted for SES, parental criminal record, parental education, and parental alcoholism, and although effects estimates decreased in adjusted models, associations remained statistically significant.

Several studies of misconduct and delinquent behavior aimed to characterize whether associations with biomarkers of Pb exposure were independent of effects on IQ and educational attainment. Most studies found that associations of Pb biomarkers with misconduct and delinquent behavior remained statistically significant in a model that additionally adjusted for child IQ or educational attainment, indicating that Pb exposure may have a direct effect on misconduct independent of its effect on IQ (Chandramouli et al., 2009; Fergusson et al., 2008; Burns et al., 1999). It is important to note that because a decrement in IQ may on the causal pathway to behavioral problems, including both IQ and behavioral problems in the same model may result in an underestimate of the effect on behavior. Chen et al. (2007) used path analysis to characterize the direct effects and indirect effects (mediated through child IQ) of blood Pb level on externalizing problems (i.e., outbursts of behavior); however, results were inconclusive. A direct effect was estimated for externalizing problems assessed by teachers and an indirect effect was estimated for problems assessed by parents. These findings may have limited applicability to the general population given that the children in the study population had been referred for chelation therapy at enrollment because of high blood levels, and it is uncertain whether the observed associations were due to the residual effect of high blood Pb levels (20-44 µg/dL) four years earlier.

5.3.3.2 Toxicological Studies of Behavior

Neurobehavioral Changes

The effects of Pb on neurobehavioral changes in animals are well characterized with various targeted sites including the prefrontal cerebral cortex, cerebellum, and hippocampus; affected functions include cognition, execution of motor skills, and memory/behavior. As discussed in earlier Pb AQCDs, young animals are especially susceptible to the effects of Pb due to the ongoing development of the nervous system with greater Pb absorption and retention. Pb exposure has been documented to induce neurobehavioral changes in exposed animals including effects on learning, social behavior, memory, attention, motor function, locomotor ability and vocalization. At the

cellular level, Pb impairs axon and dendritic development and contributes to neurochemical changes in proteins, membranes, redox/antioxidant balance, and neurotransmission through a multitude of mechanisms, many of which involve the capability of Pb to mimic calcium. Very early toxicological research on neurobehavioral endpoints failed to capture the disposition of Pb and its resulting body burden or blood Pb level and was thus difficult to use in risk assessment.

The 1986 Pb AQCD reported findings of Pb-induced aberrant operant conditioning tasks in rodents and non-human primates (some with resulting blood Pb levels: 11 to 15 µg/dL) as well as hyperactive or inappropriate Pb-mediated responses (U.S. EPA, 1986b). It was indicated that these effects were possibly of hippocampal origin and showed a curvilinear response, decreasing at higher Pb doses possibly due to impairment of motor function (Ma et al., 1999; Crofton et al., 1980). Pb exposure in laboratory animals resulted in distractibility, reduced to adapt to changes in behavior, impaired ability to inhibit inappropriate responses, and perseveration (U.S. EPA, 2006b). Pb has been shown to impair learning in Fixed Interval tasks (FI) as indicated by premature responses in the absence of a fixed schedule of reinforcement or reward (Section 5.3.2.2). These findings in animals are consistent with observations in children that blood Pb levels are associated with poorer impulse control as rated by parents or teachers or assessed using the continuous performance test (Figure 5-14 and Table 5-9). Interresponse rates and overall run rate are the two subcomponents of FI response rate. The 2006 Pb AQCD reported consistent findings for Pb exposure (resulting in blood Pb levels: 58 to 94 µg/dL) affecting FI response rates, by means of decreased interresponse times. Some studies indicated decreased interresponse times in animals with blood Pb levels of 11 µg/dL (U.S. EPA, 2006b). Discrimination reversal has been shown to be especially sensitive to Pb exposure. Spatial and non-spatial discrimination reversal or reversal of a previously learned habit was significantly affected after developmental Pb exposure and was exacerbated with distracting stimuli. Repeat-acquisition testing revealed that these deficits were likely not due to sensory or motor impairment at this dose. Together, the data from the 2006 Pb AQCD showed that social behavior and learning in rodents and nonhuman primates is significantly affected by Pb exposure that results in blood Pb levels 15-40 µg/dL.

In the new literature, gestationally and early postnatally (gestation to PND10, G+P) Pb-exposed male mice (low and high dose Pb: 10 and 42 µg/dL blood Pb level at PND10, respectively) were significantly less active than were control mice, and low dose mice were significantly less active than were high dose mice, demonstrating a nonlinear concentration-response relationship (Leasure et al., 2008). A similar nonlinear concentration-response relationship was observed for changes in corticosterone in male mice exposed post-weaning to Pb (Virgolini et al., 2005). Activity level of G+P Pb-

exposed female mice versus controls was unaffected (Leasure et al., 2008). Amphetamine-induced motor activity was monitored in male and female G+P Pb-exposed mice at 1 year of age. Amphetamine-induced activity of male low and high dose G+P Pb-exposed offspring was significantly elevated over that in controls; G+P Pb-exposed females had no change in sensitivity to amphetamine-induced motor activity (Leasure et al., 2008).

Herring gull chicks injected with a single i.p. bolus dose of Pb (100 mg/kg Pb-acetate, a dose created to be similar to that which wild herring gulls are exposed in the wild) on PND2 were found to have neurobehavioral deficits and learning deficits. Pb-exposed chicks displayed multiple deficits related to impaired survival skills including decreased time spent begging the parent for food, decreased accuracy at pecking for food in the mouth of the parent bird, decreased time spent in the shade (behavioral thermoregulation), decreased learning in food location, decreased recognition of familiar individuals (caretaker or sibling), and slower development of motor skills (treadmill test) versus control birds (Burger and Gochfeld, 2005). The impaired thermoregulation with Pb exposure agrees with earlier work in Pb-exposed rat pups that also showed impaired thermoregulatory behavior, i.e., impaired ultrasonic vocalization (Davis, 1982). These studies in herring gull chicks demonstrate that a single dose of Pb early in life can induce neurobehavioral deficits that affect survival skills.

Rhesus monkeys exposed to Pb in daily milk formula from PND8 to 1 or 2 years of age (Pb-acetate/50% glucose in 4 cc of commercial milk formula producing blood Pb of 35-40 µg/dL) were assessed for tactile defensiveness using the Sensory Processing Scale for Monkeys, an adaptation of laboratory observational measures of sensory processing for children (Baranek and Berkson, 1994). Tactile defensiveness in children is defined as "feelings of discomfort and a desire to escape the situation when certain types of tactile stimuli are experienced" (Ayres, 1964) and is associated with emotional dysregulation, inattention, and difficult social relations. Other reports have shown that tactile defensiveness in monkey offspring is affected by prenatal stress alone without Pb exposure (Schneider et al., 2008), a factor that has been shown to affect other Pb-related outcomes.

Attention

Epidemiologic studies consistently have reported associations between higher blood Pb level and deficits in attention (inattention, distractibility, impulsivity, or ADHD) in children (Section 5.3.3.1). Animal toxicological studies in the 2006 Pb AQCD detailed attention deficits in animals undergoing various tests including FR/waiting-for-reward

testing and tests that employed signal detection with distraction, a test recording omissions after exposure to an external distraction.

With FR testing, rats are trained on a FR/waiting-for-reward behavioral baseline, learning to produce food delivery by pressing a lever 50 times. Rodents can earn additional food by withholding lever presses by waiting; free food is given at increasing time intervals after completion of the FR. Brockel and Cory-Slechta (1998) exposed male Long-Evans rats to 0, 50, or 150 ppm Pb-acetate in water from weaning, which produced respective blood Pb levels of <5, 11, and 29 µg/dL after 3 months of exposure. After 40 days of exposure, rats were trained on a FR schedule, and the higher dose animals had significantly more frequent response rates and resets of the waiting period than did the low dose group and controls. In the waiting behavior component, wait time was significantly lower in both treated groups compared to controls. The higher dose group animals also had an increased number of reinforcers and a higher response to reinforcement ratio than did low dose and controls. Mechanistic understanding of the aforementioned FR deficits was studied using the same FR schedule with similar postweaning dosing of 0, 50, and 150 ppm Pb that yielded respective blood Pb levels of <5, 10, and 26 µg/dL after 3 and 7 months of exposure. Administration of dopamine receptor antagonists attenuated Pb-induced effects on FR schedule testing, suggested a role for D2 receptors in Pb-induced behavioral impairments.

Another study used a similar postweaning Pb exposure as that in earlier studies (Cory-Slechta et al., 1998) to yield blood Pb levels of <5, 16, and 28 µg/dL and evaluate sustained attention using testing of signal detection during a distraction (Brockel and Cory-Slechta, 1999). Rats earned food rewards by discriminating correctly between a target and distracter light. A 13 second time-out was given for incorrect responses. Pb exposure produced no deficits in attention with this testing. Further work since the 2006 Pb AQCD affirmed these findings. Testing for signal detection with distraction showed no effect after postnatal Pb exposure in female rats (Stangle et al., 2007). The two dose groups (20 ppm or 300 ppm Pb-acetate in drinking water with lactational, and drinking water exposure, PND1-PND30) yielded blood Pb levels of 13 µg/dL and 31 µg/dL (Stangle et al., 2007). Another recent study reported that impaired auditory threshold task related behavioral testing was likely due to inattention in Pb-exposed animals. The inability of some of the monkeys to engage or focus on the task at hand yielded fewer available measurements in Pb-exposed animals versus control animals (Laughlin et al., 2009). These rhesus monkeys were exposed to Pb-acetate gestationally (dam drinking water, 3 months prior to mating) through age 5.5 months (weaning) and had resulting bone Pb levels at 11 years of 7 and 13 µg/dL for prenatal and postnatal groups, respectively, and blood Pb levels during Pb exposure of 35 and 46 µg/dL, respectively. Animals were tested at age 13 years when blood Pb levels had returned to baseline levels.

Thus, the inattention literature demonstrates that impulsivity, waiting-for-reward behavior, and sustained attention may all be affected by Pb with the first two possibly affected to a greater extent than is sustained attention.

5.3.3.3 Epidemiologic Studies of Mood in Children

A majority of investigation of the effects of Pb on behavior in children has focused on externalizing behaviors such as inattention, hyperactivity, aggression, and delinquency. However, studies also have linked biomarkers of Pb exposure with internalizing behaviors related to emotional dysfunction, including withdrawn behavior, depression, fearfulness, and anxiety. These behaviors were assessed frequently in school-aged children using the Child Behavior Checklist, and as with inattention, hyperactivity, and misconduct, often were rated by parents and/or teachers.

Several earlier results were provided by the prospective cohort studies in Boston, Cincinnati, Port Pirie, Australia, and Yugoslavia. Collectively, these studies found higher ratings for internalizing behaviors in association with concurrent blood Pb level as well as biomarkers of cumulative Pb exposure such as multiyear average blood, tooth, and bone Pb levels (Burns et al., 1999; Wasserman et al., 1998; Bellinger et al., 1994b; Dietrich et al., 1987b). While several studies demonstrated associations with biomarkers of long-term, cumulative exposures, results from the Cincinnati cohort provided support for the effects of shorter-duration exposures. Among CLS infants, blood Pb level at age 3 months and average blood Pb level at age 6 months was associated with less positive mood in white infants at age 6 months (Dietrich et al., 1987b). In the Boston cohort, subjects were examined at age 8 years and 19-20 years. Pb levels measured in deciduous teeth but not cord blood were associated with a higher rating of internalizing behaviors at age 8 years but not in adulthood, indicating the lack of persistence of effects of early exposure (Bellinger et al., 1994a; Bellinger et al., 1994b). Wasserman et al. (1998) also examined blood Pb levels measured at various lifestages in the Yugoslavia cohort and found that concurrent blood Pb was associated more strongly with anxious-depressed and withdrawn behaviors at age 3 years than were blood Pb levels measured prenatally or between ages 6 months and 2 years. Thus, while biomarkers of Pb exposure were consistently associated with poorer mood and emotional state in children, there was no clear indication of differences in association among biomarkers measured at various lifestages. Associations between Pb biomarkers with mood also were consistently reported in recent studies, with most studies examining concurrent blood Pb level (Liu et al., 2011a; Bao et al., 2009; Roy et al., 2009b; Chiodo et al., 2004). However, several had limited generalizability to the general population of U.S. children due to the examination

of children residing near Pb sources or high prevalence of prenatal alcohol or drug exposure (Liu et al., 2011a; Bao et al., 2009; Chiodo et al., 2004).

Associations of Pb biomarkers with mood and emotional state in children were observed after adjusting for a wide range of potential confounding variables including parental education and HOME score. Several studies that each adjusted for a different set of covariates found similar effect estimates in univariate and multivariate models (Burns et al., 1999; Wasserman et al., 1998; Bellinger et al., 1994b), supporting the robustness of associations with Pb biomarkers. Associations between blood Pb level and internalizing behaviors also were observed in studies that adjusted for maternal psychopathology (Burns et al., 1999; Wasserman et al., 1998). Thus, the evidence indicates that associations observed between Pb biomarkers and internalizing behaviors in children are not driven by confounding by any particular measured variable.

In the collective body of evidence, associations between blood Pb level and internalizing behaviors were observed in populations of school-aged children with mean blood Pb levels between 8 and 28 µg/dL. Mean blood Pb levels were not related to the age of the study population. In the limited investigation of populations with mean blood Pb levels of approximately 5 µg/dL, results were inconclusive. Chiodo et al. (2004) found an association with internalizing behaviors in children (age 7 years) in Detroit, in whom the prevalence of prenatal alcohol and drug use was high. Neither exposure was found to influence associations with blood Pb level. Another study that examined Inuit children (age 5 years) in Quebec, Canada, did not find an association between concurrent blood Pb level and internalizing behaviors (Plusquellec et al., 2010).

A common observation across studies was finding that Pb biomarkers were associated with multiple indices of neurodevelopmental function, i.e., FSIQ, executive function, externalizing, and internalizing behaviors, within the same population. Whereas some studies found stronger associations for externalizing behaviors than for internalizing behaviors (Plusquellec et al., 2010; Bellinger et al., 1994a; Sciarillo et al., 1992), most did not find a clear difference in the strength of association (Roy et al., 2009b; Chiodo et al., 2004; Wasserman et al., 1998; Bellinger et al., 1994b). In the Port Pirie population, Burns et al. (1999) found that lifetime average blood Pb levels were associated with externalizing behaviors more strongly in boys and with internalizing behaviors more strongly in girls, indicating potential sex-based differences. These findings demonstrating Pb effects on a wide spectrum of cognitive and behavioral indices are not surprising given that Pb exposure is linked to changes in the HPA axis and dopaminergic and GABAergic systems, which are involved in mediating cognitive function, behavior, and mood. Dietrich et al. (1987b) provided support for Pb exposure affecting a wide range of neurodevelopmental outcomes by characterizing the direct and indirect effects of Pb

using structural equations. The associations of prenatal Pb exposure (maternal and infant day 10 blood) with poorer mood in infants aged 6 months were found to be mediated through lower birth weight and/or shorter gestation. These results suggested that Pb may exert its effects by impairing nervous system development. It is well known that the fetal period is an active period for neuronal differentiation, dendritic branching, and synaptogenesis. Thus, it is not surprising that prenatal Pb exposure effects on nervous system development could result in a wide range of neurodevelopmental effects assessed later in childhood.

5.3.3.4 Epidemiologic Studies of Mood and Psychiatric Effects in Adults

Examination of the potential effects of Pb exposure on mood and psychiatric outcomes in adults has received far less attention than that in children and cognitive function in adults. Nonetheless, evaluation of mood states is an integral part of the neurocognitive test battery of the World Health Organization (WHO), and it has been suggested that indices of the Profile Of Mood States may be particularly sensitive to toxicant exposures (Johnson et al., 1987). As with other nervous system endpoints in adults, several early studies of Pb-exposed workers (mean blood Pb levels ranging from 23.5 to 64.5 µg/dL) found higher prevalence of symptoms related to mood disorders and anxiety among Pb-exposed workers than unexposed controls (mean blood Pb levels ranging from 15-38 µg/dL) (Schwartz et al., 2005; Maizlish et al., 1995; Parkinson et al., 1986; Baker et al., 1985; Baker et al., 1984; Lilis et al., 1977).

While comprising a smaller body of evidence, studies of adults without occupational exposures demonstrated associations of blood and bone Pb level with mood. Analyses of men ages 48-70 years in the NAS indicated associations of both concurrent blood (mean: 6.3 µg/dL [SD: 4.16]) and tibia (mean: 21.9 µg/g [SD: 13.5]) Pb levels with greater self-reported symptoms of depression and anxiety (Rhodes et al., 2003). As bone Pb is a major contributor to blood Pb levels in adults without current occupational Pb exposure, associations with both biomarkers may indicate effects of cumulative Pb exposure. In a subsequent analysis of the same dataset, Rajan et al. (2007) found effect modification of the associations for patella and tibia Pb levels by ALAD genotype, although results were not in a consistent direction for a particular genotype. For a majority of the mood symptoms considered, tibia bone Pb levels were associated with larger ORs among men with the ALAD 1-1 genotype. In contrast, ORs for associations between patella Pb levels and several mood symptoms such as depression and positive symptom distress index were larger among ALAD 1-2/2-2 carriers. In the NAS, inconsistent effect modification

by ALAD genotype also was observed for associations between tibia Pb levels and cognitive performance (Rajan et al., 2008) (Section 5.3.2.5).

A cross-sectional study of 1,987 adults age 20-39 years participating in NHANES 1999-2004 was the largest study of mood and included both men and women (Bouchard et al., 2009). However, only concurrent blood Pb levels were available for analysis. Investigators assessed major depressive disorder (MDD), panic disorder and generalized anxiety disorder (GAD) using the WHO Composite International Diagnostic Interview, which follows criteria defined in DSM. Adults with concurrent blood Pb levels higher than 0.7 µg/dL had higher prevalence of all three symptoms. Adults in the highest quintile of blood Pb level (≥ 2.11 µg/dL) had the highest OR for MDD (OR: 2.32 [95% CI: 1.13, 4.75]) and panic disorder (OR: 4.94 [95% CI: 1.32, 18.48]) compared with adults with blood Pb levels < 0.7 µg/dL. For all endpoints, ORs were larger in analyses excluding current smokers. While this study demonstrated associations with relatively low concurrent blood Pb levels, it is important to note the uncertainty of the magnitude, timing, frequency, and duration of Pb exposure that contributed to the observed associations.

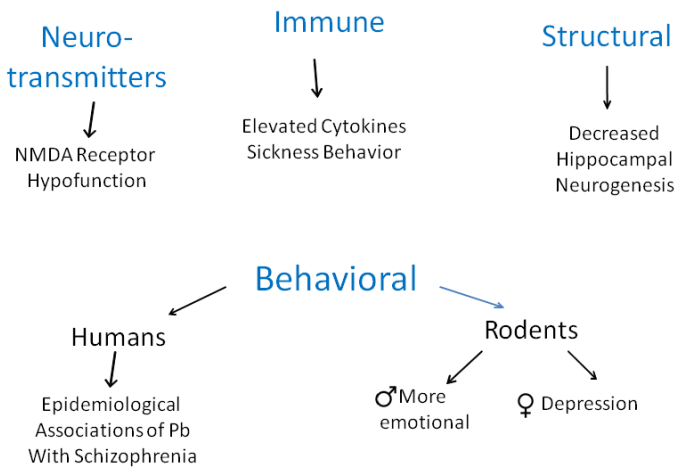
In analyses of cohorts in California and New England, Opler et al. (2008; 2004) reported associations between higher prenatal levels of plasma δ-ALA and subsequent diagnosis of schizophrenia spectrum disorder (ascertained using DSM-IV criteria) in adolescence and adulthood. In the absence of blood Pb levels, investigators measured δ-ALA levels in stored serum samples to serve as a surrogate for Pb exposure citing previous observations of a high correlation (0.90) between δ-ALA levels ≥ 9.05 ng/mL and blood Pb levels ≥ 15 µg/dL. In the California cohort, a δ-ALA level ≥ 9.05 ng/mL was associated with schizophrenia spectrum disorder with an OR (95% CI) of 2.43 (0.99, 5.96), adjusting for maternal age at delivery. In analyses combining the California and New England cohorts, a δ-ALA level ≥ 9.05 ng/mL was associated with schizophrenia spectrum disorder with an OR (95% CI) of 1.92 (1.05, 3.52), adjusting for maternal age and education. A covariate-adjusted OR was not presented for the New England cohort alone, and it appeared that the association in the combined cohorts was driven by that observed in the California cohort. Studies in other populations with direct measurements of blood Pb levels are warranted to characterize the potential effects of Pb exposure on schizophrenia. These limited available data indicate associations with higher blood Pb levels (≥ 15 µg/dL) in individuals born in the 1950s and 1960s who likely had higher early Pb exposures. Thus, these findings may have limited relevance to current lower levels of Pb exposure.

5.3.3.5 Toxicological Studies of Mood, Emotional, and Psychotic Changes

As in epidemiologic studies, neurotoxicological studies often focus more on motor, sensory, behavioral or cognitive outcomes and less on psychological pathologies. As described in Section 5.3.3.3 above, epidemiologic studies indicating associations of Pb biomarkers with mood disorders in children and adults have grown in recent years. Likewise, studies increasingly have found that developmental Pb exposure (gestation and lactation) affects emotional state and mood disorder-like behavior in adult animal offspring. Offspring of Wistar rats treated with 10 mg of Pb-acetate daily by gavage during pregnancy (G) or pregnancy plus lactation (G+L) were tested in the open field test and the forced swimming test also known as the Porsolt test (de Souza Lisboa et al., 2005). Blood Pb levels in the pups at PND70 were 5-7 µg/dL. The open field test monitors activity levels and movements of animals in three dimension and is a measure of hyperactivity, emotion (grooming or freezing), and exploratory behavior (rearing). In the forced swim test, animals are placed in a tank and monitored for helplessness, a response common in animal models of depression. (G+L) Pb-treated male rats had increased emotionality with the open field test as indicated by decreased rearing and increased immobility. (G+L) Pb-exposed female offspring had a significantly increased depressive phenotype in the forced swim test as indicated by increased immobility (de Souza Lisboa et al., 2005). It is interesting to note that this is one of many Pb-induced changes that seem to be sex-specific with males showing increased emotionality and females showing elevated depressive-like symptoms (Figure 5-16). In another study, anxiety was assessed in offspring after G+L Pb exposure. Dams received Pb-enriched drinking water (2.84 mg/mL Pb-acetate trihydrate) and produced pups with blood Pb levels of 698 ng/g at PND25. Using the elevated plus maze test, Pb-exposed animals displayed no signs of anxiety (Molina et al., 2011). However, it is important to note the high concentrations of Pb exposure used in this study. Another study found that female pups exposed to Pb-acetate (0.2% to pups PND1-30) had increased anxiety at PND30 as measured by a decreased percentage of entries and time spent in the open arms of the plus-maze (Fox et al., 2010).

Depression may seem initially like an unexpected comorbidity for immune inflammatory dysfunction, but many forms of depression are linked with the same cytokine imbalances that occur with Pb-induced innate immune dysfunction (Maes; Pace and Miller, 2009). Some researchers use sickness behavior and its associated malaise as a model for depression. Sickness behavior is characterized by overall malaise, decreased food intake, immobility and changes in core body temperature. Dyatlov and Lawrence (2002) observed in mice that sickness behavior, which is due to an interaction of the immune system and the CNS, was potentiated by Pb exposure (resulting in blood Pb level:

17 µg/dL) and was correlated with depletions in specific thymic T-cell populations (Figure 5-16). Pb exposure also potentiated the infection-dependent elevation in IL-1β, a cytokine that has been shown to inhibit hippocampal glutamate release in young but not aged animals. Sickness behavior was induced with *Listeria monocytogenes* infection; Pb exposure occurred from birth through lactation and was continued for a brief period after weaning until the experiment was terminated.



Note: The blue headings provide four independent possible contributors to development of psychiatric disorders in Pb-exposed individuals.

Figure 5-16 Animal toxicology evidence of possible Pb-induced contributors to the development of mood and psychotic disorders.

Schizophrenia is associated with a shortened lifespan in humans as reflected by increased standardized mortality ratio (McGrath et al., 2008). An environmental origin of schizophrenia was proposed years ago (Tsuang, 2000), and prenatal Pb exposure, assessed using ALAD activity as a biomarker, was linked to schizophrenia in a group of adolescents and young adults in California (Opler et al., 2008; Opler et al., 2004). Because of these observations, the animal toxicological field is beginning to explore the mechanisms that may contribute to schizophrenia development and has proposed two explanations. These are Pb-induced NMDA receptor (NMDAR) hypofunction and Pb-induced decreases in hippocampal neurogenesis (Figure 5-16 to Figure 5-18). Pb may bind a divalent cation site in the NMDAR and allosterically inhibit glycine binding (Hashemzadeh-Gargari and Guilarte, 1999); human studies of patients with schizophrenia

have shown aberrations at this site (Coyle and Tsai, 2004). These findings are consistent with the glutamatergic hypothesis of schizophrenia which purports that NMDAR noncompetitive antagonist use in patients with schizophrenia exacerbates their psychotic symptoms and that administration of antagonist to non-psychotic subjects can induce a schizophrenic phenotype. The second mechanistic hypothesis for Pb-associated schizophrenia induction is decreased hippocampal degenerate gyrus (DG) neurogenesis, which is seen in patients with schizophrenia (Kempermann et al., 2008; Reif et al., 2006), in animal models of schizophrenia (Maeda et al., 2007) and in animal models with developmental Pb exposure (Verina et al., 2007; Jaako-Movits et al., 2005) (Figure 5-16 to Figure 5-18). Animal models of schizophrenia (i.e., phencyclidine administration) show decreased hippocampal DG neurogenesis that can be reversed by treatment with clozapine, which is often used to treat schizophrenia (Maeda et al., 2007). These DG pathways are also NMDAR-dependent. Studies cited in this section are further detailed in other sections of the ISA. Another study gives insight into pathways involved in Pb-induced changes in neurogenesis in the developing brain. Exposure of zebrafish embryos to Pb (50–700 µM Pb-acetate in embryo medium from 0 to 6 days post hatch) caused significant apoptosis (increased TUNEL positive brain cells) and impaired neurogenesis as shown by decreased levels of gfap and huC in the brain; however two other genes involved in neurogenesis, crestin and neurogenin1, were unaffected in brains of Pb exposed embryos (Dou and Zhang, 2011). Thus, toxicological studies indicate that Pb exposure may result in mood disorders via behavioral, neurochemical, and ultrastructural changes.

5.3.3.6 Integrated Summary of Behavior and Mood

Epidemiologic studies in children demonstrate associations of higher blood Pb levels with a range of behavioral problems, with the weight of evidence demonstrating associations with inattention and hyperactivity as rated by parents or teachers and as assessed using objective neuropsychological tests. Previous studies found associations with early childhood blood or tooth Pb level (i.e., ages 2-6 years), and recent studies expanded evidence to include associations with concurrent blood Pb level. Recent epidemiologic studies consistently found associations with inattention and hyperactivity in children ages 1 to 12 years with mean concurrent blood Pb levels of 2 to 5 µg/dL (Cho et al., 2010; Nicolescu et al., 2010; Plusquellec et al., 2010; Chiodo et al., 2007; Plusquellec et al., 2007), similar to those associated with cognitive function decrements. The epidemiologic findings are strengthened by observations in animals of Pb-induced

inattention and impulsivity in homologous tests of response inhibition (e.g., DSA, FI, DR). Tests in children such as CPT, Stroop, WCST share homology with tests in animals such as DSA, DR, and FR tasks in that they all test the ability to inhibit inappropriate responses, organize behavior in response to varying stimuli, and learn from the consequences of previous actions. Inattention and impulsivity in animals are most clearly indicated with gestational and early postnatal Pb exposures that result in blood Pb levels of 10 to 40 µg/dL. These findings in children and animals for Pb-associated dysfunction in response inhibition and response variability may be explained by observations that Pb affects dopaminergic neurons of the frontal striatum of the brain by altering dopamine release and receptor density . The circuitry in this regions is thought to mediate response inhibition. Whereas previous evidence was inconsistent, several recent epidemiologic studies indicate associations between higher concurrent blood Pb level and higher prevalence or incidence of ADHD diagnosis and its contributing diagnostic indices in children ages 8–17 years (Cho et al., 2010; Nicolescu et al., 2010; Roy et al., 2009a; Nigg et al., 2008; Braun et al., 2006). The biological plausibility for associations with ADHD is strongly supported by the large epidemiologic and toxicological evidence base demonstrating Pb-associated increases in inattention and impulsivity, both of which are primary symptoms of ADHD. A smaller but equally consistent body of evidence indicated associations of concurrent and early childhood blood Pb levels with social misconduct in children and delinquent behaviors in adolescents and young adults (Chandramouli et al., 2009; Braun et al., 2008; Wright et al., 2008; Chiodo et al., 2007). Associations of blood Pb levels with ADHD, misconduct, and delinquency were observed in populations of children with a wide range of blood Pb levels, 1 to 11 µg/dL, all similar in the strength of evidence.

While mood and emotional state have been examined less frequently compared with inattention and misconduct, several studies found associations of biomarkers of cumulative Pb exposure (i.e., tooth or childhood average blood Pb) and concurrent blood Pb levels with parental or teacher reports of withdrawn behavior or depression in children with mean blood Pb levels 8-28 µg/dL (Section 5.3.3.3). These findings in children are supported by a small body of toxicological studies in which prenatal plus lactational Pb exposure resulted in depression-like behavior in rodents.

Rather than examining externalizing behaviors and criminal behavior, a small body of studies of behavior in nonoccupationally-exposed adults examined and found associations of blood (Bouchard et al., 2009) and tibia (Rajan et al., 2008) Pb levels with depression and anxiety symptoms. All of these studies used single assessments of Pb biomarker levels and outcomes and analyzed associations in a cross-sectional manner. Thus, there is uncertainty regarding the critical level, timing, frequency, and duration of Pb exposure associated with mood and psychiatric symptoms. The associations with bone

Pb levels indicate an effect of cumulative Pb exposure. Concurrent blood Pb levels in adults reflect both cumulative and recent exposure, and it is uncertain what are the relative contributions of past versus recent Pb exposures to the observed associations. Associations of Pb biomarkers with withdrawn behavior and anxiety in children and adults may by explained by evidence for Pb-induced changes in the HPA axis, dopaminergic and GABAergic CNS processes. These processed have been shown to mediate anxiety and depression. While it may seem that Pb exposure affects different behaviors in children and adults, it is important to acknowledge differences in the evidence base. Studies of behavior in children and young adults have focused on inattention and misconduct; studies of older adults did not examine externalizing behaviors or misconduct. Differential effects in children and adults also may be expected given the predominance of different neurophysiological processes operating at different ages, for example, neurogenesis and brain development in children and neurodegeneration in adults.

5.3.4 Sensory Organ Function

5.3.4.1 Epidemiologic Studies of Sensory Organ Function in Children

Although not as widely examined as cognitive and behavioral outcomes, several studies found associations of higher blood Pb level with higher hearing thresholds and poorer auditory processing in children (U.S. EPA, 2006b). Such evidence is limited largely to studies described in the 2006 Pb AQCD. The prospective CLS with repeat measurements of blood Pb prenatally to age 5 years provided information on potentially important lifestages of exposure. In this cohort with higher blood Pb levels than those in contemporary U.S. children (lifetime average mean: 17.4 [SD: 8.8] µg/dL), poorer auditory processing was associated with higher prenatal (maternal), neonatal (10-day), early childhood, and lifetime average blood Pb levels, with the strongest associations observed for neonatal blood Pb level. A 1 µg/dL higher neonatal blood Pb level was associated with a 0.20-point ($p \leq 0.01$) and 0.26-point ($p \leq 0.10$) lower score on the total and left ear Filtered Word test (indicative of incorrectly identified filtered or muffled words), after adjusting for hearing screen, social class, HOME score, birth weight, gestational age, obstetrical complications, alcohol consumption, and prenatal and postnatal blood Pb levels (Dietrich et al., 1992). Overall, the findings pointed to an effect of early Pb exposure during infancy.

Large U.S. studies, including NHANES II (Schwartz and Otto, 1987) and the Hispanic Health and Nutrition Examination Survey (HHANES) also found associations between higher blood Pb level and lower auditory function; however, their cross-sectional design precluded comparisons among various lifestages of exposure (Schwartz and Otto, 1991). In these studies, concurrent blood Pb level (median: 8 µg/dL) from 6 to 18 µg/dL was associated with a 2-db loss in hearing and an increase in the percentage (15%) of children with a substandard hearing threshold (2,000 Hz). Higher concurrent blood Pb level also was associated with higher hearing thresholds across several frequencies in a population of children in Poland with similar blood Pb levels (median: 7.2 µg/dL [range: 1.9 to 28]) (Osman et al., 1999). In the HHANES and Polish studies, associations persisted in analyses restricted to subjects with concurrent blood Pb levels below 10 µg/dL.

Mechanistic support for these observations in children was provided by Otto and colleagues (Otto and Fox, 1993; Otto et al., 1985b), who found associations of blood Pb level with lower brainstem auditory evoked potentials in children. Rothenberg et al. (1994b) and Rothenberg et al. (2000) reported similar findings; however, the direction of association differed between prenatal (maternal) and postnatal (ages 1-4 years) blood Pb level. Postnatal blood Pb level was associated with lower interpeak intervals in auditory evoked potentials at age 5-7 years. Prenatal maternal blood Pb level showed a biphasic relationship, with a lower evoked potentials at blood Pb levels of 1-8 µg/dL and higher evoked potentials at blood Pb levels of 8-30 µg/dL. Recent studies also aimed to identify the locus in the auditory system where Pb may exert its effects on auditory function. Investigation was limited to a population of children with high blood Pb levels (means 33 and 37 µg/dL) living in Pb glazing communities in Ecuador (Buchanan et al., 2011; Counter et al., 2011). In these studies, concurrent blood Pb level was not correlated with the acoustic stapedius reflex (Counter et al., 2011) or distortion product otoacoustic emissions (Buchanan et al., 2011), indicating lack of effect on the auditory brainstem or inner ear, respectively. Other loci were not examined.

5.3.4.2 Epidemiologic Studies of Sensory Organ Function in Adults

Studies of auditory function reviewed in the 2006 Pb AQCD provided consistent evidence of association between blood Pb levels and changes in auditory evoked brainstem potentials in occupationally-exposed adults, but less consistent findings for hearing thresholds (U.S. EPA, 2006b). A few new studies of Pb workers found Pb-associated increases in hearing thresholds. A recent study provided new evidence in nonoccupationally-exposed adults for associations of tibia Pb levels with hearing loss.

Men in the NAS study were free of hearing loss at baseline and had hearing tested repeatedly (median 5 observations per subject) over a median of 23 years (Park et al., 2010). Higher tibia Pb level, measured up to 20 years after initial hearing testing was associated with a faster rate of increase in hearing threshold for frequencies of 1, 2, and 8 kHz and a pure tone average. Blood Pb was not examined in this study. In cross-sectional analyses adjusted for age, race, education, body mass index, pack-years of cigarettes, diabetes, hypertension and occupational noise (based on a job-exposure estimate from occupations), and presence of a noise notch (indicative of noise-induced hearing loss), higher patella bone Pb level (measured within 5 years of hearing test) was associated with a higher hearing thresholds for frequencies greater than 1 kHz. A 21 μg/g (IQR) increase in patella bone Pb level was associated with pure tone average hearing loss with an OR of 1.48 (95% CI: 1.14, 1.91) in adjusted analyses. Similar, but slightly weaker associations were found for tibia bone Pb levels.

With new investigation, the weight of evidence indicates that blood Pb levels are associated increased hearing thresholds in adults with occupational Pb exposures. In a study of 183 Pb workers with relatively low blood Pb levels, 1 to 18 μg/dL, higher blood Pb level was correlated with higher hearing threshold at 4 kHz (Forst et al., 1997). Other studies examined workers with much higher blood Pb levels. In a study of 220 Pb battery workers with higher blood Pb levels (mean: 56.9 μg/dL [SD: 25.3]) (Wu et al., 2000), although hearing impairment was associated with a measure of cumulative Pb exposure based on years of work and ambient Pb measurements, no association was found with blood Pb levels at the time of hearing testing in analyses adjusted for age, sex, and duration of employment. Another cross-sectional study examined 259 steel plant workers with no parental history of ear-related problems, no congenital abnormalities, no occupational organic solvent exposure, and hearing loss difference no more than 15 dB between both ears (Hwang et al., 2009). The participants had a mean (SD) concurrent blood Pb level of 54.3 (34.6) μg/dL. Average noise levels also were measured in work areas and dichotomized at 80dB. In analyses adjusted for age and work area noise (dichotomized at 80 dB), workers with blood Pb level ≥ 7 μg/dL had a statistically significant higher prevalence (range of ORs: 3.06 to 6.26) of hearing loss at frequencies of 3, 4, 6, and 8 kHz compared to workers with blood Pb levels ≤ 4 μg/dL.

A hospital-based case-control study recruited workers referred for hearing testing (average hearing thresholds above 25 dB) as cases and workers with normal hearing thresholds who were having occupational health examinations for other reasons as controls (Chuang et al., 2007). The 121 cases had a geometric mean blood Pb level of 10.7 μg/dL, and the 173 controls had a geometric mean blood Pb level of 3.9 μg/dL based on measurements in samples collected at the time of the study. In models that adjusted for age, smoking, alcohol consumption, years of noise exposure, as well as Mn, As, and Se

levels in blood, higher blood Pb levels were associated with a statistically significant higher average hearing threshold (0.5-6 kHz).

In summary, together, the findings from NAS (Park et al., 2010) and studies of Pb-exposed workers indicate that biomarkers of Pb exposure are associated with lower auditory function in adults. Evidence for association with concurrent blood Pb levels is provided studies of adults with current occupational Pb exposures. Because only bone Pb levels measured after auditory testing were examined in the NAS study, further investigation is required to characterize the timing, level, frequency, and duration of Pb exposure contributing to lower auditory function in adults without occupational exposures.

5.3.4.3 Toxicological Studies of Sensory Organ Function

The 1986 and 2006 Pb AQCDs detailed the effects of Pb in animals on vision, including the retina and CNS visual processing areas, as well as the auditory system and described possible or known mechanisms of action where available. Pb exposure effects on sensory dysfunction and impaired sensory processing have been postulated to contribute to Pb-associated effects on neurocognition and attention. In support of this hypothesis, Dietrich et al. (1992) found that higher prenatal (maternal) and postnatal blood Pb levels were associated with both lower performance on the screening test for auditory processing disorders and lower cognitive function in 5 year-old CLS children (Section 5.3.4.1). New research in this area expands upon the extant evidence by exploring sensory function in animals with lower Pb exposures and blood Pb levels.

Auditory Effects

The 2006 Pb AQCD discussed impaired auditory function in nonhuman primates exposed to Pb from gestation through age 8-9 years (resulting in blood Pb levels 33-56 µg/dL during Pb exposure period). Brainstem auditory evoked responses (BAER), which are used as a general test to assess neurological auditory function, revealed Pb-related effects that persisted even after Pb exposure had ceased and blood Pb levels had returned to baseline. In Pb-exposed animals (birth to age 13 years), half of the pure tone detection thresholds were outside of the control range at certain frequencies (Rice, 1997). In concordance with the data from developmentally Pb-exposed laboratory animals, elevated auditory thresholds, as measured with brainstem auditory evoked response (BAER), have also been associated with blood Pb levels in children (Rothenberg et al., 2000; Rothenberg et al., 1994a). In addition to indicating hearing loss, BAER can indicate impaired synaptic maturation and incomplete neuron axon myelination leading to

impaired neuronal conduction (Schwartz and Otto, 1991; Gozdzik-Zolnierkiewicz and Moszyński, 1969. Thus, the findings from Rice (1997) indicated that early life Pb exposure impaired auditory function. The cochlear nerve in both developing and mature humans appeared to be especially sensitive to the Pb insult. At low to moderate Pb exposures, elevated thresholds and increased latencies were observed in brainstem auditory evoked potentials.

In a recent study, Laughlin et al. (2009) studied rhesus monkeys exposed to Pb-acetate gestationally through age 5.5 months (dam drinking water, 3 months prior to mating until weaning, resulting in bone Pb levels at 11 years of 7 and 13 µg/dL for prenatal and postnatal groups, respectively and blood Pb levels during Pb exposure of 35 and 46 µg/dL, respectively) and conducted auditory threshold testing and threshold task testing at 13 years of age after blood Pb levels had returned to baseline. At birth, animals were cross fostered, creating a control group, a prenatal Pb group, and a postnatal Pb group; however, Pb exposed animals were analyzed as a single group. Pb exposure induced small elevations in auditory thresholds in animals. Auditory threshold task-related behavioral testing was also impaired in Pb-exposed animals. This study has multiple limitations which likely contributed to its not finding statistically significant aberrations. These limitation included limited power with the examination of 5 animals per group, the inability of some of the monkeys to engage or focus on the task at hand and thus had fewer available measurements, differences between the sexes in inattention, and mixing of the postnatal Pb and prenatal Pb animals into one group (Pb-exposed animals).

In summary, studies in nonhuman primates have shown lower BAER due to chronic Pb exposure (gestation through adulthood) that result in blood Pb levels in the range of 33-56 µg/dL. In concordance with these findings, previous epidemiologic studies described lower BAER in children with higher prenatal maternal blood Pb levels and concurrent blood Pb levels. Collectively, these findings provide support for the associations observed between higher blood Pb levels and increased hearing thresholds (concurrent blood Pb) and lower auditory processing in children (neonatal) (Section 5.3.4.1). The animal evidence for long-term Pb exposure effects provide coherence with findings in adults with occupational Pb exposures for associations between blood Pb levels and increasing hearing thresholds and in nonoccupationally-exposed adults, for associations with biomarkers of cumulative Pb exposure (i.e., tibia and patella Pb level) (Section 5.3.4.2).

Effects on Vision

In toxicological studies, Pb has been shown to affect multiple aspects of the visual system from the retina, to the sensory processing areas of the brain, to neurons involved in vision. The selective action of Pb on retinal rod cells and bipolar cells is well documented in earlier Pb AQCDs (Fox et al., 1997; Fox and Sillman, 1979) and research in this area continues to date. Pb exposure during perinatal development and adulthood has also been shown to affect the visual cortex (Costa and Fox, 1983) and subcortical neurons (Cline et al., 1996). Extensive work in nonhuman primates with various Pb exposure paradigms (development or lifetime Pb) showed sensory impairment, i.e., dysfunction of spatial and temporal visual function (Rice, 1998). Environmentally-relevant doses of Pb (10^{-3} µM) administered to tadpoles inhibited the growth of developing neurons in the subcortical retinotectal pathway, the main efferent from the retina (Cline et al., 1996). Functional tests like electroretinograms (ERGs) show Pb-related aberrations in children, rodents and nonhuman primates.

The animal toxicological data show that developmental windows and the dose of Pb contribute to the complex and variable effects of Pb with the retina. Table 5-12 summarizes Pb-related effects in retinal ERG studies. Female rats exposed postnatally to moderate and high levels of Pb (0.02 or 0.2% Pb-acetate exposure in dam drinking water from birth through weaning, resulting in weaning blood Pb levels of 19 and 59 µg/dL, respectively) had subnormal scotopic ERGs (decreased A- and B-wave amplitudes) with decreased sensitivity and temporal resolution when assessed at 90 days of age (Fox et al., 1991) (Table 5-12). Similar results were obtained in multiple studies conducted in in vitro models (Otto and Fox, 1993; Fox and Farber, 1988; Fox and Chu, 1988). Monkeys exposed to moderately high levels of Pb continuously from the prenatal period to age 7 years (350 or 600 ppm Pb-acetate, resulting in blood Pb levels of 40 and 50 µg/dL, respectively) had persistently increased maximal retinal ERG amplitude (B-wave only, supernormality) and increased mean ERG latency when assessed 2 years after termination of Pb exposure when blood Pb levels were <10 µg/dL (Lilienthal et al., 1988) (Table 5-12).

Table 5-12 Summary of Pb-related retinal ERG studies

Study	Species	Sex[a]	Pb Exposure Protocol/Dose	Maximal Blood Pb Level (µg/dL)	ERG Abnormality	Progenitor cell proliferation	Retinal Cellular Apoptosis	Retinal Dopamine Levels	Retinal Cell Layer Thickness

A recent study exposed female Long-Evans rats to low (27 ppm), moderate (55 ppm), and high (109 ppm) levels of Pb-acetate in drinking water beginning 2 weeks before mating, throughout gestation, and until PND10 (G+P exposure) (Fox et al., 2008) (Table 5-12). Blood Pb levels in G+P Pb-exposed pups in the three groups were 10-12 µg/dL (lower), 21-24 µg/dL (moderate), and 40-46 µg/dL (higher). This developmental window in the retina of the rat is equivalent to gestational human retinal development. Results of this rodent study demonstrated persistent supernormal scotopic rod photoreceptor-mediated ERGs (lower and moderate Pb exposure) similar to the associations observed between ERG and prenatal maternal blood Pb levels ≥ 10.5 µg/dL in male and female children (Rothenberg et al., 2002a). Supernormal scotopic ERGs may be recorded without other overt opthalogical changes and are rarely seen in the clinical setting (Terziivanov et al., 1983). Lower and moderate levels of G+P Pb exposure increased neurogenesis of rod photoreceptors and rod bipolar cells without affecting Müller glial cells and statistically significantly increased the number of rods in central and peripheral retina. Higher-level G+P Pb exposure (109 ppm, blood Pb level of 46 µg/dL) or moderate to higher level postnatal exposure (PND1-21, blood Pb levels 19 and 59 µg/dL) statistically significantly decreased the number of rods in central and peripheral retina, induced scotopic ERG subnormality in adult rats (Table 5-12), and statistically significantly decreased the retinal

Zn concentration. Pb exposure induced concentration-dependent decreases in adult rat retinal dopamine synthesis and utilization/release (Fox et al., 2008). Thus, the dose of Pb and the exposure window produce complex interactions in the retina that differentially affect retinal histology and functional tests, i.e., ERG as summarized in Table 5-12.

A recent study of adult zebrafish that were exposed as embryos (2 to 24 hours post-fertilization) to water containing 0.03 μM $PbCl_2$ showed fish with impaired response to visual stimulation (visual response to a rotating bar) under low light conditions. These zebrafish also failed to respond normally to mechanosensory stimulation (0.01 and 0.03 μM $PbCl_2$), showing a significantly impaired startle response. These data show that low-level developmental Pb exposure causes sensorimotor deficits in fish (Rice et al., 2011). Another study evaluating visual spatial acuity in rhesus monkeys (Laughlin et al., 2008) exposed to Pb-acetate postnatally (PND8-26 weeks of age via commercial milk formula, achieving a target blood Pb of 35-40 μg/dL) found no effects of Pb exposure on spatial acuity as assessed with modified the Teller preferential looking paradigm.

Mechanistic understanding of the effect of Pb on the visual system includes its capability to displace divalent cations, act as an inhibitor of physiological enzymes, regulate cell proliferation and apoptosis, impair and perturb normal neuroanatomy formation, i.e., cytoarchitecture in the brain, and affect neurotransmitters. The effects of Pb on the retina have been shown to by mediated by its capability to act as a cGMP phosphodiesterase (PDE) inhibitor (Srivastava et al., 1995; Fox and Farber, 1988). The drug sildenafil citrate, another cGMP PDE inhibitor, can also cause visual problems including alterations in scotopic ERGs (Laties and Zrenner, 2002). With postnatal exposure of animals or in vitro Pb exposure of isolated rods, Pb has been shown to induce elevated cGMP which contributes to elevated rod calcium concentration (Fox and Katz, 1992) and subsequently to apoptotic cell death in a concentration-dependent fashion. In

separate work in mice, low and moderate doses of Pb (27 or 55 ppm Pb-acetate in dam drinking water from gestation to PND10, resulting in blood Pb levels of 12 and 25 μg/dL, respectively), induced greater rod and rod bipolar cell neurogenesis (proliferation) and greater thickness and cell number of the outer and inner neuroblastic layers of the retina (Giddabasappa et al., 2011; Fox et al., 2008). Rodents with moderate dose G+P Pb exposure (resulting in blood Pb level of 25 μg/dL) had 27-fold greater and prolonged retinal progenitor cell proliferation (Giddabasappa et al., 2011); at higher doses of Pb (109 ppm Pb-acetate, resulting in blood Pb levels of 56 μg/dL) there was no rod neurogenesis. Nitric oxide has been shown to regulate retinal progenitor cell proliferation in chick embryos (Magalhaes et al., 2006). Thus, these authors postulated that impaired NO production may contribute to aberrant retinal cell proliferation (Giddabasappa et al., 2011). Pb exposure has been shown to impair NO synthase activity in other organs (Section 5.2.4.5). Pb has been shown to affect a plethora of neurotransmitters in the brain and it has recently been shown to affect neurotransmitters in the retina. In the aforementioned model of G+P rodent Pb exposure through PND10, Pb decreased dopamine (DA) synthesis and use in a concentration-dependent manner (Fox et al., 2008) (Figure 5-20). These new data provide further insight into retinal changes by showing increased proliferation of Pb-exposed retinal progenitor cells without changes in apoptosis in G+P exposed rats (Fox et al., 2008).

Figure 5-20 Retinal dopamine metabolism in adult control and gestationally lead-exposed (GLE) rats.

As discussed in the 2006 Pb AQCD, Pb-induced decreased Na/K+ ATPase activity have been reported in vitro and in vivo. Also, structural changes from chronic Pb exposure (birth to age 6) included cytoarchitectural changes in visual projection areas of the brain of monkeys; maximum blood Pb level in the low and high dose group reached 20 µg/dL and 220 µg/dL, respectively (Reuhl et al., 1989). Within the visual system, Pb has been shown to affect multiple pathways including signaling, enzyme inhibition, neurotransmitter levels, neuroanatomy formation, and cell proliferation and apoptosis.

In summary, developmental windows of exposure as well as exposure dose (Table 5-12) are important factors that contribute to Pb-induced changes in retinal function. The retina is a sensitive target for Pb-induced altered histology and retinal function. Prenatal, postnatal, lifetime or occupational exposures provide windows with different effects on the retina, effects that are modified by dose of Pb.

5.3.5 Motor Function

Some studies in children have assessed fine motor function, i.e., response speed, dexterity, eye-hand coordination, as part of a battery of cognitive function and behavioral testing, and most have found associations with blood Pb level. Fewer studies have examined gross motor function, i.e., postural balance, action tremor, agility but also have found associations with blood Pb level.

Multiple studies were conducted in the CLS cohort at age 6 years and in adolescence at ages 12 and 15-17 years. Assessments in younger children indicated associations of concurrent and lifetime average blood Pb levels but not prenatal blood Pb levels with poorer visuomotor control and upper limb dexterity (Dietrich et al., 1993b) and poorer postural balance (Bhattacharya et al., 1995). Associations with both fine and gross motor function were adjusted for HOME score and race. Additional covariates included maternal IQ, SES, and sex for fine motor functions (Dietrich et al., 1993b) and height, BMI, birth weight, bilateral ear infection, and foot area for postural balance (Bhattacharya et al., 1995). Blood Pb levels were associated with fine and gross motor function in unadjusted and adjusted analyses, indicating that bias from the measured confounders was not driving the observed associations. Subsequent analyses in the CLS demonstrated associations of earlier childhood average blood Pb levels (0-5 year average or 78 month average) with poorer fine (Ris et al., 2004) and gross motor function (Bhattacharya et al., 2006) assessed in adolescence. While these findings suggest the persistence of Pb effects or early, long-term exposure effects, it is important to note that blood Pb levels measured later in childhood or concurrently with motor function were not examined.

Studies in other populations found associations of blood Pb level (primarily concurrent) with poorer fine motor function in children ranging in age from 3 to 16 years (Palaniappan et al., 2011; Min et al., 2007; Wasserman et al., 2000). Among children in New England participating in NECAT (described in Section 5.3.2.1) Surkan et al. (2007) found higher blood Pb levels to be associated with lower FSIQ but better fine motor function as indicated by faster finger tapping speed. Gross motor function also was assessed in other populations of children. In the Yugoslavian cohort, lifetime average blood Pb level was not associated with gross motor function (Wasserman et al., 2000). Concurrent blood Pb level was associated with greater sway oscillation, alternating arm movements, and action tremor in a group of Inuit preschool children in Quebec, Canada (Despres et al., 2005). Investigators considered potential confounding by several variables including HOME score, maternal education and nutrient levels. In animal studies, Pb exposure has shown mixed effects on endurance, balance and coordination as measured by rotarod performance. G+P Pb-exposed male mice had significantly shorter

mean latencies to fall from the rotarod compared with controls; females were unaffected. Further, low dose G+P Pb-exposed male mice had significantly poorer rotarod performance (i.e., fell off more quickly) than did high dose G+P male mice (resulting blood Pb levels at PND10: 10 µg/dL and 42 µg/dL, respectively), indicative of a nonlinear concentration-dependent relationship (Leasure et al., 2008). Other rotarod experiments at higher doses of Pb exposure and at various speeds of rotarod rotation yielded mixed results (Kishi et al., 1983; Grant et al., 1980; Overmann, 1977).

The collective body of evidence demonstrates that within the same population of children, blood Pb levels are associated with decrements in cognitive function, attention, and fine and gross motor function. Studies found associations with concurrent and childhood average blood Pb levels mostly in populations with mean levels ranging from 11 to 28 µg/dL. Despres et al. (2005) found impaired gross motor function in a children with a mean blood Pb level of 5 µg/dL. Min et al. (2007) found impaired fine motor function in children with a mean concurrent blood Pb level of 2.9 µg/dL; however, the results were not adjusted by SES-related variables. motor skills are the result of the coordination of complex cognitive and physical processes in the cortex, cerebellum, vestibular systems, and visual system, and biological plausibility for the associations of blood Pb levels with fine motor skills observed in children is provided by observations that Pb exposure affects development and function of these systems.

5.3.6 Seizures in Animals

One neurological sign of high dose Pb exposure has been the development of epileptic form activity or seizures in animals (Krishnamoorthy et al., 1993). However, earlier studies in the animal toxicological literature exploring the effects of Pb on seizure activity and threshold showed mixed results. Pb-acetate (250, 500, or 1,000 ppm for 30 days in drinking water to PND60 male Wistar rats, resulting in blood Pb levels of ~20, 35, and 42 µg/dL, respectively) significantly decreased the elapsed time required to develop the first myoclonic jerk and tonic-clonic seizure (Arrieta et al., 2005); also, the dose of pentylenetetrazol (PTZ) required to induce seizures was significantly decreased across all Pb dose groups. Some studies showed no effect of Pb on kindled animals (Schwark et al., 1985; Alfano and Petit, 1981). Other studies showed differential susceptibility to convulsant-inducing agents in developmentally Pb-exposed rats (Chen and Chan, 2002). Sprague Dawley rats were exposed to Pb-acetate (0.2% w/v in drinking water from PND1-25, followed by 25 days with no Pb exposure). Seizures were induced at PND25 or PND50. At PND25, Pb exposure significantly decreased (PTZ)-, picrotoxin (PIC)-, and strychnine (STRY)-induced convulsion thresholds, but increased N-methyl-D-aspartate (NMDA) and 4-aminopyridine (4-AP)-induced convulsion thresholds. At

PND50, the effects of PTZ, NMDA, and 4-AP remained similar to those at PND25, but PIC and STRY-dependent convulsion thresholds were reversed and significantly increased (Chen and Chan, 2002). Chen and Chan (2002) hypothesized that this differential effect may be due to selective effects on inhibitory and excitatory neurotransmission as an effect of age and blood Pb level.

Recent investigation expands on the work by Arrieta et al. (2005) by showing similar effects in another rodent species, BALB/c mice. Adult male BALB/c mice were exposed to Pb for 30 days via drinking water (resulting in blood Pb levels in control and 50, 100, 200 and 400 ppm Pb groups of 0.02, 6, 11, 15 and 18 µg/dL, respectively) (Mesdaghinia et al., 2010). Exposure to 50 ppm Pb did not affect PTZ-induced seizure threshold, but all other doses significantly reduced the thresholds of face and forelimb clonus, myoclonic twitch, running and bouncing clonus, and tonic hindlimb extension. These studies show that Pb exposure may modulate seizure activity in animals.

5.3.7 Neurodegenerative Diseases

5.3.7.1 Epidemiologic Studies of Neurodegenerative Diseases in Adults

The 2006 Pb AQCD described several studies examining associations of blood and bone Pb levels with neurodegenerative diseases such as Alzheimer's disease and dementia. Among NAS men, higher bone Pb levels were associated with lower MMSE scores (Weisskopf et al., 2004; Wright et al., 2003b), which indirectly pointed to a potential association with dementia, given that the MMSE is widely used as a screening tool for dementia. Overall, studies had sufficient limitations (e.g., indirect assessment of dementia, comparison of Alzheimer's Disease patients and healthy controls, lack of Pb biomarker data), and findings were inconclusive (U.S. EPA, 2006b). New studies on dementia are not available to assess further the associations with Pb biomarkers. Similarly, new studies examining Alzheimer's disease are not available, and as in 2006, the evidence is still inconclusive regarding the association with Pb biomarkers. In contrast, there has been additional investigation of ALS, Parkinson's disease (PD), and essential tremor, which is described below.

Amyotrophic Lateral Sclerosis

Most studies of the association between Pb and ALS have relied on indirect methods of assessing Pb exposure and overall, have produced inconsistent results. Case-control

studies that measured blood Pb levels produced contrasting results. A study of 16 ALS cases (mean blood Pb level: 12.7 µg/dL) and 39 controls (mean blood Pb level: 10.8 µg/dL) found a small difference in the mean concurrent blood Pb level (Vinceti et al., 1997). Another case-control study that examined concurrent blood and bone Pb levels in a New England-area population found higher odds of ALS among subjects with concurrent blood Pb levels ≥ 3 µg/dL (e.g., OR: 14.3 [95% CI: 3.0, 69.3] for blood Pb levels 3-4 µg/dL) (Kamel et al., 2002). In analyses of tibia or patella Pb tertiles, subjects in the highest two tertiles (≥ 10 µg/g patella Pb and ≥ 8 µg/g tibia Pb) had higher ALS prevalence. For example, the ORs (95% CIs) for patella Pb levels 10-20 µg/g and tibia Pb levels 8-14 µg/g were 2.1 (0.6, 7.4) and 1.6 (0.5, 5.6), respectively. Also in this population, an estimate of cumulative Pb exposure based on occupational history was found to be associated with ALS (Kamel et al., 2002). The stronger findings for blood Pb level were surprising given that bone Pb level is a better biomarker of cumulative Pb exposure. One explanation for these findings is that the association could be the result of reverse causality since the half-life of blood Pb is only about 30 days, and blood was collected from people who already had ALS. If, for example, reduced physical activity among those with ALS led to more bone turnover, then more Pb would be released from bones into circulation leading to elevations in blood Pb levels among cases as a result of effects of the disease.

Since the 2006 Pb AQCD, a few additional studies have been conducted with the same New England-area case-control study population. Kamel et al. (2005) reported that the association between blood Pb level and ALS was not modified by the ALAD genotype (Kamel et al., 2005). Another report examined survival of ALS among 100 of the original 110 ALS cases (Kamel et al., 2008). Higher tibia Pb levels were associated with longer survival time. Findings were similar for patella and blood Pb levels, although they were associated with smaller increases in survival time. These paradoxical findings raise the concern that in a case-control study of ALS, the association between bone Pb levels and ALS may be biased because the case group may comprise more individuals with longer survival time. Consequently, their bone Pb levels may be higher because they reflect a longer period of cumulative exposure. On the other hand, the decreased mobility due to the disease itself would tend to increase bone resorption and lower bone Pb levels over time. This process might mitigate this effect for bone Pb but would tend to increase blood Pb levels among cases. However, this was not observed in the one study that had bone and blood Pb biomarkers (Kamel et al., 2002). Because the strongest findings for survival were found for tibia Pb, it is unlikely that the findings were biased due to increased survival of cases.

Another case-control study examined concurrent blood Pb levels and ALS among 184 cases (33 were either progressive muscular atrophy or primary lateral sclerosis, mean

blood Pb level: 2.41 µg/dL) and 194 controls (mean blood Pb level: 1.76 µg/dL) (Fang et al., 2010). The cases were recruited from the National Registry of U.S. Veterans with ALS, and controls were recruited from among U.S. Veterans without ALS and frequency matched by age, gender, race, and past use of the Veterans Administration system for health care. A doubling of blood Pb levels was associated with ALS with an OR (95% CI) of 2.6 (1.9, 3.7). Associations did not differ substantially by indicators of bone turnover but were slightly higher among ALAD 1-1 carriers. The association with blood Pb level was similar in analyses that excluded the progressive muscular atrophy and primary lateral sclerosis cases. The similar results by degree of bone turnover suggest that reverse causation is not likely driving the association between blood Pb level and ALS. Whether other types of reverse causality are contributing, however, cannot be ruled out. This study did not have measures of bone Pb and therefore could not assess the association with biomarkers of cumulative Pb exposure.

In summary, studies have found associations of blood and bone Pb levels with ALS but in relatively few different cohorts. The case-control design of most studies and issues of reverse causality and bias due to survival time make it difficult to draw firm conclusions. Studies in additional cohorts using designs other than case-control comparisons are needed to address the limitations of the available studies and characterize better the potential effects of Pb on ALS.

Parkinson's Disease

A few previous studies, some ecological (Rybicki et al., 1993; Aquilonius and Hartvig, 1986) and some case-control relying on questionnaire data or occupational history (Gulson et al., 1999; Gorell et al., 1997; Tanner et al., 1989) indicated associations between exposure to heavy metals, particularly Pb, and risk of PD. Available evidence was limited and far from conclusive. A recent large case-control study (330 cases, 308 controls) recently reported on associations between biomarkers of Pb and PD in a population with virtually no occupational exposures to Pb (Weisskopf et al., 2010). Subjects in the highest quartile of tibia Pb level (>16.0 µg/g) had higher odds of PD compared to those in the lowest quartile (≤ 5 µg/g) (OR: 1.91 [95% CI: 1.01, 3.60]). In this study, cases and controls were recruited from several different sources including movement disorder clinics and community-based cohorts, which could have introduced some biases. However, when analyses were restricted to cases recruited from movement disorder clinics and to their spouse, in-law, or friend as controls, the results were even stronger (OR: 3.21 [95% CI: 1.17, 8.83]). Although the use of spouse, in-law, and friend controls can introduce bias, this is expected to be toward the null as these groups are likely to share many exposures.

Manganese exposure has been associated with Parkinsonian symptoms and could potentially confound associations between Pb and PD. Weisskopf et al. (2010) did not adjust for Mn exposure in analyses. However, unlike a setting of occupational exposure to Pb, general environment exposure to Pb is much less likely to be correlated with environmental Mn exposure. Thus, the likelihood of any associations with Pb being confounded by co-occurring Mn exposure is less likely.

Coon et al. (2006) conducted a smaller case-control study of 121 PD patients and 414 age-, sex-, and race-, frequency-matched controls all receiving health care services from the Henry Ford Health System. Subjects in the highest quartile of both tibia (OR: 1.62 [95% CI: 0.83, 3.17] for levels ≥ 15 μg/g) and calcaneus (OR: 1.50 [95% CI: 0.75, 3.00] for levels ≥ 25.29 μg/g) bone Pb levels had higher odds of PD compared to those in the lowest quartiles (0-5.91 μg/g for tibia and 0-11.70 μg/g for calcaneus). The highest OR for PD was estimated for subjects in the highest quartile of whole-body lifetime exposure to Pb (≥ 80.81 μg/g) estimated using PBPK modeling), compared to the lowest quartile of exposure (0-40.04 μg/g) (OR: 2.27 [95% CI:1.13, 4.55] for levels ≥ 80.81 μg/g). These analyses did not adjust for Mn either; however, in this study it was not clear what the extent of occupational exposure to Pb was among the participants. Thus, it is uncertain whether the observed associations were specifically related to Pb exposure or could have resulted from co-occurring Mn exposure.

In summary, a small number of recent studies expand on previous evidence by finding associations of bone Pb levels, biomarkers of cumulative Pb exposure, with PD in adults. Nonetheless, additional investigation is warranted to establish the temporality between Pb exposure and development of PD and to assess potential confounding by Mn exposure.

Essential Tremor

In a relatively small body of literature, concurrent blood Pb levels have been consistently associated with essential tremor, although studies have had relatively small sample sizes and have produced imprecise effect estimates. The 2006 Pb AQCD described case-control studies that found associations between concurrent blood Pb levels and essential tremor in New York City metropolitan area populations (Louis et al., 2005; Louis et al., 2003). In Louis et al. (2005), the magnitude of association was larger among carriers of an ALAD2 allele than among adults with only ALAD1 alleles.

Since 2006, Dogu et al. (2007) reported on a case-control study of 105 essential tremor cases from a movement disorder clinic in Turkey and 105 controls (69 spouses and 36 other relatives living in the same district). After adjusting for age, sex, education, cigarette smoking, cigarette pack-years, and alcohol use, a 1 μg/dL higher blood Pb level

(measured at the time of study recruitment) was associated with essential tremor with an OR (95% CI) of 4.19 (2.59, 6.78). This OR was much larger than that obtained in the New York area study (OR: 1.19 [95% CI: 1.03, 1.37]) (Louis et al., 2003). The magnitude of association in Dogu et al. (2007) is even more striking because so many of the controls were spouses who are expected to share many environmental exposures as cases. Most of the essential tremor cases were retired at the time of the study, but past occupational history was not reported. Occupational Pb exposures were less likely in the New York area population.

In this small body of studies, associations were observed between blood Pb level and essential tremor in adults. However, due to the case-control design of studies, temporality between exposure and development of essential tremor cannot be established. Further, the level, timing, frequency, and duration of Pb exposure associated with PD is uncertain as all studies examined blood Pb level at the time of study recruitment. Occupational histories were not reported in these studies. Thus, it is not clear what past exposure to Mn may have contributed to the associations observed with blood Pb levels.

5.3.7.2 Toxicological Studies of Neurodegenerative Disease

Although epidemiologic studies have provided weak evidence for associations of blood Pb level and ALS in adults, toxicological studies have found that Pb exposure induces neurophysiologic changes consistent with ALS. For example, chronic Pb exposure (Pb-acetate in drinking water at 200 ppm from weaning onward, resulting blood Pb level: 27 µg/dL) reduced astrocyte reactivity and induced increased survival time in the superoxide dismutase transgenic (SOD1 Tg) mouse model of severe ALS (Barbeito et al., 2010). In this model, Pb exposure did not significantly increase the onset of the ALS disease but increased survival time in SOD1 Tg mice (Barbeito et al., 2010). This finding does provide biological plausibility for the association observed between blood Pb level and longer survival time in patients diagnosed with ALS (Kamel et al., 2008). In mice, astrocyte of vascular endothelial growth factor (VEGF) also was examined to understand its possible contribution to Pb effects on increasing survival time in ALS models. Baseline levels VEGF were elevated in astrocytes from the ventral spinal cord of untreated SOD1 Tg mice versus untreated nontransgenic animals. VEGF was not induced in the astrocytes of Pb-treated nontransgenic mice. Pb-exposed SOD1 Tg mice had significant elevations of astrocyte VEGF versus vehicle-treated SOD1 Tg animals (Barbeito et al., 2010). Nontransgenic animals exposed to Pb showed no elevation in VEGF expression above that in nontransgenic vehicle-treated animals (Barbeito et al., 2010). Other research has suggested that ALS initiation is dependent on motor neuron function and ALS progression is dependent on astrocyte and microglia function

(Yamanaka et al., 2008; Boillee et al., 2006). Thus, the aforementioned findings for Pb-induced effects on astrocytes provide a mechanistic explanation for Pb effects on ALS progression in animals.

Others have reported that VEGF administration to the SOD1 Tg mice significantly reduced glial reactivity, a marker or neuroinflammation (Zheng et al., 2007). Using a cell-based co-culture system of neurons and astrocytes, Barbeito et al. (2010) found that an up-regulation of VEGF production by astrocytes in the Pb-exposed SOD1 Tg mice was protective against motor neuron death in the SOD1 Tg cells (Barbeito et al., 2010). Chronic Pb exposure in a mouse model of ALS was associated with increased survival time and was correlated with higher spinal cord VEGF levels, making astrocytes less cytotoxic to surrounding motor neurons (Barbeito et al., 2010). Also, in another study the metal chelators DP-109 and DP-460 were neuroprotective in the ALS mouse model or Tg(SOD1-G93A) (Petri et al., 2007).

Improper activation of microglia and release of inflammatory cytokines and metabolites can contribute to neurodegeneration (Zhang et al., 2010b; Qian and Flood, 2008). These two cell types are known to accumulate or sequester Pb in the nervous system. Researchers have implicated dysfunctional astrocytes as playing an important role in the chain of misregulated inflammation leading to neurodegenerative conditions (Barbeito et al., 2010; De Keyser et al., 2008).

Cell Death Pathways

Earlier work has documented that Pb exposure can induce cell death or apoptosis in various models including rat brain (Tavakoli-Nezhad et al., 2001), retinal rod cells (He et al., 2003; He et al., 2000), cerebellar neurons (Oberto et al., 1996), and PC12 cells (Sharifi and Mousavi, 2008). These observations indicate that Pb-induced cell apoptosis may mediate its neurodegenerative effects. A recent study reported that chronic (40 days) Pb exposure induced hippocampal apoptosis in young (exposure starting at 2-4 weeks of age) and adult (exposure starting at 12-14 weeks of age) male rats exposed to 500 ppm Pb by drinking water (resulting in blood Pb levels of 98 µg/dL); apoptosis was verified by light and electron microscopy, and increased pro-apoptotic Bax protein levels (Sharifi et al., 2010). Another study followed the developmental profile of changes in various apoptotic factors in specific brain regions of animals exposed to Pb-acetate (0.2% dam drinking water) during lactation. Male offspring blood Pb level at the end of lactation or PND20 was 80 µg/dL. The data showed that hippocampal mRNA for various apoptotic factors including caspase-3, Bcl-x and Brain-derived neurotrophic factor (BDNF) was significantly upregulated on PND12, PND15 and PND20. The cortex of these male pups also showed upregulation of Bcl-x and BDNF on PND 15 and PND20 (Chao et al.,

2007). The cerebellum did not have elevated apoptotic mRNA levels in this model. This study showed temporal and regional changes in activation of death protein message levels in male offspring.

Pb exposure has also been shown to induce apoptosis during spinal cord development in chicks exposed to 150 or 450 µg in ovo Pb-acetate exposure at embryonic day 3 or 5 and visualized six days later; TUNEL positive cells were at significantly higher levels in Pb-exposed animals and were visualized in all layers of the developing spinal cords (Müller et al., In Press). Also, levels of glial fibrillary acidic protein (GFAP), a factor important in neuronal migration and cellular differentiation during nervous system development, was significantly attenuated in spinal cords of Pb-exposed chicks. Another recent study examined Pb treatment animals (i.p. injections of 350 mg/kg, twice daily, blood Pb levels at PND14 of 0.15 µg/dL in controls and 8.10 µg/dL in Pb-treated animals) during PND7-14, a known period of sensitivity to NMDA antagonist-dependent neuronal apoptosis (Ikonomidou et al., 1999). Liu et al. (2010b) examined apoptotic effects in 30 day-old male rats that were exposed to Pb-acetate 1x/d for 6 weeks via intragastric infusion. Four dose groups: control, low (2), medium (20), and high (200 mg/kg BW) had blood Pb levels of 1.0 to 7.5 µg/dL; 4.5 to 11 µg/dL; 9 to 42 µg/dL; and 48 to 73 µg/dL, respectively. Liu et al. (2010b) reported Pb-induced apoptosis in the brain with hippocampal XIAP (statistically significant at high dose only) and Smac (statistically nonsignificant trend) downregulation and associated histopathology showing hippocampal neuronal apoptosis (TUNEL positive staining, significant at all doses) at the termination of the 6 week treatment. In another study, Pb exposure (500 ppm Pb-acetate in drinking water for 8 weeks) of adult male rats induced regional-specific changes in brain apoptotic proteins poly(ADP-ribose) polymerase, Bcl-2, caspase-3) with a greater effect observed in the hippocampus and cerebellum and a lesser effect observed in the brainstem and the frontal cortex (Kiran Kumar et al., 2009)

Collectively, studies have shown that Pb exposure induces neuronal apoptosis in animals during various developmental windows: early postnatal and adulthood. The new data continue to show that Pb exposure induced apoptosis in brains of animals.

Lead-Induced Neuronal Plaque Formation

Epidemiologic studies have not provided compelling evidence that Pb exposure is associated with Alzheimer's Disease in adults (Section 5.3.7.1); however, Pb exposure in early life has been shown to promote Alzheimer’s Disease-like pathologies in the brains of aged adult animals. Alzheimer’s disease is characterized by amyloid-beta peptide (Ab) accumulation, hyper-phosphorylation of the tau protein, neuronal death and synaptic loss. In the last decade, the developmental origins of adult health and disease (DoHAD)

paradigm and the similar Barker hypothesis have indicated that early life exposures can result in aberrant adult outcomes. Bolin et al. (2006) demonstrated the connection between developmental exposure to Pb in the rat with early life programming and the resulting inflammation-associated DNA damage with neurodegenerative loss in the adult brain. Wu and colleagues (2008a) had similar findings in a study using infantile exposure to Pb in monkeys. The investigations reinforce the need to directly examine the long-term effects of developmental exposure to toxicants rather than relying on adult exposure alone to predict probable health risks from prenatal, neonatal or juvenile exposure (Dietert and Piepenbrink, 2006). Mechanistically, some of these pathologies have been associated with changes in the epigenome.

The fetal basis of amyloidogenesis has been examined extensively by the Zawia laboratory in both rodents and nonhuman primates. Mechanistically, amyloid plaques originate from the cleavage of the amyloid precursor protein (APP) to Ab, which comprises the plaque. In rodents exposed to Pb as neonates or as adults, neonatal Pb exposure induced amyloidogenesis in the aged animal brains; adult exposure to Pb did not contribute to plaque formation. Basha et al. (2005) exposed male rodents neonatally via lactation to Pb (PND1-PND20 exposure, dam drinking water Pb-acetate 200 ppm, resulting in pup PND20 blood Pb level of 46 µg/dL and cortex 0.41 µg/g wet weight of tissue) and examined cortical APP gene expression over the lifetime. A bimodal response was observed, with a significant increase in APP expression above that in control animals first manifesting neonatally and second manifesting in old age (82 weeks of age) (Basha et al., 2005). A concomitant bimodal response was observed in specificity protein 1 (Sp1), a transcription factor known to be related to APP expression. Ab, the amyloid plaque constituent, was also significantly elevated in these aged animals developmentally exposed to Pb. A subset of rodents exposed to Pb only as aged adults (18-20 weeks of age) was unresponsive in APP or Sp1 expression or Ab production after Pb exposure, indicating the developmental lifestage and not adult lifestage as the susceptible period for Pb-induced amyloidogenesis. The Zawia lab (Wu et al., 2008a) produced similar findings for amyloid plaques in the brains of monkeys that were exposed to Pb as infants (PND1-PND400), i.e., significantly higher gene expression of APP, and Sp1 and significantly higher protein expression of APP and Ab in aged female monkey cortex tissue (23 year-old *Macaca fascicularis*) from a cohort of animals established in the 1980s by Rice (1992, 1990). After weaning but with continued Pb exposure, the monkeys had blood Pb levels of 19-26 µg/dL. However, in old age when amyloid plaques had manifested, blood Pb levels and brain cortex Pb levels had returned to control or baseline levels. Together, the rodent and nonhuman primate toxicological studies concur and show that developmental Pb exposure induced elevations in neuronal plaque proteins in aged animals.

Mechanistic understanding of Ab production and elimination after Pb exposure was explored in human SH-SY5Y neuroblastoma cells exposed to Pb concentrations of 0, 5, 10, 20, and 50 µM for 48 hours. These studies showed that Pb affected two separate pathways to contribute to elevated Ab. Pb exposure induced both the overexpression of APP and repression of neprilysin, a rate-limiting enzyme involved in Ab metabolism or removal (Huang et al., 2011a). Further mechanistic understanding of how Ab peptide formation is affected by Pb exposure was examined by Behl et al. (2009). The choroid plexus is capable of removing beta-amyloid peptides from the brain extracellular matrix; however, Pb was shown to impair this function, possibly via the metalloendopeptidase, insulin-degrading enzyme (IDE), which metabolizes Ab (Behl et al., 2009). In another study, the effect of Pb on transcription factors essential in the regulation of the developing brain was explored. Pb exposure has been shown to perturb DNA binding of transcription factors including SP1 at essential sites like zinc finger proteins. In Long-Evans hooded rat pups exposed to Pb during lactation, these Pb-induced developmental perturbations of SP1 DNA binding were found to be ameliorated by exogenous zinc supplementation (Basha et al., 2003).

An additional study with developmental Pb exposure (gestational plus lactational, dam drinking water solutions of 0.1%, 0.5% or 1%, blood Pb level 40, 80 and 1,00 µg/dL) showed that the hippocampus contained neurofibrillary changes as early as PND21. These changes manifested with Tau hyper-phosphorylation, and increased tau and beta amyloid hippocampal protein levels in Pb-exposed offspring (Li et al., 2010b).

In summary, the multiple recent studies showed that developmental Pb exposure induced significant increases in neuronal plaque associated proteins, which is the pathology found in humans with Alzheimer's disease. Adult exposure to Pb did not generate this neurofibrillary pathology, further demonstrating that early life Pb is a sensitive window for Pb-induced pathology including Ab-peptide accumulation, activation of Ab-supporting transcription factors, as well as tau hyperphosphorylation. Epidemiologic evidence for Pb-associated Alzhemier's disease is weak, and although several study design limitations were noted (Section 5.3.7.1), the animal evidence indicates that epidemiologic studies assessing concurrent bone or brain Pb levels or occupational Pb exposure may not have examined the etiologically relevant exposure period. Notably, animals were not behaviorally assessed for dementia.

5.3.8 Modes of Action for Lead Nervous System Effects

5.3.8.1 Effects on Brain Physiology and Activity

A small body of available epidemiologic evidence with small sample sizes demonstrated associations of Pb biomarkers with electrophysiologic changes in the brains of young adults as assessed by magnetic resonance imaging (MRI) or spectroscopy (MRS) (Yuan et al., 2006; Cecil et al., 2005; Meng et al., 2005; Trope et al., 2001). By characterizing underlying mechanisms by which Pb exposure may disrupt brain function, these studies have provided biologically plausible evidence for the effects of Pb exposure on cognitive and psychological and behavioral function observed in adults.

Findings such as lower levels of N-acetylaspartate (NAA), creatine (Cr), and choline are linked to decreased neuronal density and alteration in myelin. Notably, Trope et al. (2001) and Meng et al. (2005) reported that all subjects had normal MRIs with no evidence of structural abnormalities. Thus, the clinical significance of the observed physiological changes was unclear. Additionally, these studies compared subjects with relatively high childhood blood levels (23-65 µg/dL) to those with childhood blood Pb levels <10 µg/dL. Therefore, it is unclear whether physiological changes would be observed in association with lower blood Pb levels. Cecil et al. (2005) and Yuan et al. (2006) conducted functional MRI in 42 adult (ages 20-23 years) participants from the CLS cohort during a verb generation language task and found that childhood average blood Pb level was associated with decreased activation in the left frontal gyrus and left middle temporal gyrus, regions traditionally associated with semantic language function. Although these findings were in adults, they were consistent with findings in the same cohort of subjects that indicated associations of blood Pb level with other indices of language skills in childhood.

Since the 2006 Pb AQCD, studies examining MRI data were largely limited to CLS cohort participants as adults (ages 19-24), and recent results continue to support associations of childhood blood Pb levels with physiological changes in the brain of adults. These recent studies expanded on previous studies by including larger sample sizes, aiming to characterize important lifestages of Pb exposures, and evaluating potential links between changes in brain activity and functional neurodevelopmental deficits. Whereas previous CLS analyses focused on activity in specific regions of the brain, Cecil et al. (2011) examined brain metabolites in 159 subjects and found that childhood average blood Pb levels were associated with lower levels of NAA and Cr in the basal ganglia and lower levels of choline in white matter. These results were adjusted for age and FSIQ. A recent analysis of 31 men in the NAS cohort similarly reported an

association between biomarkers of cumulative, long-term Pb exposure and changes in brain metabolites in older adults. Weisskopf et al. (2007a) found higher tibia and patella Pb levels to be associated with a higher myoinositol/Cr ratio, which may be indicative of glial activation and is a signal reportedly found in the early stages of HIV-related dementia and Alzheimer's disease.

Other studies in CLS young adults found that childhood average blood Pb levels were associated with altered brain architecture. Brubaker et al. (2009) reported associations of childhood average blood Pb levels with diffusion parameters that were indicative of less organization of fibers throughout white matter. Results were adjusted for potential confounding by variables such as maternal IQ, prenatal alcohol and tobacco exposure, and adult marijuana use. In regions of the corona radiata, higher blood Pb levels were associated with less myelination axonal integrity. In regions of the corpus callosum, higher blood Pb levels were associated with greater myelination and axonal integrity. The differential impact on different neural elements may be related to the stage of myelination development at various periods of exposure.

Another study of 157 CLS participants provided evidence of region-specific reductions in adult gray matter volume in association with childhood blood Pb levels (Cecil et al., 2008). The most affected regions included frontal gray matter, specifically the anterior cingulate cortex and the ventrolateral prefrontal cortex (i.e., areas traditionally related to executive functions, mood regulation, and decision-making). Further, investigators found that fine motor factor scores positively correlated with gray matter volume in the cerebellar hemispheres; adding blood Pb level as a variable to the model attenuated this correlation. These findings suggested that MRI changes associated with blood Pb levels may be indicative of decrements in cognitive function. The functional relevance of these structural changes in the brain also is supported by observations from other studies that link changes in brain architecture and activity with changes in cognitive function (e.g., visuoconstruction, visual memory, eye-hand coordination) (Schwartz et al., 2007) and behavior (impulsivity, aggression, violence) (Yang et al., 2005; Raine et al., 2000).

In a subsequent comparison of blood Pb levels measured at various lifestages, Brubaker et al. (2010) found that blood Pb levels at older ages were associated with greater losses in gray matter volume than were childhood average or maximum blood Pb levels. Both Cecil et al. (2008) and Brubaker et al. (2010) found that Pb-associated reductions in gray matter were more pronounced in CLS males than females.

Studies of Pb-workers also found associations of blood and bone Pb levels with changes in brain structure and physiology, adding support for the effects of chronic Pb exposure. Pb-associated changes included white matter lesions, smaller brain volumes, less total gray matter, and lower levels of brain metabolites such as NAA and Cr (Hsieh et al.,

2009b; Jiang et al., 2008; Bleecker et al., 2007a; Stewart et al., 2006). In a few of these occupational groups, Pb-associated brain changes were linked to poorer performance in cognitive function tests (Caffo et al., 2008; Bleecker et al., 2007a).

In summary, results in a few different populations indicated associations of blood or bone Pb levels with changes in brain structure and physiology as assessed by MRI or MRS. A majority of evidence was derived from the CLS study. Several studies linked these changes to functional changes in cognitive performance or motor skills. While the collective findings pointed to the effects of long-term or past Pb exposures, it is important to recognize that other lifestages of exposure, including recent adult, were not widely examined.

5.3.8.2 Oxidative Stress

Pb has been shown to induce oxidative stress in multiple animal models, and this oxidative stress can contribute to DNA damage, which can be measured with the adduct 8-hydroxy-2'-deoxyguanosine (8-oxo-dG). The contribution of reactive oxygen or nitrogen species to these Pb induced changes was assayed by examining the ratio of 8-oxo-dG to 2-deoxyguanosine (2-dG). 2-dG is product of oxidative cleavage that can generate 8-oxo-dG from a parent compound forming a DNA adduct during conditions of nitrosative or oxidative stress. The 8-oxo-dG to 2-dG ratio data from rodent male offspring were similar to the amyloid data with significant biphasic elevations in developmentally Pb-exposed animals (0.2% Pb-acetate in dam drinking water from PND1-20) versus control, nonPb-exposed animals at early (PND5) and late life time points (80 weeks of age) (Bolin et al., 2006). Activity of the base-excision DNA repair enzyme oxoguanine glycosylase or Ogg1 was unaffected by Pb exposure (Bolin et al., 2006). Interestingly, similar findings were reported in a monkey study. The ratio of 8-oxo-dG to 2-dG in the brains of aged monkeys (23 years) after being exposed to Pb as infants, was significantly elevated above that in controls (Wu et al., 2008a). Several lines of evidence indicate that oxidative stress is involved in neurodegenerative pathologies including Alzheimer's disease; hydrogen peroxide-induced oxidative stress has been shown to induce intracellular accumulation of amyloid beta-protein (Abeta) in human neuroblastoma cells (Misonou et al., 2000). Similar to the amyloid findings in Pb-exposed animals the oxidative stress markers showed no significant changes above baseline when animals were exposed to Pb only as aged adults (Wu et al., 2008a; Bolin et al., 2006). Thus, the data for biomarkers of oxidative stress concur with the amyloidogenesis data with both demonstrating kinetically similar biphasic significant elevations in markers of oxidative stress and amyloidogenesis with early life Pb exposure and an absence of effect with adult only exposure.

Because the brain has the highest energy demand and metabolism of any organ, energy homeostasis is of utmost importance. Pb has been shown to inhibit various enzymes involved in energy production or glucose metabolism including glyceraldehydes-3 phosphate dehydrogenase, hexokinase, pyruvate kinase, and succinate dehydrogenase (Verma et al., 2005; Yun and Hoyer, 2000; Regunathan and Sundaresan, 1984; Sterling et al., 1982). Mitochondria produce ATP or energy through oxidative phosphorylation. Aberrant mitochondrial function can decrease the energy pool and contribute to ROS formation via electron transport chain disruption. ATP depletion can also affect synaptic and extracellular neurotransmission. The mitochondrial Na/K ATPase is important in maintaining the inner mitochondrial membrane potential (delta omega sub m) and the functioning of the mitochondria.

To characterize the effect of Pb exposure on these mitochondrial parameters, brains from the offspring of Pb-exposed mice were collected at PND8 (Baranowska-Bosiacka et al., 2011b). Cerebellar granular cells were harvested from PND 8 control and Pb-exposed animals (0.1% Pb-acetate in dam drinking water, resulting in blood Pb levels of 4 µg/dL and cerebella Pb levels of 7.2 µg/g dry weight). These neuronal cells were cultured for 5 days in vitro, at which point various mitochondrial parameters were measured. With Pb exposure, reactive oxygen species were significantly increased in both the cortical granule cells and in the mitochondria. Intracellular ATP concentration and adenylate energy charge values were significantly decreased in cells of Pb-exposed mice versus controls. Neuronal Na/K ATPase activity was significantly lower in cortical granule cells from Pb-exposed mice versus cells from controls. Mitochondrial mass was unaffected with Pb treatment, but mitochondrial membrane potential was significantly decreased with Pb exposure. Pb-exposed crayfish that were placed under hypoxic conditions adapted to the situation by decreasing their metabolism (Morris et al., 2005) and showed mitochondrial changes consistent with those observed in granule cells (Baranowska-Bosiacka et al., 2011b). These studies showed impaired mitochondrial function and energy production in neuronal cells from mice with gestational and lactational Pb exposure with concomitant increases in mitochondrial and cellular ROS production.

The effects of co-administration of flaxseed oil (FSO) with Pb-acetate on oxidative stress and neurotoxicity were examined in adult male Wistar albino rats (Abdel Moneim et al.). Animals were administered Pb-acetate i.p. for 5 days (20mg/kg, resulting in blood Pb level ~31 µg/dL the day after the last Pb injection) or FSO (oral gavage 1000mg/kg body weight for 5 days, 1 hour prior to Pb dosing, resulting in blood Pb level ~12 µg/dL). Administration of the polyunsaturated fatty acid FSO significantly attenuated the blood Pb level of Pb-exposed animals and control animals, indicating that FSO may alter Pb toxicokinetics in animals. As would be expected with a lower blood Pb level, FSO+Pb exposed animals had significant attenuations in Pb-induced histological neuronal damage

and brain tissue DNA fragmentation. Pb exposure effects on indicators of oxidative stress included decreased antioxidant GSH levels, elevated lipid peroxidation, and decreased antioxidant enzyme activity in brain tissue. These Pb-induced effects were attenuated in FSO+Pb exposed animals. These results indicated that FSO likely attenuates Pb-related neurotoxicological damage and oxidative stress via its action on altering Pb toxicokinetics.

Green tea extract (GTE) was shown to be protective against Pb-induced oxidative stress in the brains of adult male rats (1.5% GTE +/- 0.4% Pb-acetate for 6 weeks) (Hamed et al., 2010). GTE+Pb-exposed animals had significantly less brain Pb than did Pb-exposed animals (1.2 versus 1.9 ppm). Levels of pro-oxidants or antioxidants including lipid peroxides (LPO), nitric oxides (NO), total antioxidant capacity (TAC), glutathione (GSH), glutathione-S-transferase (GST), and superoxide dismutase (SOD) were measured in brain tissue homogenate 24 hours after the termination of Pb exposure. Comparing the Pb-exposed animals to controls, brain LPO was significantly elevated and brain GSH, GST and NO were significantly decreased. GTE and Pb co-exposure significantly attenuated the Pb-related changes. This study reported a positive correlation between whole blood Pb levels and brain tissue LPO levels and a negative correlation between whole blood Pb and NO levels. The antioxidant quercetin (Que) rescued chronic Pb exposure-related (0.2% Pb-acetate in drinking water from birth to PND67, 30 mg/kg BW Que for one week from PND60-67) impaired synaptic plasticity in adult male and female Wistar rat dentate gyrus (DG) (Hu et al., 2008a). Pb-related impaired long-term potentiation, paired-pulse reactions, and input/output functions were significantly attenuated with Que treatment at PND67. Que treated animals had significantly less hippocampal Pb than did the Pb-exposed animals and this decreased Pb brain burden likely contributed to the attenuated response observed with Que exposure.

The vulnerability of the highly energetic brain tissue to stressors and cell death can be exacerbated with an energy imbalance. Baranowska-Bosiacka et al. (2011b) showed that Pb exposure induced energy imbalances in immature rat brains exposed to Pb. Wistar rat pups (PND15) of both sexes were injected daily for 2 weeks with Pb-acetate (15mg/kg BW, i.p., resulting in blood Pb levels of 3 and 30 µg/dL, control and Pb-exposed, respectively) and thereafter sacrificed for analysis of regional brain purines and purinergic receptors. ATP and ADP were significantly decreased in various brain regions with Pb exposure, with the cerebellum and hippocampus more strongly affected than the forebrain cortex. Also, enhanced expression of the proinflammatory P2XR receptor was observed in the glial fraction, indicating the astrocyte pool may be involved in the pathological changes found in Pb-exposed immature rat brains.

5.3.8.3 Nitrosative Signaling and Nitrosative Stress

The nitric oxide system is increasingly being recognized as a signaling system in addition to its more classical role as a marker of cellular stress. In studies of learning and memory using the Morris water maze, hippocampal changes in NO were noted in Pb-exposed animals after completion of the test. Pb exposure has been repeatedly shown to increase the escape latency in Pb-exposed animals (Section 5.3.2.2). Chetty (2001) initially reported decreased hippocampal neuronal nitric oxide synthase (NOS) with perinatal Pb exposure. Namely, with repeated swim tests, control animals more quickly found a submerged platform (i.e., escaped), than did Pb-exposed animals. After either 4 or 8 weeks of Pb exposure to weanling male rats (resulting in blood Pb level of 6.2 µg/dL), hippocampal NOS and NO were significantly decreased. Dietary supplementation with taurine or glycine concomitant with 8 weeks of Pb exposure induced significant increases in hippocampal NOS, whereas Pb plus dietary supplementation with vitamin C, methionine, tyrosine, or vitamin B1 decreased hippocampal NOS. Supplementation also changed Pb-related effects on hippocampal NO. Pb-induced NO increased with taurine and decreased with vitamin C, tyrosine or glycine. Dietary supplementation with tyrosine, methionine, or ascorbic acid after 4 weeks of Pb exposure in weanling males (4-week blood Pb level of 47.6 µg/dL and 8-week blood Pb level of 8.1 µg/dL), induced significant increases in NO. Zinc supplementation in this model had no effect on the NO system. The investigators concluded various combinations of nutrients significantly attenuate Pb-related decreases in NO/NOS. Specifically, nutrients prevented (8 weeks Pb plus concomitant exposure to methionine, zinc, ascorbic acid, and glycine) or restored (4 weeks Pb exposure followed by 4 weeks nutrient exposure, taurine and thiamine) Pb-related decrements in NO/NOS concentrations (Fan et al., 2009a).

5.3.8.4 Synaptic Changes

Previous toxicological studies point to an effect of developmental Pb exposure on synapse development, which mechanistically may contribute to multiple Pb-related aberrant effects, including changes in long-term potentiation (LTP) and facilitation. Earlier work has shown that developmental Pb exposure results in altered density of dendritic hippocampal spines (Király and Jones, 1982; Petit and LeBoutillier, 1979), aberrant synapse elimination (Lohmann and Bonhoeffer, 2008), and abnormal long-term and short-term plasticity (MacDonald et al., 2006). Newer research using the *Drosophila* larval neuromuscular junction model has shown that compared with unexposed controls, Pb-exposed larvae had significant increases in intracellular calcium and significant delays in calcium decays back to baseline levels at the pre-synaptic neuronal bouton (as stimulated with multiple action potentials, also called AP trains). Pb-exposed larvae had

reduced activity of the plasma membrane calcium ATPase, which is responsible for extravasations of calcium from the synaptic terminal (He et al., 2009). Intracellular calcium in Pb exposed-larvae was no different from that in controls under resting conditions or in neurons with stimulation by a single action potential. Pb media concentrations in these experiments were 100 or 250 µM with the low-dose body burden (100 µM) of Pb calculated to be 13-48 µM per larvae. Facilitation of a neuronal terminal is defined as the increased capability to transmit an impulse down a nerve due to prior excitation of the nerve. After stimulation of the axon, facilitation of the excitatory post-synaptic potential, which is dependent on residual terminal calcium, was significantly elevated in Pb-exposed larvae versus control (He et al., 2009). The data from this synapse study demonstrate that developmental Pb exposure affected the plasma membrane calcium ATPase, induced changes in the intracellular calcium levels during impulse activation, and produced changes in facilitation of the neuronal networks of *Drosophil*a. Thus, the neuromuscular junction is a potential site of Pb interaction.

A study by Li et al. (2009c) focused on inflammatory endpoints and synaptic changes after gestational plus lactational dam drinking water Pb exposure (solutions of 0.1%, 0.5% or 1%, resulting in offspring blood Pb levels of 40, 80 and 100 µg/dL, respectively at PND 21). Hippocampal TNF-α was significantly elevated with Pb exposure and proteins that comprise the SNARE complex were all changed with Pb exposure. The SNARE complex of synaptic proteins includes SNAP-25, VAMP-2 and Syntaxin 1a and is essential in exocytotic neurotransmitter release at the synapse (Li et al., 2009c). Thus, Li et al. (2009c) found significant differences in hippocampal synaptic protein composition and increased pro-inflammatory cytokine levels in the brains of Pb-exposed offspring.

Neurotransmission is an energy-dependent process as indicated by the presence of calcium-dependent ATP releases at the synaptic cleft. At the synapse, ATP is metabolized by ectonucleotidases. In heme synthesis, Pb is known to substitute for the cation zinc in another nucleotidase, pyrimidine 5′-nucleotidase, and thus, the nucleotidase is used as a biomarker of Pb exposure. Acute exposure (96 hours) of male and female zebrafish to Pb-acetate (2 µg/dL) in their water induced significant decreases in ATP hydrolysis in brain tissue. This dose is deemed to be environmentally relevant. With chronic exposure (30 days), Pb-acetate promoted the inhibition of ATP, ADP and AMP hydrolysis; these findings were consistent with findings in rodents (Baranowska-Bosiacka et al., 2011b). The authors hypothesized that at 30 days, this Pb-induced change in nucleotide hydrolysis was likely due to post-translational modification because expression of enzymes responsible for the hydrolysis, NTPDase1 and 5′-nucleotidase, were unchanged (Senger et al., 2006). Thus, Pb has been shown to affect nucleotidase

activity in the central nervous system of zebrafish, possibly contributing to aberrant neurotransmission.

Another enzyme important in synaptic transmission at cholinergic junctions in the CNS and at neuromuscular junctions peripherally is acetylcholinesterase (AChE). After 24 hours of exposure to Pb-acetate (2 µg/dL water), AChE activity was significantly inhibited in zebrafish brain tissue. In Pb-exposed fish, AChE activity returned to baseline by 96 hours and maintained baseline activity after chronic exposure of 30 days. Thus, Pb was shown also to affect synaptic homeostasis of AChE in the brains of zebrafish (Richetti et al., 2010).

Pb has been shown to act as an antagonist of the NMDA receptor (NMDAR). The NMDAR is essential for proper presynaptic neuronal activity and function. Primary cultures of mouse hippocampal cells were exposed to Pb (10 or 100 µM solutions in media) during the period of synaptogenesis (Neal et al., 2010a). This exposure induced the loss of two proteins necessary for presynaptic vesicular release, synaptophysin (Syn) and synaptobrevin (Syb), without affecting a similar protein synaptotagmin (Syt). This deficit was found in both GABAergic and glutamatergic neurons. Pb also induced an increase in number of presynaptic contact sites. But, these sites may be nonfunctional as they lack the protein receptor complexes necessary for proper vesicular exocytosis. Another factor involved in growth and signaling of presynaptic neurons is BDNF, which is synthesized and released by postsynaptic neurons. BDNF is regulated by the NMDAR and acts in a retrograde fashion, participating in presynaptic maturation. In hippocampal cells, both pro-BDNF and BDNF release were significantly attenuated with Pb exposure (Neal et al., 2010a). Further, exogenous BDNF administration rescued the aforementioned Pb-related presynaptic effects. Thus, this cell culture model showed that Pb-related presynaptic aberrations are controlled by NMDAR-dependent BDNF effects on synaptic transmission.

Animals exposed to Pb postnatally (Wistar Albino rats, drinking water 300 mg/L Pb-acetate, resulting in blood Pb levels of 17 µg/dL at 6 weeks of age), from birth through lactation and through 12 weeks of age showed decreased learning ability and decreased hippocampal glutamate at 6, 8, 10 and 12 weeks of age (Niu et al., 2009) as well as significant decrements in the hippocampal glutamate synthesis-related enzymes aspartate aminotransferase and alanine aminotransferase.

5.3.8.5 Blood Brain Barrier

Two barrier systems exist in the body to separate the brain or the central nervous system from the blood. These two barriers are the blood brain barrier (BBB) and the blood

cerebrospinal fluid barrier (BCB). The BBB, formed by tight junctions at endothelial capillaries forming the zonulae occludens (occludins, claudins, and cytoplasmic proteins), separates the brain from the blood and its oncotic and osmotic forces, allowing for selective transport of materials across this barrier.

Pb exposure during various developmental windows has been shown to increase the permeability of the BBB (Dyatlov et al., 1998; Struzynska et al., 1997b; Moorhouse et al., 1988; Sundstrom et al., 1985). Possibly due the underdevelopment of the BBB early in life, prenatal and perinatal Pb exposure has been found to result in higher brain Pb accumulation than have similar exposures later in life (Moorhouse et al., 1988). Studies reviewed in earlier Pb AQCDs have shown that the chemical form of Pb and its capability to interact with proteins and other blood components affects its capability to penetrate the BBB (U.S. EPA, 2006b). Pb also has been shown to compromise the function of the BCB and decrease the CSF level of transthyretin, a thyroid binding protein made in the choroid plexus. The choroid plexus and cerebral endothelial cells that form the BBB and BCS tight junctions have been shown to accumulate Pb more than other cell types and regions of the CNS do. Hypothyroid status can contribute to impaired learning and IQ deficits (Lazarus, 2005).

Recent research with weanling rats exposed to Pb-acetate via drinking water showed leaky cerebral vasculature, an indication of a compromised BBB, as detected histologically with lanthanum nitrate staining of the brain parenchyma. Cerebral vasculature leakiness was ameliorated or resembled controls after iron supplementation. These weanlings also had significant Pb-induced decreases in the BBB tight junction protein occludin in the hippocampus, brain cortex, and cerebellum that were rescued to control levels with iron supplementation (Wang et al., 2007b). These data demonstrate that Pb induced a leaky BBB in weanling rats with associated decreases in the junctional protein occludin; dietary supplementation with iron ameliorated these Pb-induced impairments of the BBB in male rats. This loss of integrity at the junctional protein level was affirmed with additional experiments using the rat brain vascular endothelial cell line RBE4, in which 10 µM Pb-acetate exposure for 2, 4, 8, 16 and 24 hours resulted in decreases in junctional proteins occludin and claudin 5 as well as scaffold proteins ZO1 and ZO2 (Balbuena et al., 2011). Because expression of these junctional and scaffold proteins did not show decrements, it was determined that these protein decrements were due to post-translational modifications.

A study examined the effects of Pb on transendothelial electrical resistance (TEER), a marker of BBBB integrity, in an in vitro co-culture system employing endothelial cells (RBE4 or bovine brain microvascular endothelial cells) and astrocytes (primary Sprague-Dawley neonatal pup astrocytes, in utero day 21) as the barrier between Pb containing

exposure media and neurons. After 14 hours of exposure to Pb, TEER was significantly impaired in a concentration-dependent manner, with the lowest significant effects found with 1 µM Pb-acetate exposure. Thus, Pb exposure was found to contribute to leakiness of the BBB by decreasing the resistance across the junction.

Adult male rats exposed to Pb-acetate in drinking water for 4 or 12 weeks (50 or 500 ppm, resulting in blood Pb levels of 12 and 55 µg/dL, respectively) were assessed by diffusion weighted imaging for changes in apparent diffusion coefficent (ADC), a measure of tissue water diffusivity that changes under pathological conditions like cerebral edema. After 4 weeks of exposure to 500 ppm Pb, the water ADC was significantly increased in the hippocampus, mesencephalic reticular formation, and cerebellum but unaffected in other brain areas. After 12 weeks of 500 ppm Pb exposure, ADC was significantly increased in the corpus callosum and caudate putamen. Exposure to 50 ppm Pb for 12 weeks increased the ADC values in the cerebellum and mesencephalic reticular formation. The brain areas with elevated ADC also showed increased BBB permeability as measured with evans blue albumin complex. These data show that adult animals with chronic Pb exposure are susceptible to regional edema and regional increased permeability of the BBB, even with low blood Pb levels (12 µg/dL) (López-Larrubia and Cauli, 2011).

5.3.8.6 Cell Adhesion Molecules

Classic cell adhesion molecules including NCAM and the cadherins are junctional or cell surface proteins that are critical for cell recognition and adhesion. Cell adhesion molecules, particularly the cadherins, are calcium-dependent and thus interaction from competing cations like Pb can potentially contribute to nervous system barrier function disruption, tissue development dysregulation, immune dysfunction, and affect learning and memory (Prozialeck et al., 2002).

5.3.8.7 Glial Effects

Astroglia and oligodendroglia are supporting cells in the nervous system that maintain the extracellular space in the brain and provide support and nutrition to neurons via nutrient transport, structural support to neurons, and myelination. Glial cells provide immune surveillance in the brain or contribute to inflammation-mediated pathologies. In the central nervous system, Pb treatment of Wistar rats 15 mg/kg of Pb-acetate, i.p.) during early postnatal maturation was observed to produce chronic glial activation with coexisting features of inflammation and neurodegeneration (Struzynska et al., 2007).

Among the cytokines detected in the brains of these Pb-treated rats were IL-1β, TNF-α and IL-6. Glial cells have been shown to serve as Pb sinks in the developing and mature brain (Tiffany-Castiglioni et al., 1989) by sequestering Pb. This glial sequestration of Pb has been shown to decrease brain glutamine concentrations at doses of 0.25 ± 1.0 µM Pb-acetate via Pb-related reduction in glutamine synthetase activity in the astroglia; astroglia take up glutamate after its release and convert it to glutamine. Pb has been shown to induce hypomyelination and demyelination (Coria et al., 1984) mediated through the oligodendrocytes with younger animals being more susceptible to the effects of Pb (Tiffany-Castiglioni et al., 1989). Pb accumulation in young glial cells may contribute to a lifelong exposure of neurons to Pb as Pb is released from the sink over time. Thus, Pb accumulation in glial cells can contribute to continual damage of surrounding neurons (Holtzman et al., 1987).

Glial transmitters

To determine the contribution of the gliotransmitter serine to Pb-mediated changes in long-term potentiation (LTP), Sun et al. (2007) exposed pups to Pb-acetate in utero, lactationally, through PND28 via drinking water and collected hippocampal sections. CA1 section LTPs were examined using in vitro patch clamp monitoring. Chronic Pb exposure impaired the magnitude of hippocampal LTPs, but the magnitude of LTDs was restored with supplementation with D-serine (Sun et al., 2007), which is known to be regulated by the NMDAR (Bear and Malenka, 1994). The use of 7-chlorokynurenic acid, an antagonist of the glycine binding site of the NMDAR, which also is the binding site of D-serine, effectively abolished the rescue to LTP by D-serine. NMDAR-independent LTP hippocampal neurotransmission, which was examined in slices of Pb-exposed mossy-CA3 synapses, was not rescued by exogenous D-serine supplementation. These data indicate that glial transmission is affected with Pb exposure and that the NMDAR may also be involved in this aberrant glial transmission.

5.3.8.8 Neurotransmitters

Pb has been shown to compete with calcium for common binding sites and second messenger activation. When Pb activates a calcium-dependent system in the nervous system, it can contribute to aberrant neurotransmitter regulation and release because this system intimately relies on calcium signaling for its homeostasis. Pb also has been shown to interfere with other physiological divalent cations. Pb-related alterations in neurotransmission are discussed in further detail below.

Monoamine Neurotransmitters and Stress

Combined exposures of maternal stress and Pb exposure can synergistically enhance behavioral and neurotoxic outcomes in offspring of exposed animals and can sometimes potentiate an effect that would otherwise be sub-threshold. Virgolini et al. (2008a) found that CNS effects of developmental Pb exposure (50 or 150 ppm via drinking water, 2 months prior to mating through lactation, resulting in blood Pb levels of 11 µg/dL and 35 µg/dL, respectively) were enhanced with combined maternal and offspring stress. Offspring neurotransmitter concentrations were significantly affected with Pb exposure, but the most interesting findings were those of potentiated effects, i.e., effects that were not observed with Pb exposure alone or stress alone. These potentiated effects were only observed when Pb was combined with stress (maternal [MS] and/or offspring stress [OS]). Potentiation of serotonin (5HT) levels in females was significant in the frontal cortex in females and in the nucleus accumbens (NAC) in the male offspring (50 and 150 ppm Pb drinking water exposure) (Cory-Slechta et al., 2009). Regional 5HT levels were unaffected in offspring with Pb exposure alone. The concentration of 5-Hydroxyindoleacetic acid (5HIAA), the main metabolite of 5HT, was significantly increased with Pb exposure alone in the striatum of male offspring with 150 ppb Pb exposure alone; with the remaining Pb-stress exposure combinations, Pb plus stress potentiated striatal and frontal cortex 5HIAA in males. Potentiated 5HIAA levels in females were significant in the NAC at both Pb doses; stress alone also significantly increased 5HIAA levels in females with no Pb exposure. Pb-induced changes in brain neurochemistry with or without concomitant stress exposure are complex with differences varying by brain region, neurotransmitter type and sex of the animal.

Monoamine Neurotransmitters and Auditory Function

The monoamine neurotransmitters include DA, 5HT, and norepinephrine (NE). Earlier work has shown that perinatal Pb exposure of rats induced increased tyrosine hydroxylase, increased DA and increased cerebral cortex catecholamine neurotransmission (Devi et al., 2005; Leret et al., 2002; Bielarczyk et al., 1996). Earlier publications detailing important time windows of exposure, duration of exposure, and dose of Pb indicated varying effects on monoamine transmitters. In more recent work, these neurotransmitters, among others, have been implicated in Pb effects on auditory function in the brainstem in various integration centers there including the lateral superior olive (LSO), and the superior olivary complex (SOC). Among various functions, the SOC is vital for sound detection in noisy settings. Low-level Pb exposure has been associated with altered processing of auditory temporal signals in animal studies (Lurie et al., 2006; Finkelstein et al., 1998). Blood Pb levels for control, very low Pb (VLPb) and low Pb (LPb) exposure groups were 1.4, 8.0, and 42.2 µg/dL, respectively. Developmental Pb

exposure from the formation of breeding pairs to PND21, which is at the end of auditory development in the mouse, led to significant decreases in immunostaining of LSO and SOC brainstem sections for monoamine vesicular transporter VMAT2, and for 5HT and dopamine beta-hydroxylase (DbH), a marker for NE. Statistically significant alterations in VMAT2 and DbH were found with both VLPb and LPb exposure; however, decrements in 5HT were statistically significant only with VLPb. Immunostaining for TH and transporters including VGLUT1, VGAT, VAChAT indicated that they were unaffected by developmental Pb exposure. These data provide evidence that specific regions of the brainstem involved in auditory integration are affected by developmental Pb exposure via effects on the monoamine neurotransmitter system (Fortune and Lurie, 2009). The Pb-induced effects on the auditory portion of the brainstem at the level of the monoamine system provide possible mechanistic understanding of the animal data showing Pb-induced impaired auditory processing.

Dopamine

The 2006 Pb AQCD detailed evidence for low-dose Pb-related decreased dopaminergic cell activity in the substantia nigra and ventral segmental areas. Earlier studies with moderate- to high-dose postnatal or adult Pb exposure have reported changes in DA metabolism, as indicated by changes in DA and DOPAC, a DA metabolite. Given these findings, a recent study measured DA and DOPAC in various brain regions of year-old male rodents to examine if GLE affected DA metabolism. Low- and high-dose GLE in male rodents induced significant elevations in DOPAC concentration and the DOPAC to DA ratio in the forebrain. In the forebrain, DA was significantly decreased in low-dose GLE males and significantly elevated in high-dose GLE males compared to controls. In the striatum, DOPAC was significantly elevated with both low- and high-dose GLE males, but DA concentration was only significantly elevated in high-dose GLE males. The striatum ratio of DOPAC to DA was not significantly different from that in controls. These new data expand upon the monoamine literature base in which indicates low concentration perinatal Pb exposure of rats was found to induce increased sensitivity of the dopamine receptors (D2 and D3) (Gedeon et al., 2001; Cory-Slechta et al., 1992), produce higher DA levels (Devi et al., 2005; Leret et al., 2002), and enhance catecholamine neurotransmission in the cerebral cortex, cerebellum, and hippocampus (Devi et al., 2005).

The interaction of DA and the nitric oxide system in the striatum was studied after prenatal Pb exposure (Nowak et al., 2008). Blood Pb levels were not reported in this study, but similarly treated Wistar rat pups had blood Pb levels at parturition in range of 50-100 µg/dL (Grant et al., 1980). 7-nitroinidazole (7-NI), a selective inhibitor of nNOS, enhanced amphetamine-evoked DA release in the rat striatum (Nowak et al., 2008).

Prenatal Pb exposure attenuated the facilitatory effect of 7-NI on DA release in the striatum. This interaction is ROS-independent; using spin trap measurements, there were no significant concentration changes in hydroxyl radical with Pb exposure (Nowak et al., 2008). Thus, the neuronal NO system appears to be involved in specific aspects of Pb-related dopaminergic changes.

Dopamine and Vision

In various experimental animal models, the loss of retinal DA or zinc is associated with abnormal rod-mediated scotopic ERGs. These effects may explain observations of Pb-associated retinal effects (Rothenberg et al., 2002a; Lilienthal et al., 1994; Lilienthal et al., 1988; Alexander and Fishman, 1984). In the human and animal toxicological literature, prenatal maternal blood Pb level (humans), gestational + early postnatal Pb exposure (rodents, low and moderate dose Pb only), or gestational continuing to lifetime (non-human primate) Pb exposure has been associated with increased amplitude (supernormality) of ERGs (Rothenberg et al., 2002a; Lilienthal et al., 1994; Lilienthal et al., 1988). In the animal toxicological literature, subnormality of the ERGs has been observed with postnatal Pb exposure (Fox et al., 2008; Otto and Fox, 1993; Fox et al., 1991; Fox and Farber, 1988) and high-dose developmental (prenatal + early postnatal, rodent) Pb exposure (Fox et al., 2008). Producing results consistent with observations in humans (Rothenberg et al., 2002a), Fox et al. (2008) showed that low- (LPb) and moderate-level (MPb) gestational+early postnatal Pb exposure in the rat, a period equivalent to the human gestational retinal development period, produced supernormal retinal ERGs. In children, supernormal ERGs were associated with prenatal Pb maternal blood Pb levels >10.5 µg/dL (Rothenberg et al., 2002a). The animal data provide mechanistic information that may begin to explain these supernormal ERGs that are seen in children and rodents, i.e., significant increases in retinal neurogenesis and significant decreases in retinal DA use and dopamine turnover (DOPAC:DA ratio). High-dose developmental (rodent, gestational+early postnatal to PND10) Pb exposure (HPb) produced significant subnormal retinal ERGs. Subnormal ERGs also were found in occupationally-exposed adults (Otto and Fox, 1993; Guguchkova, 1972). Female rats were exposed to Pb-acetate in drinking water from 2 weeks prior to mating throughout gestation and lactation until PND 10, a period of developmental exposure that is equivalent to gestational exposure in humans. Peak blood Pb levels in the offspring at PND1-10 were 12, 24, and 46 µg/dL in the LPb, MPb, and HPb groups, respectively. LPb and MPb gestational exposure induced increased cellularity or retinal thickness in the outer nuclear layer, inner nuclear layer and total retina (Leasure et al., 2008). In summary, the retina is affected by low-dose Pb exposure and gestational Pb exposure, as indicated by concentration-dependent decreases in DA use and turnover. Inverted U-

shaped Pb concentration-response relationship were reported for retinal endpoints including ERG and retinal thickness.

NMDA

NMDA receptors (NMDAR) have been shown to contribute to synaptic plasticity, and Pb exposure at different developmental stages has been shown to contribute to aberrations in LTP or long term depression (LTD) in the hippocampus via reduced NMDA current, among other mechanisms (Liu et al., 2004). The 2006 Pb AQCD indicated that Pb induced decreases in stimulated glutamate release that affected LTP. Further, the relationships between Pb exposure and decreased magnitude and increased threshold of the LTP in the hippocampus were found to be biphasic or nonlinear. NMDAR subtypes have been shown to be significantly decreased with developmental Pb exposure (Guilarte and McGlothan, 1998). Recent work examining dietary supplement use, found that Pb-related decreases in the gene expression and protein level of NMDAR subunit NR1 in weanling male rats were rescued with methioninecholine co-exposure (Fan et al., 2010). Fan et al. (2010) found that Pb-related suppression of the NMDAR subunits NR2A and NR2B was not rescued with methioninecholine treatment. Other recent mechanistic studies found that pretreatment of primary fetal brain neuronal rat cultures with glutamic acid, a NMDAR agonist, reversed Pb-induced reductions in NMDAR subunits (Xu and Rajanna, 2006) whereas pretreatment with the NMDA antagonist MK-801 exacerbated Pb-induced NMDAR deficits (Xu and Rajanna, 2006).

Studies continue to show that Pb exposure affects neurogenesis or proliferation of new cells in the hippocampus. Earlier work by Schneider et al. (2005) showed that postnatal Pb exposure (30-35 days starting at PND25, 1,500 ppm Pb-acetate in chow, resulting in blood Pb level of 20 µg/dL) of male Lewis rats induced significant decrements in BrdU incorporation (proliferation) at PND50-55. Recent publications affirm this original finding with different sex of animals, dosing and exposure time windows. Postnatal Pb exposure to Wistar rat pups (0.2% Pb-acetate from PND1-30, resulting in blood Pb levels of 34 and 6.5 µg/dL at PND21 and PND80, respectively) induced a statistically significant decrement in the number of new cells (BrdU positive cells) in the dentate gyrus at PND80 (Fox et al., 2010) (Figure 5-18). In another study, developmental/lifetime Pb exposure (1,500 ppm Pb-acetate in chow from 10 days before mating to termination of experiment at PND50, resulting in blood Pb levels of 0.8 µg/dL in controls and 26 µg/dL in Pb-exposed animals) to female Long-Evans rats induced significant decrements in hippocampal granule cell neurogenesis or proliferation of new cells in adult rats (Verina et al., 2007), outcomes that affect LTP, spatial learning, neuronal outgrowth, and possibly mood disorders such as schizophrenia. NMDAR mediates the integration of new neurons into existing neuronal pathways in the adult hippocampal DG, which is important to

learning and memory. Lifetime Pb exposure (dam Pb-acetate chow exposure 10 days prior to mating through pregnancy to PND50 or PND78) induced significant decrements in hippocampal granule cell neurogenesis or proliferation of new cells in adult rats. Also, Pb-exposed animals had significant decreases in brain volume in the stratum oriens (SO) region of the hippocampus, specifically significant decreases in the mossy fiber terminals of the SO. Pb-exposed animals also showed a significant decrease in the length-density of immature or newly-formed neuron in the outer portion of the DG. These findings show that exposure to environmentally-relevant doses of Pb induced significant aberrations in adult hippocampus granule cell neurogenesis and morphology, providing mechanistic explanations for Pb-induced neuronal aberrations. Guilarte et al. (2003) demonstrated that Pb exposure of rats from an enriched environment was associated with reduced learning impairment, increased expression of hippocampal NMDA receptor subunit 1, and increased induction of brain derived neurotrophic factor mRNA (Guilarte et al., 2003).

Glutamate Receptor

Glutamate receptors including the ionotropic NMDAR and the metabotropic glutamate receptors (mGluR) are known targets of Pb toxicity with recent findings showing a role for mGluR5 in learning and memory. In vitro (GD18 fetal rat cultures, 100 µM, 1 µM, 0.01 µM $PbCl_2$ in culture media) and in vivo studies (gestational and lactational Pb-acetate exposure; control, 0.05, 0.2, or 0.5% in dam drinking water, with respective weanling blood Pb levels of 3, 18, 57, 186 µg/dL) showed that Pb exposure induced mGluR5 mRNA and protein decrements in a concentration-dependent manner (Xu et al., 2009c).. The Pb-related attenuation of mGlu5 expression may contribute to the effect of Pb on LTP and LTD.

5.3.8.9 Neurite Outgrowth

The 2006 Pb AQCD reported that Pb decreased neurite outgrowth at 20µg/dL and noted that Pb interfered with neurite outgrowth via protein kinase mediated pathways (MAPK/ERK); earlier work had documented decreased primary DA neuron outgrowth with 0.001 µM Pb exposure (Lidsky and Schneider, 2004). Recent studies have shown that exposure of dams to low-dose Pb (resulting in blood Pb level of 4 µg/dL) significantly decreased pup hippocampal neurite outgrowth (pup blood Pb level: 12 µg/dL) and reduced the expression of hippocampal polysialylated neural cell adhesion molecule (PSA-NCAM), NCAM, and sialytransferase (Hu et al., 2008b). PSA-NCAM is transiently expressed in newly formed neurons during the period of neurite outgrowth from embryrogenesis until the early postnatal period and is down-regulated in the adults

except in areas known to exhibit synaptic plasticity (Seki and Arai, 1993). NCAM is important for memory formation, plasticity and synapse formation, and early-life Pb exposure was found to affects its expression in laboratory rats.

5.3.8.10 Epigenetics

Many investigators are beginning to show that environmental chemical exposures are associated with epigenetic changes. Air pollution exposure is being linked increasingly with epigenetic changes (Baccarelli and Bollati, 2009; Pavanello et al., 2009; Tarantini et al., 2009; Bollati et al., 2007). Epigenetic changes involve changes in DNA expression without changes in the DNA sequence, and these changes may be heritable. Epigenetic changes are mediated by histone modification, DNA methylation, miRNA changes, or pathways that affect these processes. Differential epigenetic modification has the potential to contribute to disease by silencing or activating genes in an aberrant manner. Monozygotic twins are often used to study epigenetic changes, and a recent study identified differential methylation of a specific locus in twins discordant for schizophrenia (Dempster et al., 2011); Pb was not examined in this study.

DNA methyltransferases catalyze the transfer of a methyl group to DNA and are important in epigenetics (i.e., silencing of genes like tumor suppressors) and imprinting. DNA methyltransferase activity was significantly decreased in cortical neurons from Pb-exposed monkeys (aged animals, blood Pb) and mouse brains (fetal cells exposed to Pb in culture, 0.1 µM Pb) (Wu et al., 2008b). Changes in DNA methyltransferases (Dnmt1, Dnmt3a) were noted in control primate brains as they aged and these changes were further exacerbated by Pb exposure (Bihaqi et al., 2011). Another enzyme involved in DNA methylation, methyl CpG binding protein 2 MECP2, showed a similar trend as the Dnmts. Profiles of the histone modifying gene H34mc2 increases with age in control animals. This age-related increase is significantly attenuated in Pb-exposed animals. The cerebral cortex tissue used in this experiment was obtained from female primates who had received 1.5 mg/kg • day Pb-acetate via diet from birth until 400 days of age (resulting in blood Pb levels 19-26 µg/dL at age 400 days) (Rice, 1990). Methyltransferases catalyze biological methylation reactions and are dependent on the cofactor S-adenosyl methionine (SAM) for this transfer to acceptor molecules. SAM exposure after gestational and lactational Pb exposure (dam Pb-acetate exposure to 1,500 ppm Pb-acetate followed by 20-22 days of daily 20 mg/kg BW SAM exposure) improved hippocampal LTP and Morris water maze performance at PND 44-54. Thus, the impaired cognition and synaptic plasticity induced by developmental Pb exposure were attenuated with SAM treatment (Cao et al., 2008).

5.3.8.11 Cholesterol and Lipid Homeostasis

Various pathological conditions are associated with elevated plasma free fatty acids or elevated cholesterol. Adult male rats exposed to Pb-acetate (200, 300, or 400 ppm) in their drinking water for 12 weeks had increased cholesterogenesis and phospholipidosis in brain tissue (Ademuyiwa et al., 2009). Pb-induced changes in brain cholesterol showed an inverse U concentration-response relationship, with the largest increase in brain cholesterol observed with 200 ppm Pb followed by 300 ppm Pb. Animals exposed to 400 ppm Pb did not have significant changes in brain cholesterol. Mechanistically, Pb exposure has been shown to depress the activity of cholesterol-7-a-hydroxylase, an enzyme involved in bile acid biosynthesis (Kojima et al., 2005); bile acids are the route by which cholesterol is eliminated from the body. Pb exposure produced significant increases in brain triglycerides with an 83% increase at 300 ppm and a 108% increase at 400 ppm. At 200 ppm, Pb exposure induced a statistically nonsignificant decrease in brain triglycerides. Pb exposure across all three dose groups induced significantly increased brain phospholipids. Interestingly, plasma free fatty acids were significantly elevated in a concentration-dependent manner; plasma triglycerides and cholesterol were unaffected by Pb exposure. The molar ratio of brain cholesterol to phospholipids, an indicator of membrane fluidity (Abe et al., 2007), was significantly increased at 200 and 300 ppm Pb exposure indicating increased membrane fluidity. Brain Pb in all dose groups was below the limit of detection (0.1 ppm). Blood Pb levels at 0, 200, 300, and 400 ppm were 7, 41, 61, and 39 µg/dL, respectively. In summary, based on limited examination, Pb exposure significantly increased brain cholesterol, triglycerides, and phospholipids as well as significantly increased plasma free fatty acids. These effects were sometimes more prominent at lower doses of Pb. Future characterization of molecular and cellular pathways affected by Pb exposure may bring insight to these Pb-related changes in phospholipidosis and cholesterogenesis.

5.3.9 Lifestage of Lead Exposure and Neurodevelopmental Deficits

Environmental exposures during critical lifestages can affect key physiological systems that orchestrate plasticity (Feinberg, 2007). Exposure to environmental toxins during prenatal and/or early postnatal development may alter the normal course of morphogenesis and maturation that occurs in utero and early in life, resulting in changes that affect structure or function of the central nervous system via altered neuronal growth and/or synaptogenesis/pruning structure (Rice and Barone, 2000; Landrigan et al., 1999). Synaptic pruning, which is active throughout early childhood (ages 1-4 years), may underlie the elevated risk of young children to environmental exposures. MRI studies have provided understanding of brain development in normally developing children and

adults, ages 3-30 years (Giedd et al., 2009; Lenroot and Giedd, 2006). Total cerebral volume was found to peak at age 10.5 and 14.5 years in females and males, respectively. The volume of the cerebellum was found to peak 2 years after the cerebral volume peaks. Lateral ventricular volume showed the most inter-individual variation and was found to increase throughout childhood and adolescence. White matter volume generally increased throughout childhood and adolescence. Gray matter volume and associated structures show inverted U-shaped developmental trajectories with peak volumes found in late childhood or early adolescence. Females generally had gray matter volume peaks 1 to 3 years earlier than did males. Thus, the anatomical development of the brain during childhood and adolescence is found to be a dynamic process with variation by age, brain region, and sex. Observations that brain development is active throughout childhood and in adolescence indicates that Pb exposure may affect neurodevelopment throughout this period.

The elevated risk of Pb-associated neurodevelopmental deficits in children is well supported by findings in animals that prenatal and postweaning Pb exposure alters brain development via changes in synaptic architecture (Section 5.3.8.4) and neuronal outgrowth (Section 5.3.8.9) and leads to impairments in memory and learning (Section 5.3.2.2) and emotional and depressive changes postnatally (Section 5.3.3.5). Unlike other organ systems, the unidirectional nature of CNS development limits the capability of the developing brain to compensate for cell loss, and environmentally-induced cell death can result in a permanent reduction in cell numbers (Bayer, 1989). Hence, when normal development is altered, the early effects may persist into adult life even in the absence of current exposure, magnifying the public health impact. Supporting evidence is provided by a few available new toxicological studies that find that Pb exposure during neonatal development but not in adulthood leads to neurodegenerative amyloid plaque formation in the brains of aged rodents and monkeys (Section 5.3.7.2).

With repeated assessments of children prenatally to later childhood and early adulthood, the prospective cohort studies have aimed to distinguish among neurodevelopmental effects associated with blood Pb levels measured at different periods of development. In the collective body of evidence, cognitive function decrements in children have been associated with prenatal, early childhood, childhood average, and concurrent blood Pb levels, without clear indication that the risk of neurodevelopmental decrements is greatest for blood Pb levels measured at a particular lifestage. In these studies, the identification of developmental periods when children are at increased risk of Pb-associated neurodevelopmental decrements has been complicated by the high degree of correlation in the blood Pb levels of children over time and the confounding of age and peak blood Pb levels (Lanphear et al., 2005; Dietrich et al., 1993b; Needleman et al., 1990).

As described in detail in the 2006 Pb AQCD, several studies with varying lengths of follow-up demonstrated associations of prenatal blood Pb levels (maternal and umbilical cord) with neurodevelopmental deficits throughout childhood and into early adulthood (U.S. EPA, 2006b). Pb exposure during the prenatal lifestage may be associated with increased risk of neurodevelopmental effects not only because of the nervous system developmental processes that are active as described above but also because of factors that result in elevated Pb exposures. Substantial fetal Pb exposure may occur from mobilization of maternal skeletal Pb stores that may be related to past Pb exposures (Gulson et al., 2003; Hu and Hernandez-Avila, 2002). Pb can cross the placenta to affect the developing fetal nervous system (Rabinowitz, 1988). Maternal and cord blood Pb levels generally have been shown to be highly correlated, indicating that blood Pb levels in a newborn infant reflects that of the mother (Schell et al., 2003).

Prenatal blood Pb levels (maternal and cord) were consistently associated with cognitive function decrements and behavioral problems assessed between infancy and age 3 years (Table 5-4 and Table 5-13). Among studies that had blood Pb measurements at both lifestages, some found stronger associations for prenatal blood Pb levels (Hu et al., 2006; Bellinger et al., 1984), and other found stronger associations for concurrent blood Pb levels (Wasserman et al., 1998; Wasserman et al., 1992). Studies that found associations with concurrent blood Pb levels also tended to find associations with prenatal cord or maternal blood Pb levels. Thus, both postnatal child and maternal Pb exposures may contribute to lower cognitive function in young children. Several studies found that prenatal or neonatal blood Pb levels were associated with neurodevelopmental decrements assessed neonatally (within 30 days) or early in infancy (within 3 months), which indicated that relatively short durations of Pb exposure were associated with neurodevelopmental decrements (Shen et al., 1998; Rothenberg et al., 1989; Dietrich et al., 1987a; Ernhart et al., 1986). In the studies of neurodevelopmental effects in infancy, prenatal blood Pb level may be serving as a surrogate of postnatal blood Pb levels as both are expected to be highly correlated.

Table 5-13 Associations of cognitive function and behavioral outcomes with blood Pb levels measured at different lifestages[a]

Study	Population/Location	Blood Pb Levels (µg/dL)	Statistical Analysis	Outcome	Effect Estimate (95% CI)[b]
Assessments in children up to age 3 years					
Rothenberg et al. (1989)	42 children followed prenatally to child age 30 days Mexico City, Mexico	Maternal week 36 gestation mean (SD): 15.0 (6.4) Maternal at birth mean (SD): 15.5 (5.7)	Regression model adjusted for smoking, single mother, problems in pregnancy, alcohol use in previous month, use of spinal block, gravidity, income	Self-quieting ability (regulation of state) at age 30 days Assessed using Newborn Brazelton Assessment System	Prenatal: -0.091 (-0.18, 0)
Dietrich et al. (1986)	305 children followed prenatally to age 6 mo. in Cincinnati, OH	Prenatal (maternal) mean (SD): 8.0 (3.8) Concurrent mean (SD): 5.9 (3.4)	Log linear regression model adjusted for birth weight, gestation, sex	Bayley MDI assessed at age 6 mo	**Prenatal: -0.6 (-1.1, -0.09)** Concurrent: -0.23 (-0.58, 0.12)
Bellinger et al. (1987)	249 children followed from birth (1979-1981) to age 36 mo Boston area, MA	Prenatal (cord blood) mean (SD): 6.6 (3.2)	Regression and longitudinal analyses adjusted for the mother's age, race, IQ, education, number of years of cigarette smoking, number of alcoholic drinks per week in the third trimester, mean family social class over the period of the study, quality of the care-giving environment, infant's sex, birth weight, gestational age, birth order	Bayley MDI assessed at age 6, 12, 18, 24 mo	**Prenatal: -4.8 (-7.3, -2.3)**, blood Pb levels ≥ 15 µg/dL vs. blood Pb levels <3[c]
Hu et al. (2006)	146 children born 1997-1999 followed prenatally to age 24 mo Mexico City, Mexico	Prenatal (maternal 1st trimester) mean (range): 7.1 (1.5-43.6) Early childhood (12 mo) mean (SD): 5.2 (3.4) Concurrent mean (SD): 4.8 (3.7)	Log linear regression model adjusted for concurrent blood Pb, sex, maternal age, current weight, height-for-age Z score, maternal IQ	Bayley MDI assessed at age 24 mo	**Prenatal 1st trimester: -4.1 (-8.1, -0.17)** Prenatal (avg): -3.5 (-7.7, 0.63) 12 month: -2.4 (-6.2, 1.49) Concurrent: -1.0 (-3.9, 1.9)
Gomaa et al. (2002)	197 children followed prenatally to age 24 mo Mexico City, Mexico	Prenatal (cord blood) mean (SD): 6.7 (3.4)	Log linear regression model adjusted for maternal IQ, maternal age, sex, parental education, marital status, breastfeeding duration, child hospitalization status	Bayley MDI assessed at age 24 mo	**Prenatal: -2.1 (-3.9, -0.39)**
Wasserman et al. (1992)	392 children followed prenatally to age 24 mo Kosovo, Yugoslavia (K. Mitrovica, Pristina)	Prenatal (cord blood) mean (SD): 14.4 (10.4) Concurrent means: K. Mitrovica: 35.4, Pristina: 8.5	Log linear regression model adjusted for sex, birth order, birth weight, ethnic group, HOME score, years of maternal education, maternal age, maternal intelligence	Bayley MDI assessed at age 24 mo	**Concurrent: -4.1 (-6.2, -2.0)** Prenatal: -3.2 (-7.2, 0.86)
Jedrychowski et al. (2009b)	444 children born 2001-2004 followed prenatally to age 36 mo Krakow, Poland	Prenatal (cord blood) geometric mean (range): 1.29 (0.44-5)	Linear regression model adjusted for maternal education, birth order, prenatal ETS, sex	Bayley MDI assessed at age 36 mo	**Prenatal: -2.9 (-5.0, -0.75)**
Cognitive function assessments at school age					
Wasserman et al. (1994)	332 children followed prenatally to age 3-4 yr Kosovo, Yugoslavia (K. Mitrovica, Pristina)	Prenatal (cord blood) mean (SD): 14.4 (10.4) Concurrent means: K. Mitrovica: 39.9 Pristina: 9.6	Log linear regression model adjusted for HOME score, maternal age, maternal intelligence, maternal education, language, birth weight, sex	McCarthy GCI assessed at age 3-4 yr	**Concurrent: -4.1 (-6.2, -2.0)** **Prenatal: -3.2 (-5.1, -1.2)**

Study	Population/Location	Blood Pb Levels (µg/dL)	Statistical Analysis	Outcome	Effect Estimate (95% CI)[b]
Dietrich et al. (1992)	259 followed from birth (1979-1984) to age 5 yr Cincinnati, OH	Prenatal (cord blood) mean (SD): 8.2 (3.8) Neonatal (10 days) mean (SD): 4.8 (3.3) Concurrent mean (SD): 11.9 (6.4)	Linear regression model adjusted for fetal distress and growth, perinatal complications, postnatal indices of health and nutritional status, sociodemographic characteristics, HOME score	Total FWS assessed using KABC at age 5 yr	**Neonatal: -0.38, p ≤ 0.01**[d] **Prenatal: -0.25, p ≤ 0.01**[d] **Concurrent: -0.19, p ≤ 0.01**[d] **Lifetime avg: -0.16, p ≤ 0.01**[d]
Bellinger et al. (1991)	170 children followed from birth (1979-1981) to age 57 mo Boston area, MA	Early childhood (24 mo) mean (SD): 6.8 (6.3) Early childhood tooth mean (SD): 2.8 (1.7) µg/g Concurrent mean (SD): 6.4 (4.1)	Log linear regression model adjusted for family social class, maternal IQ, marital status, preschool attendance, HOME score, out of home care, number of residence changes, recent medication use, number of adults in household, sex, race, birth weight, birth order	McCarthy GCI assessed at age 57 mo	**Early childhood blood: -3.0 (-5.7, -0.2)** Early childhood tooth: -2.5 (-10.2, 5.2) Concurrent blood: -2.3 (-6.0, 1.4)
Dietrich et al. (1993b)	245 children followed from birth (1979-1984) to age 6 yr Cincinnati, OH	Prenatal (cord blood) mean (SD): 8.4 (3.8) Neonatal (10 days) mean (SD): 4.8 (3.1) Concurrent mean (SD): 10.1 (5.6)	Linear regression model adjusted for obstetric complications, perinatal status, sex, social class, maternal intelligence, quality of rearing environment, earlier measures of neurobehavioral status	Bruininks-Oseretsky Test of Motor Proficiency assessed at age 6 yr	**Concurrent: -0.18 (-0.26, -0.10)** Neonatal: -0.15 (-0.33, 0.03) **Lifetime avg: -0.11 (-0.19, -0.03)** Prenatal: -0.04 (-0.20, 0.12)
Dietrich et al. (1993b)	253 children followed from birth (1979-1985) to age 6.5 yr Cincinnati, OH	Prenatal (cord blood) mean (SD): 8.3 (3.7) Neonatal (10 days) mean (SD): 5.0 (3.4) Concurrent mean (SD): 11.8 (6.3)	Linear regression model adjusted for fetal distress and growth, perinatal complications, prenatal maternal substance abuse, postnatal indices of health and nutritional status, sociodemographic characteristics, maternal IQ, HOME score	FSIQ assessed using WISC-R at age 6.5 yr	**Concurrent: -0.33 (-0.60, -0.06)** Lifetime avg: -0.13 (-0.35, 0.09) Neonatal: -0.03 (-0.42, 0.36) Prenatal: 0.15 (-0.26, 0.56)
Baghurst et al. (1992)	494 children followed from birth (1979-1982) to age 11-13 yr Port Pirie, Australia	Prenatal mean of second quartile: 7.4 Early childhood (2 yr) mean of second quartile: 16.6 Lifetime avg mean of second quartile: 15.7	Log linear regression model adjusted for sex, birth weight, birth order, feeding method, breastfeeding duration, parental education, maternal age, parental smoking, SES, quality of home environment, maternal IQ, parents living together	FSIQ assessed using WISC-R at age 7-8 yr	**Early childhood: -2.0 (-3.8, -0.21)** Lifetime avg: -1.6 (-3.7, 0.52) Prenatal: 0.26 (-0.67, 1.5)

[a]Studies are organized by age of neurodevelopmental assessment. Effect estimates are presented in order of increasing magnitude, with statistically significant results in bold.

[b]Effect estimates are standardized to a 1 µg/dL increase in blood Pb level in analyses of blood Pb as a continuous variable.

[c]Effect estimate represent comparisons between children in different categories of blood Pb level, with children in the lower blood Pb category serving as the reference group.

[d]Sufficient data were not provided in order to calculate 95% CI.

Prenatal and neonatal (10 days after birth) blood Pb levels also were associated with cognitive function and behavioral outcomes in children examined at school-age (ages 4-17 years) (Table 5-13). Concurrent blood Pb levels generally were estimated to have similar or larger magnitudes of effect (Wasserman et al., 1998; Wasserman et al., 1994;

Dietrich et al., 1993a; Dietrich et al., 1993b; Bellinger et al., 1992; Dietrich et al., 1992). Studies conducted in the Cincinnati cohort examined diverse neurodevelopmental effects and found that prenatal and neonatal blood Pb levels were associated with impairments in behavior and auditory processing (Ris et al., 2004; Dietrich et al., 2001; Dietrich et al., 1992) but not cognitive function or motor function in children at age 6 years or in adolescence (Bhattacharya et al., 2006; Bhattacharya et al., 1995; Dietrich et al., 1993a; Dietrich et al., 1993b). These findings suggest that the effects of prenatal Pb exposure may vary among different populations and specific endpoints.

Early childhood blood Pb levels were associated with diverse neurodevelopmental effects assessed later in childhood and into early adulthood in both recent (Chandramouli et al., 2009; Min et al., 2009; Miranda et al., 2009) and previous studies that did not compare various lifestages of Pb exposure (Yuan et al., 2006; Cecil et al., 2005; Tong et al., 2000). In a meta-analysis of results from five cohort studies (Pocock et al., 1994), a larger decrease in FSIQ was estimated for an increase in peak (around age 2 years) blood Pb level than for blood Pb level measured around birth or after age 2 years (Table 5-13). This lag effect may be the result of a toxicological process in which some period of time is required for past Pb exposure to affect CNS function. Alternatively, associations with early childhood or peak blood Pb levels may reflect the greater reliability of neurodevelopmental assessments at later ages when the processes modalities of children are more highly differentiated. Early testing may lead to false negative results and fail to identify a child who is at risk for later neurodevelopmental dysfunction. Further, due to the correlation of blood Pb levels over time, it is difficult to assess whether early childhood or peak blood Pb levels were serving as surrogates of concurrent or cumulative blood Pb levels.

As presented in Table 5-13, several studies of school-aged children estimated larger blood Pb-associated decreases in neurodevelopmental function for concurrent or lifetime average (range: 5 to 13 years) blood Pb levels than for blood Pb levels at other lifestages. These findings were substantiated in the analysis pooling data from seven prospective studies, in which concurrent, peak, average lifetime (5- to 10-year average), and age 2 year blood Pb levels all were negatively associated with IQ measured between ages 5 and 10 years, with the larger magnitude of decrease associated with increases in concurrent and peak blood Pb levels (Lanphear et al., 2005). Childhood average blood Pb levels (Lanphear et al., 2005; Dietrich et al., 1993a; Dietrich et al., 1993b) and deciduous tooth Pb levels (Bellinger et al., 1994a) have been associated with neurodevelopmental effects. While the ages of children varied among these studies as did the years over which blood Pb levels were averaged, the results nonetheless indicate cumulative Pb exposure over multiple years may contribute to neurodevelopmental effects in children. Associations with concurrent blood Pb level also were demonstrated consistently in

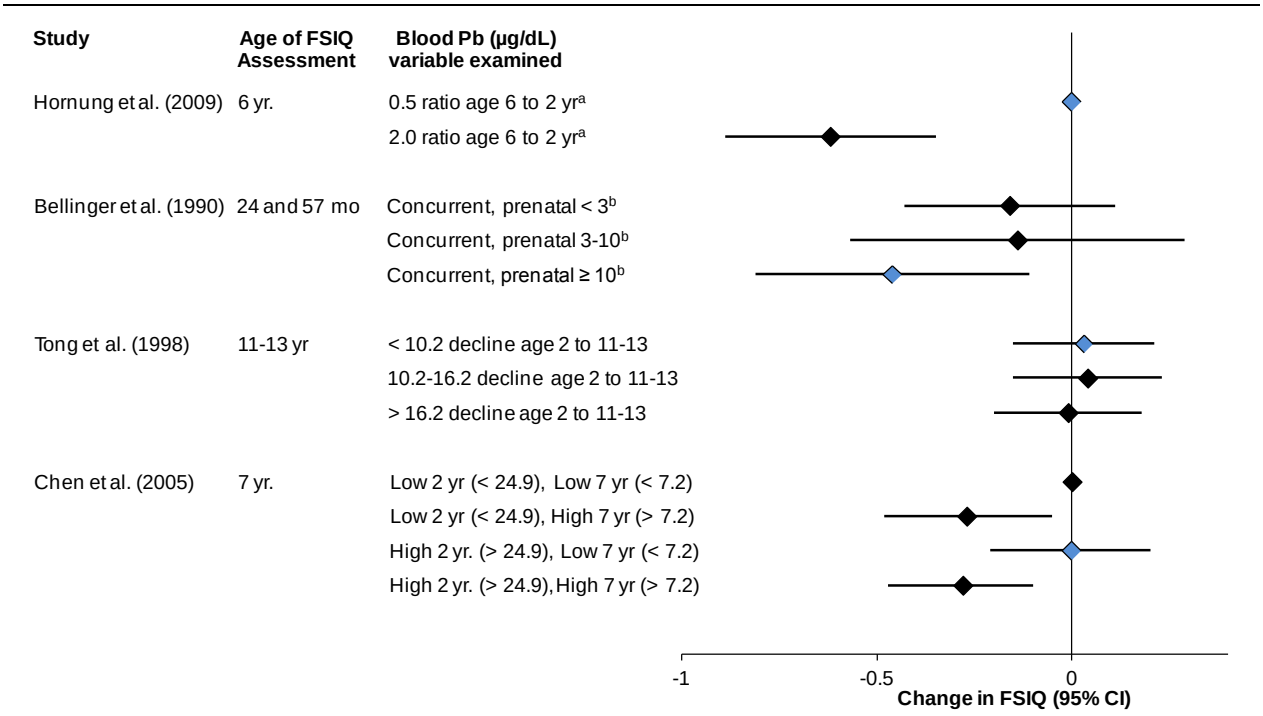
studies without comparisons to blood Pb levels during other lifestages (Figures and Tables in Sections 5.3.2.1 and 5.3.3.1).

Some studies have aimed to improve the characterization of important lifestages of Pb exposure by examining children in whom blood Pb levels are weakly correlated over time (i.e., children whose blood Pb level ranking changed over time) (Hornung et al., 2009; Schnaas et al., 2006; Chen et al., 2005; Tong et al., 1998; Bellinger et al., 1990). Collectively, the results did not conclusively demonstrate stronger findings for concurrent blood Pb level. However, with the exception of Schnaas et al. (2006), the results did not preclude an association with concurrent blood Pb level. Schnaas et al. (2006) followed children in Mexico City prenatally through age 10 years and found prenatal blood Pb levels (maternal blood at 28-36 weeks of pregnancy) to be weakly correlated with repeated measures of blood Pb between ages 1 and 10 years (Pearson $r \leq 0.25$). In a mixed effects model that included prenatal and multiple postnatal blood Pb measures, only prenatal blood Pb level was associated with a decrement in FSIQ (Table 5-13). Analysis of variance inflation factors indicated a lack of collinearity among the serial blood Pb measures.

Tong et al. (1998) found that higher early-life blood Pb level was associated with a larger deficit in IQ (Figure 5-21 and Table 5-14). As part of the Port Pirie, Australia cohort study, investigators separately examined intellectual attainment in groups of children with different degrees of decline in blood Pb levels between ages 2 and 11-13 years. Although the mean blood Pb level in the study population declined overall from 21.2 µg/dL at age 2 years to 7.9 µg/dL at age 11-13 years, the magnitude of decline varied among children. In comparisons of tertiles of change in blood Pb level between age 2 and 11-13 years, investigators found that FSIQ at ages 2, 4, 7, and 11-13 years did not significantly differ between children with the largest declines (>16 µg/dL) in blood Pb level and children with a smaller decline (<10 µg/dL). These findings indicated an influence of higher blood Pb levels early in life despite declines in blood Pb with age and a persistence of Pb effects. The results do not preclude an independent association with concurrent blood Pb level.

In several different cohorts of U.S. children, larger decrements in cognitive function were estimated for concurrent blood Pb levels with consideration of blood Pb levels measured earlier in childhood (Hornung et al., 2009; Chen et al., 2005; Bellinger et al., 1990) (Figure 5-21 and Table 5-14). In the Boston cohort, Bellinger et al. (1990) found that at age 57 months, FSIQ, as assessed by McCarthy GCI, was similar between children with higher (≥ 10 µg/dL) and lower (<3 µg/dL) prenatal cord blood Pb levels. Additionally, higher concurrent blood Pb level (age 57 months) was associated with the largest decline in GCI score over time (score at age 57 months-score at age 24 months) among children

with high prenatal blood Pb levels (≥ 10 µg/dL), which pointed to a larger decrease in FSIQ in children with both high early and concurrent blood Pb levels (Figure 5-21 and Table 5-14). The findings indicated that by age 5 years, children with higher prenatal blood Pb levels appeared to recover the Pb-associated decrements in cognitive function unless concurrent blood Pb levels remained high. The investigators also demonstrated that positive home and caregiving environment (e.g., HOME score >52, higher SES, higher maternal IQ) may also protect against decrements in cognitive function associated with higher postnatal Pb exposures. Collectively, these results suggest that cognitive development is not fixed early in childhood and can be affected negatively or positively by postnatal influences.



[a]Values represent the ratio of blood Pb level at age 6 years to that at age 2 years.

[b]Results represent the decrease in FSIQ per 1 µg/dL increase in concurrent blood Pb level in children in different groups of prenatal cord blood Pb levels. FSIQ scores were standardized to their standard deviation. Effect estimates in blue represent associations for higher prenatal or early childhood blood Pb levels relative to concurrent blood Pb levels.

Note: Effect estimates represent associations between concurrent blood Pb level and cognitive function (standardized to standard deviation) in children. Studies are presented in order of increasing prenatal level.

Figure 5-21 Associations of cognitive function in children with different degrees of changes in blood Pb levels over time.

Table 5-14 Additional characteristics and quantitative results for studies presented in Figure 5-21

Study	Population/ Location	Blood Pb Levels (µg/dL)	Statistical Analysis	Outcome	Effect Estimate (95% CI)[a]

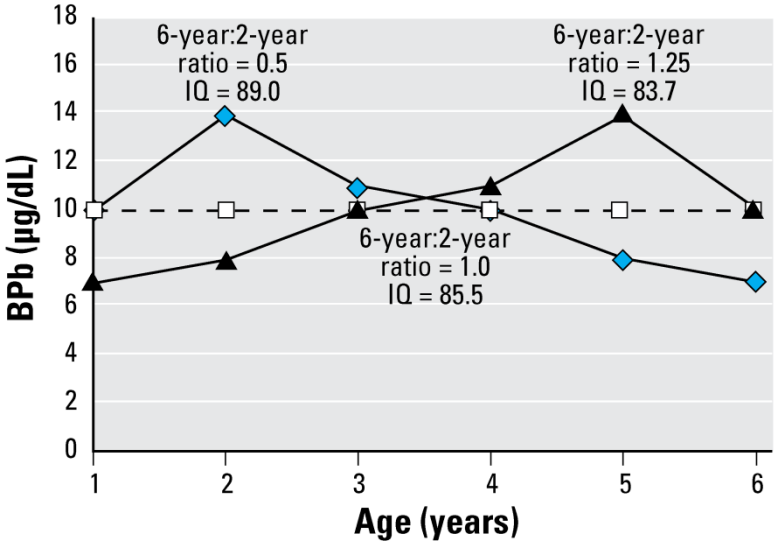
(1990)	170 children followed prenatally to age 57 mo Boston area, MA	NR	Log linear regression adjusted for HOME score, social class, maternal IQ, maternal age, sex, ethnicity	Change in McCarthy GCI score (z-score) between age 57 and 24 mo	For concurrent blood Pb level[b] Prenatal <3 µg/dL: -0.16 (-0.43, 0.11) Prenatal 3-10 µg/dL: -0.14 (-0.57, 0.29) Prenatal ≥ 10 µg/dL: -0.46 (-0.81, -0.11)
Tong et al. (1998)	375 children followed from birth (1979-1982) to age 11-13 yr Port Pirie, Australia	Means: 21.2 (age 2 yr), 7.9 (age 11-13 yr)	Log linear regression model adjusted for sex, birth weight, birth rank, feeding style, breastfeeding duration, maternal IQ, maternal age, SES, HOME score, parental smoking, parents living together. ANOVA to assess association of change in IQ with change in blood Pb across time intervals	Change in cognitive function (z-scores) using Bayley MDI at age 2 yr, McCarthy GCI at age 4 yr, WISC-R at ages 7, and 11-13 yr	<10.2 µg/dL decline: 0.03 (-0.15, 0.21)[c] 10.2-16.2 µg/dL decline: 0.04 (-0.15, 0.23)[c] >16.2 µg/dL decline: -0.01 (-0.20, 0.18)[c]
Chen et al. (2005)	780 children participating in the TLC trial from age 12-33 mo to age 7 yr Baltimore, MD; Cincinnati, OH; Newark, NJ; Philadelphia, PA Children underwent chelation therapy	Mean (SD): Age 2 yr: 26.2 (5.1) Age 5 yr: 12.0 (5.2) Age 7 yr: 8.0 (4.0) Low age 2 yr: <24.9 Low age 7 yr: < 6.2	Linear regression model adjusted for city, race, sex, language, parental education, parental employment, single parent, age at blood Pb measurement, caregiver IQ	WISC-III at age 7 yr	Low age 2, Low age 7: 0[d] Low age 2, High age 7: -0.27 (-0.48, -0.05) High age 2, Low age 7: 0 (-0.21, 0.20) High age 2, High age 7: -0.28 (-0.47, -0.10)

[a]Effect estimates represent the cognitive function score or change in score over time standardized to its standard deviation.
[b]Effects are estimated for concurrent blood Pb level (continuous variable) in children in different categories of prenatal blood Pb level: <3 µg/dL, 3-10 µg/dL, and ≥ 10 µg/dL.
[c]Investigators estimated changes in IQ in groups of children with different degrees of decline in blood Pb levels over the study period: children with <10.2 µg/dL decline, children with a 10.2-16.2 µg/dL decline, and children with >16.2 µg/dL.
[d]Investigators compared IQs among children with different categories of blood Pb level early and later in childhood: low levels at age 2 (<11.4 µg/dL) and age 7 (<7.2 µg/dL), low levels at age 2 (<11.4 µg/dL) and high levels at age 7 (>7.2 µg/dL), high levels at age 2 (>11.4 µg/dL) and low levels at age 7 (<7.2 µg/dL), and high levels at age 2 (>11.4 µg/dL) and age 7 (>7.2 µg/dL). Cutoffs were based on the median blood Pb levels.

Pooling the Cincinnati and Rochester cohorts (n = 397), Hornung et al. (2009) created a new indicator of Pb exposure: the ratio of blood Pb level at 6 years of age to that at 2 years of age. The greatest decrease in cognitive and behavioral development was observed for children with blood Pb ratios greater than 1 (indicating an increase in blood Pb level from 2 to 6 years of age) (Figure 5-21, Figure 5-22, and Table 5-14). Presumably areas under the curve would be similar among children with blood Pb level ratios of 1,

greater than 1, and less than 1, indicating that cumulative blood Pb levels would not be predictive.

As part of the multicenter TLC, Chen et al. (2005) also found higher concurrent blood Pb level (≥ median 7.2 µg/dL) to be associated with lower IQ at age 7 years, regardless of whether blood Pb level at age 2 years was low or high (less than or greater than the median of 24.9 µg/dL, respectively). Blood Pb levels at ages 2 and 7 years were weakly correlated (r = 0.27). It is important to note that children participating in TLC had undergone chelation therapy due to high blood Pb levels (20-44 µg/dL) at age 12 to 33 months, and the findings may have limited application to the general population of children currently living in the U.S. In fact, in all of the studies that examined weakly correlated serial blood Pb measurements, blood Pb levels were higher than those currently measured in U.S. children. Additionally, in several study populations, children experienced large decreases in blood Pb levels over time. It is unclear whether these findings would apply to children in the U.S. who currently are within the same age range and who would be expected to have smaller decreases in blood Pb levels over time.



Source: Hornung et al. (2009)
Note: All three patterns have an identical mean blood Pb level of 10 µg/dL.

Figure 5-22 Estimated IQ in combined Cincinnati and Rochester cohorts, for three patterns of blood Pb level levels from 1 through 6 years of age: peak at 2 years (blue diamonds), peak at 5 years (black triangles), and constant blood Pb level (white squares).

To conclude, in the collective body of epidemiologic evidence in children, it is difficult to ascertain which lifestage of Pb exposure is associated with the greatest risk of Pb-associated neurodevelopmental effects. Associations have been observed with prenatal, early-childhood, lifetime average, and concurrent blood Pb levels as well as with childhood tooth Pb levels. Comparisons among different lifestages of exposure is complicated further by the fact that blood Pb levels in children, although highly affected by recent exposure, are also influenced by Pb stored in bone due to rapid growth-related bone turnover in children relative to adults. Thus, concurrent blood Pb level in children also may reflect body burden (Section 4.3.4.6). Nonetheless, while the evidence indicates that prenatal and early-childhood blood Pb levels are associated with neurodevelopmental deficits, subsequent exposures that are reflected in concurrent, cumulative blood Pb levels or tooth Pb levels also are demonstrated to contribute to neurodevelopmental deficits throughout school-age and into adolescence. With additional results from studies described in Sections 5.3.2.1 and 5.3.3.1, the weight of epidemiologic evidence supports associations of concurrent blood Pb level with neurodevelopmental effects in children. These findings are consistent with the understanding that the nervous system continues to develop throughout childhood.

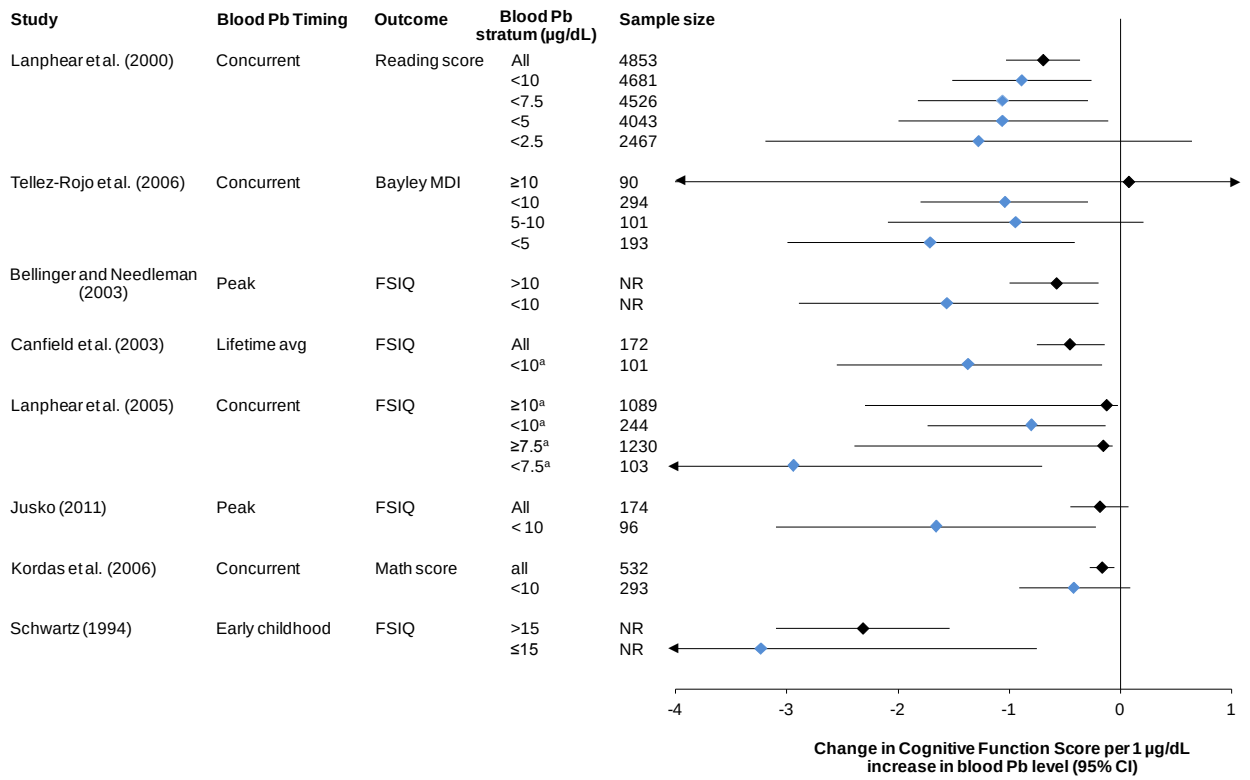
5.3.10 Examination of the Lead Concentration-Response Relationship

With each successive Pb AQCD and supplement, epidemiologic and toxicological studies find that progressively lower blood Pb levels are associated with cognitive deficits and behavioral impairments. For example, among children, such effects were observed in association with blood Pb levels in the range of 10-15 µg/dL in the 1986 Addendum and 1990 Supplement and 10 µg/dL and lower in the 2006 Pb AQCD (U.S. EPA, 2006b). Furthermore, in the 2006 Pb AQCD, several individual studies, pooled analyses, and meta-analyses estimated a supralinear blood Pb concentration-response relationship in children, i.e., greater decrements in cognitive function per incremental increase in blood Pb level among children in lower strata of blood Pb levels compared with children in higher strata of blood Pb levels (Figure 5-23 and Table 5-15). As lower concentrations of Pb exposure are being used experimentally, the toxicological literature also has reported nonlinear concentration-response relationships for various endpoints, including those coherent with cognitive function decrements observed in children. Also consistent with the epidemiologic literature, some toxicological studies have shown larger magnitudes of effect (absolute effects) in lower Pb exposure groups (relative to control groups) than in the higher exposure groups.

In epidemiologic studies, a supralinear concentration-response relationship was observed for concurrent, early childhood, and lifetime average blood Pb levels. Most

epidemiologic studies used a blood Pb level of 10 µg/dL to define lower and higher blood Pb levels. Several of these observations were made in groups of children aged 2 to 10 years, and the mean blood Pb levels in the lower strata of blood Pb levels were in the range of 3-5 µg/dL (Bellinger, 2008; Canfield, 2008; Hornung, 2008; Rojo-Tellez, 2008). Except for the pooled analysis, lower strata of blood Pb levels comprised at least 55% of the study population and consequently the concentration-response relationships calculated for these lower strata likely are not outliers comprised a minimum 55% of the study population and consequently the concentration-response relationships calculated for these lower strata are not outliers or unrepresentative of the overall study population. Using data pooled from seven prospective studies, Lanphear et al. (2005) fit various types of models to the data and observed that a cubic spline, log-linear model, and piece-wise linear model all supported a more negative concentration-response relationship at concurrent blood Pb levels <10 µg/dL. A linear model was found to be inadequate as the polynomial terms for concurrent blood Pb were statistically significant. These findings were corroborated in a separate analysis by Rothenberg and Rothenberg (2005) who found that the log-linear model fit the relationship between blood Pb level and IQ better than a linear model did.

A few studies demonstrated larger Pb-associated decreases in cognitive function with blood Pb levels < 5 µg/dL. Tellez-Rojo et al. (2006) estimated a larger decrement in IQ per unit increase in blood Pb level for children (age 2 years) with concurrent blood Pb levels <5 µg/dL compared with children with levels 5-10 µg/dL, and > 10 µg/dL (Figure 5-23 and Table 5-15). In an NHANES analysis 1989-1994, Lanphear et al. (2000) found larger decrements in reading and math skills and memory per unit increase in blood Pb level in children with concurrent blood Pb levels <2.5 µg/dL compared with children with levels <5 µg/dL, <7,5 µg/dL, <10 µg/dL, and all subjects. However, as the study population included adolescents, the oldest of whom were 16 years of age and born 1972-1978, higher Pb exposures earlier in childhood may have contributed to associations.



Note: Studies are presented in order of increasing mean blood Pb level. Strata refer to peak blood Pb level measured in child at any point during follow up. FSIQ = full-scale IQ, MDI = mental development index. Effect estimates are standardized to a 1 µg/dL increase in blood Pb level. Black symbols represent effect estimates among all subjects or in the highest blood Pb stratum. Blue symbols represent effect estimates in lower blood Pb strata

Figure 5-23 Comparison of associations between blood Pb level and cognitive function among various blood Pb strata.

Table 5-15 Additional characteristics and quantitative results for studies presented in Figure 5-23

Study	Population/Location	Blood Pb Levels (µg/dL)	Statistical Analysis	Outcome	Blood Pb stratum (µg/dL)	Effect Estimate (95% CI)[a]
Lanphear et al. (2000)	4,853 children ages 6-16 yr NHANES 1988-1994	Concurrent mean (SE): 1.9 (0.1)	Linear regression model adjusted for sex, race/ethnicity, poverty index ratio, reference adult education level, serum ferritin level, serum cotinine level	WRAT reading subtest at ages 6-16 yr	All subjects <10 <7.5 <5 <2.5	-0.70 (-1.03, -0.37) -0.89 (-1.52, -0.26) -1.06 (-1.82, -0.30) -1.06 (-2.00, -0.12) -1.28 (-3.20, -0.64)

(2005)	1,333 children pooled from Boston, Cincinnati, Cleveland, Mexico City, Port Pirie, Rochester, and Yugoslavia cohorts	Concurrent Median (5th-95th) 9.7 (2.5-33.2)	Linear regression model adjusted for HOME score, birth weight, maternal IQ, maternal education	FSIQ measured at ages 4.8-10 yr	≥ 10 <10 ≥ 7.5 <7.5	-0.13 (-2.3, -0.03) -0.80 (-1.74, -0.14) -0.16 (-2.4, -0.08) -2.94 (-5.16, -0.71)
Jusko et al. (2011)	194 children in Rochester, NY followed from age 6 mo (1994-1995) to age 6 yr.	Peak Mean (SD): 11.4 (7.3)	Linear regression model adjusted for sex, birth weight, transferrin saturation, maternal race, maternal IQ, maternal education, HOME score, family income, and maternal prenatal smoking	WPPSI-R at age 6 yr	All < 10	-0.19 (-0.46, 0.07) -1.66 (-3.1, -0.23)
Kordas et al. (2006)	602 children in 1st grade Torreon, Mexico	Concurrent mean (SD): 11.4 (6.1)	Linear regression model adjusted for sex, age, hemoglobin, family possessions, forgetting homework, house ownership, crowding, maternal education, birth order, family structure, arsenic exposure, tester, school	Math achievement test in 1st grade	all <10	-0.17 (-0.28, -0.06) -0.42 (-0.92, 0.08)
Schwartz (1994)	Meta-analysis of 7 studies with sample sizes 75-579 children	Early childhood (2-3 yr) range in study means: 6.5-23	Meta-analysis of combining effect estimates from individual studies	FSIQ measured at school-age	Studies with mean >15 Studies with mean ≤ 15	-2.32 (-3.10, -1.54) -3.23 (-5.70, -0.76)

[a]Effect estimates are standardized to a 1 µg/dL increase in blood Pb level.
[b]95% CIs calculated from reported p-value.

Several studies also found a nonlinear blood Pb-cognitive function relationship in nonparametric regression analyses using lowess with smoothing parameters or using splines (Min et al., 2009; Jusko et al., 2008; Schnaas et al., 2006). Min et al. (2009) performed a formal test of nonlinearity using nonparametric regression by testing the statistical significance of a restricted cubic spline term for blood Pb level. Although the

term was not statistically significant, the concurrent blood Pb level-FSIQ curve appeared to be more negative at blood Pb levels < 7 µg/dL. In a similar analysis in a Mexico City cohort, Schnaas et al. (2006) found a more negative blood Pb-FSIQ slope at concurrent blood Pb levels < 6 µg/dL and found a test of nonlinearity to be statistically significant. Among children in India ages 3-7 years, Palaniappan et al. (2011), most associations of concurrent blood Pb level with various indices of executive function in nonparametric regression analyses were found to be linear.

Studies of adults have not assessed widely whether the relationship between blood or bone Pb level and cognitive performance is described better with a linear or nonlinear function. In the various NHANES analyses, only log-linear models were used to fit the data (Krieg et al., 2010; Krieg and Butler, 2009; Krieg et al., 2009). Nonlinearity in the BMS and NAS cohorts was examined with the use of quadratic terms, penalized splines, or visual inspection of bivariate plots (Bandeen-Roche et al., 2009; Weisskopf et al., 2007a; Shih et al., 2006). There was some evidence for nonlinearity for some (Figure 5-12 and Figure 5-13) but not all cognitive tests or all subjects in the NAS cohort. For example, Wang et al. (2007a) found that among NAS men with an HFE variant, there was a steeper Pb-associated decline in MMSE score at higher tibia Pb levels (20-25 µg/g, Figure 5-13). In the BMS cohort, observations of a statistically nonsignificant quadratic term (Shih et al., 2006) or spline (Bandeen-Roche et al., 2009) for tibia Pb indicated that a linear model adequately fit the relationship between tibia Pb level and various tests of cognitive performance.

Attenuation of the concentration-response relationships at higher exposure or dose levels has been reported in the occupational literature, and explanations have included greater exposure measurement error, competing risks, and saturation of biological mechanisms at higher levels; larger proportions of at-risk populations at lower exposure levels; and variations in other risk factors among exposure levels (Stayner et al., 2003). Other explanations for nonlinearity include differential activity of mechanisms at different exposure levels, confounding by omitted or misspecified variables, and the lower incremental effect of Pb due to covarying risk factors such as low SES, poor caregiving environment, and higher exposure to other environmental factors.

The contribution of these factors to the supralinear relationship between blood Pb levels and cognitive function in children has not been examined widely in epidemiologic studies to date. However, in several different populations, higher blood Pb levels have been measured in potentially at-risk groups such as those with higher poverty, greater exposure to tobacco smoke, lower parental education, and lower birth weight, which argues against a larger proportion of at-risk populations at lower blood Pb levels (Lanphear et al., 2005; Lanphear et al., 2000). It has been suggested that in populations of low SES, poorer

caregiving environment, and greater social stress, the incremental effect of Pb exposure may be attenuated due to the overwhelmingly larger effects of these other risk factors (Schwartz, 1994). Several studies found statistically significant associations of these sociodemographic risk factors with neurocognitive deficits, and Miranda et al. (2009) found that indicators of SES (i.e., parental education and enrollment in a free/reduced fee lunch program) accounted for larger decrements in EOG scores than did blood Pb level (Figure 5-7). Few studies have compared blood Pb level effect estimates among groups in different sociodemographic strata, and the limited data are mixed. Greater Pb-associated neurocognitive deficits were reported in low-SES groups by Bellinger et al. (1990). In a meta-analysis of eight studies, Schwartz (1994) found a smaller decrement in IQ per 1 µg/dL increase in blood Pb level for studies in disadvantaged populations (-2.7 points [95% CI: -5.3, -0.07]) than for studies in advantaged populations (-4.5 points [95% CI: -5.6, -2.8]). It is important to note that blood Pb level is associated with deficits in cognitive function in both higher and lower SES groups; however, it is unclear what differences there are between groups in the decrement per unit increase in blood Pb and whether these differences can explain the observed nonlinear concentration-response relationship.

Rothenberg and Rothenberg (2005) formally assessed the influence of residual confounding on the nonlinear blood Pb-FSIQ concentration-response relationship by comparing model fit between linear and spline transformations (df = 2) of covariates such as maternal IQ, HOME score, and maternal education. Inclusion of covariates as spline functions did not significantly improve model fit either with a linear blood Pb term or log blood Pb term, which indicated that their inclusion as linear functions was adequate. These findings demonstrate that the improved model fit with log-specification of blood Pb level was not due to residual confounding by covariates.

Bowers and Beck (2006) postulated that a supralinear slope necessarily will be found when modeling a relationship between a log-normally distributed variable and a normally distributed variable. However, as discussed in the 2006 Pb AQCD, this modeling strategy was not employed in the epidemiologic analyses showing a supralinear concentration-response function. IQ scores generally were not forced into a normal distribution. Four of the seven studies included in the pooled analysis by Lanphear et al. (2005) did not use normalized IQ scores, and scores were not normalized in the pooled analysis (Hornung et al., 2006). Further, a log-linear model (a linear relationship between IQ and the log of blood Pb) provided the best fit of the pooled data.

In support of the nonlinear associations between blood Pb levels and cognitive function observed in children, toxicological studies provided some evidence of nonlinear relationships between Pb exposure and effects related to impaired learning and memory

in animals. Multiple studies showed U- or inverse U-shaped curves with lower exposures of Pb having different or often the opposite effect from higher exposures. Coherent with epidemiologic findings, results summarized across multiple studies in multiple species demonstrated that lower Pb exposures increased FI response rates relative to controls and higher Pb exposures decreased FI response rates (Cory-Slechta, 1994). Consistent with these findings, Rossi-George et al. (2011) found that 50 ppm gestational plus lactational Pb exposure when combined with stress increased FI responses of 2-month old rats whereas 150 ppm Pb exposure with stress did not affect FI responses. It is important to note that the larger effects observed with lower Pb exposures were less consistently observed with longer duration exposures (e.g., 8-11 months) (Rossi-George et al., 2011; Cory-Slechta, 1990). As discussed in Section 5.3.2.2, FI responses measure learning and memory by reflecting the ability of animals to learn to respond to one schedule of reinforcement and change responses according to a change in reinforcement.

Toxicological studies provided additional support for nonlinear relationships between Pb exposure and neurodevelopmental effects by finding that lower and higher Pb exposures differentially activate mechanisms underlying such effects. Gilbert et al. (1999) found reduced LTP with Pb exposures ranging between 0.1 and 0.5% but not 1.0%. LTP is one indication of synaptic plasticity (Section 5.3.8.4) and is considered to contribute to learning and memory. Likewise, glutamate release in the hippocampus was reduced in animals with blood Pb levels 27-40 µg/dL but not with blood Pb levels of 62-117 µg/dL (Lasley and Gilbert, 2002). Glutaminergic neurotransmission via its NMDA receptor has been implicated in learning and memory (Section 5.3.8.8).
