Dopaminergic neurotransmission is involved in many CNS processes including cognition, behavior, and motor function. The shape of the Pb-DA concentration-response relationship varied among toxicological studies. Some studies found that lower Pb exposures (~ 50 ppm) did not affect or increased DA activity relative to controls and higher Pb exposure (109-250 ppm) (Leasure et al., 2008; Virgolini et al., 2005; Lewis and Pitts, 2004). However, compared with control and lower Pb exposures, higher Pb exposures (109 or 150 ppm) were found both to increase and impair DA activity (Leasure et al., 2008; Virgolini et al., 2005). These differential responses of DA may be related to the diverse actions of DA in different regions of the brain and on a range of CNS effects. For example, the increased dopamine turnover with 50 ppm Pb exposure may explain the greater spontaneous and amphetamine-induced motor activity in males induced by 50 ppm GLE (Leasure et al., 2008).

Lower and higher Pb exposures also were found to differentially affect calcineurin enzyme activity; activity was inhibited by higher Pb exposure and stimulated by lower Pb exposure (Kern and Audesirk, 2000). While calcineurin activity has been found to

modulate learning, LTP, and behavior in animals, studies have found lower calcineurin activity to be associated with both impaired and improved effects related to learning (Zeng et al., 2001). Thus, it is uncertain whether altered calcineurin activity contributes to the nonlinear relationships observed between Pb exposure and learning. Nonetheless, results indicated that lower and higher Pb exposures may have different modes of action. At lower concentrations, Pb may displace calcium at its binding sites on calmodulin and by acting as a calmodulin agonist at the catalytic A subunit of calcineurin, stimulate calcineurin activity. At higher Pb exposure, Pb may bind directly to a separate calcium-binding B subunit, override the calmodulin-dependent effect and turn off the activity of calcineurin. Similarly, Lasley and Gilbert (2002) also indicated that at higher concentrations (i.e., 1%), Pb stimulated gluatamate release by acting as a calcium mimetic.

While epidemiologic studies have not examined widely the shape of the concentration-response relationship for other nervous system effects, toxicological studies have found nonlinear relationships for diverse outcomes. U-shaped Pb concentration-response relationships were found for rotarod performance, amphetamine-induced motor activity, and latency to fall from rotarod (Leasure et al., 2008). Inverted U-shaped Pb concentration-response relationships were found for histological parameters such as the numbers of rod photoreceptors and bipolar cells, activity level, and adult body weight (Leasure et al., 2008) as well as ERG wave amplitudes (Fox et al., 2008) and hippocampal neurogenesis (Fox et al., 2008; Gilbert et al., 2005). Additional evidence points to differences in hormonal homeostasis by Pb exposure level. In male mice with chronic Pb exposure (PND21-9 months of age), basal corticosterone levels were significantly lower in the 50 ppm exposure group than in the control or 150 ppm Pb exposure group.

Sensory organ functions in animals also have shown to be differentially affected by lower versus higher Pb exposure (developmental Pb exposurefrom gestation to PND10, pup blood Pb levels 12, 24, and 46 µg/dL. Inverted U-shaped dose-response curves have been observed for rod photoreceptor numbers or neurogenesis (Giddabasappa et al., 2011) and retinal thickness (Fox et al., 2010). Thus, these dichotomous histological findings may give insight to the complex sensory organ findings that vary by exposure window and exposure dose (Section 5.3.4.3).

The supralinear concentration-response relationship widely documented for Pb is consistent with the lack of a threshold for Pb-associated neurodevelopmental effects as a smaller effect estimate would be expected at lower blood Pb levels if a threshold existed. Schwartz (1994) explicitly assessed evidence for a threshold in data from the Boston prospective cohort by regressing FSIQ and blood Pb level on potential confounders

including age, race, maternal IQ, SES, and HOME score and fitting a nonparametric smoothed curve to the residuals of both regression models (variation in FSIQ or blood Pb level not explained by covariates). A 7-point decrease in IQ was observed over the range of blood Pb residuals below 0, which corresponds to the mean blood Pb level in the study (6.5 µg/dL). Thus, in the Boston study, the association between blood Pb level and FSIQ was clearly demonstrated at blood Pb levels below 5 µg/dL.

An important limitation of previous studies in terms of characterizing the concentration-response relationship, in particular, identifying whether a threshold exists, was the limited examination of associations in populations or subgroups with blood Pb levels more comparable to the current U.S. population mean. While Schwartz (1994) did not find evidence for a threshold in the Boston study data, the mean blood Pb in that population was 6.5 µg/dL, and 56% of subjects had a blood Pb level >5 µg/dL. Recent studies indicate a downward shift in the distribution of blood Pb levels. In the various NHANES analyses of children, a large proportion of children had blood Pb levels <1 µg/dL, for example, 50% of subjects in the 2001-2004 NHANES population (Braun et al., 2008).

More sensitive quantification methods have improved the detection limits, for example, from 0.6 µg/dL in 1999-2002 NHANES to 0.025 µg/dL in 2003-2004 NHANES. In analyses of children in multiple blood Pb quantiles below 1 µg/dL, Braun et al. (2008) found higher odds ratios for conduct disorder and ADHD among children with blood Pb levels 0.8-1.0 µg/dL (2nd quartile) compared with children with blood Pb levels 0.2-0.7 µg/dL (1st quartile). Despite the availability of large proportions of subjects at blood Pb levels below 1 µg/dL, the ability to discern a threshold for Pb-associated neurodevelopmental effects is limited due to the large proportions of adolescents in NHANES analyses who were born the 1970s and whose higher past exposures may have contributed to associations observed with concurrent blood Pb levels. Nonetheless, several recent studies reported associations between blood Pb levels and deficits in cognitive and behavioral endpoints in children ages 8-11 years with mean or quantile blood Pb levels <2 µg/dL (Cho et al., 2010; Kim et al., 2009b; Miranda et al., 2009). In comparisons of various quantiles of blood Pb, Miranda et al. (2009) reported lower EOG scores in children in North Carolina with blood Pb levels of 2 µg/dL compared with children with blood Pb levels of 1 µg/dL. Collectively, these new findings in children, do not provide evidence for a threshold for the neurodevelopmental effects of Pb in the range of blood Pb levels examined to date.

It is important to note, however, that the lack of a reference population with blood Pb levels reflecting pre-industrial Pb exposures limits the ability to identify a threshold. Estimates of “background” blood Pb levels have been garnered from the analysis of ancient bones in pre-industrialized societies. These studies suggest that the level of Pb in

blood in preindustrial humans was approximately 0.016 µg/dL (Flegal and Smith, 1992), approximately 65-fold lower than that currently measured in U.S. populations and lower than the levels at which neurodevelopmental effects have been observed (1 µg/dL). Thus, the current evidence does not preclude the possibility of a threshold for neurodevelopmental effects in children existing in the large range of blood levels between 1 µg/dL and preindustrial "background" levels.

To conclude, several studies found a supralinear blood Pb-cognitive function concentration-response relationship in children based on comparisons of effect estimates in lower and higher strata of blood Pb level and nonparametric regression. Supporting evidence was provided by some toxicological studies that showed that lower Pb exposures induced learning and memory impairments in animals compared to control exposures or higher Pb exposures. While explanations for this supralinear relationship have not been well characterized by epidemiologic studies, recent toxicological studies that examined lower concentrations of experimental Pb exposure suggest that mechanisms may be differentially activated at lower and higher Pb exposures.

Nonlinear concentration-response relationships were found for effects such as LTP, hippocampal glutamate release, and calcineurin expression. Observations of associations between blood Pb levels and deficits in cognitive and behavioral endpoints in children (ages 8-11 years) with mean or range of blood Pb levels ≤ 2 µg/dL (Cho et al., 2010; Kim et al., 2009b; Miranda et al., 2009) do not provide evidence for a threshold for neurodevelopmental effects of Pb in the range of blood Pb levels examined to date.

5.3.11 Confounding in Epidemiologic Studies of Nervous System Effects

In addition to Pb exposure, many factors influence cognitive function and behavior in children, including parental IQ and education, SES of the family, quality of the caregiving environment, and other environmental exposures (Wasserman and Factor-Litvak, 2001). These other risk factors often are correlated with blood, tooth, and bone Pb levels, thus, a major challenge to observational studies examining associations of Pb biomarker levels with cognitive and behavioral function in children has been the assessment and control for potential confounding factors. By definition, a confounder is associated with both the exposure and the outcome and consequently has the potential to bias the association between the exposure of interest and the outcome. Epidemiologic studies of Pb biomarkers in children have most commonly examined potential confounding by quality of the caregiving environment (i.e., HOME score), parental IQ, and SES-related variables such as parental education, household income, and the Hollingshead Four-Factor Index of Social Position, which incorporates education and

income of both parents. A relatively smaller number of studies have considered confounding by other environmental exposures, measures of parental substance abuse, and psychopathology. Studies have varied with respect to the number of potential confounders examined, with some studies considering multiple SES-related variables and other studies focusing on a smaller set. It is important to note that the extent of confounding by a particular variable likely is study-specific, i.e., dependent on the population examined. Thus, the impact of adjustment for specific covariates on the Pb effect estimate also is likely to be study-specific.

Studies have used various methods to control for confounding, including examining a homogeneous population with respect to SES, examining populations in which factors are not correlated, conducting multivariate regression, characterizing the magnitude of change in the blood Pb level effect estimate with adjustment for a covariate, and examining associations in different strata of a covariate. While no single method is without limitation, the consistency of findings among different methodologies substantiates independent associations of blood Pb level with cognitive function decrements and behavioral problems in children. The evidence derived from each of these control strategies is discussed below.

In the Boston Prospective Study, potential confounding by SES was largely controlled for by study design. The study subjects were generally middle- to upper-middle-class children with married, college-educated parents. Hence, the potential for confounding by SES in this study was considerably less compared to other studies examining the same associations. Yet, in this cohort, blood Pb levels measured prenatally, at age 2 years, and integrated over ages 2 and 5 years were associated decrements in full-scale IQ and various measures of executive function (Stiles and Bellinger, 1993); (Bellinger et al., 1992; Bellinger et al., 1990). In some analyses of this cohort, larger effects were estimated as compared with other studies.

Studies also have demonstrated associations between blood Pb levels and cognitive function in populations in which blood Pb levels were not associated with SES-related variables (Factor-Litvak et al., 1999; Bellinger et al., 1987). In the Boston cohort, parental education, social class, and HOME score were similar among low (<3 µg/dL), medium (6-7 µg/dL), and high (≥ 10 µg/dL) cord blood Pb level groups. Nonetheless, adjusting for these and other demographic variables, Bellinger et al. (1987) found that children in the high cord blood Pb group had a 4.8-point lower Bayley MDI score at age 24 months than did children in the low cord blood Pb group. In the Yugoslavia cohort, blood Pb levels at age 4 years were higher in groups with higher maternal education, maternal IQ, and HOME score in one city and were lower in another city. Among all children, higher blood Pb level was associated with lower FSIQ and specific indices of

learning and memory and with greater depression and withdrawn behavior (Factor-Litvak et al., 1999).

The primary method used by epidemiologic studies to control for potential confounding has been multivariate regression. This was the main method employed in recent studies that examined children with blood Pb levels in the range of current U.S. levels. Some studies selected a set of covariates based on a priori knowledge, whereas others selected particular covariates based on their association with the outcome in a model with all potential covariates and/or a greater than 10% change in the blood Pb level effect estimate. Studies also varied in the number of variables included in models as potential confounders. Some included multiple SES-related variables, whereas others analyzed one or two variables. Regardless of the method used to select model covariates or the number of covariates included, studies consistently demonstrated associations of higher blood Pb level with lower cognitive function and greater behavioral problems. This consistency suggests that confounding by particular variables may be specific to the population examined and that no single measured variable or set of variables fully accounts for the associations observed with blood Pb levels and neurodevelopmental effects in children.

The consistency of associations across populations with different SES and across studies examining different covariates was reinforced in pooled and meta-analyses (Marcus et al., 2010; Lanphear et al., 2005; Schwartz, 1994). Pooling data from seven international longitudinal cohorts, Lanphear et al. (2005) found similar blood Pb-FSIQ effect estimates (-2.6 to 8.6% difference) among models, each with one study omitted. These results indicated that the pooled estimate is relatively stable despite between-study differences in population characteristics, including SES. In a meta-analysis, Schwartz (1994) found that individual study blood Pb-IQ effect estimates fell within a relatively narrow range despite large differences among studies in the correlation between blood Pb level and SES. A wider range of effect estimates would be expected if omitted SES factors confounded the blood Pb level association. A recent meta-analysis examined the association between blood Pb level and conduct problems in older and recent studies of children (Marcus et al., 2010). Among the studies included, adjustment for variables such as SES and home environment did little to attenuate the association between Pb and conduct problems.

Among studies that provided both unadjusted and adjusted effect estimates, most indicated statistically significant associations of blood Pb level with neurodevelopmental outcomes in children before and after adjusting for potential confounders. Although examples exist where blood Pb level was estimated to have a weaker, statistically nonsignificant effect after adjustment for potential confounders (Tong and Lu, 2001; Ernhart et al., 1989), most notably in multiple analyses of the Cleveland cohort, studies also reported stronger blood Pb level associations in covariate-adjusted models (Canfield

et al., 2003b; Factor-Litvak et al., 1999). In recent studies with population mean blood Pb levels between 5 and 10 µg/dL, associations between blood Pb levels and cognitive function (e.g., FSIQ, executive function, learning, and memory) remained statistically significant after adjusting for covariates (Min et al., 2009; Chiodo et al., 2007; Froehlich et al., 2007; Kordas et al., 2006; Schnaas et al., 2006). Although most effect estimates changed by 20-50% in multivariate models, they remained within the 95% CI of the unadjusted estimate. In particular, Schnaas et al. (2006) and Froehlich et al. (2007) found some adjusted effect estimates to be larger in magnitude compared with unadjusted estimates. Although information was not provided on the magnitude of change in effect estimates after adjustment for confounding, Chiodo et al. (2007) found statistically significant associations between blood Pb level and behavioral problems (e.g., inattention, hyperactivity, social problems, impulsivity) in models with blood Pb level alone and with covariates. These findings demonstrate that SES-related and demographic factors may partially account for but do not fully explain the associations observed between higher blood Pb level and neurodevelopmental impairments.

A challenge to separating the effects of Pb exposure from those related to SES and quality of the caregiving environment is the high correlation typically observed among these measures. In such cases, it is difficult to know how much variation in the outcome to attribute to each of the various risk factors (Needleman and Bellinger, 2001). For example, the high correlation between blood Pb level and SES may lead to an underestimation of the Pb effect when SES is added to the model. A reduction in the magnitude and statistical significance of the Pb effect estimate following adjustment for some measure of SES may be the result of the misattribution of the variance in outcome due to Pb to the variance due to SES. SES may be a proxy for Pb exposure rather than a confounder of the association of interest. This misattribution may be exacerbated when several correlated variables are included in the same model (i.e., overcontrol).

Instead of being a confounder, Pb may be on the causal pathway of the association between social class and IQ. Lower social class in urban children is closely linked to residence in older housing in poor condition that, in turn, increases exposure of children to environmental Pb and increases their risk of cognitive deficits (Clark et al., 1985). In such cases, statistical adjustment for SES will lead to the underestimation of the Pb effect (Bellinger, 2004a). One extreme example of overcontrol of this nature can be found in the New Zealand studies where investigators regularly adjusted for residence in older wooden housing, which is associated with higher exposure to Pb paint and accumulated dust and soil (Fergusson et al., 1988a, b). However, it is worth noting that, even in the models including this variable, Pb remained a statistically significant predictor of intellectual and academic under-attainment in the Christchurch Health Study. Variables related to SES have been shown to be effect modifiers in studies of Pb and child

development (Tong et al., 2000; Bellinger et al., 1990). That is, increases in blood Pb level have been associated with larger decreases in cognitive function among children from less advantaged (e.g., lower SES, lower HOME score, lower maternal IQ) household than among those from more advantaged households. Similarly, a larger decrease in cognitive function in association with higher blood Pb level was found among children with mothers with lower self-esteem, an indicator of stress and less connection with the child (Surkan et al., 2008).

In the collective body of epidemiologic evidence, higher blood Pb levels are consistently associated with cognitive function decrements and behavioral problems in children, with the weight of evidence indicating decrements in FSIQ and diverse measures of executive function and inattention and hyperactivity, respectively. These associations have been observed in diverse populations in the U.S., Mexico, Europe, Asia, and Australia. Associations have been observed across studies that use different methods of control for confounding and adjust for different potential confounders. While no single method is without limitation, the consistency of findings among different methodologies and sets of covariates substantiates independent associations of blood Pb level with cognitive function decrements and behavioral problems in children. In addition, Pb exposure has been extensively studied in animals that produce blood Pb levels in the range of those examined in children. Experimental animal studies are not vulnerable to confounding by such factors as social class and correlated environmental factors. Adding further support for the independent associations of blood Pb levels with neurodevelopmental outcomes in children is the coherence of findings in animal studies for Pb-induced impairments in tests of learning, inattention, and impulsivity, especially tests that are directly homologous to those in children, i.e., spatial memory, rule learning and reversal, and response inhibition. Further, an extensive body of toxicological evidence for Pb-induced changes in brain physiological processes that mediate cognition and behavior, including changes in neurogenesis, synaptic pruning, and neurotransmitter function in the frontal lobe and striatum of the brain provides biological plausibility for observations in children.

5.3.12 Public Health Significance of Associations between Lead Biomarkers and Neurodevelopmental Effects

As described in Section 5.3.2.1, most studies found that a 1 µg/dL increase in blood Pb level was associated with fractional decrements in FSIQ in school-aged children (Figure 5-2 and Table 5-3) and Bayley MDI in infants (Table 5-4). Similarly, a 1 µg/dL increase in blood Pb level typically was associated with decreases in specific cognitive abilities (Figure 5-5 and Table 5-5) and increases in inattention and hyperactivity (Section 5.3.3.1,

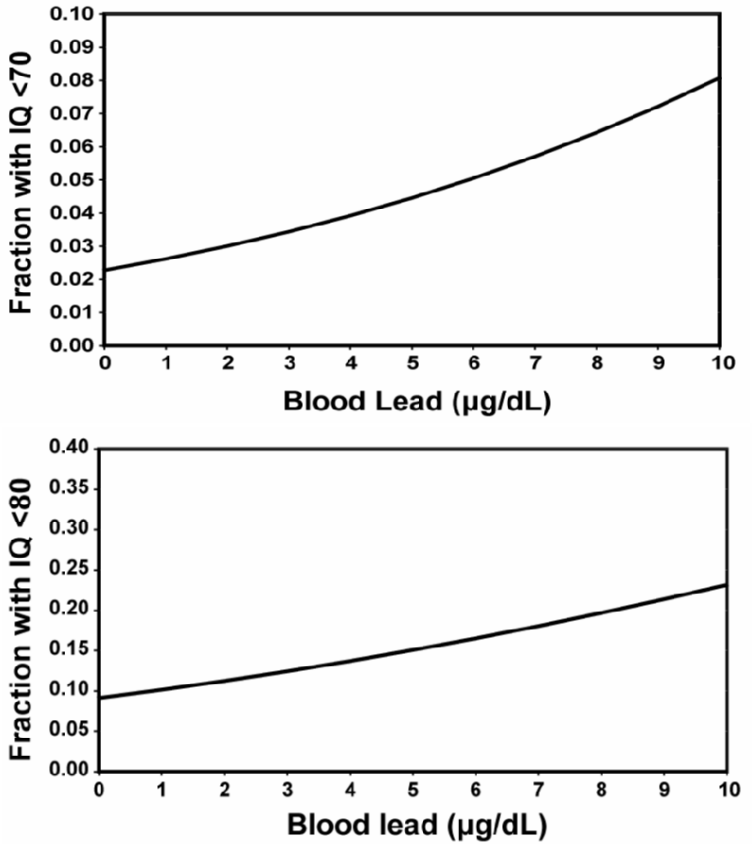
Figure 5-14 and Table 5-9) on the order of less than 1 standard deviation. These findings have generated discussion of the public significance of blood Pb level-associated changes in cognitive function and behavior in children, specifically, whether these fractional changes have consequences on the health and life-success of individuals. The World Health Organization definition of health is the following: "Health is a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity" (WHO, 1948). By this definition, even decrements in health status that are not severe enough to meet diagnostic criteria might be undesirable if they reflect a decrement in the well-being of an individual. Deficits in health indices or life-success may not be observable except in aggregate, at the population level. The American Thoracic Society discussed the need to consider the prevalence of exposures in the population and exposure to other risk factors in evaluating whether shifts in the population-level risk are adverse (ATS, 2000). It should also be noted that these deficits when measured in children may set affected children on trajectories more prone toward lower educational attainment and financial well-being. Thus, early deficits in children may have lifetime consequences.

It has been argued that fractional decrements in IQ points are meaningless given that these Pb-associated changes are within the 3- to 4-point standard error on a single test (i.e., the statistic that defines the range within which the true value of an individual is likely to lie) (Kaufman, 2001). However, this argument incorrectly assumes that conclusions drawn from individual-level data apply to populations. It is important to note that evidence does not indicate that the standard error is nonrandom, i.e., biased in one direction. In particular, evidence has not indicated that children with higher blood Pb levels systematically test lower than their true IQ value and that children with lower blood Pb levels test higher than their true IQ value. Thus, in a population of children, on a given assessment, some children will test lower than their true value and others will test higher than their true value. In such cases, between-group differences will be measureable on a population basis. Error in the measurement of IQ in an individual will contribute nondifferential error on a population-level and bias the association to the null.

The issue of individual-level versus population-level risk also pertains to the relevance of the magnitude of decrease in cognitive function or increase in behavioral problems per incremental increase in blood Pb level. Although fractional changes in IQ, memory, or inattention may not be consequential for an individual, they may be consequential on a population level, especially in the two tails of the distribution (Bellinger, 2007, 2004b). Weiss (1990) predicted, on purely statistical grounds, that a downward shift of five points in mean IQ, if the amount of dispersion in the distribution remained the same, should be accompanied by a doubling of the numbers of individuals with scores two or more standard deviations below the mean and a reduction by half of the number of individuals

with scores two or more standard deviations above the mean. Thus, for an individual functioning in the low range of the IQ distribution, a Pb-associated decline of several points might be sufficient to drop that individual into the range associated with increase risk of educational, vocational, and social failure.

This hypothesis is supported by several observations. In a recent study of fourth graders across the entire state of North Carolina, Miranda et al. (2009) found that higher blood Pb level measured once in each child between age 9 months and 3 years was associated with larger decreases in EOG scores in lower distribution of EOG scores (Figure 5-7). Needleman et al. (1982) found that a downward shift in the mean IQ value was associated not only with a substantial increase in the percentage of individuals achieving very low scores, but also with substantial decreases in percentages achieving very high scores. Based on the study by Bellinger et al. (1987) examining associations between blood Pb level and IQ scores in children, Weiss (1988) discussed the shift in the population distribution of IQ from a mean of 100 and a standard deviation of 15 to a mean of 95, a 5% reduction. When the mean IQ level is 100, 2.3% of the individuals in a given population would score above 130. However, with the population distribution shift and the resulting mean decline in IQ, only 0.99% of the individuals would score above 130. Weiss (1988) stated that the implication of such a loss transcends the current circumscribed definitions of risk. In a similar analysis presented in the 2006 Pb AQCD, using a blood Pb-IQ effect estimate of −0.9 points/µg/dL (based on the median of effect estimates for blood Pb levels <10 µg/dL), the fraction of the population with an IQ level less than 80 more than doubles from 9% with a blood Pb level of 0 µg/dL to 23% with a blood Pb level of 10 µg/dL (Figure 5-24). The proportion with an IQ level below 70, a level often requiring community support to live (WHO, 1992) increases from a little over 2% with a blood Pb level of 0 µg/dL to about 8% with a blood Pb level of 10 µg/dL (Figure 5-24) (U.S. EPA, 2006b).



Source: U.S. EPA (2006) Pb AQCD

Figure 5-24 Effect of blood Pb level on the proportion of the population with IQ levels <70 and <80 points.

Evidence also has demonstrated larger changes in neurodevelopmental outcomes in children with additional risk factors such as lower SES (Tong et al., 2000; Bellinger et al., 1990), mothers with low self-esteem (Surkan et al., 2008), or co-exposures to manganese (Kim et al., 2009a). Moreover, interventions that shift the population mean, in a beneficial direction, by an amount that is without clinical consequence for an individual have been shown to produce substantial decreases in the percentage of individuals with values that are clinically significant (Bellinger, 2007, 2004b).

Also supporting the public health significance of blood Pb level-associated changes in cognitive function and behavior are observations within the same cohorts that higher blood Pb level are associated with decrements in IQ and measures of executive function earlier in age and with lower academic performance, antisocial behavior, or delinquent behavior assessed later in adolescence or in early adulthood (Chandramouli et al., 2009; Wright et al., 2008; Kordas et al., 2006; Canfield et al., 2004; Kordas et al., 2004; Canfield et al., 2003b; Dietrich et al., 2001; Dietrich et al., 1993a; Bellinger et al., 1992).

Thus, the blood Pb-associated deficits measured in children may set affected children on trajectories more prone toward lower educational attainment and life success. Studies also found that higher blood Pb level is associated with measures of inattention and hyperactivity as rated by teachers or parents and by objective tests and with ADHD diagnosis or diagnostic indices (Nicolescu et al., 2010; Roy et al., 2009a; Nigg et al., 2008). These findings demonstrate that associations of blood Pb level with small changes in a health index can be markers or indicators of other changes that are likely to have occurred whose significance is more certain.

5.3.13 Summary and Causal Determination

Recent epidemiologic and toxicological studies substantiated the strong body of evidence presented in the 2006 Pb AQCD for the role of Pb in nervous system effects in two domains: cognitive function and behavior in children. Specifically, new studies of cognitive function focused on indices of learning, memory, and measures of executive function in children consistently showed Pb-related impairments. Coherence for these findings in children was provided by extensive toxicological evidence for Pb-induced impairments in homologous tests of learning and memory in juvenile rats and monkeys. New epidemiologic studies of behavior focused on and found evidence for Pb-related effects on inattention and impulsivity in children. These findings were supported by a large historical evidence base in juvenile animals. Consistent with these observations, new evidence demonstrated associations with ADHD in children. Recent studies of adults without current occupational Pb exposures continued to find associations between bone Pb levels, a biomarker of cumulative Pb exposure, and poorer cognitive function. Additional toxicological evidence for Pb-induced inhibition of neurotransmitter release, decline in synaptic plasticity, and decreases in the magnitude of LTP strengthened the biological plausibility for Pb exposure effects on decrements in both cognitive function and behavior in children. This section presents a summary of the collective body of evidence and identifies the new insights provided by recent studies.

5.3.13.1 Cognitive Function in Children

Epidemiologic studies provide robust evidence for higher blood Pb levels being associated with lower FSIQ in children ages 3-11 years (Figure 5-2 and Table 5-3), with the strongest evidence demonstrated by the consistency of association in prospective studies in diverse populations (e.g., varying distributions of blood Pb levels, SES, parental intelligence, and quality of caregiving) and the persistence of associations after adjustment for potential confounding by SES, parental intelligence, caregiving

environment, and other environmental exposures. Recent epidemiologic studies in children focused on and found associations of concurrent blood Pb levels with specific indices of cognitive function such as reading and verbal skills, memory, learning, and visuospatial processing. Several new studies shifted the weight of evidence for associations with cognitive performance to lower blood Pb levels (primarily concurrent), with populations means in the range of 2-7 µg/dL (2011; Kim et al., 2009b; Min et al., 2009; Miranda et al., 2009; Zailina et al., 2008; Chiodo et al., 2007). Evidence clearly indicates that prenatal cord and concurrent blood Pb levels are associated with lower cognitive function in younger children ages 6 months to 3 years (Table 5-4). Coherence for findings in children is derived from extensive evidence in animals that gestational and early postnatal Pb exposures resulted in impaired learning and memory, in particular, in homologous tests of spatial memory and rule learning and reversal. Reflecting the tendency to examine higher Pb exposures, toxicological studies most clearly demonstrated neurodevelopmental effects with blood Pb levels of 20-40 µg/dL in animals. However, several new studies added to the evidence for impaired learning and memory in animals with lower blood Pb levels, 8-17 µg/dL (Cory-Slechta et al., 2010; Li et al., 2009c; Niu et al., 2009; Virgolini et al., 2008a; Stangle et al., 2007).

The large body of evidence indicating associations between blood Pb levels and decrements in the diverse set of indices related to learning, memory, and other executive functions provides coherence with findings for FSIQ, a global measure of cognitive function that reflects the integration of these individual domains. Further, evidence for effects on various diverse measures of cognitive function provides biological plausibility for associations observed between blood Pb levels and factors that may be indicators of life success, including the level of educational attainment and academic performance.

5.3.13.2 Behavior in Children

Epidemiologic studies in children demonstrate associations of higher blood Pb levels with a range of behavioral problems, with the weight of evidence demonstrating associations with inattention and hyperactivity as rated by parents or teachers and as assessed using objective neuropsychological tests. Previous studies found associations with early childhood blood or tooth Pb level (i.e., ages 2-6 years), and recent studies expanded evidence to include associations with concurrent blood Pb level. Recent epidemiologic studies consistently found associations with inattention and hyperactivity in children ages 1 to 12 years with mean concurrent blood Pb levels of 2 to 5 µg/dL (Cho et al., 2010; Nicolescu et al., 2010; Plusquellec et al., 2010; Chiodo et al., 2007; Plusquellec et al., 2007), similar to those associated with cognitive function decrements. The epidemiologic findings are strengthened by observations in animals of Pb-induced

inattention and impulsivity in homologous tests of response inhibition. Such effects in animals are most clearly indicated with gestational and early postnatal Pb exposures that result in blood Pb levels of 10 to 40 µg/dL. Whereas previous evidence was inconsistent, several recent epidemiologic studies indicate associations between higher concurrent blood Pb level and higher prevalence or incidence of ADHD diagnosis and its contributing diagnostic indices in children ages 8–17 years (Cho et al., 2010; Nicolescu et al., 2010; Roy et al., 2009a; Nigg et al., 2008; Braun et al., 2006). The biological plausibility for associations with ADHD is strongly supported by the large epidemiologic and toxicological evidence base demonstrating Pb-associated increases in inattention and impulsivity, both of which are primary symptoms of ADHD. A smaller but equally consistent body of evidence indicated associations of concurrent and early childhood blood Pb levels with social misconduct in children and delinquent behaviors in adolescents and young adults (Chandramouli et al., 2009; Braun et al., 2008; Wright et al., 2008; Chiodo et al., 2007). Associations of blood Pb levels with ADHD, misconduct, and delinquency were observed in populations of children with a wide range of blood Pb levels, 1 to 11 µg/dL, all similar in the strength of evidence.

While the different behavioral indices are examined, Pb exposure also was found to affect behavior (decreased ability to escape predators or capture prey) in aquatic and terrestrial species (Sections 7.2 and 7.3).

5.3.13.3 Other Nervous System Effects in Children

A few new toxicological studies augmented the evidence for Pb-related effects to the visual system by demonstrating retinal changes in male rodent offspring in association with lower blood Pb levels (<15 µg/dL) than previously examined (20 to > 100 µg/dL) (Section 5.3.4.3). A small body of epidemiologic evidence together with a large historical base of toxicological evidence indicated associations of Pb biomarkers or exposure with impaired auditory function. Associations were found in children ranging from 4 to 19 years in age and with mean concurrent blood Pb levels of 7-12 µg/dL Section 5.3.4.1). While mood and emotional state have been examined less frequently compared with inattention and misconduct, several studies found associations of biomarkers of cumulative Pb exposure (i.e., tooth or childhood average blood Pb) and concurrent blood Pb levels with parental or teacher reports of withdrawn behavior or depression in children with mean blood Pb levels 8-28 µg/dL (Section 5.3.3.3). These findings in children are supported by a small body of toxicological studies in which prenatal plus lactational Pb exposure resulted in depression-like behavior in rodent models. Studies also reported associations of early childhood average and concurrent blood Pb levels with lower fine and gross motor function in children ages 3 to 17 years (Section 5.3.5). A common

observation across studies was finding that biomarkers of Pb exposure were associated with decrements in multiple neurodevelopmental outcomes, including cognitive function, externalizing behaviors, internalizing behaviors, and motor function, within the same population. These findings indicate that Pb exposure affects a broad spectrum of neurodevelopmental effects in children.

5.3.13.4 Factors that Modify Risk in Children

Several host and environmental factors were examined for their modification of associations between blood Pb levels and nervous system effects in children. Although each particular factor was examined in only one to two epidemiologic studies, it is important to note that several findings are supported by a larger base of toxicological evidence. Interactions of blood Pb levels with race/ethnicity and SES are not well characterized. Most investigation focused on sex-based differences. Cumulative epidemiologic evidence does not conclusively demonstrate increased risk of males or females for Pb-associated cognitive function decrements. Animal studies continue to demonstrate differential effects in males and females that vary depending on the endpoint.

The weight of evidence from animal studies continues to support interactions between developmental Pb exposure and stress. New animal studies find a potentiating effect of stress, whereby lower concentration Pb exposures impact behavior and memory with co-exposures to stress than with Pb exposures alone. In comparison, epidemiologic evidence for such interactions is sparse; however, a recent study indicated that among children with a positive social environment, as characterized by maternal self-esteem, blood Pb level is not associated with a decrease in cognitive function (Surkan et al., 2008). This finding was consistent with a previous study in rats, in which Pb-exposed animals reared in cages with enriched environments (i.e., toys) performed better in a test of spatial learning and memory than did their Pb-exposed littermates reared in traditional caging,

Studies have examined modification of Pb-associated cognitive function by genes that affect Pb toxicokinetics and/or function in neurophysiological and neurochemical processes that mediate cognition. Most investigation has focused on ALAD variants but has not consistently found to be in a consistent direction. Inconsistencies also have been observed for VDR and dopamine receptor variants. In addition to host factors, recent studies suggested that associations between blood Pb levels and cognitive function in children are greater with co-exposures to environmental tobacco smoke (Froehlich et al., 2007) and manganese (Claus Henn et al.; Kim et al., 2009b)..

5.3.13.5 Nervous System Effects in Adults

Among adults, associations of blood Pb level with the spectrum of nervous system effects (e.g., impairments in memory, attention, mood, balance, motor function) were most consistently observed in occupationally-exposed adults with blood Pb levels ≥ 14 µg/dL. Evidence in adults without occupational Pb exposures is derived primarily from cross-sectional analyses in a few different cohorts, thus the important magnitude, timing, frequency, and duration of Pb exposures contributing to the observed associations are uncertain. The weight of evidence demonstrated associations of bone Pb levels and not blood Pb levels with poorer cognitive performance, including declines in function over time (Bandeen-Roche et al., 2009; Weisskopf et al., 2007a). These findings point to a stronger effect of cumulative Pb exposure, including likely higher past exposures. One explanation for the overall weaker body of evidence in adults may be that cognitive reserve may compensate for the effects of Pb exposure on learning new information. Compensatory mechanisms may be overwhelmed with age, which may provide an explanation for more consistent associations observed for higher tibia Pb levels, representing higher long-term or cumulative Pb exposure.

Based on a smaller body of epidemiologic studies, blood and bone Pb levels were associated with essential tremor and PD, respectively, in adults (Section 5.3.7.1). However, in these case-control studies, it is difficult to establish temporality between Pb exposure and disease. Support for epidemiologic findings for PD is provided by toxicological evidence for Pb-induced decreased dopaminergic cell activity in the substantia nigra, which contributes to the primary symptoms of Parkinson's disease. Whereas evidence for association with Alzheimer's Disease in adults is weak, developmentalbut not adult-only Pb exposures of monkeys (early postnatal, PND 1-400) and rats (lactational) has been shown to induce formation of amyloid plaques, pathology that underlies Alzheimer's Disease (Section 5.3.7.2). Thus, epidemiologic studies that examined concurrent bone or brain Pb levels or occupational Pb exposure may not have examined the etiologically relevant exposure period.

Rather than examining externalizing behaviors and criminal behavior, a small body of studies of behavior in adults examined and found associations of blood (Bouchard et al., 2009) and tibia (Rajan et al., 2008) Pb levels with depression and anxiety symptoms. It is not surprising that Pb exposure may increase the risk of different nervous system endpoints in children and adults given the predominance of different neurophysiological processes operating at different ages, for example, neurogenesis and brain development in children and neurodegeneration in adults.

5.3.13.6 Neurophysiological and Neurochemical Changes

Extensive evidence from toxicological studies clearly provides the coherence and biological plausibility for effects observed in epidemiologic and toxicological studies on cognitive function, behavior, mood, and neurodegenerative conditions by characterizing underlying mechanisms (Section 5.3.8). Dopamine plays a key role in cognitive functions mediated by the prefrontal cortex and also motor functions mediated by the substantia nigra. Thus, extensive evidence for Pb-induced dopaminergic changes in animals provides mechanistic support for associations in humans between blood Pb levels and cognitive deficits and in adults for associations with Parkinson's Disease. Current toxicological research has been expanded to document that early-life Pb exposure can contribute to neurodegeneration and neurofibrillary tangle formation in the aged brains of animals. Pb has been shown to induce complex neurochemical changes in the brain that differ by region of the brain, neurotransmitter type, age and sex of the organism. These changes remain aberrant over time and are dynamic in nature. Pb exposure affects NMDA receptors, which may explain findings in animals and humans for Pb-associated symptoms of depression and withdrawn behavior. Recent toxicological studies continue to document Pb exposure effects on synapse formation, adhesion molecules, and nitrosative stress. A new study of epigenetics details that Pb exposure affects methylation patterns in rodent brains, which may provide a mechanism by which prenatal Pb exposure leads to impaired neurodevelopmental function later in life. Biological plausibility also is provided by a small body of evidence in young adults in which childhood blood Pb levels are associated with altered structure and activity in regions of the brain (assessed by MRI or MRS) that mediate cognitive processes and behavior.

5.3.13.7 Lifestages and Duration of Lead Exposure

Toxicological studies clearly demonstrate that in utero and early postnatal exposure to Pb results in impaired learning, memory, and behavior. This evidence is well supported by knowledge that processes such as neurogenesis, synaptogenesis, and synaptic pruning are most active during this developmental period. In epidemiologic studies reviewed in the 2006 Pb AQCD, biomarkers of prenatal, early life, concurrent, and cumulative Pb exposures were associated with decrements in neurodevelopmental function in children, with no clear indication that blood Pb levels measured at a particular lifestage was more strongly associated with neurodevelopmental effects (Section 5.3.9). Distinguishing among the effects of Pb exposures at different lifestages is difficult in epidemiologic studies due to the high correlations among blood Pb levels within children over time. Recent studies in children primarily examined concurrent blood Pb levels but also found association with prenatal cord (Pilsner et al., 2010; Jedrychowski et al., 2009b;

Plusquellec et al., 2007) and early childhood blood Pb levels (Chandramouli et al., 2009; Min et al., 2009; Miranda et al., 2009). Thus, while biomarkers of Pb exposure across lifestages were associated with neurodevelopmental decrements in children, the weight of cumulative evidence demonstrated associations with concurrent blood Pb levels. In adults, the weight of evidence supported associations of cumulative Pb exposure (i.e., tibia Pb) with poorer cognitive performance.

With regards to duration of exposure, several epidemiologic studies indicated that Pb exposures of less than 1 year, represented by blood Pb levels prenatally (maternal or cord) and at age 6, 12, or 24 months, were associated with lower cognitive function in children ages 6 months to 3 years (Table 5-4). Toxicological studies supported these observations with effects observed with gestational and early postnatal Pb exposures.

5.3.13.8 The Lead Concentration-Response Relationship

In the 2006 Pb AQCD, several individual epidemiologic studies, pooled analyses, and meta-analyses estimated a supralinear blood Pb concentration-response relationship in children, i.e., greater decrements in cognitive function per incremental increase in blood Pb level or more negative slope among children in lower strata of blood Pb levels compared with children in higher strata of blood Pb levels (Figure 5-23 and Table 5-15). Although a majority of epidemiologic evidence used a blood Pb level of 10 μg/dL to define lower and higher blood Pb levels, some found that among children less than age 10 years with mean concurrent blood Pb levels of 3 μg/dL, the blood Pb-cognitive function slope was more negative with blood Pb levels <7.5 (Lanphear et al., 2005) or <5 μg/dL (Tellez-Rojo et al., 2006).

While explanations for this supralinear relationship have not been well characterized by epidemiologic studies, recent toxicological studies that examined lower concentrations of experimental Pb exposure suggest that mechanisms may be differentially activated at lower and higher Pb exposures. Multiple studies showed U- or inverse U-shaped curves with lower Pb exposures having different levels or often the opposite effect from higher exposures. Nonlinear concentration-response relationships were found for effects such as learning (Section 5.3.2.2), adult forebrain dopamine levels (Leasure et al., 2008), and neurogenesis (Fox et al., 2008). Sensory organ parameters in animals, namely, the numbers of rod photoreceptors and bipolar cells and ERG wave amplitudes also show vastly different changes with low versus higher Pb exposure (Table 5-12).

The examination of populations of children with large proportions of subjects at very low blood Pb levels has improved the ability to discern a threshold for Pb-associated effects on cognitive function and behavior. Several recent epidemiologic studies reported

associations between blood Pb levels and deficits in cognitive and behavioral endpoints in children (ages 8-11 years) with mean or range of blood Pb levels ≤ 2 µg/dL (Cho et al., 2010; Kim et al., 2009b; Miranda et al., 2009). Collectively, these new findings in children do not provide evidence for a threshold for neurodevelopmental effects of Pb in the ranges of blood Pb levels examined to date.

5.3.13.9 Evidence that Forms the Basis of the Causal Determination

In summary, recent findings strengthen epidemiologic and toxicological evidence indicating that Pb exposure is associated with nervous system effects. The weight of epidemiologic and toxicological evidence clearly supports associations of higher blood Pb levels with lower cognitive function in children, i.e., full-scale IQ and various measures of learning and memory. In epidemiologic studies, these associations were substantiated in children ages 1 to 11 years and in populations with mean blood Pb levels between 2 and 7 µg/dL. Observation of a supralinear concentration-response relationship and associations with mean (or quantile) blood Pb levels < 2 µg/dL do not provide evidence for a threshold for the neurodevelopmental effects of Pb exposure. Epidemiologic and toxicological evidence clearly demonstrates Pb-associated increases in behavioral problems, in particular, inattention and impulsivity. Associations are substantiated in children ages 1 to 12 years with mean concurrent blood Pb levels of 2 to 5 µg/dL. In animals, the weight of evidence demonstrates effects on cognition and behavior with prenatal and early postnatal Pb exposures that resulted in blood Pb levels of 10 to 40 µg/dL. In epidemiologic studies, associations with cognitive function and behavior were observed after adjustment for a range of potential confounding variables, but most commonly, parental IQ, parental education, and other SES-related variables. In children, the weight of evidence supports cognitive function decrements and behavioral problems in association with concurrent blood Pb levels. Associations also are observed with prenatal, early childhood, and childhood average blood Pb levels, thus uncertainty remains regarding the lifestage of exposure within childhood that is associated with the greatest risk. The weight of toxicological evidence demonstrates neurodevelopmental effects with prenatal and early postnatal Pb exposures that can have effects persisting to adulthood. The biological plausibility for epidemiologic and toxicological findings for effects on cognitive function and behavior is provided by evidence characterizing underlying mechanisms, including Pb-induced changes in neurogenesis, synaptogenesis and synaptic pruning, long term potentiation, and neurotransmitter function. In adults, the timing, level, frequency, and duration of Pb exposure implicated in nervous system effects remain uncertain. Among occupationally-exposed adults, a spectrum of nervous system effects is associated with concurrent blood Pb level (≥ 14 µg/dL), which reflects

both current and cumulative exposure. However, in adults without occupational exposure, cognitive performance is more strongly associated with tibia Pb levels than blood Pb levels, which indicates an effect of long-term, cumulative Pb exposures. Based most heavily on cognitive function decrements and inattention in children, the collective body of evidence integrated across epidemiologic and toxicological studies is sufficient to conclude that there is a causal relationship between Pb exposures and nervous system effects.

5.4 Cardiovascular Effects

5.4.1 Introduction

The 2006 Pb AQCD (U.S. EPA, 2006b) concluded that both epidemiologic and animal toxicological studies support the relationship between increased Pb exposure and increased cardiovascular effects, in particular, increased BP and increased incidence of arterial hypertension. Although fewer in number, epidemiologic studies demonstrated associations of blood and bone Pb levels with other cardiovascular diseases (CVDs) in adults, such as ischemic heart disease, cerebrovascular disease, peripheral vascular disease, and CVD-related mortality. As the cardiovascular and renal systems are intimately linked, cardiovascular effects can arise secondarily to Pb-induced renal injury (Section 5.5). Toxicological studies also provided compelling evidence supporting the biological plausibility for Pb-associated cardiovascular effects by characterizing a number of the underlying mechanisms by which Pb exposure can lead to human cardiovascular health effects. Such studies demonstrated that the Pb content in heart tissue of animals reflects the increases in blood Pb levels (Lal et al., 1991), indicating that the cardiovascular morbidity associated with blood Pb levels may represent the effects of the bioavailable Pb in the target tissue. The strongest evidence supported the role of oxidative stress in the pathogenesis of Pb-induced hypertension. Additionally, several toxicological studies characterized other pathways or cellular, molecular, and tissue events promoting the Pb-induced increase in BP. These mechanisms included inflammation, adrenergic and sympathetic activation, renin-angiotensin-aldosterone system (RAAS) activation, vasomodulator imbalance, and vascular cell dysfunction.

With regard to the concentration-response relationship, meta-analysis of human studies found that each doubling of blood Pb level (between 1 and >40 μg/dL measured concurrently in most studies) was associated with a 1 mmHg increase in systolic BP and a 0.6 mmHg increase in diastolic BP (Nawrot et al., 2002). On a population-wide basis, the estimated effect size could translate into a clinically significant increase in the

segment of the population with the highest BP. In a moderately-sized population, a relatively small effect size thus has important health consequences for the risk of sequelae of increased BP, such as stroke, myocardial infarction, and sudden death. It was also noted that most of the reviewed studies examining bone Pb levels, biomarkers of cumulative Pb exposure, also showed increased BP (Cheng et al., 2001; Hu et al., 1996b) or increased hypertension with increasing bone Pb level (Lee et al., 2001a). Across studies, over a range of bone Pb concentrations (<1.0 to 96 μg/g), every 10 μg/g increase in bone Pb was associated with increased odds ratios of hypertension between 1.28 and 1.86. Studies observed an average increase in systolic BP of ~0.75 mmHg for every 10 μg/g increase in bone Pb concentration over a range of <1 to 52 μg/g.

With regard to etiologically-relevant timing of Pb exposure, the weight of toxicological evidence demonstrated increases in BP after long-term (> 4 weeks) Pb exposure. In epidemiologic studies, as cardiovascular outcomes were most often examined in cross-sectional studies with one or a limited number of Pb biomarker measurements, uncertainty exists as to the specific Pb exposure level, timing, frequency, and duration that contributed to the observed associations. While associations of adult bone Pb (particularly tibia Pb) with health outcomes in adults are indicative of effects related to past or cumulative exposures, interpretation of similar associations involving adult blood Pb levels, especially those measured concurrently with outcomes, are complicated by the generally higher past exposures common in this population. Detailed interpretation of Pb in blood and bone are provided in Sections 4.3 and 4.7.3. Briefly, higher past Pb exposures in adults increased their bone Pb stores which contribute to current blood Pb levels through the normal process of bone remodeling, as well as during periods of increased bone remodeling and loss (e.g., osteoporosis and pregnancy). Due to the long latency period for the development of increased BP and CVD, associations of cardiovascular effects with low concurrent blood Pb levels (e.g., population means 1.6-4 μg/dL) in adults may be influenced by higher past Pb exposures (Section 4.4.1).

This section reviews the published studies pertaining to the cardiovascular effects of Pb exposure in humans, experimental animals, isolated vascular tissues, and cultured vascular cells. With the large and strong existing body of evidence serving as the foundation, emphasis was placed on studies published since the 2006 Pb AQCD (U.S. EPA, 2006b). Epidemiologic and toxicological studies continued to augment the evidence for increases in BP and hypertension development associated with long-term Pb exposure and expanded the evidence for the biological pathways of these effects. Epidemiologic studies strengthened the evidence for associations between Pb biomarkers and cardiovascular effects after adjusting for potential confounding factors such as age, diet, alcohol use, BMI, comorbidities, and smoking. The epidemiologic evidence was

substantiated with results from several available prospective studies indicating associations between Pb biomarkers and the incidence of cardiovascular health effects.

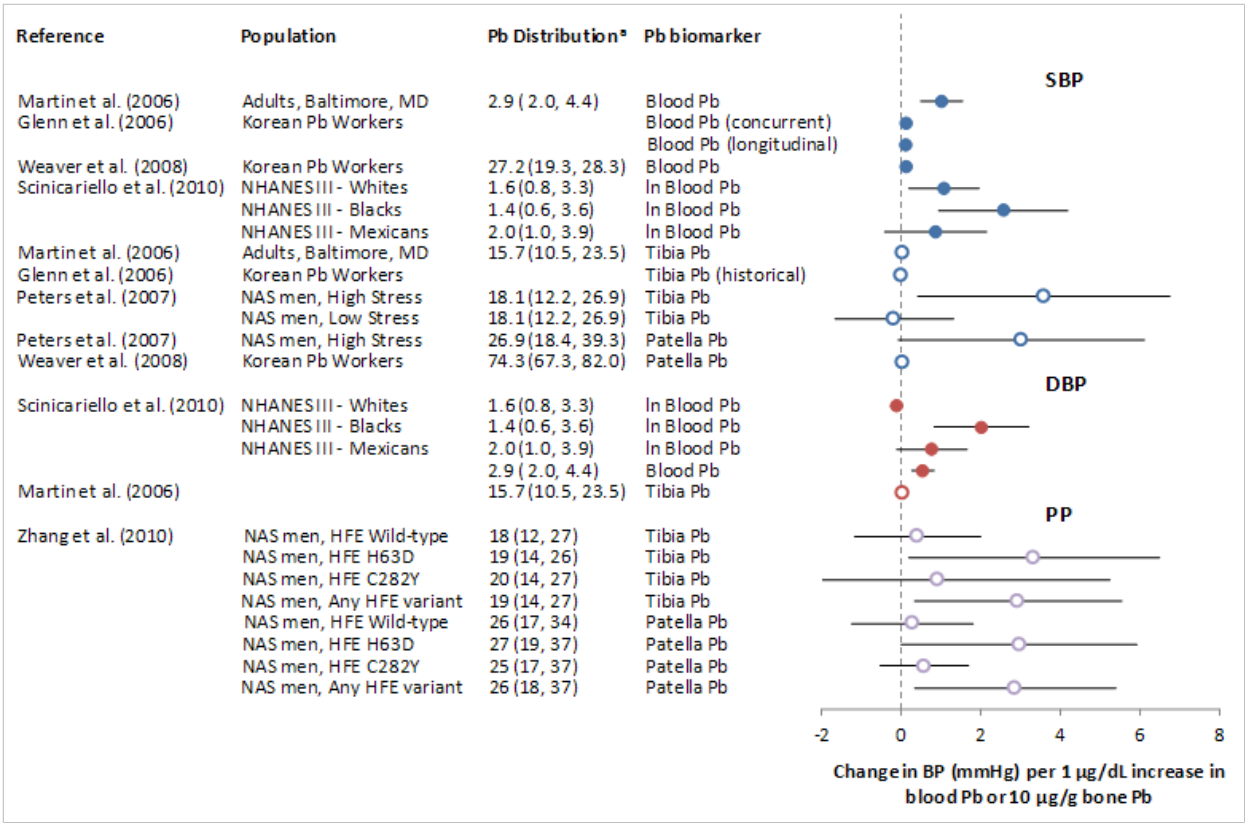
5.4.2 Blood Pressure and Hypertension

5.4.2.1 Epidemiology

The most commonly used indicator of cardiovascular morbidity was increased BP and its derived index, hypertension. Hypertension in these studies was defined as diastolic and/or systolic BP above certain cut-points or use of anti-hypertensive medicines. The BP cut-points employed have been historically established by reference to informed medical opinion, and as medical knowledge has improved BP cut-points defining hypertension have been lowered over time. Consequently, different studies using "hypertension" as a cardiovascular outcome may have assigned different cut-points, depending on the year and location of the study and the individual investigator. All of the new studies in the current review used the same criteria for hypertension (e.g., systolic BP at or above 140, diastolic BP at or above 90, or use of anti-hypertensive medications). Studies in the medical literature show that elevated BP is associated with increased risk of CVD including coronary disease, stroke, peripheral artery disease, and cardiac failure. Coronary disease (i.e., myocardial infarction, angina pectoris, sudden death) is the most lethal sequela of hypertension (Ingelsson et al., 2008; Chobanian et al., 2003; Pastor-Barriuso et al., 2003; Prospective Studies Collaboration, 2002; Kannel, 2000a, b; Neaton et al., 1995). Several recent general population and occupational cohort and cross-sectional studies strengthened the evidence that blood and bone Pb level were associated consistently with measures of BP (Figure 5-25 and Table 5-16) as well as with the prevalence and incidence of hypertension (Figure 5-26 and Table 5-17). Further, recent studies expanded evidence by finding differences in association among racial/ethnic groups, perceived stress, diet, and genetic variants and thus, identified populations potentially at increased risk of Pb-associated cardiovascular effects.

In a cross-sectional analysis, Martin et al. (2006) examined the associations of concurrent blood and tibia Pb levels with BP and hypertension in a community-based study of older adults (n = 964, age ranging from 50 to 70 years) in Baltimore, MD. A key strength of this study was the extensive consideration of potential confounding variables. Four models evaluated associations for BP and hypertension. The base model included age, sex, BMI, sodium intake, potassium intake, total cholesterol, time of day, testing technician, and hypertensive medication use. Other models added SES, race/ethnicity, or both as covariates. Blood Pb but not tibia Pb level was a strong predictor of BP in all

models; a 1 µg/dL increase in concurrent blood Pb level was associated with an approximately 1 mmHg increase in systolic BP and an approximately 0.5 mmHg increase in diastolic BP. Tibia Pb but not blood Pb was associated with hypertension in logistic regression models. The authors applied propensity analysis to their models to better account for the effect of other risk factors for hypertension such as race/ethnicity, age, and SES that were strongly associated with tibia Pb level. The propensity score analysis and model adjustment did not substantially change the numerical findings and conclusions (e.g., tibia Pb and hypertension were positively associated independently of race/ethnicity and SES), indicating that neither SES nor race/ethnicity confounded the association between tibia Pb level and hypertension. No evidence for effect modification by race/ethnicity was found either. Martin et al. (2006) concluded that Pb in blood has an acute effect on BP and that Pb contributes to hypertension risk as a function of cumulative, chronic exposure (as represented as bone Pb in this population). While different aspects of Pb exposure may contribute differentially to increases in BP and hypertension, it is important to note that concurrent blood Pb levels in adults also reflect cumulative Pb exposure. Thus, its association with BP may not reflect an acute effect but may also reflect an effect of cumulative Pb exposure.



[a]Pb distribution presents the median (IQR) that were estimated from the mean and SD assuming a normal distribution.

[b]Effect estimates were standardized to 1 µg/dL blood Pb or 10 µg/g bone Pb.

Note: In general, results are categorized by specific BP parameter, then by Pb biomarker. For categories with multiple studies, the order of the studies follows the order of discussion in the text. For associations of a 1 µg/dL increase in blood Pb level (closed circles) or 10 µg/g increase in bone Pb (open circles) with systolic BP (SBP; blue), diastolic BP (DBP; red), and pulse pressure (PP; purple) in adults.

Note: Studies are categorized by Pb biomarker. Within each category, studies generally are presented in order of discussion in the text. (a) The outcomes plotted are hypertension prevalence with the exception of Yazbeck et al. (2009) which measured pregnancy induced hypertension and Peters et al. (2007) which measured hypertension incidence. (b) ALAD2 vs. 1 indicates comparison between ALAD 2 carriers (e.g., ALAD1-2 and ALAD2-2) and ALAD 1 homozygotes (e.g., ALAD1-1). (c) Effect estimates were standardized to a 1 µg/dL increase in blood Pb. (d) Effect estimates were standardized to a 10 µg/g increase in bone Pb.

In an occupational cohort in South Korea, Glenn et al. (2006) simultaneously modeled multiple Pb dose measures of individuals collected repeatedly over four years of follow up. Thus, through the assessment of cross-sectional and longitudinal relationships with BP, this study provided key insight on potentially important time periods of Pb exposure. The initial blood Pb level was used as a baseline covariate and the difference in blood Pb level between visits was computed for each subsequent visit. The bone Pb measures were used to indicate historical exposure and cumulative dose. Four models were specified: Model 1 was conceptualized to reflect short-term changes in BP associated with recent dose; Model 2 to reflect longer-term changes associated with cumulative dose controlling for association of baseline BP with recent dose; Model 3 to reflect longer-term changes associated with cumulative dose controlling for cross-sectional influence of cumulative dose on baseline BP; and Model 4 to reflect both short-term change with recent dose and longer-term change with cumulative dose. Concurrent blood Pb and increases in blood Pb between visits were associated with increases in systolic BP in Model 1 (short-term dose) and Model 4 (short- and longer-term dose). No association was observed between BP and tibia Pb at baseline while higher tibia Pb was associated with a decrease in systolic BP in each of the models.

These results indicate that circulating Pb (e.g., blood Pb) may act continuously on systolic BP and reduction in blood Pb may contribute to reductions in BP, while cumulative Pb exposure (represented by bone Pb in this study) may contribute to hypertension incidence by different mechanisms over longer time periods and in older subjects. This analysis in relatively young subjects with a low prevalence of hypertension suggests that at least one of the biological pathways that influences how systolic BP

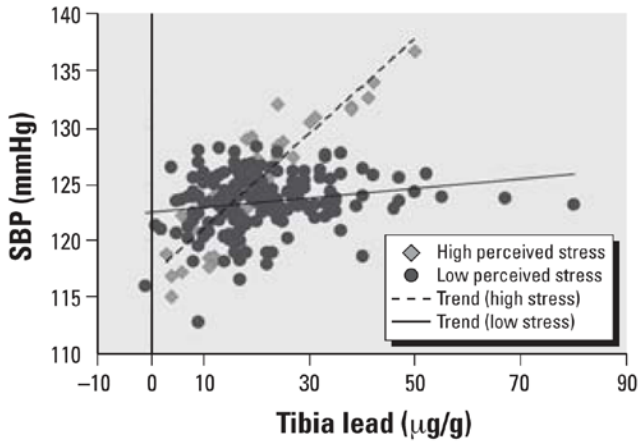
responds to Pb operates over a relatively rapid timeframe and may reflect an immediate response to Pb at a biochemical site of action as a consequence of the biologically available Pb circulating in blood. A persistent effect of cumulative doses over a lifetime may occur via other mechanisms. This study was strengthened by the analysis of associations between changes in blood Pb and changes in BP over time within individual subjects. Bone Pb level may exert influence on blood Pb levels and consequently on BP in an aging population with prolonged Pb exposure. Thus, there is strength in the conclusions drawn from this study that inform various short and long-term exposure relationships with increases in BP and hypertension. It is important to acknowledge the uncertainty regarding the applicability of these findings regarding short-term and long-term effects in Pb workers with relatively high current Pb exposures contributing to blood Pb levels (mean blood Pb levels over time: 20-37 µg/dL) to adults in the U.S. general population whose concurrent blood Pb levels are influenced more by Pb mobilized from bone stores.

In a separate analysis of the same occupationally exposed group in year three of follow-up, Weaver et al. (2008) examined cross-sectionally associations of concurrent patella Pb and blood Pb level with systolic BP, diastolic BP, and hypertension and effect modification by ALAD and vitamin D receptor (VDR) polymorphisms. None of the Pb biomarkers were associated with diastolic BP. Patella Pb alone was not significantly associated with systolic BP, while blood Pb, either alone or with patella Pb was significantly associated with higher systolic BP. The patella Pb-age and blood Pb-age interactions were not statistically significant. There were no significant associations of blood Pb or patella Pb with hypertension status or effect modification by age or sex. Further, interactions between polymorphisms of the VDR and of ALAD with blood Pb and patella Pb on systolic BP were not statistically significant. Mean blood Pb level was high (30.9 µg/dL) compared to non-occupational groups.

Weaver et al. (2010) provided the results of further analysis of this Korean worker cohort, with a focus on determining the functional form of the concentration-response relationships. In a log linear model, the coefficient indicated that every doubling of blood Pb level was associated with a systolic BP increase of 1.76 mmHg. The J test, a statistical test for determining which, if either, of two functional forms of the same variable provides a superior fit to data in non-nested models (Davidson and MacKinnon, 1981), returned a p-value of 0.013 in favor of the natural log blood Pb level over the linear blood Pb level specification. This analysis indicates that the systolic BP increase in this cohort is better described as a logarithmic function of blood Pb level within the blood Pb level range of the study than by a linear function.

Several analyses in the NAS cohort of predominantly white older men in the greater Boston area found associations of blood and bone Pb level with BP and hypertension and indicated effect modification by calcium intake, perceived stress, and HFE gene variants. In a cross-sectional analysis, Perlstein et al. (2007) found a statistically significant association between blood Pb and diastolic BP in adjusted models. The subjects in this study had at least one bone Pb measurement during the years 1991-1997 and were not on antihypertensive medication at the time of the measurement. While tibia Pb was not significantly associated with BP, it was associated with pulse pressure (PP). Men with tibia Pb above the median (19 μg/g) had a higher mean PP (4.2 mmHg [95%CI: 1.9, 6.5]) compared to men with tibia Pb below the median. The trend toward increasing PP with increasing quintile of tibia Pb was statistically significant although none of the confidence intervals for PP referenced to the lowest quintile of tibia Pb (< 7.4 μg/g) excluded the null value.

Peters et al. (2007) examined cross-sectionally the modification of the associations of tibia and patella Pb with BP and hypertension by self-reported stress (assessed by questionnaire) in NAS men. High stress also has been linked with higher BP, potentially via activation of sympathetic pathways, ROS, and the HPA axis. Among all subjects, higher bone Pb level was associated (statistically nonsignificant) with greater odds of hypertension status and higher systolic BP. As indicated in Figure 5-27, the association between systolic BP and tibia Pb differed between those with high and low self-reported stress (β for tibia Pb x stress interaction = 3.77 [CI: 0.46, 7.09]) per SD increase in tibia Pb. Stress also was found to modify the patella Pb-BP association (β for patella Pb x stress interaction = 2.60 [CI: -0.95, 6.15] per SD increase in patella Pb). Neither bone, self-reported stress, nor their interaction was associated significantly with diastolic BP. Peters et al. (2007) also used Cox proportional hazards models to assess the interaction of stress and bone Pb level in the development of hypertension among those free of hypertension at baseline. The results of this analysis showed that increasing tibia and patella Pb were associated with greater risk of developing hypertension among those with high stress compared with those with lower perceived stress (RR of developing hypertension among those with high stress: 2.66 [CI: 1.43, 4.95] per SD increase in tibia Pb and 2.64 [CI: 1.42, 4.92] per SD increase in patella Pb). These results provide evidence supporting adults with higher stress as a population at increased risk of Pb-associated cardiovascular effects.



Source: Peters et al. (2007)

Figure 5-27 The relationship between tibia Pb and estimated systolic BP (SBP) for those with high self-reported stress versus those with low self-reported stress.

Elmarsafawy et al. (2006) examined the modification of the relationship between Pb and hypertension risk by dietary calcium, with 467 subjects from the NAS. Responses on a semi-quantitative dietary frequency questionnaire with one-year recall were used to estimate calcium intake. Effect modification by calcium intake (dichotomized at 800 mg/day) was examined using interaction terms in logistic regression models and by conducting analyses stratified on the calcium variable. Increasing bone and blood Pb increased the risk of hypertension, particularly among subjects with low dietary calcium.

Zhang et al. (2010a) examined the effect of polymorphisms of the hemochromatosis gene (HFE) on the relationship of bone Pb with PP in NAS men. Subjects had up to three PP measurements during the 10 year study period. The overall results demonstrated a strong relationship between bone Pb and PP in this study, similar to an earlier cross-sectional PP study of many of the same subjects (Perlstein et al., 2007). Zhang et al. (2010a) extended these findings by demonstrating larger increases in PP per unit increase in tibia and patella Pb level among those with the H63D variant compared to those with the wild-type or the C282Y variant.

A small number of cross-sectional studies examined and found that blood Pb level was associated with hypertension in pregnancy. Yazbeck et al. (2009) examined a community-based group of pregnant women in France and unlike most other studies, adjusted for potential confounding by blood concentrations of cadmium, manganese, and selenium. Pregnancy induced hypertension (PIH) was defined as systolic BP >140 mmHg and/or diastolic BP >90 mmHg during at least two clinic visits after week 22 of gestation. Patients with pre-existing chronic hypertension were excluded. The mean (SD) blood Pb

levels measured during pregnancy were 2.2 (1.4 µg/dL) in PIH cases and 1.9 (1.2) µg/dL in normotensive women. An association between blood Pb and PIH was observed (OR 3.29 [95% CI: 1.11, 9.74] per unit increase in log-transformed blood Pb level). Cadmium and selenium concentrations were comparable between PIH and no PIH groups. Adjustment for the metals slightly attenuated but did not eliminate the association between blood Pb levels and the risk of PIH. Investigators observed no significant interactions among blood Pb level, any of the other elements, and maternal characteristics in predicting the risk of PIH. Interaction between blood selenium and Pb concentrations was not significant, and the putative protection effects of selenium through antioxidative properties were not found in this study.

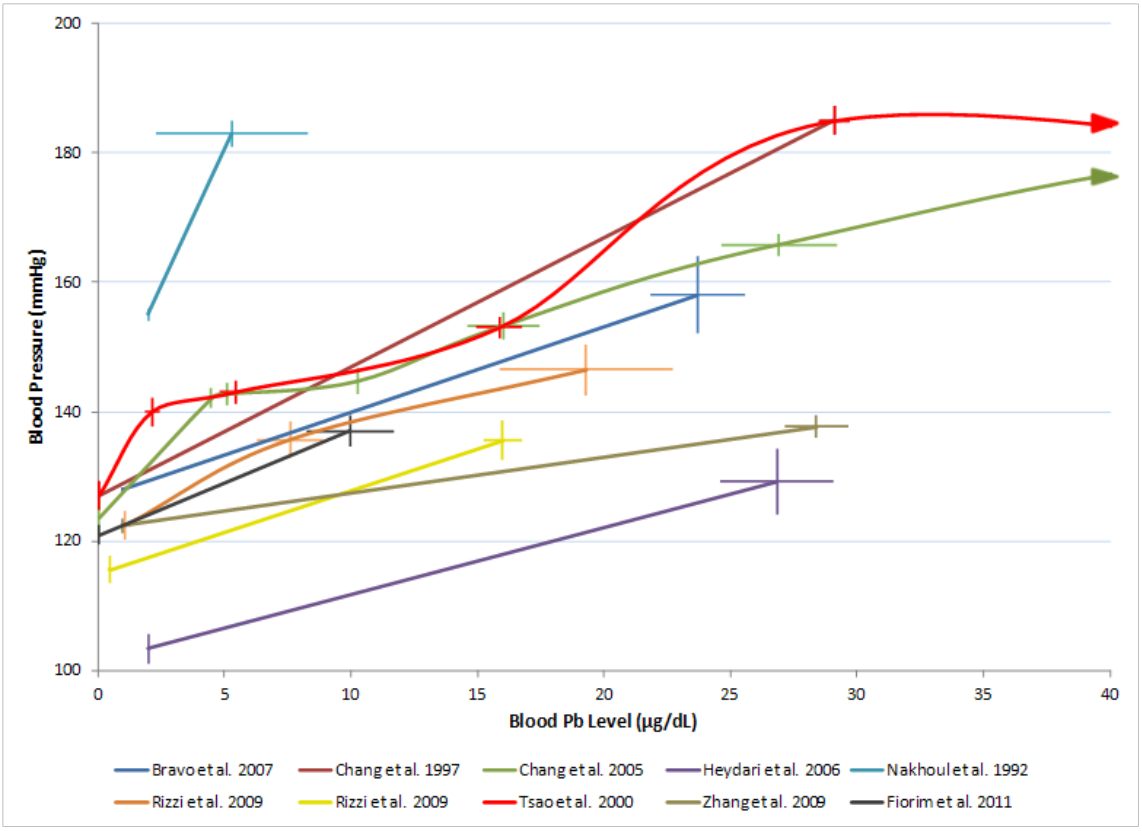
Wells et al. (2011b) measured the relationship of cord blood Pb with BP in 285 women at admission to the Johns Hopkins Hospital in Baltimore, MD, during labor and delivery. Women with cord blood Pb levels in the highest quartile for the study group (>0.96 µg/dL) had significantly higher systolic and diastolic BP (upon admission and for maximum BP) compared to women in the first quartile (<0.46 µg/dL). The authors used Benchmark Dose Software V2.1, developed by the EPA, to estimate the blood Pb level (benchmark dose or BMD) and the associated lower confidence limit (BMDL) that was associated with one standard deviation (SD) increase in BP. In this study group, one SD is approximately equivalent to a 10% increase above the mean for the first quartile blood Pb reference group. The BMD approach was used only as a means of quantifying the relationship of blood Pb with BP in this population. This analysis indicated that the 95% lower bound confidence limit on the maternal blood Pb level (estimated from cord blood Pb levels) that was associated with a 1 SD increase in all blood pressure outcomes was about 1.4 µg/dL. These reported results are similar to those reported in the 2006 Pb AQCD as well as those found 25 years ago but with blood Pb levels in the more recent study an order of magnitude lower.

New analyses using NHANES data continued to indicate associations of Pb biomarkers with BP and hypertension. Muntner et al. (2005) previously used the NHANES 1999-2002 data to indicate that concurrent blood Pb levels were associated with hypertension, peripheral artery disease (PAD), and chronic kidney disease. The PAD results are discussed later in Section 5.4.3.4, and chronic kidney disease results are discussed in Section 5.5.2.2. Blood Pb increased regularly with age (geometric means [95% CIs]: 1.28 µg/dL [1.23, 1.33] in the 18-39 age group to 2.32 µg/dL [2.20, 2.44] in the 75 and older age group). Associations were observed between concurrent blood Pb level and hypertension across race/ethnicity groups with significant trends observed for non-Hispanic blacks and Mexican Americans.

In the NHANES III 1988-1994 population, Scinicariello et al. (2010) found a gene-environment interaction between blood Pb level and ALAD genotype in relation to SBP and DBP in a cross-sectional analysis. These interactions varied across race/ethnicity strata. The strongest associations were observed among non-Hispanic blacks (Figure 5-25, Table 5-16). A statistically significant interaction was observed between concurrent blood Pb level and ALAD1-2/2-2b among non-Hispanic whites and non-Hispanic blacks. Scinicariello et al. (2010) also found an interaction between ALAD genotype and blood Pb level in the association with hypertension. Statistically significant associations between concurrent blood Pb level and hypertension were observed among non-Hispanic blacks and nonsignificant increases were observed among non-Hispanic whites and Mexican Americans (with the exception of Q2 association for Mexican Americans) (Figure 5-26, Table 5-17). In addition, non-Hispanic white ALAD2 carriers in the highest blood Pb level quartile 3.8-52.9 µg/dL) had a significantly higher association with hypertension compared with ALAD1 homozygous individuals in the highest quartile of blood Pb. In the same NHANES population, Park et al. (2009a) predicted bone Pb levels using a model developed with NAS data. Concurrent blood Pb was associated with hypertension overall in the NHANES population, with larger associations observed among black men and women as well as older adults Figure 5-26, Table 5-17). Associations also were observed with estimated bone Pb.

5.4.2.2 Toxicology

Studies on the effect of Pb (as blood Pb level) on systolic BP in unanesthetized adult rats consistently reported an increase in BP with increasing blood Pb level as shown in Figure 5-28 (results summarized in Table 5-18). An array of studies have provided evidence that long-term Pb exposure (> 4 weeks), resulting in blood Pb levels below 10 µg/dL can result in the onset of hypertension (after a latency period) in experimental animals that persists long after the cessation of Pb exposure (U.S. EPA, 2006b). Tsao et al. (2000) presented evidence for increased systolic and diastolic BP in rats with blood Pb levels relevant to those in humans (mean [SD]: 2.15 [0.92] µg/dL blood Pb; 140 [7] mmHg systolic BP, 98 [7] mmHg diastolic BP) compared to untreated controls (mean [SD]: 0.05 [0.05] µg/dL blood Pb; 127 [7] mmHg systolic BP, 88 [7] mmHg diastolic BP). As this was the lowest Pb level tested, no evidence of a threshold was evident. Further, a test for linear trend revealed a statistically significant, positive trend for increasing BP with increasing blood Pb levels up to 56 µg/dL (e.g., mean [SD]: 5.47 [2.1] µg/dL blood Pb; 143 [6] mmHg systolic BP, 97 [8] mmHg diastolic BP), with the effect leveling off at higher blood Pb levels.



Note: Crosses represent standard error for blood Pb and BP measurements. If no crossbar is present, error results were not reported. Arrows represent higher doses tested.

Figure 5-28 Changes in BP after Pb exposure (represented as blood Pb level) in unanesthetized adult rats across studies.

[a]Studies are presented in order of increasing duration of exposure.
[b]Standard deviation converted to SEM.
[c]Difference in systolic BP (SBP) between group means not within one exposure group.

Experimental animal studies continued to provide evidence that long-term Pb exposure results in sustained arterial hypertension after a latency period. Systolic BP increased in rats after exposure to 90-10,000 ppm Pb (as Pb-acetate in drinking water) for various time periods that resulted in blood Pb levels between 19.3-240 µg/dL (Mohammad et al., 2010; Zhang et al., 2009a; Badavi et al., 2008; Grizzo and Cordellini, 2008; Reza et al., 2008; Bravo et al., 2007; Vargas-Robles et al., 2007; Heydari et al., 2006; Bagchi and Preuss, 2005). Past studies have shown statistically significant elevations in BP in rats with lower blood Pb levels. For example, long-term Pb exposure to spontaneously hypertensive rats (resulting in mean [SEM] blood Pb level: 5.3 [3] µg/dL) led to increased BP (Nakhoul et al., 1992). Consistent with measurements of systolic BP by tail-cuff plethysmography, Pb exposure (100 ppm for 14 weeks; mean blood Pb level: 24 µg/dL) also caused an increase in intra-aortic mean arterial pressure (Bravo et al., 2007). In a study that tested low levels of Pb exposure (30 ppm; mean blood Pb level: 7.6 µg/dL), a statistically significant increase in systolic BP was not observed despite elevated blood Pb level after 8 weeks of treatment. Nonetheless, there was a trend of higher BP with higher blood Pb levels (Rizzi et al., 2009).

Studies found that Pb-induced increased BP persisted long after cessation of Pb exposure. Bagchi and Preuss (2005) found that elevated systolic BP was maintained for 210 days after Pb exposure cessation. However, chelation therapy using $Na_2CaEDTA$ returned systolic BP to levels comparable to those in rats not treated with Pb (Bagchi and Preuss, 2005). Chang et al. (2005) reported a partial reversibility of effect after cessation of Pb exposure, where Pb-induced elevated BP decreased but did not return to control levels 7 months post Pb exposure. After Pb exposure was removed, blood, heart, aorta, and kidney Pb levels decreased quickly within the first three months (Chang et al., 2005). Pb-induced elevated systolic BP persisted for one month following Pb exposure cessation, followed by obvious decreases in BP until 4 months after Pb exposure cessation. Between 4 and 7 months after Pb exposure cessation, the still-elevated BP did not decrease further, thus never returning to control BP levels. Decreases in BP were strongly correlated with decreases in blood Pb level after exposure cessation.

The aforementioned studies all assessed the relationship between long-term exposure (> 4 weeks) of rats to Pb and measures of BP. However, recent research also investigated BP elevation occurring after short-term treatment with Pb (< 4 weeks). Studies found increased systolic BP after 7 days of Pb treatment (daily injections resulting in mean [SEM] blood Pb levels of 9.98 [1.7] µg/dL) (Fiorim et al., 2011) and after 2 weeks of Pb exposure (100 ppm via drinking water) (Sharifi et al., 2004). A study utilizing intra-arterial pressure measurements found that a single high-dose Pb injection (resulting in mean [SEM] blood Pb levels of 37 [1.7] µg/dL) increased systolic arterial pressure after only 60 minutes (Simões et al., 2011). These studies suggest that there is the potential for increase in BP following short-term Pb treatment. It is possible that the increases in BP following short- and long-term Pb exposures are occurring through separate mechanisms; however, studies using both short- and longer-term Pb exposure have correlated increased BP with an activation of the renin-angiotensin system (i.e., increase in angiotensin converting enzyme (ACE) activity) (Section 5.4.2.3). Several of these aforementioned studies used the injection route of Pb administration, and the relevance of these bolus doses over short periods of time to human routes of short-term exposure is uncertain. However, it is important to acknowledge that the results were similar to those from the study that examined short-term exposure to Pb via drinking water,

5.4.2.3 Hypertension Modes of Action

The 2006 Pb AQCD examined a number of mechanisms leading to Pb-induced hypertension, including oxidative stress, hormonal and blood pressure regulatory system dysfunction, vasomodulation, and cellular alterations. As described below, recent studies

in experimental animals and cells further supported roles for these potential mechanisms in mediating hypertension from Pb exposure.

Oxidative Stress Response - Reactive Oxygen Species and Nitric Oxide

Several studies discussed in the 2006 Pb AQCD demonstrated a role for oxidative stress in the pathogenesis of Pb-induced hypertension, mediated by the inactivation of nitric oxide ($^{\bullet}$NO) and downregulation of soluble guanylate cyclase (sGC) (Dursun et al., 2005; Attri et al., 2003; Gonick et al., 1997; Vaziri et al., 1997; Khalil-Manesh et al., 1994; Khalil-Manesh et al., 1993b). Pb-induced reduction of biologically active $^{\bullet}$NO was found not to be due to a reduction in $^{\bullet}$NO-production capacity (Vaziri and Ding, 2001; Vaziri et al., 1999b); instead it was found to result from inactivation and sequestration of $^{\bullet}$NO by ROS (Malvezzi et al., 2001; Vaziri et al., 1999a). Oxidative stress from Pb exposure in animals may be due to upregulation of NAD(P)H oxidase (Ni et al., 2004; Vaziri et al., 2003), induction of Fenton and Haber-Weiss reactions (Ding et al., 2001; Ding et al., 2000), and failure of the antioxidant enzymes, CAT and GPx, to compensate for the increased ROS (Farmand et al., 2005; Vaziri et al., 2003). Many biological actions of $^{\bullet}$NO, such as vasorelaxation, are mediated by cGMP, which is produced by sGC from the substrate GTP. Oxidative stress also has been found to play a role in Pb-induced downregulation of sGC (Farmand et al., 2005; Courtois et al., 2003; Marques et al., 2001). The reduction of the vasodilator $^{\bullet}$NO leads to increased vasoconstriction and BP.

Pb-induced oxidative stress also has been found to induce renal tubulointerstitial inflammation which plays a crucial role in models of hypertension (Rodriguez-Iturbe et al., 2005; Rodriguez-Iturbe et al., 2004). Tubulointerstitial inflammation from treatment with Pb has been coupled with activation of the redox sensitive NF-κB (Ramesh et al., 2001). Pb-induced hypertension, inflammation, and NF-κB activation can be ameliorated by antioxidant therapy (Rodriguez-Iturbe et al., 2004). There is mixed evidence to suggest that Pb-induced hypertension may also be promoted by activation of PKC leading to enhanced vascular contractility (Valencia et al., 2001; Watts et al., 1995).

Recent studies continued to provide evidence for the role of ROS and $^{\bullet}$NO metabolism in Pb-induced hypertension and vascular disease. Increased systolic BP after Pb exposure was accompanied by increased superoxide ($O_2^{\cdot-}$) and $O_2^{\cdot-}$ positive cells (Bravo et al., 2007; Vargas-Robles et al., 2007), elevated urinary malondialdehyde (MDA, a measure of lipid peroxidation) (Bravo et al., 2007), and increased 3-nitrotyrosine (Vargas-Robles et al., 2007). Inhibition of NAD(P)H oxidase, an enzyme that generates $O_2^{\cdot-}$ and hydrogen peroxide, was able to block Pb-induced (1 ppm) aortic contraction to 5-hydroxytryptamine (5-HT) (Zhang et al., 2005). Increases in systolic BP, intra-aortic mean arterial pressure, and MDA after Pb exposure (100 ppm; mean blood Pb level:

23.7 µg/dL) were also prevented by treatment with the immunosuppressant, mycophenolate mofetil (MMF) (mean blood Pb level in MMF-treated animals: 27 µg/dL) (Bravo et al., 2007). MMF has been shown to inhibit endothelial NAD(P)H oxidase, which could explain how it decreases Pb-induced increases in oxidative stress and BP. MMF was not found to alter blood Pb levels of animals. Red grape seed extract and ascorbic acid supplementation were also able to protect rats from Pb-induced (100 ppm) increased BP and heart rate, perhaps through the antioxidant properties of the extract (Badavi et al., 2008) and vitamin (Mohammad et al., 2010). Red grape seed extract did not alter the accumulation of Pb in blood, indicating that its protective effect was not mediated through altered Pb toxicokinetics; however, internal doses of Pb were not measured in the vitamin C study to clarify the mechanism of action of vitamin C. Another study found that the antioxidant, anti-inflammatory chemical, curcumin, as well as physical exercise training reversed Pb-induced increases in serum creatinine kinase-MB (CK-MB), low density lipoprotein (LDL), heart high-sensitivity C-reactive protein (hs-CRP), and MDA, and Pb-induced decreases in serum total antioxidant capacity, high density lipoprotein (HDL), and heart glutathione peroxidase (GPx); however, internal doses of Pb were not measured to clarify the mechanism of action in this study (Roshan et al., 2011).

Exposure to Pb can also affect the activity and levels of antioxidant enzymes. Male (♂) and female (♀) rats exposed to Pb for 18 weeks (100-1,000 ppm) had altered responses in antioxidant enzymes in heart tissue (Sobekova et al., 2009; Alghazal et al., 2008a). Pb exposure in female rats increased the activity of cardiac SOD, GST, GR, and GPx (> 100 ppm) and increased cardiac thiobarbituric acid reactive substances (TBARS, measure of lipid peroxidation) (1,000 ppm). Pb exposure in male rats did not affect the activity of SOD or production of TBARS, however decreased the activity of GST and GR (>100 ppm). Male and female rats also accumulated different amounts of Pb in the cardiac tissue after similar exposure (♂ 100 ppm: 205% of control, 1,000 ppm: 379%; ♀ 100 ppm: 246%, 1,000 ppm: 775%), which could explain the sex differences observed in antioxidant enzyme responses.

Oxidative stress can trigger a cascade of events that promote cellular stress, renal inflammation, and hypertension. As was shown previously (Rodriguez-Iturbe et al., 2005), Pb exposure can increase renal NF-κB, which was associated with tubulointerstitial damage and infiltration of lymphocytes and macrophages (Bravo et al., 2007). These events could also be ablated by MMF treatment, likely due to its anti-inflammatory and antioxidant properties. Pb also was found to induce inflammation in human endothelial cells as a model for vessel intima hyperplasia (Zeller et al., 2010). The pro-inflammatory cytokine, interleukin (IL)-8 protein and mRNA were increased, concentration- and time-dependently, after in vitro Pb exposure (5-50 µM). Enhanced IL-

8 production was mediated through activation of the transcription factor Nrf2 (but not NF-κB, hypoxia inducible factor-1, or aryl hydrocarbon receptor), as shown through increased nuclear translocation and Nrf2 cellular knockdown experiments. Additionally, measures of endothelial stress, NQO1 and HO-1 protein, were induced by Pb exposure (Zeller et al., 2010). Pb treatment (20 ppm, i.p., 3 days/week, 8 weeks) increased the inflammatory markers hs-CRP and CK-MB in rat hearts (Roshan et al., 2011).

Oxidative stress affects vascular reactivity and tone through inactivation and sequestration of •NO, causing a reduction in biologically active •NO. Recent studies affirmed past conclusions on the interplay of ROS and •NO metabolism in the cardiovascular effects of Pb. Elevated systolic BP and altered vasorelaxation after Pb exposure was accompanied by a decrease in total nitrates and nitrites (NO_X) (Mohammad et al., 2010; Zhang et al., 2007a; Heydari et al., 2006). Serum NO_X levels in Pb-treated rats remained depressed for 8 weeks and then reversed after 12 weeks, despite continued elevation in systolic BP (Heydari et al., 2006). This return of serum NO_X levels to levels similar in controls could be a result of compensatory increases in endothelial NOS (eNOS) attempting to replenish an over-sequestered •NO supply. With this in mind, studies showed increased eNOS protein expression after long-term Pb exposure in kidney (Zhang et al., 2007a) and isolated cultured aorta (Vargas-Robles et al., 2007). No change in inducible NOS was observed in isolated cultured aorta after 1 ppm Pb exposure (Zhang et al., 2007a). In contrast to long-term exposure, Pb treatment over a short time period (daily injections resulting in mean [SEM] blood Pb levels of 9.98 [1.7] µg/dL) was found to increase iNOS and phosphorylated eNOS protein (Fiorim et al., 2011) which may cause an increase in •NO production and a short-term increase in •NO bioavailability. This increase in •NO bioavailability early after Pb exposure could be the immediate compensatory mechanism against the elevation in BP.

•NO, also known as endothelium-derived relaxing factor, is a potent endogenous vasodilator. Toxicological studies continued to investigate the effects of Pb on •NO-dependent vascular reactivity by using •NO stimulating vasodilators, such as acetylcholine (ACh) and sodium nitroprusside (SNP), and •NO inhibiting vasoconstrictors, such as L-NAME. Studies provided mixed evidence; however, results suggested that Pb disrupts the vasorelaxant response to •NO in the aorta due to damage to the endothelium. Pb exposure (1 ppm and 100 µM, 1 hour) decreased ACh-induced vasorelaxation, which triggers the release of •NO from the endothelial cell, in isolated rat tail artery, suggesting damage to the endothelium (Silveira et al., 2010; Zhang et al., 2007a). In aortic rings of perinatally exposed rats (1,000 ppm through pregnancy and lactation, mean blood Pb level: 58.7 µg/dL), blocking NOS with L-NAME abolished the relaxant response evoked by ACh (Grizzo and Cordellini, 2008). However, there was no change observed in the relaxation response to ACh by Pb alone (Fiorim et al., 2011; Rizzi

et al., 2009; Grizzo and Cordellini, 2008). Conversely, Skoczynska and Stojek (2005) found that Pb exposure (50 ppm; blood Pb level 11.2 µg/dL) enhanced •NO-mediated vasodilation by ACh in rat mesenteric arteries, and NOS inhibition enhanced the ACh relaxant response. A number of studies found that Pb exposure did not affect smooth muscle integrity since SNP-induced vasorelaxation, which is endothelium independent, was unchanged (Fiorim et al., 2011; Silveira et al., 2010; Rizzi et al., 2009; Grizzo and Cordellini, 2008).

•NO also was found to play a role in the interaction between Pb and the vasoconstrictor response. Blocking NOS with L-NAME or inhibiting iNOS specifically, which decreases •NO production, increased the contraction of aortic rings to the vasoconstrictor phenylephrine (PHE) and Pb exposure potentiated this response (Fiorim et al., 2011). Also, L-NAME increased the Pb pressor response to PHE after perinatal Pb exposure (1,000 ppm through pregnancy and lactation, blood Pb level 58.7 µg/dL) (Grizzo and Cordellini, 2008). Conversely, in rat renal interlobar arteries, Pb exposure blunted the increase in renal angiotensin II (AngII)-mediated contraction from NOS inhibition by L-NAME (Vargas-Robles et al., 2007). Treatment with the SOD mimetic tempol, which would increase •NO bioavailability, decreased, but did not eliminate, the Pb pressor response (Silveira et al., 2010).

In summary, recent studies continued to provide evidence for the role of ROS in Pb-induced hypertension and vascular disease by indicating Pb-induced increases in ROS and modulation of cardiovascular responses by antioxidant substances. Additionally, recent studies continued to show that Pb-induced hypertension and vascular responses are mediated primarily via inactivation of •NO not via inhibition of •NO production.

Vascular Reactivity

Alteration of the adrenergic system from Pb exposure, which can increase peripheral vascular resistance, and thereby arterial pressure, may be one cause of Pb-induced hypertension. Pb exposure in animals can increase stimulation of the sympathetic nervous system (SNS), as shown by increased plasma levels of norepinephrine (NE) and other catecholamines (Carmignani et al., 2000; Chang et al., 1997), and decreased β adrenergic receptor density and β agonist-stimulated cAMP production in the aorta and heart (Tsao et al., 2000; Chang et al., 1997). These stimulatory effects on the SNS paralleled the effects of Pb on BP, cardiac contractility, and carotid blood flow. Pb-induced elevations in arterial pressure and heart rate were abrogated by ganglionic blockade (Simões et al., 2011; Lai et al., 2002). Arterial pressure and heart rate gradually decreased 7 months after Pb exposure cessation as did the Pb-induced SNS alterations (Chang et al., 2005).

Increases in BP can be caused by activation of the SNS, which can lead to vascular narrowing, in turn, resulting in increased total peripheral resistance. In this neural mechanism, activation of the SNS leads to vasoconstriction, whereas inhibition leads to vasodilation. It has been suggested that Pb leads to increased vascular reactivity to catecholamines (i.e., epinephrine, NE, and dopamine), hormones of the SNS. Indeed, the isolated mesenteric vessel bed from Pb-treated rats (50 ppm with blood Pb level: 11.2 µg/dL, but not 100 ppm with blood Pb level: 17.3 µg/dL) exhibited increased reactivity to NE (Skoczynska and Stojek, 2005). However, in another study, 100 ppm Pb did not affect the NE-induced contractile response after 10 months of exposure (Zhang et al., 2009a), suggesting a small range of Pb doses affects pressor response to NE. Catecholamines act primarily through the adrenergic and dopaminergic receptors. Antagonists of α1-adrenergic, α2-adrenergic, β-adrenergic, and dopamine D1 receptors were found to abolish Pb-induced aortic contraction (Fazli-Tabaei et al., 2006; Heydari et al., 2006). However, the α1-adrenergic receptor agonist PHE induced aortic contractions and these were enhanced by treatment with Pb (100 ppm; blood Pb level: 26.8 µg/dL), indicating a specific role for the α1-adrenergic receptor (Silveira et al., 2010; Grizzo and Cordellini, 2008; Heydari et al., 2006). Removal of the endothelium blunted the PHE-induced contraction. Conversely, short-term Pb exposure (7 days) decreased the contractile response induced by PHE in rat aortas resulting in a decreased vascular reactivity (Fiorim et al., 2011). This decrease may be playing a compensatory role in attempting to correct the Pb-induced BP elevation. Additionally, Pb blunted the isoproterenol-induced relaxation, supporting a role for the β-adrenoceptors (Vassallo et al., 2008; Heydari et al., 2006).

Recently, there was mixed evidence for Pb disrupting vascular reactivity to other pressor agents. Pb (1 ppm) treatment of isolated rat thoracic aorta increased 5-HT induced contraction, which was endothelium dependent, but not due to 5-HT2B receptor expression (Zhang et al., 2005). Follow-up of this study in whole animals found, on the contrary, that Pb (100 ppm; blood Pb level: 28.4 µg/dL) decreased the maximum contractile response to 5-HT, but did not affect 5-HT plasma levels or 5-HT2B receptor expression (Zhang et al., 2009a). In addition, Pb exposure (100 ppm, 12 weeks) increased the renal vascular response to AngII in isolated perfused kidneys from Pb-exposed rats (Vargas-Robles et al., 2007).

Studies continued to investigate the effects of Pb on $^{\bullet}$NO-dependent vascular reactivity by using $^{\bullet}$NO stimulating vasodilators, such as ACh and SNP, and $^{\bullet}$NO inhibiting vasoconstrictors, such as L-NAME. These studies were discussed in the preceding section (Oxidative Stress Response).

Renin-Angiotensin-Aldosterone and Kininergic Systems

The adrenergic system also affects the renin-angiotensin-aldosterone system (RAAS), which is responsible for fluid homeostasis and BP regulation, and has been shown to be affected by Pb exposure. A meta-analysis found that Pb exposure (resulting in blood Pb levels: 30-40 µg/dL) increased plasma renin activity and renal tissue renin in young but not old rats (Vander, 1988). Exposure of experimental animals to Pb also induced increases in plasma, aorta, heart, and kidney angiotensin converting enzyme (ACE) activity; plasma kininase II, kininase I, and kallkrein activities; and renal AngII positive cells (Rodriguez-Iturbe et al., 2005; Sharifi et al., 2004; Carmignani et al., 1999). ACE activity declined over time while arterial pressure stayed elevated, suggesting that the RAAS may be involved in the induction, but not the maintenance of Pb-induced hypertension in rats.

Recent studies continued to implicate the RAAS in the development of Pb-induced hypertension, especially during early exposure in young animals. AngII, a main player in the RAAS, induces arteriolar vasoconstriction leading to increased BP. Pb exposure increased the vascular reactivity to AngII (Vargas-Robles et al., 2007). Acute (60 minutes) or short-term (7 days) exposure of Pb to rats increased the plasma ACE activity (Fiorim et al., 2011; Simões et al., 2011), and Fiorim et al. (2011) additionally found this increase to be correlated with the Pb-induced increase in systolic BP. However, at these short time points there were no changes in the AngII receptors 1 or 2 protein levels or expression. Treatment with the AngII receptor (AT_1R) blocker, losartan, or the ACE inhibitor, enalapril, blocked the Pb-induced systolic BP increase (Simões et al., 2011) and decreased the PHE-induced vasoconstrictor response in Pb-treated aortas (Fiorim et al., 2011). Similarly, treatment with Losartan resulted in a greater decrease in systolic BP in highly Pb exposed rats (1% Pb, 40 days; blood Pb level >240 µg/dL after exposure, 12-13 µg/dL after chelation after 1 year) compared to control rats that continued into later periods of follow-up (day 283) (Bagchi and Preuss, 2005). Increased systolic BP after early exposure to Pb corresponded with increased water intake, urine output, potassium excretion, and decreased urinary sodium and urine osmolality. These functional changes in renal behavior are consistent with the actions of a stimulated RAAS. Lower level Pb (100 ppm, 14 weeks; range of blood Pb levels: 23.7-27 µg/dL) exposure increased renal cortical AngII content and the number of tubulointerstitial AngII-positive cells (Bravo et al., 2007). This heightened intrarenal angiotensin corresponded with sodium retention and increased systolic BP and was ablated by the anti-inflammatory antioxidant, MMF. Sodium reabsorption is important for the maintenance of BP, and Na^+ transporters play a key role in this process. In other studies, Pb exposure increased activity and levels of the α-1 subunit protein of $Na^{+/}K^{+-}$ATPase, which plays a major role in Na^+ reabsorption and is regulated by the RAAS (Fiorim et al.,

2011; Simões et al., 2011). These studies point to the activation of the RAAS in the course of Pb-induced hypertension, particularly in the early stages of elevated BP.

Vasomodulators

The balance between production of vasodilators and vasoconstrictors is important in the regulation of BP and cardiovascular function. The 2006 Pb AQCD reported that Pb did not affect all vasomodulators in the same way. Urinary excretion of the vasoconstrictor, thromboxane (TXB_2), and the vasodilatory prostaglandin, 6-keto-PGF1α, were unchanged in rats with Pb-induced hypertension (Gonick et al., 1998). However, in vitro Pb exposure promoted the release of the prostaglandin substrate, arachidonic acid, in vascular smooth muscle cells (VSMCs) via activation of phospholipase A_2 (Dorman and Freeman, 2002). Plasma concentration and urinary excretion of the vasoconstrictive peptide, endothelin (ET) 3 was increased after low (100 ppm), but not high-level (5,000 ppm) Pb exposure in rats (Gonick et al., 1997; Khalil-Manesh et al., 1994; Khalil-Manesh et al., 1993b). Antagonism of the ET receptor A blunted the downregulation of sGC and cGMP production by Pb in isolated rat artery segments, suggesting that some of the hypertensive effects of Pb exposure may be mediated through ET (Courtois et al., 2003). Additionally, Pb-exposed animals exhibited fluid retention and a concentration-dependent decline in the vasodilator, atrial natriuretic factor (ANF) (Giridhar and Isom, 1990). Results from these studies suggest that Pb may interfere with the balance between vasodilators and vasoconstrictors that contribute to the complex hormonal regulation of vascular contraction and BP.

The imbalance in vasomodulators is one explanation for the concentration-dependent vasoconstriction observed in animals after Pb exposure (Valencia et al., 2001; Watts et al., 1995; Piccinini et al., 1977). Vasoconstriction after Pb exposure was not reported in all studies (Shelkovnikov and Gonick, 2001) and is likely varied depending on the type of vessel used, the Pb concentration employed, and the animal species being studied. Studies have reported Pb-induced attenuation of ACh- and $^{\bullet}NO$-mediated vasodilation (Marques et al., 2001; Oishi et al., 1996) in some, but not all vascular tissues and in some, but not all studies (Purdy et al., 1997). These effects have been variably attributed to Pb-mediated activation of PKC and direct action on the VSMCs through the Ca^{2+} mimetic properties of Pb among other possibilities (Valencia et al., 2001; Watts et al., 1995; Piccinini et al., 1977).

A recent study investigated the role of the endothelial-derived vasoconstrictor, ET-1, in Pb-induced hypertension. ET-1 from the endothelium acts on the ET_A-type receptors located on the vascular smooth muscle layer and may be involved in vascular reactivity by $^{\bullet}NO$ and COX derivatives. Pb exposure (1 ppm, 24 hours) to rat aortic segments

decreased expression of sGC-β1 subunit, an enzyme involved in •NO-induced vasodilation, and increased expression of COX-2 in an endothelium-dependent manner (Molero et al., 2006). Even though Pb treatment did not alter ET-1 or ET_A-type receptor protein expression in this system, blocking the ET_A-type receptors partially reversed Pb-induced changes in sGC and COX-2 in vascular tissue. This study suggests that the endothelium and ET-1 may contribute to Pb-induced hypertension through activation of ET_A-type receptors that alter expression of COX-2 and sGC-β1 subunit, which affects •NO signaling.

COX-2 blockade has been shown to prevent Pb-induced downregulation of sGC expression (Courtois et al., 2003). Inhibition of COX-2 also decreased the Pb-induced pressor response to ACh (Grizzo and Cordellini, 2008) and PHE (Silveira et al., 2010) in experimental animals. These studies suggest that Pb-induced vascular reactivity may depend on the participation of a COX-derived vasoconstrictor, such as prostaglandins, prostacyclins, or thromboxanes.

In summary, a small number of available recent studies continued to show that Pb exposure affect vasomodulatory pathways that are important for the maintenance of vascular tone; however, results indicated that not all vascular cell types are similarly affected by Pb exposure. Further, effects appeared to vary according to the concentration of Pb exposure. Pb exposure has been shown to interrupt baseline or endogenous •NO-mediated vasodilation of vessels via alterations in PKC, sGC, VSMC, endothelial cells, NADPH oxidase, and Ca^{+2} levels. Recent studies indicated that Pb exposure may affect vascular reactivity by increasing COX-2 and COX-2-dependent vasoconstrictors. Also, the vasoconstrictor endothelin may contribute to Pb-induced vasomodulation via similar pathways as •NO including sGC and COX-2.

5.4.2.4 Summary of Blood Pressure and Hypertension

The 2006 Pb AQCD reported a clear association between higher blood Pb levels and higher BP. The effect was modest, but robust, as determined by a meta-analysis (Nawrot et al., 2002) of over 30 studies comprising over 40,000 adults (Figure 5-29). In the meta-analysis, each doubling of concurrent blood Pb was associated with a 1 mmHg increase in systolic BP and a 0.6 mmHg increase in diastolic BP. Recent epidemiologic studies supported this conclusion at lower concurrent blood Pb levels (in populations with mean blood Pb levels < 2 µg/dL) and added to the evidence base regarding populations potentially at increased risk (i.e., high stress, genetic variants) and regarding associations of bone Pb levels with BP and hypertension in populations with mean bone Pb levels less than 20 µg/g. As these studies were mostly cross-sectional in design and were conducted

in adults whose concurrent blood Pb levels are influenced both by current Pb exposures and past Pb exposures mobilized from bone, uncertainty exists over the Pb exposure conditions that contributed to the associations observed between concurrent blood Pb level with increased BP and hypertension (Sections 4.3 and 4.7.3).

A recent study in an ethnically diverse community-based cohort of women and men aged 50-70 years of age found associations of both blood and tibia Pb levels with BP (Martin et al., 2006). This study also affirmed findings from other studies by demonstrating that with each increase of 1 µg/dL concurrent blood Pb level, systolic BP increased 1 mmHg and diastolic BP increased 0.5 mmHg and strengthened the evidence for an independent association with blood Pb level through the extensive examination of potential confounding. Additionally, recent epidemiologic studies provided evidence for associations in an adult cohort between blood Pb and BP and hypertension with relatively low blood Pb levels; a positive relationship was found in the NHANES adult data (1999-2002) with a geometric mean blood Pb level of 1.64 µg/dL (Muntner et al., 2005). However, as noted above, in adults, uncertainty exists regarding the magnitude, timing, frequency, and duration of Pb exposure that contribute to the associations observed with concurrent blood Pb levels. A new prospective study in Pb workers found independent associations of both baseline blood Pb level and subsequent changes in blood Pb over follow-up with changes in BP over follow-up and bone Pb level with hypertension (Glenn et al., 2006). Although these Pb workers had higher current Pb exposure compared with nonoccupationally-exposed adults, the results indicated that different mechanisms may mediate shorter-term Pb-associated increases in BP and longer-term Pb-associated development of hypertension.

In concordance with epidemiologic evidence, collectively, the animal toxicological studies providing blood Pb level and BP measurements reported higher BP with higher blood Pb levels (Figure 5-28). While the contribution of low concurrent blood Pb levels to the findings is difficult to ascertain in adults, animal toxicological studies provide support for low blood Pb level effects with increases in BP observed in groups of animals with blood Pb levels as low as 2 µg/dL (Rizzi et al., 2009; Tsao et al., 2000; Nakhoul et al., 1992). However, the majority of animal toxicological studies showing Pb-induced hypertension were conducted at higher Pb exposure levels that result in blood Pb levels > 10 µg/dL. In addition, new animal evidence suggests the potential for increased BP following short-term (4 weeks) Pb treatment that included injected boluses (Fiorim et al., 2011; Simões et al., 2011; Sharifi et al., 2004). New studies also demonstrated partial reversibility (not to levels in controls) of Pb-induced elevations in BP following Pb exposure cessation or chelation.

Figure 5-29 Change in systolic BP (SBP), in mmHg with 95% CI, associated with a doubling in the blood Pb concentration.

Epidemiologic studies continued to investigate the relationship between bone Pb and BP. A recently published meta-analysis (Figure 5-30) (Navas-Acien et al., 2008) included several studies (three prospective, five cross-sectional) which individually showed that bone Pb level was associated with systolic BP but not diastolic BP. In the cross-sectional studies, a pooled estimate indicated an increase in systolic BP of 0.26 mmHg (95% CI: 0.02, 0.50) per 10 µg/g tibia Pb. In the longitudinal studies, a 0.33 mmHg (95% CI: -0.44, 1.11) increase was estimated per 10 µg/g bone Pb. Most studies also reported associations of bone Pb with hypertension. Pooled estimates of 1.04 (95% CI: 1.01, 1.07) per 10 µg/g

increase in tibia Pb and 1.04 (95% CI: 0.96, 1.12) per 10 µg/g increase in patella Pb were reported.

In the Normative Aging Study, Hu et al. (1996b) reported the cross-sectional association between bone Pb levels and the prevalence of hypertension and Cheng et al. (2001) reported the cross-sectional association between bone Pb levels and systolic BP in study participants free of hypertension at baseline.

Note: The studies are ordered by increasing mean bone Pb levels. The area of each square is proportional to the inverse of the variance of the estimated change or log relative risk. Horizontal lines represent 95% confidence intervals. Diamonds represent summary estimates from inverse-variance weighted random effects models. Because of the small number of studies, summary estimates are presented primarily for descriptive purposes. RR indicates risk ratio.

Figure 5-30 Prospective and cross-sectional increase in systolic BP (SBP) and diastolic BP (DBP) and relative risk of hypertension per 10 µg/g increase in bone Pb levels.

A few recent epidemiologic studies also emphasized the potential interaction between measures of long-term Pb exposure, i.e., bone Pb levels, and factors such as chronic stress and HFE genetic variants to moderate or modify the relationship of BP and hypertension with Pb. For example, among NAS men, tibia Pb level was associated with a larger risk of developing hypertension in an originally nonhypertensive group among men with higher self-reported stress (Peters et al., 2007).

In addition to stress, recent epidemiologic studies investigated effect modification by race/ethnicity and genetic variants. In the NHANES 1988-1994 population of adults, the association of concurrent blood Pb with systolic BP was higher among Mexican Americans. In the same NHANES population, the association between blood Pb level and hypertension was higher among non-hispanic Blacks with the ALAD2 allele (Figure 5-25 and Figure 5-26 for results) (Scinicariello et al., 2010). Additionally, the association between blood Pb and PP was larger among NAS men with the HFE H63D variant (Figure 5-25). PP represents a good predictor of cardiovascular morbidity and mortality and an indicator of arterial stiffness (Zhang et al., 2010a). The aforementioned genes are related to iron metabolism and have been linked with differences in Pb distribution in blood and bone. Park et al. (2009b) provided further evidence of variants in iron metabolism genes impacting the association of bone Pb levels with QT interval changes (Table 5-19 for results).

Animal toxicological evidence continued to build on the evidence characterizing the mechanisms leading to these Pb-induced cardiovascular alterations. Biological plausibility for the consistent associations observed between blood and bone Pb and cardiovascular effects is provided by enhanced understanding of Pb-induced oxidative stress including $^{\bullet}$NO inactivation, endothelial dysfunction leading to altered vascular reactivity, activation of the RAAS, and vasomodulator imbalance.

5.4.3 Vascular Effects and Cardiotoxicity

Not only has Pb been shown to increase BP and alter vascular reactivity, but Pb can alter cardiac function, initiate atherosclerosis, and increase cardiovascular mortality. Past toxicological studies have reported that Pb can increase atheromatous plaque formation in pigeons, increase arterial pressure, decrease heart rate and blood flow, and alter cardiac energy metabolism and conduction (Prentice and Kopp, 1985; Revis et al., 1981). A limited number of available epidemiologic studies discussed in the 2006 Pb AQCD provided evidence of associations of blood Pb level with ischemic heart disease (IHD) and peripheral artery disease (PAD).

5.4.3.1 Effects on Vascular Cell Types

The endothelial layer is an important constituent of the blood vessel wall, which regulates macromolecular permeability, VSMC tone, tissue perfusion, and blood fluidity. Damage to the endothelium is an initiating step in development of atherosclerosis, thrombosis, and tissue injury. Given that epidemiologic and toxicological evidence suggests that long-

term Pb exposure is associated with a number of these conditions, numerous toxicological studies have investigated and found an effect of Pb on endothelial dysfunction. A recent occupational study found that endothelial function assessed by flow-mediated dilatation was impaired in highly Pb exposed workers (mean blood Pb levels: 24.1 in workers versus 7.8 µg/dL in unexposed controls) (Poręba et al., 2010).

The endothelial layer makes up only a small part of the vascular anatomy; the majority of the vessel wall is composed of VSMCs, which work in concert with the endothelial cells (EC) in contraction and relaxation of the vessel, local BP regulation, and atherosclerotic plaque development. Since Pb has been shown repeatedly to result in hypertension and vascular disease in experimental animals, studies continued to investigate and find an effect of Pb on VSMCs.

In in vitro assays, Pb (50 µM, 2 weeks) stimulated VSMC invasiveness in isolated human arteries leading to the invasion of medial VSMC into the vessel intima and development of intimal hyperplasia, a key step in atherosclerotic progression (Zeller et al., 2010). In addition, treatment with Pb (50 µM, 12 hours) promoted VSMC elastin expression and increased arterial extracellular matrix in isolated human arteries. VSMC invasiveness was also increased in culture by treatment with supernatant of Pb-treated human EC (50 µM), suggesting that Pb-exposed ECs secrete an activating compound. This compound was confirmed to be IL-8. Pb exposure (5-50 µM) was able to, in a concentration-dependent manner, increase IL-8 synthesis and secretion in human umbilical vein EC cultures through activation of the transcription factor Nrf2. Neutralization of IL-8 could block VSMC invasion and arterial intima thickening (Zeller et al., 2010). This study provides evidence that Pb exposure stimulates ECs to secrete IL-8 in an Nrf2-dependent manner that stimulates VSMC invasion from the vessel media to intima leading to a vascular thickening and possibly atherogenesis.

A number of CVDs, including atherosclerosis, are characterized by increased inflammatory processes. Numerous studies have shown that Pb exposure is associated with an inflammatory environment in vascular tissues of humans and animals as indicated by higher levels of inflammatory mediators like prostaglandin E_2 (PGE_2). Human aortic VSMCs treated with Pb (1 µM, 1-12 hours) exhibited increased secretion of PGE_2 time-dependently through enhanced gene transcription (Chang et al., 2011). This was preceded by a Pb-induced increase in the gene expression of the rate limiting enzymes in the regulation of prostaglandins, cytosolic phospholipase A_2 ($cPLA_2$) and COX-2. The induction of these enzymes was mediated by activation of ERK1/2, MEK1, and MEK2. Further investigation into the entrance of Pb into the cell revealed that inhibition of the store-operated calcium channels (SOC) could only partially suppress $cPLA_2$ and COX activation by Pb; however inhibition of epidermal growth factor receptor (EGFR)

attenuated Pb-induced PGE_2 secretion and activation of $cPLA_2$ and COX. A follow-up to this study found that Pb treatment (1µM) of a human epithelial cell line increased COX-2 gene expression, promoter activity, and protein (Chou et al., 2011). Inhibition of NF-κB decreased the Pb-induced COX-2 activation; whereas EGFR inhibition blocked COX-2 upregulation and NF-κB nuclear translocation. Overall these studies suggest that Pb can induce pro-inflammatory events in VSMC in the form of increased PGE_2 secretion and $cPLA_2$ and COX-2 expression through activation of EGFR via ERK1/2 and NF-κB pathways.

Damage to the endothelium is a hallmark event in the development of atherosclerosis. Past studies have shown that Pb exposure results in de-endothelialization, impaired proliferation, and inhibition of endothelium repair processes after injury (Fujiwara et al., 1997; Ueda et al., 1997; Kaji et al., 1995; Kishimoto et al., 1995). However, Pb exposure was not found to lead to nonspecific cytotoxicity at low exposure levels (2-25 µM) as shown by the lack of release of lactate dehydrogenase (LDH) from Pb-treated bovine aortic EC (Shinkai et al., 2010). Instead, Pb induced specific cytotoxicity (caspase3/7 activation) through endoplasmic reticulum (ER) stress that was protected against by the ER chaperones glucose-regulated protein 78 (GRP78) and glucose-regulated protein 94 (GRP94). GRP78 and GRP94 play key roles in the adaptive unfolded protein response that serves as a marker of and acts to alleviate ER stress. Exposure of Pb to ECs induced *GRP78* and *GRP94* gene (2-25 µM) and protein (GRP78 [5-25 µM] and GRP94 [10-25 µM]) expression through activation of the IRE1-JNK-AP-1 pathways (Shinkai et al., 2010). This study suggests that the functional damage caused by Pb exposure to EC may be partly attributed to induction of ER stress.

5.4.3.2 Cholesterol

As blood cholesterol rises so does the risk of coronary heart disease. Early occupational studies (Ademuyiwa et al., 2005a; Bener et al., 2001a; Kristal-Boneh et al., 1999) examining higher than current adult blood Pb levels reported higher total cholesterol levels related to Pb exposure, but mixed results for HDL, LDL, and triglycerides. More recently, Poreba et al. (2010), in an occupational study, reported no significant differences in parameters of lipid metabolism between Pb exposed workers (mean blood Pb level: 25 µg/dL) and unexposed individuals. Conversely, Kamal et al. (2011) reported that occupational Pb exposure (mean blood Pb level: >40 µg/dL) was associated with higher levels of triglycerides, total cholesterol, and LDL, and decreased HDL-C. Other Pb studies adjusted models for total cholesterol to control for this coronary heart disease risk factor. Higher mean total cholesterol with higher blood Pb levels has been reported (Menke et al., 2006). In developing models to predict bone Pb levels, Park et al. (2009a)

noted that total and HDL cholesterol were selected as 2 of 18 predictors for the bone Pb level model. Their findings suggested that higher Pb exposure may be associated with higher total and HDL cholesterols. A recent study reported increased LDL and decreased HDL in rats treated with Pb (20 ppm, i.p., 3 days/week, 8 weeks) (Roshan et al., 2011). The major risk factor that lipids represent for heart disease make relating lipid levels to Pb exposures an interesting but challenging hypothesis to test.

5.4.3.3 Heart Rate Variability

Pb has been shown not only to affect vascular contractility in animals, but also is associated with cardiac contractility. Eum et al. (2011) and Park et al. (2009b) followed up a previous NAS report (Cheng et al., 1998), which found increasing duration of corrected QT interval (QTc) with increasing bone Pb levels in men <65 years, but not in men ≥ 65 years. Eum et al. (2011) prospectively examined the association between blood and bone Pb levels and the development of electrocardiographic (ECG) conduction abnormalities among 600 men who were free of ECG abnormalities at the baseline assessment. A second ECG was obtained for 496 men 8.1 (SD = 3.1) years later on average. Baseline Pb concentrations in blood (mean [SD]: 5.8 [3.6] µg/dL), patella bone (mean [SD]: 30.3 [17.7] µg/g), and tibia bone (mean [SD]: 21.6 [12.0] µg/g) were similar to those found in other samples from the general U.S. adult population and much lower than those reported in occupationally exposed groups. Higher tibia Pb was associated with increases in QTc interval and QRSc duration. Compared with those in the lowest tertile of baseline tibia Pb (< 16 µg/g), participants in the highest tertile (> 23 µg/g) had a 7.94 msec (95% CI: 1.42, 14.45) greater increase in QTc interval and a 5.94 msec (95% CI: 1.66, 10.22) greater increase in QRSc duration over 8 years after adjusting for covariates. There were no statistically significant associations with patella or blood Pb levels. These associations were observed in men with relatively low blood and bone Pb concentrations who were free of cardiac conduction abnormalities at baseline and were examined prospectively. Thus, they indicate that long-term cumulative Pb exposure may increase the risk of developing cardiac abnormalities. Uncertainty exists as to the specific Pb exposure level, timing, frequency, and duration contributing these associations observed for tibia Pb levels. A recent occupational study reported lower HRV and abnormal parameters of heart rate turbulence in Pb-exposed workers (mean blood Pb levels: ~25 µg/dL) compared to control subjects (Poręba et al., 2011a).

Park et al. (2009b) examined whether polymorphisms in genes known to alter iron metabolism (HFE, transferrin [TF] C2, heme oxygenase-1 [HMOX-1]) modify the association between Pb biomarker levels and the QT interval. Investigators examined associations in data stratified on polymorphisms in the three genes. They also analyzed

interaction models with cross-product terms for genotype and the Pb biomarker. The distributions of all genotypes but the HFE variant, H63D, were in Hardy-Weinberg equilibrium. Subjects homozygous for the other HFE variant, C282Y, had higher bone Pb levels and those homozygous for H63D and heterozygous for both C282Y and H63D had lower bone Pb levels. The HMOX-1 L variant (longer repeats of GT, associated with lower enzyme inducibility) alone, compared to the wild type, showed a statistically significant interaction with tibia Pb (11.35 msec longer QTc interval for each 13 µg/g increase in bone Pb in L-allele variants). No other gene variant alone showed different Pb-associated QTc intervals from those in wild types, either for tibia and patella Pb or for (linear) concurrent blood Pb. Lengthening of QTc with higher tibia and blood Pb was more pronounced with an increase in the total number of gene variants, driven by a joint effect between HFE variant and HMOX-1 L allele. There was a trend observed with blood and tibia Pb-associated QTc interval increasing with increasing number of gene variants from 0 to 3. This study provided further evidence of gene variants modifying associations of Pb biomarkers with cardiovascular effects.

The interaction of key markers of the metabolic syndrome with bone Pb levels in affecting HRV was investigated in a group of 413 older adults with patella Pb measurements in the NAS (Park et al., 2006). Metabolic syndrome was defined to include three or more of the following: waist circumference >102 cm, hypertriglyceridemia (>150 mg/dL), low HDL cholesterol (<40 mg/dL in men), high BP >130/85 mmHg, and high fasting glucose (>110 mg/dL). Men using antihypertensive medication or diabetes medications were counted as high BP or high fasting glucose, respectively. The strongest relationships between patella Pb levels and lower HRV were observed among those with three or more metabolic abnormalities. A trend was observed for larger patella Pb-associated decreases in HRV with increasing number of metabolic abnormalities. These results suggest multiplicative effects of cumulative Pb exposure and metabolic abnormalities on key predictors of CVD. Park et al. (2006) also reported the penalized spline fits to bone Pb in models assessing only main effects of bone Pb. The optimal degree of smoothing determined by the generalized cross-validation criterion for all HRV measures was 1, which indicated that the associations were nearly linear. The spline fits and associated statistics showed that the bone Pb main effects on HRV measures were linear. However, the relationship with LF/HF was linear with log(LF/HF).

Increased incidence of arrhythmia and atrioventricular conduction block was found in rats after 12 weeks of Pb exposure (100 ppm; mean blood Pb level 26.8 µg/dL) (Reza et al., 2008). Also, Pb exposure for 8 weeks increased heart rate and systolic BP. These increases corresponded with increased cardiac contractile force and prolonged ST interval, without alteration in QRS duration or coronary flow. In contrast, another study found that Pb (100 µM) exposure, in a concentration-dependent manner, reduced

myocardial contraction using rat right ventricular strips by reducing sarcolemmal Ca^{2+} influx and myosin ATPase activity (Vassallo et al., 2008). This study also found that Pb exposure changed the response to inotropic agents and blunted the force produced during contraction. Conversely, past studies have found that Pb exposure increases intracellular Ca^{2+} content (Lal et al., 1991; Favalli et al., 1977; Piccinini et al., 1977), which could result in increased cardiac output and hypertension.

5.4.3.4 Peripheral Artery Disease

Peripheral artery disease (PAD) is an indicator of atherosclerosis and measured by the ankle brachial index, which is the ratio of BP between the posterior tibia artery and the brachial artery. PAD is typically defined as an ankle brachial index of less than 0.9. Muntner et al. (2005), whose results describing the association of blood Pb and hypertension in the NHANES 1999-2002 data set for adults were discussed previously, also examined the association of blood Pb with PAD. The authors observed an increasing trend in the odds of PAD with increasing concurrent blood Pb level. The OR for PAD comparing the fourth quartile of blood Pb (> 2.47 µg/dL) to the first quartile of blood Pb (< 1.06 µg/dL) was 1.92 (95% CI: 1.02, 3.61). These results are consistent with those from a previous NHANES analysis conducted by Navas-Acien et al. (2004).

Navas-Acien et al. (2004) reported a trend of increasing OR for PAD with increasing quartile of concurrent blood Pb or Cd in adults who were 40 years of age in the 1999-2000 NHANES population. These authors tested both Pb and Cd in separate models, tested the metals simultaneously, and tested the interaction between the metals. The correlation coefficient between natural log Pb and natural log Cd was 0.32 ($p < 0.001$). Although the interaction was not statistically significant, when blood Pb and blood Cd were in the same model, the ORs were diminished slightly but both showed statistically significant trends of increasing OR with increasing quartile of the metal. These results indicate that blood Cd levels did not confound the association between blood Pb level and PAD. In a subsequent analysis, Navas-Acien et al. (2005) used the same 1999-2000 NHANES dataset, but constructed PAD models using a suite of urine metal concentrations. Power was reduced in this study because only 659-736 subjects (compared to 2,125) had spot urine metal tests in the data set. Urinary Cd, but not urinary Pb, was consistently associated with PAD in all models. Associations also were observed with urinary antimony and tungsten. Spot urine Pb measurements are less reliable compared to blood Pb measurements. In Navas-Acien et al. (2005), the urinary Pb level association with PAD was sensitive to adjustment for urinary creatinine, indicating that spot urine Pb measurements are affected by differences in urine dilution. This finding

illustrates the limited reliability of spot urine Pb measurements compared to blood Pb measurements.

5.4.3.5 Ischemic Heart Disease

A few studies discussed in the 2006 Pb AQCD indicated associations between Pb biomarker levels and increased risk of cardiovascular outcomes associated with IHD, including left ventricular hypertrophy (Schwartz, 1991) and myocardial infarction (Gustavsson et al., 2001). Recently, Jain et al. (2007) reported on the incidence of IHD (physician confirmed MI, angina pectoris) among older adult males enrolled in the NAS and followed during the period of September, 1991 to December, 2001. All subjects had blood Pb and bone Pb measurements with no IHD at enrollment. Fatal and nonfatal cases were combined for analysis. Baseline blood, tibia, and patella Pb levels were log-transformed. Blood Pb level and patella Pb level were associated with increased risk of IHD over the 10-year follow-up period. When blood Pb and patella Pb were included simultaneously in the model, each of their HRs was only moderately attenuated (HR: 1.24 [95% CI: 0.80, 1.93] per SD increase in blood Pb and HR: 2.62 [95% CI: 0.99, 6.93] per SD increase in patella Pb). When blood Pb and tibia Pb were included simultaneously in the model, their risk estimates were only moderately attenuated (HR: 1.38 [95% CI: 0.89, 2.13] per SD increase in blood Pb and HR: 1.55 [95% CI: 0.44, 5.53] per SD increase in tibia Pb). These findings indicate that both blood and bone Pb levels contribute independently to IHD incidence.

IHD, characterized by reduced blood supply to the heart, may result from increased thrombosis. A recent animal study suggested that Pb exposure promotes a procoagulant state that could contribute to thrombus formation (Shin et al., 2007). In a rat model of venous thrombosis, Pb treatment (i.v. 25 mg/kg) resulted in increased thrombus formation. Additionally, Pb treatment to human erythrocytes (red blood cells, RBCs) increased coagulation at a dose of 5 µM and thrombin generation in a concentration-dependent manner at doses from 2-5µM. This enhanced procoagulant activity in Pb-treated RBCs was the result of increased outer cell membrane phosphatidylserine (PS) surfacing (human RBCs: 2-5 µM; rat RBCs: 5 µM). Similar to these in vitro results, PS externalization on erythrocytes was increased in Pb-treated rats (i.v. 50-100 mg/kg, not 25 mg/kg). Increased PS externalization was likely the result of increased intracellular calcium (5 µM Pb), enhanced scramblase activity (5-10 µM Pb), inhibited flippase activity (5-10 µM Pb), and ATP depletion (1-5 µM Pb) after Pb exposure (Shin et al., 2007).

5.4.3.6 Atherosclerosis

Epidemiologic and toxicological studies provide evidence for increased atherosclerosis and intimal medial thickening (IMT) due to Pb exposure. The association between stroke subtypes and severity of cerebral atherosclerosis was examined in relation to a single concurrent blood Pb level and total 72-hour urinary Pb level (body Pb store-EDTA mobilization test) in a cross-sectional study of 153 patients (mean age 63.7 years) receiving digital subtraction angiography in Chang Gung Memorial Hospital in Taiwan from 2002 to 2005 (Lee et al., 2009). In an analysis adjusted for age, sex, hypertension, diabetes, triglyceride, uric acid, smoking, and alcohol consumption, a 1 µg increase in urine Pb was associated with ≥ 50% stenosis in the intracranial carotid system with an OR (95% CI) of 1.02 (1.00, 1.03). Urine Pb was associated with greater stenosis in the extracranial or vertebrobasilar systems. Blood Pb level was not associated with greater stenosis in any region. As the development of atherosclerosis is a lifelong process, body Pb stores, analyzed by total 72-hour urine Pb amount, may more strongly be associated with atherosclerosis than are single blood Pb measurements.

A recent study correlated greater carotid artery IMT with higher concurrent serum Pb levels (mean [SD] 0.41 [0.38] µg/dL) in hemodialysis patients (Ari et al.). A few available recent occupational studies also presented evidence for increased measures of atherosclerosis in highly Pb exposed adult populations with mean blood Pb levels around 25 µg/dL. Poręba et al. (2011b) reported increased local arterial stiffness and more frequent left ventricular diastolic dysfunction in Pb-exposed workers with hypertension compared to nonexposed controls with hypertension. Occupational exposure to Pb (mean blood Pb levels: 24 µg/dL in workers, 8.3 µg/dL in nonexposed group) was also associated with greater IMT and atherosclerotic plaque presentation, analyzed by Doppler ultrasound (Poreba et al., 2011).

Zeller et al. (2010) examined human radial and internal mammary arteries exposed to Pb in culture and reported a concentration-dependent increase in arterial intimal thickness (statistically nonsignificant at 5 µM Pb, significant at 50 µM Pb, 2 week treatment) and intimal extracellular matrix accumulation (50 µM). Also, Pb promoted EC proliferation (5 and 50 µM, 72 hours) and VSMC elastin expression (50 µM, 12 hours), as discussed above (Section 5.4.3.1) (Zeller et al., 2010). Another study showed that Pb exposure (100 ppm in drinking water for 10 months; mean blood Pb level 28.4 µg/dL) of rats also increased the aortic media thickness, media-lumen ratio, and medial collagen content (Zhang et al., 2009a). These morphological changes to the vessel due to Pb exposure indicate initiation of arteriosclerosis and could be the cause of decreased contractile response of the vessel due to altered visco-dynamic vessel properties. Alternatively, these vascular changes could be an effect of Pb-induced hypertension.

Table 5-19 Characteristics and quantitative data for associations of blood and bone Pb with other CVD measures in epidemiologic studies ordered as they appear in the text

Study	Population/ Location	Parameter	Pb Data	Statistical Analysis	Effect Estimate (95% CI)[a]
Heart rate variability					
Eum et al. (2011)	600 men free of electrographic abnormalities at the time of baseline ECG from NAS in Greater Boston, MA area (496 with follow-up ECG 8 years later)	ECG conduction[b] (QTc, QRSc, JTc, QT prolongation, JT prolongation, IVCD[c], AVCD, Arrhythmia)	Baseline Blood Pb: Mean (SD): 5.8 (3.6) µg/dL Baseline Patella Pb: Mean (SD): 30.3 (17.7) µg/g Baseline Tibia Pb: Mean (SD): 21.6 (12.0) µg/g Q1: <16 µg/g (n = 191) Q2: 16.0 - 23 µg/g (n = 208) Q3: >23 µg/g (n = 195)	Repeated measures linear regression adjusted for age, education, smoking, BMI, albumin-adjusted serum calcium, and diabetes status at baseline, and years between ECG tests and QT-prolongation drugs at the time of ECG measurement.	Tibia Pb: Adjusted 8-year change (95% CI): QTc: Q2 vs. Q1 (reference): 7.49 (1.22, 13.75) msec, Q3 vs. Q1: 7.94 (1.42, 14.45) msec p for trend = 0.03 QRSc: Q2 vs. Q1: 0.52 (-3.60, 4.65) msec Q3 vs. Q1: 5.94 (1.66, 10.22) msec p for trend = 0.005 No associations with patella or blood Pb
Park et al. (2009b)	613 men from NAS in Greater Boston, MA area (8/1991 - 12/1995)	QTc[b] interval	Baseline Blood Pb: Median (IQR): 5 (4-7) µg/dL Baseline Patella Pb: Median (IQR): 26 (18-37) µg/g Baseline Tibia Pb: Median (IQR): 19 (14-27) µg/g	Linear regression models adjusted for age, BMI, smoking status, serum calcium, and diabetes.	Per IQR (3 µg/dL) increase in blood Pb 1.3 (-0.76, 3.36) msec after 8-year follow up Per IQR (19 µg/g) increase in patella Pb 2.64 (0.13, 5.15) msec Per IQR (13 µg/g) increase in tibia Pb 2.85 (0.29, 5.40) msec
Park et al. (2006)	413 men from NAS in Greater Boston, MA area (11/14/2000 - 12/22/2004)	HRV (SDNN, HF, HF_{norm}, LF, LF_{norm}, LF/HF)	Baseline Patella Pb (measured within 6 mo of HRV: Median (IQR): 23.0 (15-34) µg/g Estimated[a]: Median (IQR): 16.3 (10.4-25.8) µg/g Baseline Tibia Pb: Median (IQR): 19.0 (11-28) µg/g	Log linear regression models adjusted for age, cigarette smoking, alcohol consumption, room temperature, season (model 2) BMI, fasting blood glucose, HDL cholesterol, triglyceride, use of β-blockers, calcium channel blockers, and/or ACE inhibitors	Tibia Pb: Model 2 Change (95%CI) HF: –0.9 (–3.8, 2.1) normalized units (nu) LF: 0.9 (–2.0, 3.9) nu Log LF/HF: 3.3 (–10.7, 19.5) (%) Per 17 µg/g tibia Pb Patella Pb: Model 2 Change (95%CI) HF: –0.6 (–3.1, 1.9) nu LF: 0.6 (–1.9, 3.1) nu Log LF/HF: 3.0 (–8.7, 16.2) (%) Per 15.4 µg/g patella Pb Effect estimates were more pronounced among those with metabolic syndrome.

5.4.3.7 Summary of Vascular Effects and Cardiotoxicity

There are a limited number of studies that investigate the associations between Pb biomarkers and cardiovascular effects other than BP or hypertension (Table 5-19). As presented in Table 5-19, these studies demonstrated associations between various biomarkers of Pb exposure and clinical cardiovascular outcomes such as atherosclerosis, IHD, PAD, and HRV occurrence in adult populations after adjusting for potential confounding by variables such as age, sex, BMI, smoking, alcohol consumption, and diabetes. In a limited body of studies, mixed evidence of association between occupational exposure to Pb and altered cholesterol was reported. Studies of Pb-induced endothelial dysfunction, VMSC invasiveness, and inflammation in isolated vascular tissues and cells provide mechanistic evidence to support the biological plausibility of these other vascular effects and cardiotoxicity. A recent study provided evidence for the

interaction between biomarkers of Pb exposure and the HFE C282Y and HMOX-1 L variant on the prolonged QT interval in nonoccupationally-exposed older men (Park et al., 2009b). Also, in the NAS population, bone Pb levels were associated with larger decreases in HRV parameters among subjects identified as having metabolic abnormalities (Park et al., 2006). These metabolic abnormalities, abdominal obesity, hypertriglyceridemia, low HDL cholesterol, high BP/medication use, or high fasting glucose, have been shown to be associated with increased risk of cardiovascular events.

A prospective NAS study reported that higher baseline tibia Pb was associated with increases in QTc interval and QRSc duration over an 8-year follow-up period (Eum et al., 2011). Concurrent blood Pb levels (population means >2.5 µg/dL) were associated with greater odds of PAD in adults in NHANES analyses (Muntner et al., 2005; Navas-Acien et al., 2004). In addition, in the NAS cohort of older adult men, blood Pb (≥ 5 µg/dL) and patella Pb levels were associated with increased morbidity from IHD (Jain et al., 2007). A recent study involving both human and toxicological studies elucidated mechanisms for observed Pb-mediated arterial IMT, an early event in Pb-induced atherogenesis (Zeller et al., 2010). Studies in isolated tissues and cells found that Pb stimulated the synthesis and secretion of IL-8 in ECs, which was responsible for stimulating VSMC invasion into the vessel intimal layer. Pb treatment also increased extracellular matrix and elastin, primary sites for lipid deposition in the vessel wall. Overall, the relatively available few studies provide support for associations between Pb biomarkers and other cardiovascular conditions, yet further research is warranted to understand these relationships.

5.4.4 Cardiovascular Function and Blood Pressure in Children

5.4.4.1 Introduction

The study of cardiovascular function effects in relation to blood Pb levels in children potentially offers unique information on several topics. First, by examining endpoints predictive of future cardiovascular pathology, these studies may offer information on the potential cardiovascular effects of Pb exposure in an understudied population. Second, examination of cardiovascular changes that are antecedent to increased BP and changes in other CVD-related endpoints at later lifestages may inform uncertainties in regards to the time course of cardiovascular changes associated with Pb exposure. Finally, these studies address gaps in knowledge regarding Pb exposure effects in populations with mean blood Pb levels in the range of < 5 to 10 µg/dL.

An advantage of examining the literature about the association between cardiovascular effects and blood Pb levels in children is that the blood Pb levels of children in new studies may better reflect their relatively recent Pb exposure and its effect on CVD than blood Pb levels do in adults because of the uncertainties related to the effects of earlier higher Pb exposure levels. A possible disadvantage of studying the associations of blood Pb levels and cardiovascular effects in children is the lower prevalence of such conditions in children. For example, the prevalence for hypertension in children (9 to 10 years old) ranges from to 2 to 5 percent (Daniels, 2011; Steinthorsdottir et al., 2011). The prevalence of hypertension increases with age. More than half of people aged 60 to 69 years have hypertension (Chobanian et al., 2003). Further, compensatory mechanisms in children may be more active than in adults, and the cardiovascular tissue of the young may be less susceptible to damage than that of adults. The lower disease prevalence may make it more difficult to find a relationship between blood Pb level and cardiovascular effects in child studies. Although studies in children may be limited with regard to study power in assessing associations with present CVD pathology, they provide for the examination of early function changes that are associated with subsequent CVD.

The limited numbers of studies published on children examined endpoints such as total peripheral resistance (TPR), BP, and autonomic nervous system activation. These new and earlier studies are presented in Table 5-20. Multiple studies in New York State evaluated two child cohorts born in the 1990s after Pb was removed from gasoline in the U.S. with mean blood Pb levels of 4.62 and 1.01 µg/dL (Gump et al., 2011; Gump et al., 2009; Gump et al., 2007; Gump et al., 2005). Zhang et al. (In Press) examined children in Mexico City born from 1994 to 2003, when Pb was being taken out of gasoline in Mexico (Martinez et al., 2007). The geometric mean cord and concurrent blood Pb levels of the children in the Mexico City cohort were 4.67 and 2.56 µg/dL.

Table 5-20 Studies of Children Cardiovascular Endpoints and Pb Biomarkers Ordered as They Appear in the Text

Study	Population/ Location	Parameters	Blood Pb Dataa	Statistical Analysis	Effect Estimates/Results
Gump et al. (2005)	122 children age 9.5 yr in Oswego, NY (born at a single hospital in New York from 1991-94)	SBP, TPR (total peripheral vascular resistance)	Cord blood Pb: GM (GSD): 2.56 µg/dL (1.16) Childhood (mean age of measurement: 2.6 yr) blood Pb: GM (GSD): 4.06 µg/dL (1.14)	Multivariate linear regression models examined the relationship of blood Pb with change in z-score for outcome (post- and pre-stress). Potential confounders considered: HOME score, SES, birth weight, child BMI, child sex.	Per 1 µg/dL increase in childhood blood Pb level, 0.088 (95% CI: 0.023, 0.153) dyne-s/cm^5 change in TPR Per 1 µg/dL increase in cord blood Pb level, 12.16 (95% CI: 2.44, 21.88) mmHg higher SBP
Gump et al. (2007)	122 children age 9.5 yr in Oswego, NY	SBP, TPR	Childhood (mean age of measurement: 2.6 yr) blood Pb: GM (GSD): 4.06 µg/dL (1.14)	Linear regression models adjusting for the same covariates as in Gump et al. (2005). Separate models testing whether Pb is a mediator of SES associations,(Sobel test) and whether Pb moderates SES associations (Pb-SES interaction).	Blood Pb was a mediator of the SES-TPR relationship SES alone: -0.62 dyne-s/cm^5 ($p < 0.05$) SES with Blood Pb: -0.40 dyne-s/cm^5 ($p > 0.10$), change in R^2 attributable to SES: -55.3% Blood Pb was a potential moderator of the SES-TPR relationship. Blood Pb × SES interaction: p = 0.07 . Blood Pb was a moderator of SES-SBP relationship Pb × SES interaction: p = 0.007 At blood Pb levels > 4 µg/dL, SES not significantly associated with SBP
Gump et al. (2009)	122 children age 9.5 yr in Oswego, NY	Salivary cortisol	Cord blood Pb: GM (GSD): 2.56 µg/dL (1.16) Childhood (mean age of measurement: 2.6 yr) blood Pb: GM (GSD): 4.06 µg/dL (1.14)	Linear regression to examine whether blood Pb level mediates or moderates the relationship between SES and salivary cortisol as in Gump et al. (2007)	Blood Pb was a mediator of the SES-cortisol association. SES was no longer significantly associated with cortisol after adjusting for blood Pb level. R^2 for SES decreased by 40, 33, 50% for cortisol measured at 21, 40, and 60 min. Blood Pb was not a significant moderator of SES-cortisol association. Blood Pb × SES interaction term was not statistically significant
Gump et al. (2011)	140 children ages 9-11 yr	SBP, TPR, HRV (heart rate variability) in response to acute stress (mirror tracing task)	Concurrent blood Pb: GM: 1.01 µg/dL Quartiles: Q1: 0.14-0.68 µg/dL Q2: 0.69-0.93 µg/dL Q3: 0.94-1.20 µg/dL Q4: 1.21-3.76 µg/dL	Outcomes were analyzed as continuous variables for the pre-stress values or the change post- and pre-stress. Regression models were adjusted for sex, SES, BMI, and age.	Blood Pb levels associated with autonomic and cardiovascular dysregulation in response to stress – greater vascular resistance, reduced stroke volume, and cardiac output Change in SBP (mmHg) across quartiles: Q1: 5.30, Q2: 7.33, Q3: 7.07, Q4: 7.23, p for trend = 0.31 Change in TPR (%) across quartiles: Q1: 2.91, Q2: 8.18, Q3: 9.55, Q4: 9.51, p for trend = 0.03 Change in Stroke Volume (%) across quartiles: Q1: 2.23, Q2: 0.91, Q3: -3.47, Q4: -0.89, p for trend = 0.04

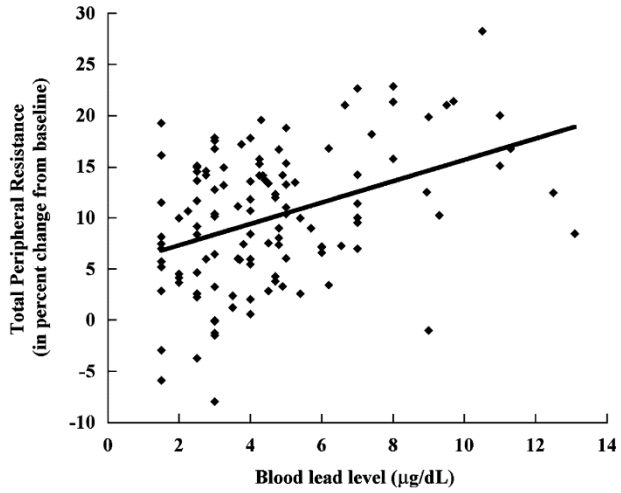
Study	Population/ Location	Parameters	Blood Pb Dataa	Statistical Analysis	Effect Estimates/Results
Zhang et al. (In Press)	457 mother child pairs in a birth cohort, born 1994 to 2003 in Mexico City. Children were evaluated 2008-2010 at ages 7-15 yr	SBP	Cord blood Pb: GM (GSD): 4.67 µg/dL (1.18) (N=323) Concurrent blood Pb: GM (GSD): 2.56 µg/dL (1.16) (N=367) Maternal post-partum bone Pb: Median (IQR): Tibia Pb: 9.3 (3.3, 16.1) µg/g Patella Pb: 11.6 (4.5, 19.9) µg/g	Multiple regression models and generalized estimating equations (log linear for cord blood, linear for concurrent blood and maternal bone). The base model considered maternal education, birth weight, BMI, sex, and child concurrent age as covariates.	Prenatal Pb exposure may be associated with higher BP in female offspring. Among girls, an IQR (13 µg/g) increase in maternal tibia Pb was associated with a 2.11 (95% CI: 0.69, 3.52) mmHg increase in SBP IQR (16 µg/g) increase in maternal patella Pb was associated with a 0.87 (95% CI: -0.75, 2.49) mmHg increase in SBP IQR (4 µg/dL) increase in cord blood Pb was associated with a 0.75 (95% CI: -1.13, 2.63) mmHg increase in SBP
Factor-Litvak et al. (1999; 1996)	260 children ages 5.5 years old in K. Mitrovica and Pristina, Yugoslavia	SBP	Concurrent blood Pb range: 4.1 to 76.4 µg/dL	Linear regression analysis. Potential confounders considered: gender, maternal education, birth weight, HOME score, and BMI.	Per 1 µg/dL increase in concurrent blood Pb level, 0.05 (95% CI: -0.02, 0.13) mmHg higher SBP Blood Pb level at birth and cumulative blood Pb level were not as strongly associated with SBP at age 5.5 yr.
Gerr et al. (2002)	Young adults age 19-29 years, born 1965-1975, male and female; half of the subjects had grown up around an active Pb smelter in Silver Valley, Idaho	BP	While the concurrent mean blood Pb level was 3.15 µg/dL for the highest bone Pb category (> 10 µg/g), early childhood mean blood Pb levels in this group were substantially elevated for all bone Pb level categories and were highest among participants in the highest bone Pb level category. The mean blood Pb level was 65 µg/dL among participants with bone Pb level >10 µg/g.	Multiple linear regression models always included age, sex, height, BMI, current smoking status, frequency of alcohol consumption, current use of birth-control medication, hemoglobin level, serum albumin, and income, regardless of significance levels. Both blood Pb (as a linear term) and bone Pb (a four category ordinal variable from <1 µg/g to >10 µg/g) were tested together.	Group in highest quartile of tibia Pb level (> 10 µg/g) had 4.26 (95% CI: 1.36, 7.16) mmHg higher SBP and 2.80 (95% CI: 0.35, 5.25) mmHg higher DBP compared to the lowest tibia Pb group (< 1 µg/g).

[a]Blood Pb data are estimates of geometric mean (GM) and geometric standard deviation (GSD) using the arithmetic mean and SD.

5.4.4.2 Cardiovascular Functioning in Children

The relationship between cardiovascular functioning (TPR, BP, stroke volume, and cardiac output,) and blood Pb levels was examined by Gump et al. (2007; 2005) in a cohort born at a single New York hospital. Higher early childhood Pb levels (average age 2.6 years) were associated with greater TPR response to acute stress induced by mirror tracing on a computer at age 9.5 years as shown in Figure 5-31. Testing blood Pb with linear, quadratic, and cubic terms did not produce significantly different Pb-TPR associations which the authors suggested showed effects that were concentration dependent and, notably were not emergent at a specific exposure threshold. TPR increased with increasing quartile of blood Pb level. A mediational analysis indicated that Pb was a significant mediator of the SES-TPR reactivity association; some evidence also suggested moderation, whereby the inclusion of blood Pb into the model reduced the effect estimate for SES. Biological plausibility for these observations in children is

provided by observations that Pb exposures increases TRP in toxicological studies and by mechanistic evidence indicating that Pb-induced changes in SNS activity may mediate such effects (Section 5.4.2.3). Additionally, higher blood Pb level measured at age 2.6 years was associated with a smaller stroke volume and cardiac output responses to acute stress at age 9.5 years. In a further analysis in this cohort, Gump et al. (2009) examined the possibility that Pb may mediate an association between SES and cortical responses to acute stress. Elevated cortisol has been associated with hypertension (Whitworth et al., 2000). Gump et al. (2009) found that lower family income was associated with greater cortisol levels following an acute stress task and that blood Pb was a mediator of this association.



Source: Reprinted with permission of Elsevier (Gump et al., 2005)

Figure 5-31 Children's adjusted total peripheral resistance (dyn-s/cm^5) responses to acute stress tasks, as a function of childhood Pb levels.

In a different cohort of 140 children 9 to 11 years of age recruited from local pediatrician offices and from mailings to homes with children in this age group, Gump et al. (2011) used a similar acute stress-producing paradigm to that used in the previous studies to examine the associations of concurrent blood Pb with cardiovascular responses. TPR significantly increased in a concentration-dependent relationship with blood Pb, with most of the increase occurring between the first quartile blood Pb (0.14-0.68 µg/dL) and the second quartile blood Pb (0.69-0.93 µg/dL). This result is consistent with those of Gump et al. (2005). Also, these new findings provided evidence of associations with concurrent blood Pb levels and with lower blood Pb levels (Gump et al., 2011) than were previously examined in Gump et al. (2005).

Studies examining HRV in adults and animal toxicology are discussed in Section 5.4.3.3. In Gump et al. (2011), cardiac autonomic regulation decreased in a concentration-dependent manner with increasing concurrent blood Pb quartile, with the largest change relative to the first quartile (0.14-0.68 µg/dL) measured in the highest blood Pb quartile (1.21-3.76 µg/dL). Also, high frequency HRV, decreased more with acute stress in the highest Pb quartile group (1.21-3.76 µg/dL). In the earlier cohort, early childhood (mean age at collection: 2.6 years) blood Pb level was associated with reduced stroke volume and cardiac output (Gump et al., 2007; Gump et al., 2005). In this new study, Gump et al. (2011) found the same but for concurrent blood Pb level and at lower blood Pb levels.

5.4.4.3 Blood Pressure in Children

Zhang et al. (In Press) conducted a longitudinal study that examined changes in BP in 323 girls and boys aged 7 to 15 years old in a Mexico City cohort for a relationship with maternal bone Pb measured one month post-partum (a measure of cumulative exposure that could expose fetuses to Pb through accelerated mobilization of bone Pb during pregnancy), and cord blood Pb at delivery. This was the first study to examine the association of maternal bone Pb, as a marker of prenatal exposure, with offspring BP. The model including both girls and boys (without adjustment for concurrent blood Pb) showed no statistically significant association overall of any Pb biomarker with child BP. A significant interaction was found between maternal tibia Pb and sex, and in models stratified by sex, maternal tibia Pb was associated with adjusted systolic and diastolic BP in females, but not males. Maternal post-partum median tibia Pb was 9.3 µg/g (IQR: 3.3, 16.1 µg/g) with no significant differences between mothers of male and female offspring. Suboptimal growth in utero is associated with accelerated weight gain in offspring during childhood and greater risk of later hypertension (Barker and Bagby, 2005; te Velde et al., 2004; Barker et al., 1989). These may represent biologically plausible mechanisms by which prenatal Pb exposure may result in increased BP later in childhood as was demonstrated in female offspring. The relationship between birth weight and Pb biomarkers is discussed in Section 5.8.7.

Gump et al. (2011; 2005) examined the relationship of blood Pb level with BP in their two cohorts of contemporary children around age 10 years in New York State. Gump et al. (2005) reported an association of cord blood levels with systolic BP (12.16 mmHg [95% CI: 2.44, 21.88] increase per 1 µg/dL increase in cord blood Pb level). Gump et al. (2011) found that with acute stress, children in higher quartiles of concurrent blood Pb level (>0.69 µg/dL) had larger increases in systolic BP. For example, children with blood Pb levels between 1.21 and 3.76 µg/dL had a 7.23 mmHg change, and children with

blood Pb levels between 0.14 and 0.68 µg/dL had a 5.30 mmHg change. A linear trend was not observed across quartiles. An interaction between long-term perceived stress and bone Pb levels in association with BP and hypertension also was reported in a study of adults (Peters et al., 2007) (described in Section 5.4.2.1). An earlier study (Factor-Litvak et al., 1999; Factor-Litvak et al., 1996), of children with higher blood Pb levels ranging from 4.1 to 76.4 µg/dL found that a 1 µg/dL increase in concurrent blood Pb was associated with a 0.05 (95% CI: -0.02, 0.13) mmHg increase in systolic BP. An additional study (Gerr et al., 2002) reported that young adults (ages 19-29 years) in the highest category of bone Pb levels (greater than 10 µg/g), in whom the mean concurrent blood Pb level was 65 µg/dL, systolic BP was 4.26 mmHg higher compared with young adults with bone Pb levels < 1 µg/dL.

The pathogenesis of CVD has been hypothesized to begin in childhood (Kapuku et al., 2006). Early markers observable in youth include increased blood pressure during stress, reduced heart rate variability, increased IMT, and vascular endothelium dysfunction. Kapuku et al. (2006) state that endothelial dysfunction is the center of the CVD paradigm. The factors measured in childhood or as a cumulative burden since childhood are predictors of outcomes in young adults who are still too young to experience coronary events (Li et al., 2003), and early-life exposures may induce changes in arteries that contribute to the development of atherosclerosis (Raitakari et al., 2003). Berenson et al. (2002) observed that the effects of multiple risk factors on coronary atherosclerosis support evaluation of cardiovascular risk in young people. Thus, evidence relating levels of biomarkers of Pb exposure of children to cardiovascular function in the groups of studies presented in the preceding text when combined with the evidence for the potential pathogenesis of CVD starting in childhood that yield effects in adulthood provides coherence with evidence in adults supporting the effects of long-term, cumulative Pb exposures in the development of cardiovascular effects.

Few animal studies have examined the effect of Pb exposure during pregnancy and lactation on BP in offspring and those that have used high levels of exposure. Recently, pups of Pb-exposed dams (1,000 ppm through pregnancy and lactation) exhibited increased blood Pb level (mean blood Pb level: 58.7 µg/dL) and increased arterial systolic BP after weaning (Grizzo and Cordellini, 2008) suggesting a role for childhood Pb exposure leading to adult disease.

5.4.4.4 Summary of Child Cardiovascular Studies

Studies have reported antecedent cardiovascular changes such as TPR responses to acute stress tasks as a function of childhood blood Pb levels. Also, a study reported associations

with acute stress-induced autonomic and cardiovascular dysregulation responses. Biomarkers of prenatal Pb exposure (maternal post-partum patella and tibia) were related to later higher BP. This may be related to intrauterine growth restriction and subsequent accelerated weight gain in childhood and may indicate greater risk of hypertension later in life. The results are not uniform with respect to the important lifestages of Pb exposure and can differ by sex and other factors. Uncertainties in these studies may be related to sample size, single measures of BP, variation of age of onset of puberty, and cross-sectional design. Some of these uncertainties result in random error, however, and result in the attenuation of observed associations rather than the generation of spurious associations. These study findings indicate that in children with mean blood Pb levels in the range of < 5 to 10 µg/dL, increasing blood Pb level may be associated with small increases in BP and changes in the cardiovascular system that may be related to later development of CVD.

Factors may limit the ability of studies to detect statistically significant Pb-associated changes with BP. The relatively young age of the subjects may have limited the ability of these studies to detect significant BP effects (as opposed to early function effects) if longer duration Pb exposure is necessary to produce the cardiovascular changes considering the lower prevalence and strength of compensatory mechanisms in children. There is uncertainty in the shape of the concentration-response relationship to cardiovascular endpoints at lower blood Pb levels since most studies modeled a linear relationship. Several studies that compared linear and nonlinear relationships between blood Pb level and decrements in cognitive function found a better fit for the nonlinear relationship (See Section 5.3.10).

Cardiovascular endpoints other than baseline BP may be more sensitive outcomes by which to measure Pb-associated cardiovascular effects in very young children. The series of studies by Gump et al. (2011; 2009; 2007; 2005) evaluating much smaller samples than did the adult studies, was able to demonstrate statistically significant relationships of blood Pb levels with cardiovascular outcomes such as TPR related to acute stress. It suggests that the stress paradigm may be useful to detect associations of blood Pb levels with effects on the cardiovascular system of children. Selection of the appropriate cardiovascular outcome in children is an important factor to consider in the design of studies. Rather than using indicators of already present cardiovascular problems, such as BP, informative evaluation of cardiovascular changes that are antecedent to increased BP and changes in other CVD-related endpoints at later lifestages may reduce uncertainties regarding the time course of cardiovascular changes associated with early Pb exposure where the relevance and persistence of these endpoints has been shown to be associated with future pathology.

Overall this body of evidence, based on different cohorts, locations, and study designs, begins to form a literature base that indicates there is a relationship between biomarkers of Pb exposure and cardiovascular effects in children. One longitudinal study ties in maternal bone Pb level, and cord and concurrent blood Pb level for the children. Limitations exist in the studies. While blood pressure increases are more prevalent in older adults than in children, BP increases have been related to higher blood Pb level in older studies of children and young adults (Gerr et al., 2002; Factor-Litvak et al., 1999; Factor-Litvak et al., 1996). The newer children studies provide information in populations with mean blood Pb levels in the range of < 5 to 10 µg/dL for BP and antecedents for CVD such as increases in TPR and changes in cardiac autonomic regulation.

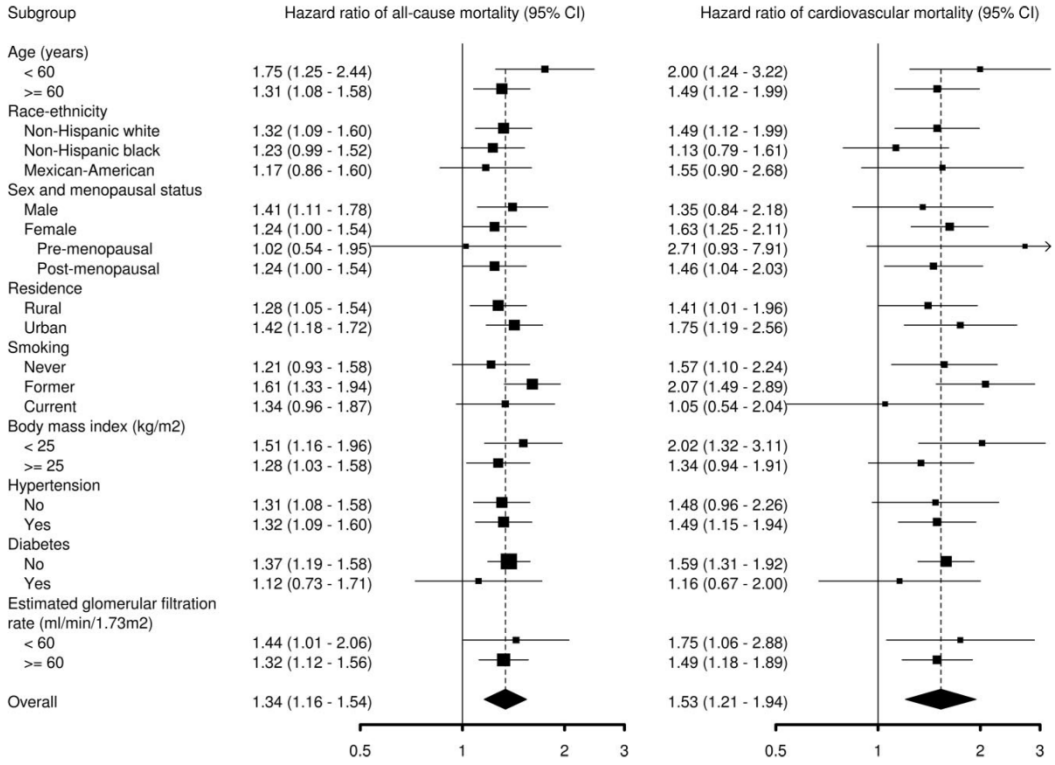
5.4.5 Mortality

The 2006 Pb AQCD stated that collectively the then available evidence suggested an effect of Pb on cardiovascular mortality in the general U.S. population but cautioned that these findings should be replicated before these estimates for Pb-induced cardiovascular mortality could be used for quantitative risk assessment purposes (U.S. EPA, 2006b). Previous results involved NHANES II and III analyses that examined the association of adult concurrent blood Pb with all cause and cause-specific mortality (Schober et al., 2006; Lustberg and Silbergeld, 2002). As blood Pb levels in adults reflect contributions from both recent Pb exposure and mobilization of historic Pb from bone, it is unclear to what extent recent, past, or cumulative Pb exposures contributed to the observed associations. Given the decline in ambient air Pb concentrations and population blood Pb levels, it is likely that study subjects had a much higher Pb exposure in their past than during the study period. Using NHANES II (1976-1980) data, Lustberg and Silbergeld (2002) found significant increases in all-cause, circulatory and cancer mortality, comparing adults with blood Pb levels (measured 12-16 years before ascertainment of vital status) of 20-29 µg/dL to those with blood Pb levels less than 10 µg/dL. Using NHANES III data, Schober et al. (2006) found significant increased all-cause mortality, cardiovascular, and cancer mortality comparing adults with blood Pb levels (measured a median of 8.8 years before ascertainment of vital status) from 5-9 µg/dL and above 10 µg/dL to those with blood Pb levels less than 5 µg/dL.

Several new studies substantially strengthen the evidence base for Pb-associated mortality. A further analysis of the NHANES III database by a different research group using different methods addressed uncertainties from other earlier analyses by considering a more extensive number of potential confounding factors and by characterizing concentration-response relationships. A few longitudinal prospective

studies in different cohorts conducted by different researchers with different methods in different parts of the U.S. provide coherence with the evidence base for blood Pb and add new evidence for mortality associated with bone Pb levels.

Menke et al. (2006) examined all-cause and cause-specific mortality using NHANES III data. Subjects at least 18 years of age were followed up to 12 years after their blood Pb was measured, and 1,661 deaths were identified. Those with baseline blood Pb levels from 3.63 to 10 µg/dL had significantly higher risks of all-cause (HR: 1.25 [95% CI: 1.04, 1.51]), cardiovascular (HR: 1.55 [95% CI: 1.08, 2.24]), MI (HR: 1.89 [95% CI: 1.04, 3.43]), and stroke (HR: 2.51 [95% CI: 1.20, 2.26]) mortality compared to those with baseline blood Pb levels less than 1.93 µg/dL and increased risk of cancer mortality (HR: 1.10 [95% CI: 0.82, 1.47]). Effect estimates adjusted for demographic characteristics were robust to the additional adjustment for factors such as smoking, alcohol consumption, diabetes, BMI, hypertension, and level of kidney function. The consistency of HRs across models with a varying number of control variables indicated little residual confounding. Hazard ratios were not higher comparing adults with blood Pb levels from 1.94 to 3.62 µg/dL to those with blood Pb levels <1.93 µg/dL. However, tests for linear trend were statistically significant for all mortality outcomes except for cancer mortality. Menke et al. (2006) evaluated several of the model covariates (e.g., diabetes, hypertension, and glomerular filtration rate [GFR]) in a subgroup analysis (Figure 5-32). The authors reported that there were no interactions between blood Pb and other adjusted variables. In the previous NHANES III analysis of the association of blood Pb with mortality, Schober et al. (2006) included participants greater than 40 years of age (N = 9686) and adjusted for covariates including age, sex, ethnicity, and smoking rather than the full suite of covariates evaluated by Menke et al. (2006). Schober et al. (2006) reported increased HRs comparing adults with blood Pb levels ≥ 10 µg/dL to those with blood Pb levels <5 µg/dL for all-cause (HR: 1.59 [95% CI: 1.28, 1.98]), CVD (HR: 1.55 [95% CI: 1.16, 2.07]), and cancer (HR: 1.69 [95% CI: 1.14, 2.52]) mortality and generally statistically nonsignificant higher HRs comparing adults with blood Pb levels from 5-9 µg/dL to those with blood Pb levels <5 µg/dL. The median follow-up time between measurement of blood Pb and death ascertainment was 8.55 years.



Source: Reprinted with permission of Lippincott Williams & Wilkins, Menke et al. (2006)

Note: Hazard ratios were calculated for a 3.4-fold increase in blood Pb level with log-blood Pb as a continuous variable. This increase corresponds to the difference between the 80th and 20th percentiles of the blood Pb distribution (4.92 µg/dL versus 1.46 µg/dL, respectively).

Figure 5-32 Multivariate adjusted relative hazards of all-cause and cardiovascular mortality.

Both Menke et al. (2006) and Schober et al. (2006) presented mortality curves that plot the HRs against blood Pb level. Figure 5-33 shows the mortality hazard ratio curves (not absolute cases of mortality) for both stroke and MI reported by Menke et al. (2006). Nonlinear associations were modeled. The curves were fitted using predetermined restricted quadratic splines with knots at the 10th percentile (1.00 µg/dL), the 50th percentile (2.67 µg/dL), and the 80th percentile (5.98 µg/dL) blood Pb levels. The authors did not explain the shape of the blood Pb-mortality curves in detail; however, the knots corresponded with the inflection points in the curve. In the tails of the blood Pb distribution, hazard ratios decreased with increasing blood Pb level. However, hazard ratios remained above 1 over most of the blood Pb distribution, and in the most heavily populated portion of the blood Pb distribution, hazard ratios increased with increasing blood Pb level. Hazard ratios peaked for all outcomes at a blood Pb level of approximately 6 µg/dL. Lower concentration-response functions at higher blood Pb

levels also have been found for blood Pb-cognitive function relationships in children (Section 5.3.10).

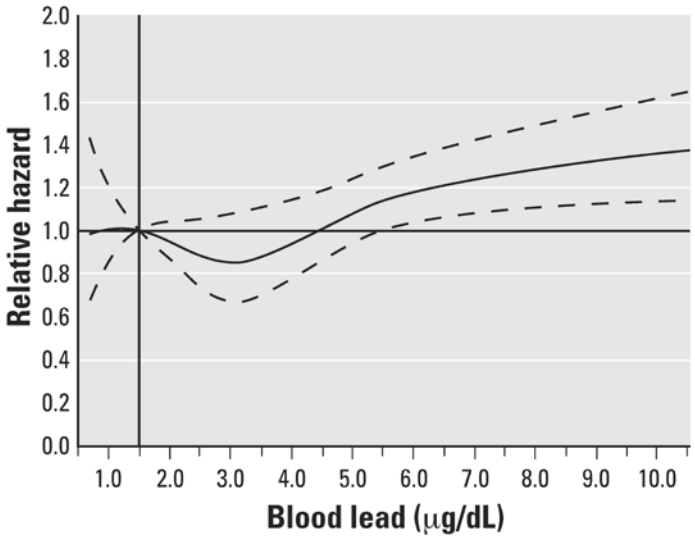
Note: A histogram of blood Pb levels is superimposed in the background and displayed on the right axis.

Figure 5-33 Multivariate-adjusted relative hazard (left axis) of mortality associated with blood Pb level between 1 µg/dL and 10 µg/dL.

Schober et al. (2006) examined proportional hazard assumptions, tested for linear trend across blood Pb tertiles, and evaluated log-transformed continuous blood Pb level as a 5-knot cubic spline (position of knots not reported). A statistically significant increasing linear trend for mortality was observed across blood Pb tertiles. The results of the spline fit of the continuous blood Pb level term to relative hazard of all cardiovascular diseases reported by Schober et al. (2006) are shown in Figure 5-34. In contrast to the curve presented by Menke et al. (2006), Schober et al. (2006) found the relative hazard axis and the blood Pb axis largely to be linear (solid line). Dashed lines are 95% CIs. The hazard ratio was fixed at 1.0 for the referent blood Pb level of 1.5 µg/dL. In this study, hazard ratios were less than one in the lower range of blood Pb levels. Despite differences in the

age groups included, follow-up time, categorization of blood Pb levels, and differences in hazard ratio across the blood Pb range, results reported by Menke et al. (2006) and Schober et al. (2006) are consistent in finding associations between higher blood Pb and increased CVD mortality.



Source: Schober et al. (2006)
Note: The solid line shows the fitted five-knot spline relationship; the dashed lines are the point-wise upper and lower 95% CIs.

Figure 5-34 Relative risk of all cause mortality for different blood Pb levels compared with referent level of 1.5 μg/dL (12.5th percentile).

In addition to the NHANES analyses described above, studies of older adult males (Weisskopf et al., 2009) and older adult females (Khalil, 2010; Khalil et al., 2009a) were conducted recently. Weisskopf et al. (2009) used data from the NAS to determine the associations of blood, tibia, and patella Pb with mortality. The authors identified 241 deaths over an average observation period of 8.9 years (7,673 person-years). The strongest associations were observed between mortality and baseline patella Pb concentration. Baseline tibia Pb levels were more weakly associated with CVD mortality. Tibia bone Pb level is thought to reflect a longer cumulative exposure period than is patella bone Pb level because the residence time of Pb in trabecular bone is shorter than that in cortical bone. IHD contributed most to the relationship between patella Pb and all CVD death with an individual HR of 2.69 (95% CI: 1.42, 5.08). Although there was high correlation between tibia and patella Pb (Pearson r = 0.77), compared with cortical bone Pb, trabecular bone Pb may have more influence on circulating blood Pb level, and thus local organ concentration of Pb, because of its shorter residence time in bone. In contrast

to the NHANES analyses, baseline blood Pb was not significantly related to cardiovascular mortality in the NAS study. This discrepancy may be related to differences in sample size and resulting power, modeling strategies (e.g., linear versus log-linear blood Pb level terms), or age range of the study populations. The duration of follow-up was similar across studies. The youngest subjects at baseline in the Weisskopf et al. (2009) study were approximately 50-55 years old, compared to the youngest in the Menke et al. (2006) and Schober et al. (2006) studies, who were 18 and 40 years, respectively. Further, the blood Pb tertile analysis of Weisskopf et al. (2009) could have been affected if the majority of a hypothesized nonlinear association was contained largely in the lowest (reference) blood Pb tertile.

Weisskopf et al. (2009) also conducted a concentration-response analysis. A linear trend was observed for increasing HR across tertiles of both tibia and patella Pb levels. The linear relationship using tertile patella Pb was confirmed in other models in which continuous patella Pb and nonlinear penalized spline terms (higher order terms) were not statistically significant. The number of knots and their placement within the Pb variable, which can influence these results, were determined by an iterative best fit procedure. Concentration-response relationships shown in Figure 5-35 were approximately linear for patella Pb on the log HR scale for all CVD, but appeared nonlinear for IHD ($p < 0.10$). The peak HR is shown around 60 µg/g, beyond which the HR tends to decrease. It is important to note the wide confidence limits, which increase uncertainty at the lower and upper bounds of patella Pb levels.

Note: The reference logHR = 0 at the mean of patella Pb concentration. The estimates are indicated by the solid line and the 95% pointwise CIs by the dashed lines. The P values for significance of the nonlinear component for all-cause, cardiovascular, and ischemic heart disease mortality were 0.42, 0.80 and 0.10 respectively. Patella Pb concentrations of all individual participants are indicated by short vertical lines on the abscissa. Adjusted for age, education, smoking status, and pack-years of smoking among participants without ischemic heart disease at baseline.

Figure 5-35 Associations between patella bone Pb level and the log of HR (logHR) for all-cause, cardiovascular, and ischemic heart disease.

The association of adult blood Pb with mortality has also been examined among women enrolled in the Study of Osteoporotic Fractures (SOF) (Khalil et al., 2009a). This prospective cohort (N = 533) enrolled female volunteers from two U.S. locations, Baltimore, MD and Monongahela Valley, PA and followed women for an average of 12 years after blood Pb measurement. All-cause mortality comparing women with blood Pb levels >8 µg/dL to those with blood Pb levels <8 µg/dL was significantly increased (HR: 1.59 [95% CI: 1.02, 2.49]). Combined cardiovascular disease mortality (HR: 1.78 [95% CI: 0.92, 3.45]), coronary heart disease mortality (HR: 3.08 [95% CI: 1.23, 7.70]), but not stroke mortality (HR: 1.13 [95% CI: 0.34, 3.81]) HR was increased among the women enrolled in this study with blood Pb levels >8 µg/dL. In addition, analyses of blood Pb tertiles and quintiles indicated that blood Pb-mortality HRs were consistently elevated in groups with blood Pb levels > 7 µg/dL (Khalil, 2010). The findings for elevated mortality HRs with the highest blood Pb levels are reinforced by the results displayed in Figure 5-36. The HR curve for all-cause mortality is relatively flat over most of population blood Pb distribution (represented by the blue dots) and increases only in the upper tail of the blood Pb distribution where there are relatively few subjects (i.e., fewer dots).

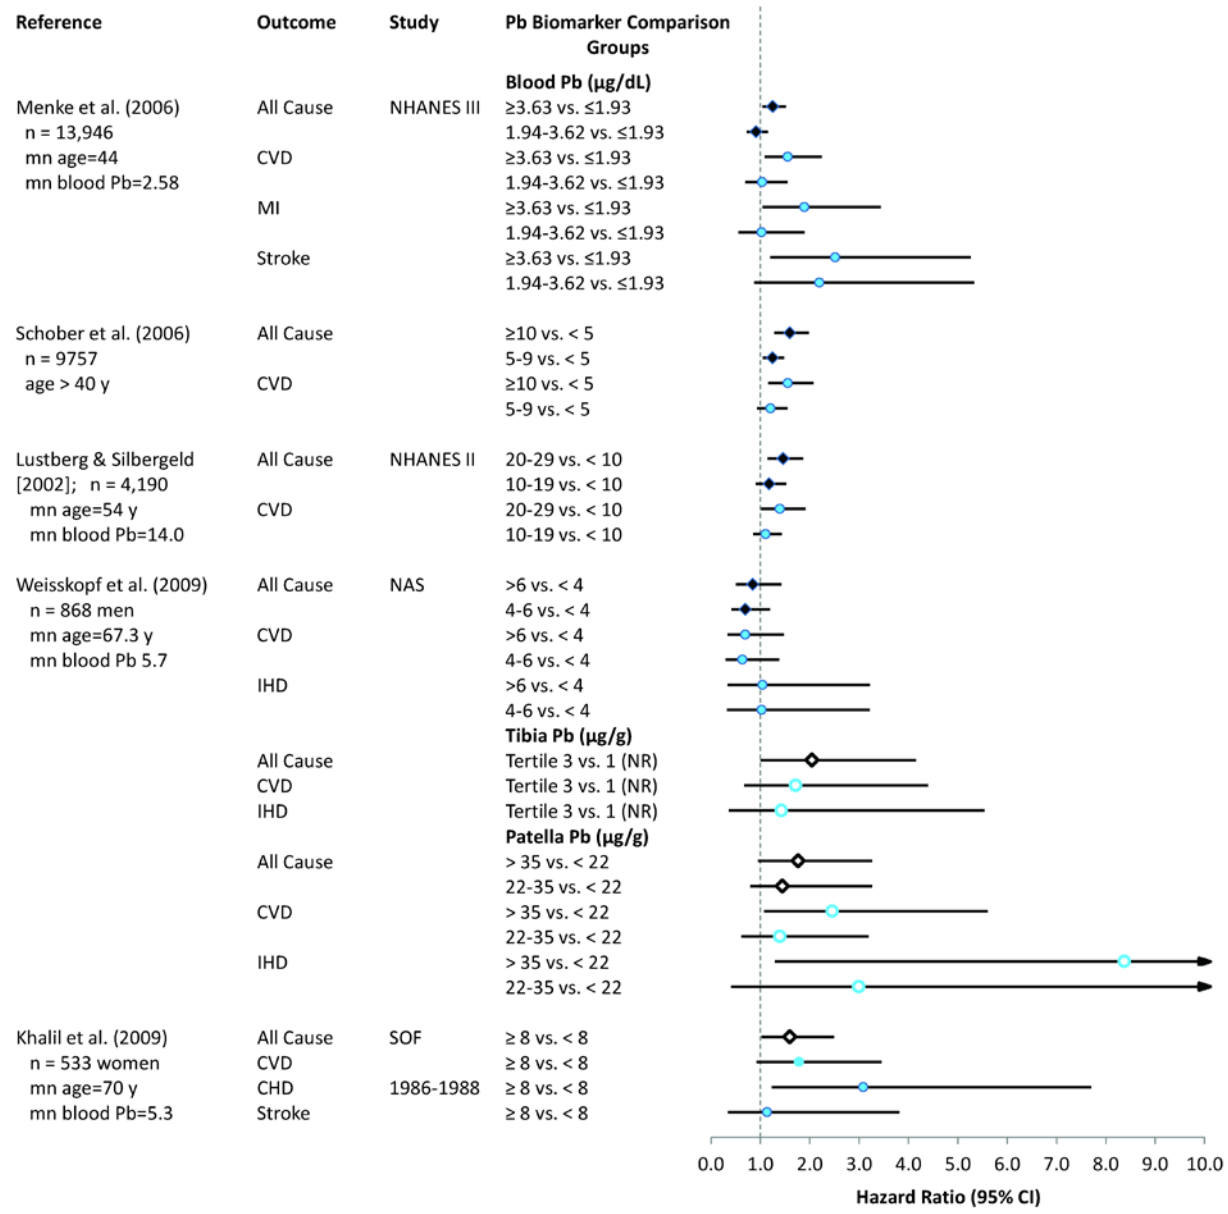
5.4.5.1 Summary of Mortality

The mortality results in this review supported and expanded upon findings from the 2006 Pb AQCD (U.S. EPA, 2006b), which included a few NHANES mortality studies (Schober et al., 2006; Lustberg and Silbergeld, 2002). The recent NHANES mortality study discussed above (Menke et al., 2006) addressed many of the limitations of the these earlier studies, including control for a wider range of potential confounders, testing for interactions with Pb, consideration of concentration-response relationships, extensive model evaluations, and examination of mortality from specific CVDs. Further, an association with increased mortality was observed at lower mean population blood Pb levels. The mean blood Pb level of the NHANES III population was 2.58 µg/dL. The Pb attributable risk of increased cardiovascular mortality in the NHANES III analysis of Menke et al. (2006) increased with increasing blood Pb level over the most heavily population portion of the blood Pb distribution and reached its maximum at blood Pb levels between of 6 and 7 µg/dL. It is important to note that the relative contributions of

recent, past, and cumulative Pb exposure to associations observed with the baseline blood Pb levels is uncertain. In addition, the first evidence that bone Pb, a metric of cumulative Pb exposure, is associated with increased mortality was reported recently among NAS men (Weisskopf et al., 2009).

Quantitative differences in Pb-associated hazard for death between studies may be influenced by age range of the study groups, follow up time to death, variation in model adjustment, central tendency and range of the Pb biomarker levels, assumptions of linearity in relationship with Pb biomarkers, and choice of Pb biomarker. Quantitative differences in Pb-associated mortality across NHANES II and NHANES III studies or between different NHANES III analyses may be explained by the use of continuous or ordered blood Pb terms and different data selection strategies. Further, studies using ordered categories of blood Pb level may obtain different results, as the range of blood Pb level represented in the reference category will affect the calculated coefficients of the remaining percentiles or groups.

Specifically, Menke et al. (2006) is the strongest study presently published for estimating the effects of Pb on cardiovascular disease-related mortality. The study uses the nationally representative NHANES III (1988-1994) sample of men and women. The results provide confirmation of earlier published NHANES studies but address some of the key weaknesses noted in those studies. For example, Menke et al. (2006) examined potential confounding by a large number of factors, including hypertension and kidney function. Weisskopf et al. (2009) is the first published mortality study using bone Pb as an exposure index. The study is a prospective study with nearly 100% successful follow-up of deaths. This rigorous study found increased cardiovascular disease mortality in association with patella bone Pb. The Khalil et al. (2010; 2009a) SOF provides supporting results in a different study cohort consisting of white females aged 65-87 years. Further, a number of prior studies have found association between accumulated Pb reflected in bone Pb measurements and higher CVD morbidity (Sections 5.4.2.1 and 5.4.3). This evidence base is augmented with new findings indicating that biomarkers of longer-term cumulative Pb exposure increases CVD mortality. The NAS and SOF examine only men and women, respectively. However, the consistency of findings between the two studies indicates that the results of either study may be applicable widely. Despite the differences in design and methods across studies, with few exceptions associations between higher levels of Pb biomarkers and higher risk of mortality were consistently observed (Figure 5-37 and Table 5-21). In studies that examined mortality from specific CVD causes, MI, stroke, and IHD mortality, which are causes related to higher BP and hypertension were all significantly elevated with higher Pb biomarker levels.



Note: Studies are presented in order of strength of study design and follow the order of discussion in the preceding text. Hazard ratios represent the hazard in the higher blood or bone Pb group relative to that in the lowest blood or bone Pb group (reference).

5.4.6 Air Lead-Particulate Matter Studies

5.4.6.1 Cardiovascular Morbidity

A relatively small number of studies used Pb measured in PM_{10} and $PM_{2.5}$ ambient air samples to represent Pb exposures. However, given that size distribution data for Pb-PM are fairly limited, it is difficult to assess the representativeness of these concentrations to population exposure (Section 3.5.3). Moreover, data illustrating the relationships of Pb-PM_{10} and Pb-$PM_{2.5}$ with blood Pb levels are lacking. A few available studies exposed rats, dogs, or humans to concentrated ambient particles (CAPS) in which Pb and several other components were measured. Consistent with epidemiologic studies of blood and bone Pb and with studies of animals exposed to Pb, exposure to Pb-containing CAPS resulted in various changes related to increased vasoconstriction (Urch et al., 2004; Wellenius et al., 2003; Batalha et al., 2002). Whereas studies of Pb biomarkers primarily found cardiovascular effects with indicators of long-term Pb exposure, studies of Pb-containing CAPS provide evidence for cardiovascular effects with short-term exposure (2-6 hours over multiple days) It is important to note that Urch et al. (2004) estimated the Pb effect on brachial artery diameter based only on the ambient concentrations of Pb but did not directly expose their young (mean age: 35 years, SD: 10), healthy adult participants to Pb isolated from CAPS.

A U.S. time-series study of almost 3 million pregnant women found that increases in ambient Pb-TSP concentrations were associated with increased odds of PIH assessed at delivery (Chen et al., 2006c). In contrast, epidemiologic studies provide weak evidence for an association between short-term changes (daily average) in ambient air concentrations of Pb- $PM_{2.5}$ and cardiovascular morbidity in adults. Some of these time-series studies analyzed Pb individually, whereas others applied source apportionment techniques to analyze Pb as part of a group of correlated components. In a time-series study of 106 U.S. counties, Bell et al. (2009) found that an increase in lag 0 Pb- $PM_{2.5}$ was associated with an increased risk of cardiovascular hospital admissions among adults ages 65 years and older. Quantitative results were not presented; however, the 95% CI was wide and included the null value. In this study, statistically significant associations were observed for other PM metal components such as nickel, vanadium, and zinc. In the absence of detailed data on correlations among components or results adjusted for copollutants, it is difficult to exclude confounding by ambient air exposures to these other components or copollutants.

To address correlations among PM chemical components, some studies applied source apportionment techniques to group components into common source categories. In these source-factor studies, it is not possible to attribute the observed association (Sarnat et al., 2008) or lack of association (Andersen et al., 2007) specifically to Pb.

5.4.6.2 Mortality

Time-series epidemiologic studies of ambient air Pb- $PM_{2.5}$ reported positive associations with mortality. Although limited in number, these studies indicated associations in multiple cities across the U.S. In the Harvard Six Cities Study, Laden et al. (2000) found a 1.16% (95% CI: 0.20, 2.9%) increased risk in all-cause mortality per 461.4 ng/m^3 (5th-95th percentile) increase in Pb- $PM_{2.5}$. In six California counties, Ostro et al. (2007) found that a 5 ng/m^3 (interquartile range) increase in Pb- $PM_{2.5}$ was associated with a 1.89% (95% CI: -0.57, 4.40%) increased risk of cardiovascular mortality and a 1.74% (95% CI: 0.24, 3.26%) increased risk of all-cause mortality during the cool season. The limitations of air-Pb studies were described in Section 5.4.6.1 above and also are relevant to the interpretation of these findings for mortality.

5.4.7 Summary and Causal Determination

The 2006 Pb AQCD concluded that there was a relationship between higher blood Pb and bone Pb and cardiovascular effects in adults, in particular increased BP and increased

incidence of hypertension (U.S. EPA, 2006b). This conclusion was substantiated by the coherence observed between epidemiologic and toxicological findings. The large evidence base comprising epidemiologic studies conducted in diverse populations using different designs clearly demonstrated a positive association between blood Pb level and BP. Meta-analysis of these studies found that each doubling of concurrent blood Pb level (between 1 and >40 µg/dL) was associated with a 1 mmHg increase in systolic BP and a 0.6 mmHg increase in diastolic BP (Nawrot et al., 2002). In addition, most of the reviewed studies using bone Pb levels also showed an association with BP, pointing to an effect of cumulative Pb exposure. Similarly, toxicological studies provided evidence that long-term exposure to Pb (> 4 weeks) results in increased BP in experimental animals that persists long after the cessation of Pb exposure. Also, animal toxicological studies provided mechanistic evidence to support the biological plausibility of Pb-induced hypertension, including Pb-induced oxidative stress, activation of RAAS, altered sympathetic activity, and vasomodulator imbalance. Studies in the 2006 Pb AQCD also found associations between Pb biomarkers and other cardiovascular diseases such as IHD, cerebrovascular disease, peripheral vascular disease, and cardiovascular disease related mortality; however, the available evidence was limited.

Building on the strong body of evidence presented in the 2006 Pb AQCD, recent epidemiologic and toxicological studies strengthened the evidence that long-term Pb exposure is associated with cardiovascular effects in adults with the largest body of evidence demonstrating associations of Pb with increased BP and hypertension. Recent epidemiologic studies addressed past uncertainties, including the potential for confounding. A recent study in an ethnically diverse community-based cohort of women and men aged 50-70 years found hypertension risk to be associated with blood and tibia Pb levels (Martin et al., 2006). These findings are consistent with those of other studies, demonstrating that with each increase of 1 µg/dL concurrent blood Pb level, systolic BP increased 1 mmHg and diastolic BP increased 0.5 mmHg. Recent epidemiologic studies in adults found associations with hypertension in populations with relatively low mean blood Pb levels. For example, a positive relationship was found in the nationally representative NHANES III (1988-1994) where the geometric mean blood Pb level of the population was 1.64 µg/dL (Muntner et al., 2005). Despite the extensive evidence for relatively low concurrent blood Pb levels, as these cardiovascular outcomes were most often examined in adults that have been exposed to higher levels of Pb earlier in life, uncertainty remains concerning the Pb exposure level, timing, frequency, and duration contributing to the observed associations. A new prospective study in Pb workers found independent associations of both baseline blood Pb level and subsequent changes in blood Pb over follow-up with changes in BP over follow-up and bone Pb level with hypertension (Glenn et al., 2006). The results indicated that different mechanisms may

mediate shorter-term Pb-associated increases in BP and longer-term Pb-associated development of hypertension.

Collectively, all animal toxicological studies providing blood Pb level and BP measurements reported increases in BP with increasing blood Pb level (Figure 5-29). Importantly, an animal toxicological study provided support for increased BP following long-term Pb exposure resulting in low blood Pb levels with mean blood Pb levels as low as 2 µg/dL (Tsao et al., 2000). However, a majority of studies examined Pb exposures that resulted in mean blood Pb levels > 10 µg/dL. Thus, the weight of the evidence demonstrated such effects in animals with blood Pb levels >10 µg/dL. New studies also demonstrated only partial reversibility of Pb-induced increased BP following Pb exposure cessation or chelation and the possibility for short-term Pb exposure-induced increases in BP.

The epidemiologic evidence for a relationship between Pb exposure and cardiovascular disease is strengthened by observations of cardiovascular effects in association with both blood and bone Pb level after adjusting for multiple potential confounding factors, including age, sex, BMI, antihypertensive medication, SES, race/ethnicity, alcohol consumption, serum total cholesterol, smoking, educational level, diabetes, and measures of renal function. The epidemiologic evidence also was substantiated by several available prospective studies that found associations between biomarkers of Pb and cardiovascular health endpoints. These studies inform the temporality of these relationship between biomarkers of Pb exposure and cardiovascular morbidity (e.g., HRV, IHD, BP, hypertension) (Eum et al., 2011; Jain et al., 2007; Peters et al., 2007; Glenn et al., 2006) and mortality (Khalil et al., 2009a; Weisskopf et al., 2009; Menke et al., 2006; Schober et al., 2006).

Epidemiologic studies continued to demonstrate a relationship between bone Pb, which is a metric of cumulative Pb exposure, and BP in adults. Studies that examined both blood and bone Pb levels did not conclusively demonstrate a stronger association for either blood or bone Pb (Perlstein et al., 2007; Glenn et al., 2006; Martin et al., 2006). In a recent meta-analysis, Navas-Acien et al. (2008) found that studies passing the detailed inclusion criteria all showed a relationship between higher bone Pb levels and higher BP. Also, all but one that characterized hypertension showed higher relative risks or odds ratios associated with higher bone Pb levels. Recent epidemiologic studies also emphasized the interaction between bone Pb levels and factors that modify the association with BP or hypertension, such as race/ethnicity, chronic stress and metabolic syndrome. Bone Pb coupled with high perceived stress was associated with an increased risk of developing hypertension in an originally nonhypertensive group of adults (Peters et al., 2007). Also, bone Pb level was associated with larger decreases in HRV (which has

been associated with increased cardiovascular events) among adults with metabolic syndrome, also associated with increased risk of cardiovascular events (Park et al., 2006). The extensive epidemiologic evidence for bone Pb levels in concert with the animal toxicological evidence for long-term Pb exposure, support an effect of long-term, cumulative Pb exposure on cardiovascular morbidity.

Recent epidemiologic studies of adults investigated the interaction of Pb biomarkers with genetic variants in associations with cardiovascular effects. Evidence was presented for a larger blood Pb-associated increase in BP in carriers of the ALAD2 allele, which is associated with greater binding affinity for Pb in the bloodstream (Figure 5-26 for results) (Scinicariello et al., 2010). Additionally, bone Pb concentration was associated with larger increases in PP, which represents as a good predictor of cardiovascular morbidity and mortality and an indicator of arterial stiffness, among adults with the HFE H63D and/or C282Y variant (Zhang et al., 2010a) (Figure 5-26 for results). Park et al. (2009b) provided further evidence of HFE and transferrin gene variants, related to iron metabolism, impacting the associations of bone Pb levels with cardiovascular effects, evaluated by QT interval changes.

Epidemiologic and toxicological evidence indicates that Pb exposure not only increases BP and hypertension, but can contribute to the development of other cardiovascular diseases in adults. However, fewer studies have been published compared to studies of BP and hypertension. Both recent epidemiologic and toxicological studies provide evidence in adults for blood Pb-associated increased atherosclerosis, thrombosis, IHD, PAD, arrhythmia, and cardiac contractility in populations with mean blood Pb levels >2.5 µg/dL (Table 5-19). Further, animal toxicological evidence continued to build on the evidence supporting the mechanisms leading to these cardiovascular system responses, as well as Pb-induced changes in BP and hypertension. Enhanced understanding of Pb-induced oxidative stress including $^{\bullet}$NO inactivation, endothelial dysfunction leading to altered vascular reactivity, activation of the RAAS, and vasomodulator imbalance provides biological plausibility for the consistent associations observed between higher blood and bone Pb levels and greater cardiovascular effects.

Several studies in children reported associations of childhood (concurrent and measured at an average age of 2.6 years) blood Pb levels with cardiovascular changes such as TPR and autonomic and cardiovascular dysregulation in response to acute stress tasks measured between ages 5 to 15 years (Gump et al., 2011; 2009; Gump et al., 2007). Also, maternal bone and cord blood Pb levels, biomarkers of prenatal Pb exposure, were related to higher BP in children (Gump et al., 2005; Zhang et al., In Press). These study findings of children add evidence that Pb exposure is associated with small increases in BP, and

that changes in the cardiovascular system precedent to later CVD are potentially impacted by early-life Pb exposure.

New evidence extended the potential continuum of Pb-related cardiovascular effects by demonstrating associations between Pb biomarkers and both cardiovascular and all-cause mortality with follow-up periods ranging between 8 and 12 years. All-cause mortality was increased with increasing blood Pb level. A recent analysis of the NHANES III sample reported associations of adult blood Pb level with cardiovascular mortality, with stronger associations observed with myocardial infarction and stroke mortality (Menke et al., 2006). These findings were supported by a community-based cohort of women age 65-87 years, in which higher effect estimates were observed for mortality from cardiovascular disease and coronary heart disease (Khalil et al., 2009a). Weisskopf et al. (2009) published the first mortality study using bone Pb as an exposure index. This prospective study found that patella bone Pb levels were associated with increased mortality from cardiovascular disease and IHD with hazard ratios of 5.6 and 8.4, respectively.

Changes in BP that have been associated with biomarkers of Pb exposure indicate a modest change for an individual; however, these modest changes can have a substantial implication at the population level. The reported effects represent a central tendency of Pb-induced cardiovascular effects among individuals; some individuals may differ in risk and manifest effects that are greater in magnitude. For example, a small increase in BP may shift the population distribution and result in considerable increases in the percentages of individuals with BP values that are clinically significant, i.e., an indication of hypertension and medication use. Studies in the medical literature show that increasing BP, even within the nonhypertensive range, is associated with increased rates of death and cardiovascular disease, including coronary disease, stroke, PAD, and cardiac failure (Ingelsson et al., 2008; Chobanian et al., 2003; Pastor-Barriuso et al., 2003; Prospective Studies Collaboration, 2002; Kannel, 2000a, b; Neaton et al., 1995).

In summary, new studies evaluated in the current review supported and expanded upon the strong body of evidence presented in the 2006 Pb AQCD that Pb exposure is associated with cardiovascular health effects. The weight of both epidemiologic and toxicological evidence continues to support a consistent relationship between Pb exposure and increased BP or hypertension development in adults. The epidemiologic evidence is strengthened by several prospective studies that find associations between biomarkers of Pb and BP and hypertension and by effect estimates that are observed after adjustment for multiple potential confounding factors. The weight of epidemiologic evidence supported associations in adults with mean concurrent blood Pb levels less than 5 µg/dL. As these outcomes in epidemiologic studies were most often observed in adults

with likely higher past than current Pb exposures, uncertainty exists as to the Pb exposure level, timing, frequency, and duration contributing to the observed associations. Recent epidemiologic studies found that bone Pb level, a metric of cumulative exposure, is strongly related to hypertension risk in adults with mean bone Pb levels greater than 20 µg/g. However, uncertainties also exist as to the specific Pb exposure conditions that contributed to the associations. The weight of animal evidence also demonstrates an increase in BP after long-term (i.e., greater than 4 weeks) exposure to Pb. Whereas the majority of studies examined and found increases in BP in animals with mean blood Pb levels greater than 10 µg/dL, a recent studies found elevated BP in animals with a mean blood Pb level of 2 µg/dL. By demonstrating Pb-induced oxidative stress including $^{\bullet}$NO inactivation, endothelial dysfunction leading to altered vascular reactivity, activation of the RAAS, and vasomodulator imbalance, toxicological studies have characterized the modes of action of Pb and provided biological plausibility for the consistent associations observed in epidemiologic studies between blood and bone Pb and cardiovascular effects. These associations of Pb with cardiovascular morbidity observed in both epidemiologic and toxicological studies support recent epidemiologic findings of increased Pb-associated cardiovascular mortality. Collectively, the evidence integrated across epidemiologic and toxicological studies as well as across the spectrum of other cardiovascular endpoints examined is sufficient to conclude that there is a causal relationship between Pb exposures and cardiovascular health effects**.**

5.5 Renal Effects

5.5.1 Introduction

This section summarizes key findings with regard to effects of Pb on the kidney in animal toxicology and epidemiologic studies. Findings summarized across epidemiologic and toxicological studies indicate that chronic Pb exposure is associated with pathological changes in the renal system such as proximal tubule (PT) cytomegaly, renal cell apoptosis, mitochondrial dysfunction, aminoaciduria, increased electrolyte excretion, ATPase dysfunction, oxidant redox imbalance, altered glomerular filtration rate (GFR), chronic kidney disease (CKD) development, and altered $^{\bullet}$NO homeostasis with ensuing elevated BP. As several of these outcomes are most often observed in adults with likely higher past Pb exposures, uncertainty exists as to the Pb exposure level, timing, frequency, and duration contributing to the associations observed with blood or bone Pb levels.

The cardiovascular and renal systems are intimately linked. Homeostatic control at the kidney level functions to regulate water and electrolyte balance via filtration, re-absorption and excretion and is under tight hormonal control. Pb exposure damages the kidneys and its vasculature and systemic hypertension ensues with effects on the cardiovascular and renal systems (Section 5.4). Chronic increases in vascular pressure can contribute to glomerular and renal vasculature injury, which can lead to progressive renal dysfunction and kidney failure. In this manner, Pb-induced hypertension has been noted as one cause of Pb-induced renal disease. However, the relationship between BP and renal function is more complicated. Not only does hypertension contribute to renal dysfunction but damage to the kidneys can also cause increased BP. Long-term control of arterial pressure is affected by body fluid homeostasis which is regulated by the kidneys. In examining the physiological definition of BP (i.e., mean BP equates to cardiac output multiplied by total peripheral resistance [TPR]) the role of the kidneys in BP regulation is highlighted. Cardiac output is driven by left ventricular and circulating blood volume. TPR is driven by vasomodulation and electrolyte balance. Thus, it is possible to dissect the causes of hypertension from features of primary kidney disease. Increased extracellular fluid volume results in increased blood volume which enhances venous return of blood to the heart and increases cardiac output. Increased cardiac output not only directly increases BP, but also increases TPR due to a compensatory autoregulation or vessel constriction. In addition, damage to the renal vasculature will alter the intra-renal vascular resistance thereby altering kidney function and affecting the balance between renal function and BP. The interactions between these systems can lead to further exacerbation of vascular and kidney dysfunction following Pb exposure. As kidney dysfunction can increase BP and increased BP can lead to further damage to the kidneys, Pb-induced damage to both systems may result in a cycle of further increased severity of disease.

In general, associations between bone Pb (particularly in the tibia) and health outcomes in adults indicate chronic effects of cumulative Pb exposure. In adults without current occupational Pb exposure, blood Pb level represents both recent and cumulative Pb exposure. In particular, blood Pb level may represent cumulative exposure in physiological circumstances of increased bone remodeling or loss (e.g., osteoporosis and pregnancy) when Pb from bone of adults contributes substantially to blood Pb concentrations. Blood Pb in children is also influenced by Pb stored in bone due to rapid growth-related bone turnover in children relative to adults. Thus, blood Pb in children is also reflective of cumulative dose. Additional details on the interpretation of Pb in blood and bone are provided in Section 4.3.5. The toxicokinetics of Pb in blood and bone are important considerations in making inferences about etiologically-relevant Pb exposures that contributed to associations observed between blood and bone Pb levels and health outcomes.

5.5.1.1 Kidney Outcome Measures

The primary function of the kidneys is to filter waste from the body while maintaining appropriate levels of water and essential chemicals, such as electrolytes, in the body. Therefore, the gold standard for kidney function assessment involves measurement of the GFR through administration of an exogenous radionuclide or radiocontrast marker (e.g., 125I-iothalamate, iohexol) followed by timed sequential blood samples or, more recently, kidney imaging, to assess clearance through the kidneys. This procedure is invasive and time-consuming. Therefore, serum levels of endogenous compounds are routinely used to estimate GFR in large epidemiologic studies and clinical settings. Creatinine is the most commonly measured endogenous compound; blood urea nitrogen (BUN) has also been examined. Increased serum concentration or decreased kidney clearance of these markers both indicate decreased kidney function. The main limitation of endogenous compounds identified to date is that non-kidney factors impact their serum levels. Specifically, since creatinine is metabolized from creatine in muscle, muscle mass and diet affect serum levels resulting in variation in different population subgroups (e.g., women and children compared to men), that are unrelated to kidney function. Measured creatinine clearance, involving measurement and comparison of creatinine in both serum and urine, can address this problem. However, measured creatinine clearance utilizes timed urine collections, traditionally over a 24-hour period, and the challenge of complete urine collection over an extended time period makes compliance difficult.

Therefore equations to estimate kidney filtration that utilize serum creatinine but also incorporate age, sex, race, and, in some, weight (in an attempt to adjust for differences in muscle mass), have been developed. Although these are imperfect surrogates for muscle mass, such equations are currently the preferred outcome assessment method. Traditionally, the Cockcroft-Gault equation (Cockcroft and Gault, 1976), which estimates creatinine clearance, a GFR surrogate, has been used. In the last decade, the abbreviated Modification of Diet in Kidney Disease (MDRD) Study equation (Levey et al., 2000; Levey et al., 1999), which estimates GFR, has become the standard in the kidney epidemiologic and clinical communities. With widespread use of the MDRD equation, it became clear that the equation underestimates GFR at levels in the normal range. Therefore, the CKD-Epidemiology Collaboration (CKD-EPI) equation was recently developed to be more accurate in this range (Levey et al., 2009). This is a decided advantage in nephrotoxicant research since most participants in occupational and many even in general population studies have GFRs in a range that is underestimated by the MDRD equation.

Both the MDRD and CKD-EPI equations use serum creatinine. Due to the inability to adjust serum creatinine levels for muscle mass, alternative serum biomarkers have been

evaluated such as cystatin C, a cysteine protease inhibitor that is filtered, reabsorbed, and catabolized in the kidney (Fried, 2009). It is produced and secreted by all nucleated cells thus avoiding the muscle mass confounding that exists with serum creatinine (Fried, 2009). However, recent research indicates that serum cystatin C varies by age, sex, and race (Kottgen et al., 2008). Thus, a cystatin C-based eGFR equation was recently developed that includes age, sex, and race (Stevens et al., 2008).

Most of the kidney outcome measures discussed above were developed for use in the clinical setting. Unfortunately, they are insensitive for detection of early kidney damage, as evidenced by the fact that serum creatinine remains normal after kidney donation. Therefore, in the last two decades, the utility of early biological effect (EBE) markers as indicators of preclinical kidney damage has been of interest. These can be categorized as markers of function (i.e., low molecular weight proteins that should be reabsorbed in the PT such as β2-microglobulin and retinol-binding protein [RBP]); biochemical alteration (i.e., urinary eicosanoids such as prostaglandin E2, prostaglandin F2 alpha, 6-keto-prostaglandin F_1 alpha, and thromboxane B2); and cytotoxicity (e.g., N-acetyl-β-D-glucosaminidase [NAG]) (Cardenas et al., 1993). Elevated levels may indicate an increased risk for subsequent kidney dysfunction. However, most of these markers are research tools only, and their prognostic value remains uncertain since prospective studies of most of these markers in nephrotoxicant-exposed populations are quite limited to date. Recently, microalbuminuria has been identified as a PT marker, not just glomerular as previously thought (Comper and Russo, 2009). Kidney EBE markers are a major recent focus for research in patients with acute kidney injury (AKI) and markers such as neutrophil gelatinase-associated lipocalin (NGAL) and kidney injury molecule-1 (Kim-1), developed in AKI research, may prove useful for chronic nephrotoxicant work as well (Ferguson et al., 2008; Devarajan, 2007).

5.5.2 Nephrotoxicity and Renal Pathology

5.5.2.1 Toxicology

Figure 5-38 and Table 5-22 presents the recent animal toxicological data for studies investigating the effects of Pb (as blood Pb level) on various measures of kidney health and function. In animals, Pb has been found to induce changes in a wide range of indicators of renal function. Most studies examined Pb exposure concentrations that resulted in higher blood Pb levels (> 20 µg/dL) than those in the current U.S. general population. As indicated in Figure 5-38 and Table 5-22, toxicological information on renal dysfunction with blood Pb levels < 10 µg/dL) generally is not available.

Dysfunction in kidney function measures, including urinary flow, ALP, microalbumin, and NAG, was observed at blood Pb concentrations above 20 µg/dL (Wang et al., 2010d).

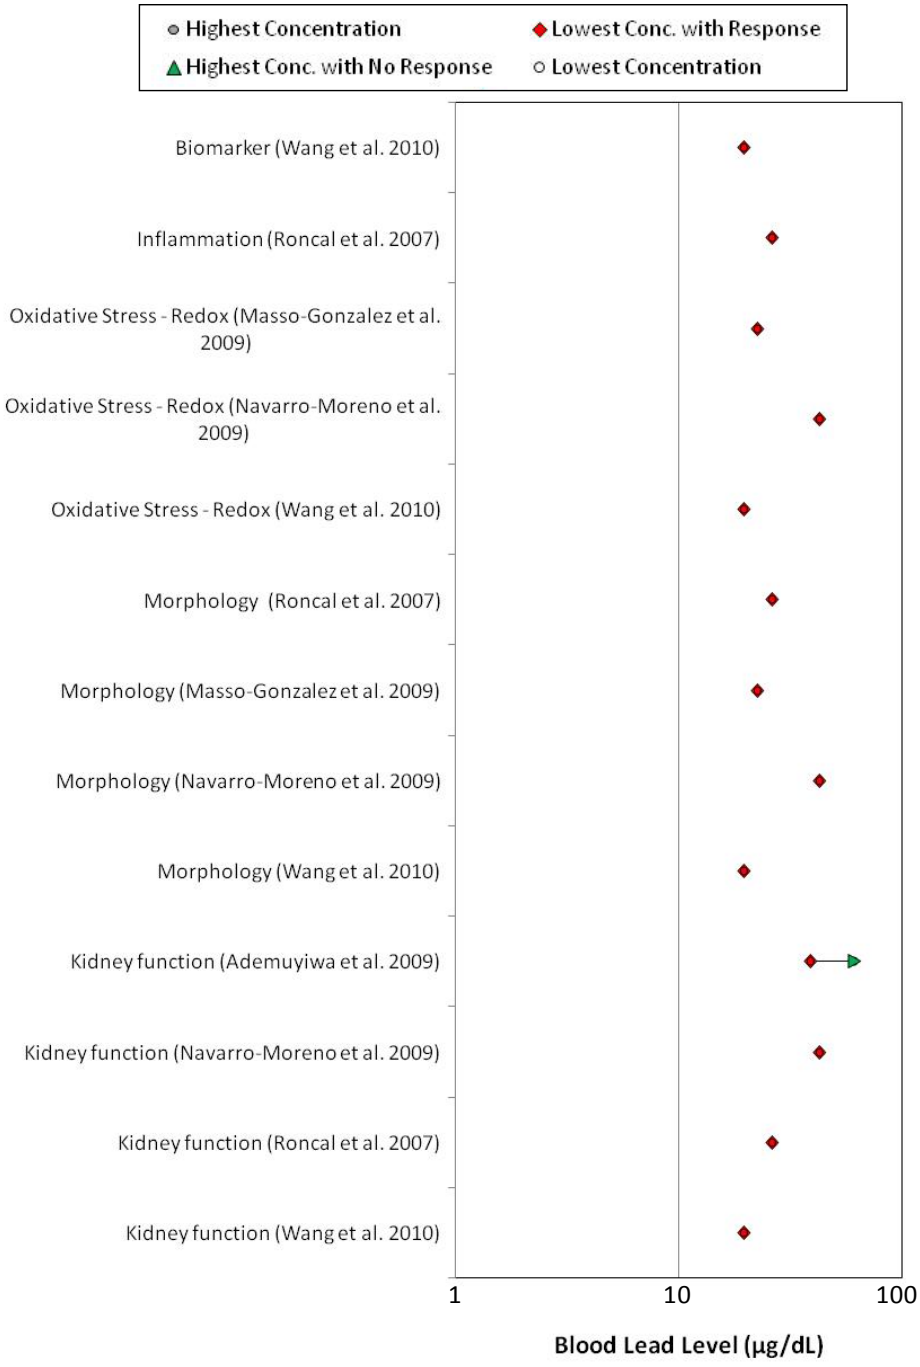

Figure 5-38 Concentration-response representation of the effect of Pb on renal outcomes in animal toxicology studies.

Table 5-22 Additional characteristics for results of toxicological studies presented in Figure 5-38

Reference	Species; Lifestage; Sex	Pb Dose; Exposure Duration	Blood Pb Level with Response (µg/dL)	Outcome
Wang et al. (2010d)	Rat; Adult; Female	300 ppm Pb-acetate in drinking water; 8 weeks	20	Biomarker - Aberrant NAG, GGT, β2-microgobulin expression
Roncal et al. (2007)	Rat; Adult; Male	150 ppm Pb-acetate in drinking water; 16 weeks with remnant kidney surgery at week 4	26	Inflammation - Elevation in number of macrophages & marker MCP-1 in Pb exposed kidneys with remnant kidney surgery.
Navarro-Moreno et al. (2009)	Rat; Adult; Male	500 ppm Pb-acetate in drinking water; 28 weeks	43	Oxidative stress - Increased kidney lipid peroxidation (i.e., TBARS)
Wang et al. (2010d)	Rat; Adult; Female	300 ppm Pb-acetate in drinking water; 8 weeks	20	Oxidative Stress - Pb caused increased lipid peroxidation (i.e., MDA production), elevated kidney antioxidant enzymes (SOD, GPx, CAT), and depleted GSH
Massó-González et al. (2009)	Rat; Weanling pups	300 ppm Pb-acetate in drinking water; GD1 to PND21	23	Oxidative stress - Elevated TBARS and catalase activity
Roncal et al. (2007)	Rat; Adult; Male	150 ppm Pb-acetate in drinking water; 16 weeks with remnant kidney surgery at week 4	26	Morphology - Pb induced pre-glomerular vascular disease of kidney (i.e., sclerosis, fibrosis, peritubular capillary loss)
Navarro-Moreno et al. (2009)	Rat; Adult; Male	500 ppm Pb-acetate in drinking water; 28 weeks	43	Morphology - Electron micrography showed lumen reduction, microvilli loss, brush border loss, and mitochondrial damage
Wang et al. (2010d)	Rat; Adult; Female	300 ppm Pb-acetate in drinking water; 8 weeks	20	Morphology - Electron micrography showed Pb damages mitochondria, basement membrane, and brush border in kidney tissue. Some focal tubal necrosis observed.
Massó-González et al. (2009)	Rat; Weanling pups	300 ppm Pb-acetate in drinking water; GD1 to PND21	23	Morphology - Pb elevated relative kidney weight at PND21
Navarro-Moreno et al. (2009)	Rat; Adult; Male	500 ppm Pb-acetate in drinking water; 28 weeks	43	Kidney function - Pb exposed males had elevated urinary pH and protein, and glucose and blood in the urine.
Roncal et al. (2007)	Rat; Adult; Male	150 ppm Pb-acetate in drinking water; 16 weeks with remnant kidney surgery at week 4	26	Kidney function - Remnant kidney surgery and Pb exposure induced decreased creatinine clearance and proteinuria.
Wang et al. (2010d)	Rat; Adult; Female	300 ppm Pb-acetate in drinking water; 8 weeks	20	Kidney function - Elevated urinary total protein, urinary albumin, and serum urea nitrogen.
Ademuyiwa et al. (2009)	Rat; Adult	200, 300, and 400 ppm Pb-acetate in drinking water; 12 weeks	39 and 61	Kidney Function - Renal phospholipidosis and depletion of renal cholesterol after gestational Pb exposure.

Renal Function and Interstitial Fibrosis

Past studies have shown that chronic continuous or repeated Pb exposure can result in interstitial nephritis and focal or tubular atrophy. After an initial 3 months of Pb exposure (in a longitudinal 12-month exposure study to either 100 ppm [lower dose] or 5,000 ppm [higher dose] Pb-acetate in drinking water, male rats), elevated GFR, consistent with hyperfiltration, and renal hypertrophy were observed; high dose animals also had increased NAG and GST (Khalil-Manesh et al., 1993a; Khalil-Manesh et al., 1992a; Khalil-Manesh et al., 1992b). At 6 months of exposure, GFR decreased in the high dose animals, albuminuria was present, and pathology ensued with focal tubular atrophy and

interstitial fibrosis formation. This pathology was persistent out to 12 months, and at 12 months glomeruli developed focal and segmental sclerosis. Similarly, GFR remained decreased after 12 months of exposure in the high dose group. The toxicological evidence for differences in GFR according to duration of Pb exposure, i.e., hyperfiltration with 3-month exposure versus decreased GFR with 6- or 12-month exposure, provide biological plausibility for epidemiological studies that observed a similar phenomenon by age in adults in association with Pb biomarker levels. These duration-dependent dichotomous changes in GFR are consistent between the toxicological and epidemiologic literature.

Biomarkers of Pb-induced renal toxicity have been developed including the enzymes lysosomal NAG, GST, brush border antigens (BB50, BBA, HF5), and Tamm-Horsfall protein. GST functions as a renal biomarker since renal ALAD is protected by the kidney antioxidant GSH. Urinary NAG and GST levels were found to increase in rats after 3 months of high dose Pb exposure (resulting in blood Pb level of 125 µg/dL) in rats (Khalil-Manesh et al., 1992a), whereas only urinary NAG was increased following low dose Pb exposure (resulting in blood Pb level of 29 µg/dL) in rats (Khalil-Manesh et al., 1993a). An in vitro study also found an increase in NAG with high-level Pb exposure (50 µg/dL) (Dehpour et al., 1999). Occupational studies found that urinary NAG correlated best with recent blood Pb changes.

The renal effects of chronic Pb exposure as detailed above were partially rescued in rats with chelation therapy such as DMSA (Khalil-Manesh et al., 1992b). Improvements include increased GFR, decreased albuminuria, and decreased inclusion body numbers but little change in tubulointerstitial scarring. Administration of an Indian herb to Pb-exposed mice, as is discussed in greater detail in the antioxidant section (Section 5.5.5), produced similar findings. There was a functional rescue however Pb-induced pathology remained (Jayakumar et al., 2009). Thus, administration of various compounds (chelators, antioxidants) to Pb-exposed animals produced hemodynamic rescue.

Recent studies have corroborated the previously observed increase in serum creatinine following Pb exposure in rats. Abdel Moneim et al. (2011b) reported Pb-induced (i.p. 20 ppm, 5 days) increased serum creatinine accompanied by histological alterations in rat kidneys. Berrahal et al. (2011) reported on the effects of age-dependent exposure to Pb on nephrotoxicity in male rats. Pups were exposed to Pb lactationally (as a result of dams consuming water containing 50 ppm Pb-acetate) until weaning. Thereafter, the offspring were exposed to the same solution from weaning (day 21) until sacrifice. Male pups were sacrificed at age 40 days (puberty; blood Pb level 12.7 µg/dL) and at age 65 days (post-puberty; blood Pb level 7.5 µg/dL). Serum creatinine was elevated at both 40 days and 65 days (0.54 and 0.60 mg/dL compared to control values of 0.45 mg/dL [$p < 0.001$]).Various parameters of Pb-induced renal dysfunction are listed in Table 5-23

below. The elevated serum creatinine in the Pb-exposed animals compared to controls suggests that animals exposed to low dosage (i.e., 50 ppm) Pb from birth may develop renal abnormalities. However, the lack of measurements of GFR or renal pathology weakens the conclusions. Other investigators have also shown that chronic Pb exposure has detrimental effects on renal function. Pb-exposed male rats (500 ppm Pb-acetate in drinking water for 7 months) had elevated urinary pH, proteinuria, as well as glucose and blood in the urine (Navarro-Moreno et al., 2009).

Table 5-23 Indicators of renal damage in male rats exposed to 50 ppm Pb for 40 and 65 days, starting at parturition

Biomarker (Mean±SD)	PND40 Control	PND40 Pb	PND65 Control	PND65 Pb
Blood Pb level (µg/dL)	1.8±0.33	12.7±1.7	2.1±0.35	7.5±0.78
Plasma Creatinine (mg/L)	4.5±0.21	5.35±0.25[a]	4.55±0.27	6.04±0.29[a]
Plasma Urea (mg/L)	0.37±0.019	0.47±0.021[a]	0.29±0.009	0.29±0.009
Plasma Uric Acid (mg/L)	7.51±0.44	7.65±0.32	9.39±0.82	5.91±0.53[a]

Qiao et al. (2006) measured the effect of Pb on the expression of the renal fibrosis-related nuclear factor-kappa B (NF-κB), transforming growth factor (TGF-β) and fibronectin in Sprague-Dawley rat kidney. Pb was administered at a dose of 0.5% Pb-acetate, continuously for either one, two or three months. All growth factors increased by the end of three months of treatment but only NF-κB increased progressively at each time period. These changes were hypothetically related to the development of Pb-induced renal fibrosis in rats, but no histology was performed.

Roncal et al. (2007) found that Pb accelerated arteriolopathy and tubulointerstitial injury in non-Pb-related CKD. Sprague-Dawley rats were administered Pb-acetate at 150 ppm for 4 weeks, then subjected to remnant kidney surgery (left kidney mass reduced by 2/3 and right kidney removed), and subsequently exposed to Pb for an additional 12 weeks. Pb-treated rats had higher systolic BP, lower creatinine clearance, and higher proteinuria than did controls. Most striking was development of worse arteriolar disease, peritubular capillary loss, tubulointerstitial damage, and macrophage infiltration. Pb treatment was associated with significant worsening of pre-glomerular vascular disease, as characterized by an increase in the media-to-lumen ratio. There was also a higher percentage of

segmental sclerosis within glomeruli and a tendency for a higher number of sclerotic glomeruli. Additionally, a loss of peritubular capillaries, as reflected by a reduction in thrombomodulin staining, was observed. This was associated with worse tubular injury (osteopontin staining) due to more interstitial fibrosis (type III collagen staining) and a greater macrophage infiltration in the interstitium. The increase in macrophages was associated with higher renal MCP-1 mRNA. As a whole, these findings indicate that Pb exposure concomitant with existing renal insufficiency due to surgical kidney resection accelerated vascular disease and glomerular pathology. These findings are consistent with the previous work of Bagchi and Preuss (2005) also showing that Pb-exposed animals with non-Pb-related CKD (remnant surgery) had kidney dysfunction including impairment of the renin-angiotensin system (Losartan challenge), elevated systolic BP, and alterations in renal excretion of Pb, K^+, and Na^+. Thus, this model shows that low Pb exposure may exacerbate pre-existing underlying kidney disease.

Histological Changes

Historical studies discussed in previous Pb AQCDs have identified Pb-related renal damage by the presence of dense intranuclear inclusion bodies, which are capable of sequestering Pb (Goyer et al., 1970a). Chelators such as $CaNa_2EDTA$ removed these inclusion bodies from affected nuclei (Goyer et al., 1978). Multiple endpoints indicate dysfunction in the PT after Pb exposure. Pb-induced formation of intranuclear inclusion bodies in the PT is protective; Pb is sequestered such that it is not in its bioavailable, free, toxicologically active form. Intranuclear inclusion bodies are found in the kidney with acute (i.e., < 4 weeks) Pb exposures but present to a lesser degree with chronic exposures (See Section 5.2.3 for further discussion). Other PT ultrastructural changes in Pb-induced nephropathy include changes to the PT epithelium, endoplasmic reticulum dilation, nuclear membrane blebbing, and autophagosome enlargement (Fowler et al., 1980; Goyer et al., 1970b). Symptoms similar to the PT transport-associated Fanconi syndrome appear with Pb exposure, albeit often at high doses of Pb, i.e., Pb-poisoning. These symptoms, which include increased urinary electrolyte excretion (zinc), decreased Na-K-ATPase activity, mitochondrial aberrations, and aminoaciduria, also have been associated with blood Pb levels in children.

New studies since the 2006 Pb AQCD are consistent with the historical findings and build upon the literature base by including the role of antioxidants. Jabeen et al. (2010) exposed pregnant albino BALB/c mice to a daily oral dose of Pb-acetate (10 mg/kg body weight, daily throughout pregnancy) until GD18, at which point the fetal kidneys were processed for histological examination. Histology revealed Pb exposure induced decreased kidney cortical thickness, decreased diameter of renal corpuscles, and increased renal tubular atrophy with desquamated epithelium and degenerated nuclei in

the distal and proximal tubules. Blood Pb levels were not reported in this study. Nonetheless, these data show that in utero Pb exposure had significant histological effects on the fetal kidney, which could contribute to altered renal function including clearance of waste products, electrolyte balance, and vasoregulation. Massanyi et al. (2007) reported on Pb-induced alterations in male Wistar rat kidneys after single i.p. doses of Pb-acetate (50, 25, and 12.5 mg/kg); kidneys were removed and analyzed 48 hours after Pb administration. Qualitative microscopic analysis detected dilated Bowman's capsules and dilated blood vessels in the interstitium with evident hemorrhagic alterations. Quantitative histomorphometric analysis revealed increased relative volume of interstitium and increased relative volume of tubules in the experimental groups. The diameter of renal corpuscles and the diameter of glomeruli and Bowman's capsule were significantly increased. Measurement of tubular diameter showed dilatation of the tubule with a significant decrease of the height of tubular epithelium compatible with degenerative renal alterations. These findings extend the observations of Fowler et al. (1980) and Khalil-Manesh et al. (1992a; 1992b); in particular, the enlarged glomeruli are consistent with the early hyperfiltration caused by Pb.

Abdel Moneim et al. (2011b) reported histological evidence of inflammation after Pb treatment in rats (i.p. 20 ppm, 5 days). This evidence included increased inflammatory cellular infiltrations, cytoplasmic vacuolation, and dilatation of some kidney tubules. Inflammation was accompanied by an increase in apoptotic cells and increased oxidative stress.

A recent study has also reported inclusion body formation in the nuclei, cytoplasm, and mitochondria of PT cells of Pb-treated rats (50 mg Pb/kg bw i.p., every 48 hours for 14 days) (Navarro-Moreno et al., 2009). These inclusion bodies were not observed in chronically Pb-exposed rats (500 ppm Pb in drinking water, 7 months). However, chronic Pb exposure resulted in morphological alterations including loss of PT apical membrane brush border, collapse and closure of the PT lumen, and formation of abnormal intercellular junctions.

Vogetseder et al. (2008) examined the proliferative capacity of the renal PT (particularly the S3 segment) following i.v. administration of Pb to juvenile and adult male Wistar rats. Proliferation induction was examined by detection of Bromo-2'-deoxyuridine (BrdU), Ki-67 (labels S, G2, and M phase cells), and cyclin D1 (an essential cell cycle progression protein). The cycling marker Ki-67 revealed a much higher proliferation rate in the S3 segment in control juvenile rats (4.8 ± 0.3%) compared with control adult rats (0.4 ± 0.1%). Pb administration (3.8 mg/100 g bw) increased the proportion of Ki-67-positive cells to 26.1 ± 0.3% in juvenile rats and 31.9 ± 0.3% in adult rats. Thus, the increased proliferation caused by Pb was age independent. The proliferation induction

caused by Pb administration may be a result of reduced cell cycle inhibition by $p27^{kip-1}$. Acute Pb treatment increased the incidence of cyclin D1 labeling in the BrdU-positive cells suggesting Pb was able to accelerate re-entry of cells into the cell cycle and cause proliferation in the PT. Pb-induced cellular proliferation has also been reported in the retina with gestational and early postnatal rodent Pb exposure (Giddabasappa et al., 2011).

Ademuyiwa et al. (2009) examined Pb-induced phospholipidosis and cholesterogenesis in rat tissues. Sprague-Dawley rats were exposed to 200, 300 and 400 ppm Pb-acetate for 12 weeks. The Pb exposure resulted in induction of phospholipidosis in kidney tissue, accompanied by depletion of renal cholesterol. The authors suggested that induction of cholesterogenesis and phospholipidosis in kidney may be responsible for some of the subtle and insidious cellular effects found with Pb-mediated nephrotoxicity. Drug-induced PT phospholipidosis is seen clinically with use of the potentially nephrotoxic aminoglycoside drugs, including gentamicin (Baronas et al., 2007).

Various antioxidants have been shown to attenuate Pb-induced histopathological changes to the kidney. Ozsoy et al. (2010) found L-carnitine to be protective in a model of experimental Pb toxicity in female rats. Markers of histopathological change in the kidney, including tubule dilatation, degeneration, necrosis, and interstitial inflammation were rescued by L-carnitine treatment in females. Male rats exposed to Pb (0.2% for 6 weeks) also displayed tubular damage, whereas concomitant treatment with Pb and an extract of *Achyranthes aspera* ameliorated the observed damage (Jayakumar et al., 2009). El-Nekeety et al. (2009) found an extract of the folk medicine plant *Aquilegia vulgaris* to be protective against Pb-acetate-induced kidney injury in Sprague-Dawley rats. Rats were treated with Pb (20 ppm; 2 weeks) and extract (administered before, during, or after Pb). Pb treatment resulted in tubular dilatation, vacuolar and cloudy epithelial cell lining, interstitial inflammatory cell infiltration, hemorrhage, cellular debris, and glomerulus hypercellularity. Concomitant exposure to Pb and extract produced histology indiscernible from that in controls. Post treatment with extract partially rescued the Pb-induced histopathology. El-Neweshy and El-Sayed (2011) studied the influence of vitamin C supplementation (20 mg/kg pretreatment every other day) on histopathological alterations in Pb-exposed male rats (20 mg/kg by intragastric feeding once daily for 60 days). Control rats showed normal histology, while Pb-treated rats exhibited karyomegaly with eosinophilic intranuclear inclusion bodies in the epithelial cells of the proximal tubules. Glomerular damage and tubular necrosis with invading inflammatory cells were also found. Rats treated with Pb-acetate plus vitamin C exhibited relatively mild or no karyomegaly with eosinophilic intranuclear inclusion bodies in the proximal tubules. Normal glomeruli were noted in animals exposed to Pb and vitamin C. These findings are presented in more detail in Section 5.5.5 but they consistently show that some

antioxidants are capable of preventing or rescuing Pb-induced renal histopathological changes.

Alteration of Renal Vasculature and Reactivity

As discussed in Section 5.5.1, changes in renal vasculature function or induction of hypertension can contribute to further renal dysfunction. Pb can increase BP through the promotion of oxidative stress and altered vascular reactivity. Also, Pb has been shown to act on known vasomodulating systems in the kidney. In the kidney, two vascular tone mediators, $^{\bullet}$NO and ET-1, are found to be affected by Pb exposure. Antioxidants attenuated Pb-related oxidative/nitrosative stress in the kidney and abrogated the Pb-induced increased BP (Vaziri et al., 1999b). Administration of the vasoconstrictor endothelin-1 (ET-1) affected mean arterial pressure (MAP) and decreased GFR (Novak and Banks, 1995). Acute high-dose Pb exposure (24 nmol/min for 15 or 30 minutes) completely blocked this ET-1-mediated GFR decrease but had no effect on MAP. Depletion of the endogenous antioxidant glutathione using the drug buthionine sulfoximine, a GSH synthase inhibitor, increased BP and increased kidney nitrotyrosine formation without Pb exposure, demonstrating the importance of GSH in maintenance of BP (Vaziri et al., 2000). Multiple studies have shown that Pb exposure depletes GSH stores. Catecholamines are vascular moderators that are also affected by Pb exposure (Carmignani et al., 2000). The effect on BP with Pb exposure is especially relevant to the kidney because it is both a target of Pb deposition and a mitigator of BP. These historic data detail the interaction of known modulators of vascular tone with Pb.

Recently, Vargas-Robles et al. (2007) examined the effect of Pb exposure (100 ppm Pb-acetate for 12 weeks) on BP and angiotensin II vasoconstriction in isolated perfused kidney and interlobar arteries. Vascular reactivity was evaluated in the presence and absence of the nitric oxide synthase inhibitor L-NAME in both Pb-treated and control animals. Pb exposure significantly increased BP (134 ± 3 versus 100 ± 6 mmHg), eNOS protein expression, oxidative stress, and vascular reactivity to angiotensin II. L-NAME potentiated the vascular response to angiotensin II in the control group, but had no effect on the Pb-treated group. Conversely, passive microvessel distensibility, measured after deactivation of myogenic tone by papaverine, was significantly lower in the arteries of Pb-exposed rats. Nitrites released from the kidney under the influence of angiotensin II in the Pb group were lower as compared to the control group whereas 3-nitrotyrosine was higher in the Pb group. The authors concluded that Pb exposure increases vascular tone through nitric oxide-dependent and -independent mechanisms, increasing renal vascular sensitivity to vasoconstrictors.

Simões et al. (2011) reported that acute Pb treatment (Pb-acetate i.v. bolus dose of 320 µg/kg bw, blood Pb of 37 µg/dL at 120 minutes after Pb administration) in adult male Wistar rats increased systolic arterial pressure 60 minutes after treatment without affecting diastolic arterial pressure or heart rate. With this single injection, serum angiotensin converting enzyme (ACE) activity was significantly elevated. The Pb-induced altered systolic BP was under the control of the renin-angiotensin system as evidenced by attenuation of the effects of Pb in Losartan (Ang II receptor blocker) or Enalapril (ACE inhibitor) co-treated animals (Simões et al., 2011). These data agree with earlier reports of Pb-related increases in ACE activity in young rats exposed to Pb for 2-8 weeks (Sharifi et al., 2004) and adult rats exposed to Pb for 10 months (Carmignani et al., 1999).

Apoptosis and/or Ischemic Necrosis of Tubules and Glomeruli

Apoptosis or programmed cell death in excess can cause cell atrophy while an insufficiency can lead to uncontrolled cell proliferation, such as cancer. Pb exposure has been shown to cause morphological changes to the kidney structure. Some of these Pb-induced changes are a result of cellular apoptosis or necrosis. Past studies have shown Pb-induced necrosis in proximal tubule cells (Fowler et al., 1980). Pb-induced apoptosis is known to act through the mitochondria (Rana, 2008). Pb-induced calcium overload may depolarize the mitochondria, resulting in cytochrome *c* release, caspase activation, and apoptosis. The apoptosis is mediated by Bax translocation to the mitochondria and can be blocked by overexpression of Bcl-xl. Also, Pb-induced ALA accumulation can generate ROS, which may damage DNA leading to apoptosis.

Mitochondria are targets of Pb toxicity and often involved in apoptosis. Pb can induce uncoupling of oxidative phosphorylation, decreased substrate utilization, and modification of mitochondrial ion transport. ATP energetics are affected when ATP-Pb chelates are formed and ATPase activity is decreased. ROS formation can contribute to these mitochondrial changes and to other changes within the kidney. Antioxidant supplementation after Pb exposure can remedy some changes. All of these outcomes, in conjunction with Pb-related depletion of antioxidants (e.g., GSH) and elevation of lipid peroxidation point to possible susceptibility of the kidney to apoptosis or necrosis.

Rodriguez-Iturbe et al. (2005) reported that chronic exposure to low doses of Pb (100 ppm in drinking water for 14 weeks) results in renal infiltration of immune cells, apoptosis, NF-κB activation and overexpression of tubulointerstitial Ang(II). Similarly, higher level Pb treatment in rats (i.p. 20 mg/kg, 5 days) induced inflammatory cellular infiltrations and an increase in apoptotic cells, accompanied by more pronounced BAX staining in kidney tubule epithelial cells (Abdel Moneim et al., 2011b). Pb treatment (0.5-

1 µM) of isolated rat proximal tubular cells increased cell death by apoptosis and necrosis
2 in a concentration- and time-dependent manner (Wang et al., 2011b). This was
3 accompanied by increased morphological changes typical of apoptosis such as
4 fragmented chromatin, condensed chromatin, and shrunken nuclei. These cells also
5 exhibited decreased mitochondrial membrane potential, decreased intracellular pH,
6 inhibition of Na+-K+ ATPase and Ca2+-ATPase activity, and increased intracellular
7 Ca2+ following Pb treatment.

8 Navarro-Moreno et al. (2009) examined the effect of 500 ppm Pb in drinking water over
9 7 months on the structure (including intercellular junctions), function, and biochemical
10 properties of PT cells of Wistar rats. Pb effects in epithelial cells consisted of an early
11 loss of the apical microvilli, followed by a decrement of the luminal space and the
12 respective apposition and proximity of apical membranes, resulting in the formation of
13 atypical intercellular contacts and adhesion structures. Inclusion bodies were found in
14 nuclei, cytoplasm, and mitochondria. Lipid peroxidation (TBARS measurement) was
15 increased in the Pb-treated animals as compared to controls. Calcium uptake was
16 diminished and neither proline nor serine incorporation that was present in controls was
17 noted in the PT of Pb-exposed animals. The authors speculated that Pb may compete with
18 calcium in the establishment and maintenance of intercellular junctions.

19 Tubular necrosis was also observed in rats treated with Pb-acetate (100 ppm s.c.) for 30
20 days (El-Sokkary et al., 2005). Histological sections of kidneys from Pb-treated rats
21 showed tubular degeneration with some necrotic cells. Similarly, El-Neweshy and El-
22 Sayed reported glomerular damage and tubular necrosis with invading inflammatory
23 cells after Pb treatment (20 mg/kg by intragastric feeding once daily for 60 days) to male
24 rats. The incidence of necrosis was decreased in both of these studies by pretreatment
25 with either melatonin or vitamin C. Pretreatment with melatonin (10 mg/kg), an
26 efficacious free radical scavenger and indirect antioxidant, resulted in a near normal
27 tubular structure. The authors concluded that melatonin protected the liver and kidneys
28 from the damaging effects of exposure to Pb through inhibition of lipid peroxidation and
29 stimulation of endogenous antioxidative defense systems (El-Sokkary et al., 2005).
30 Vitamin C supplementation (20 mg/kg pretreatment every other day) protected the renal
31 architecture and histology (El-Neweshy and El-Sayed, 2011).

32 Wang et al. (2009c) examined the effect of Pb-acetate (0.25, 0.5 and 1 µM) on cell death
33 in cultured rat primary PT cells. A progressive loss in cell viability, due to both apoptosis
34 and necrosis, was observed in cells exposed to Pb. Apoptosis predominated and could be
35 ameliorated with concomitant N-acetylcysteine exposure, whereas necrosis was
36 unaffected. Elevation of ROS levels and intercellular calcium, depletion of mitochondrial
37 membrane potential, and intracellular glutathione levels was observed during Pb

exposure. Pb-induced apoptosis was demonstrated morphologically (Hoechst 33258 staining) with condensed/fragmented chromatin and apoptotic body formation. CAT and SOD activities were significantly elevated, reflecting the response to accumulation of ROS.

Table 5-24 presents the acute and chronic renal effects of Pb exposure observed in recent and past animal toxicology studies.

Table 5-24 Effects of Pb on the kidney/renal system related to exposure duration– evidence from animal toxicology studies

Effects with less than 3 months of exposure	Effects with 6 or 12 months of exposure
Mitochondrial dysfunction	Mitochondrial dysfunction
Renal cell apoptosis	Renal cell apoptosis
Nuclear Inclusion Body Formation	Oxidant redox imbalance
Proximal Tubule Cytomegaly	Altered NO homeostasis
Glomerular Hypertrophy	ATPase dysfunction
Increased GFR	Aminoaciduria
	Increased electrolyte excretion
	Elevated blood pressure
	Decreased GFR

5.5.2.2 Epidemiology in Adults

A number of advances in research on the impact of Pb on the kidney in the 20 years following the 1986 Pb AQCD (U.S. EPA, 1986a) were noted in the 2006 Pb AQCD (U.S. EPA, 2006b). These included research in general and CKD patient populations at much lower blood Pb levels (5-10 µg/dL) at the time of evaluation than were previously studied. These advances contributed to the understanding of the effects of Pb exposure on kidney dysfunction overall in the population. Pb, at much lower doses than those causing chronic Pb nephropathy, may act as a cofactor with other more established kidney risks to increase the risk for CKD and disease progression in susceptible patients. Maric and Hall (2011) note that data from basic and clinical studies suggest that obesity, hypertension, hyperglycemia, hyperlipedemia, and other elements of the metabolic syndrome are highly interrelated and contribute to the development and progression of diabetic nephropathy and thus represent populations potentially at increased risk for kidney dysfunction.

In the 2006 Pb AQCD (U.S. EPA, 2006b), several key issues could not be completely resolved based on the Pb-kidney literature published to date. These included characterizing the lowest Pb dose at which altered kidney function effects occur, the

impact of higher past exposures on associations with current Pb biomarker levels, the impacts of Pb on the kidney in children, the use of paradoxical Pb-kidney associations on risk assessment in the occupational setting, and the impact of co-exposure to other environmental nephrotoxicants, such as cadmium. In the intervening five years, relevant data addressing several of these challenges have been published.

General Population Studies

The 2006 Pb AQCD reported studies that examined associations between indicators of Pb exposure and kidney function in general populations. This was a new approach to Pb-kidney research in the two decade time period covered by the 2006 Pb AQCD. As illustrated in Figure 5-39 and Table 5-25, studies consistently demonstrate associations between higher blood Pb level and lower renal function in adults. The studies in this category provided critical evidence that the effects of Pb on the kidney occur at much lower doses than previously appreciated based on occupational exposure data. However, because blood Pb level in nonoccupationally-exposed adults reflects both recent and past Pb exposures, the magnitude, timing, frequency, and duration of Pb exposure contributing to the observed associations was uncertain. The evidence of Pb-associated renal effects in general population studies was substantiated by results that were adjusted for multiple potential confounding factors including age, race, sex, education, household income, smoking, alcohol use, cadmium exposure, and various health indicators such as diabetes, SBP, BMI, and history of cardiovascular disease.

The landmark Cadmibel Study was the first large environmental study of this type that adjusted for multiple kidney risk factors (Staessen et al., 1992). It included 965 men and 1,016 women recruited from cadmium exposed and control areas in Belgium. Mean concurrent blood Pb was 11.4 μg/dL (range 2.3-72.5) and 7.5 μg/dL (range 1.7-60.3) in men and women, respectively. After adjustment, log transformed blood Pb was negatively associated with measured creatinine clearance. A 10-fold increase in blood Pb was associated with a decrease in creatinine clearance of 10 and 13 mL/min in men and women, respectively. Blood Pb was also negatively associated with estimated creatinine clearance.

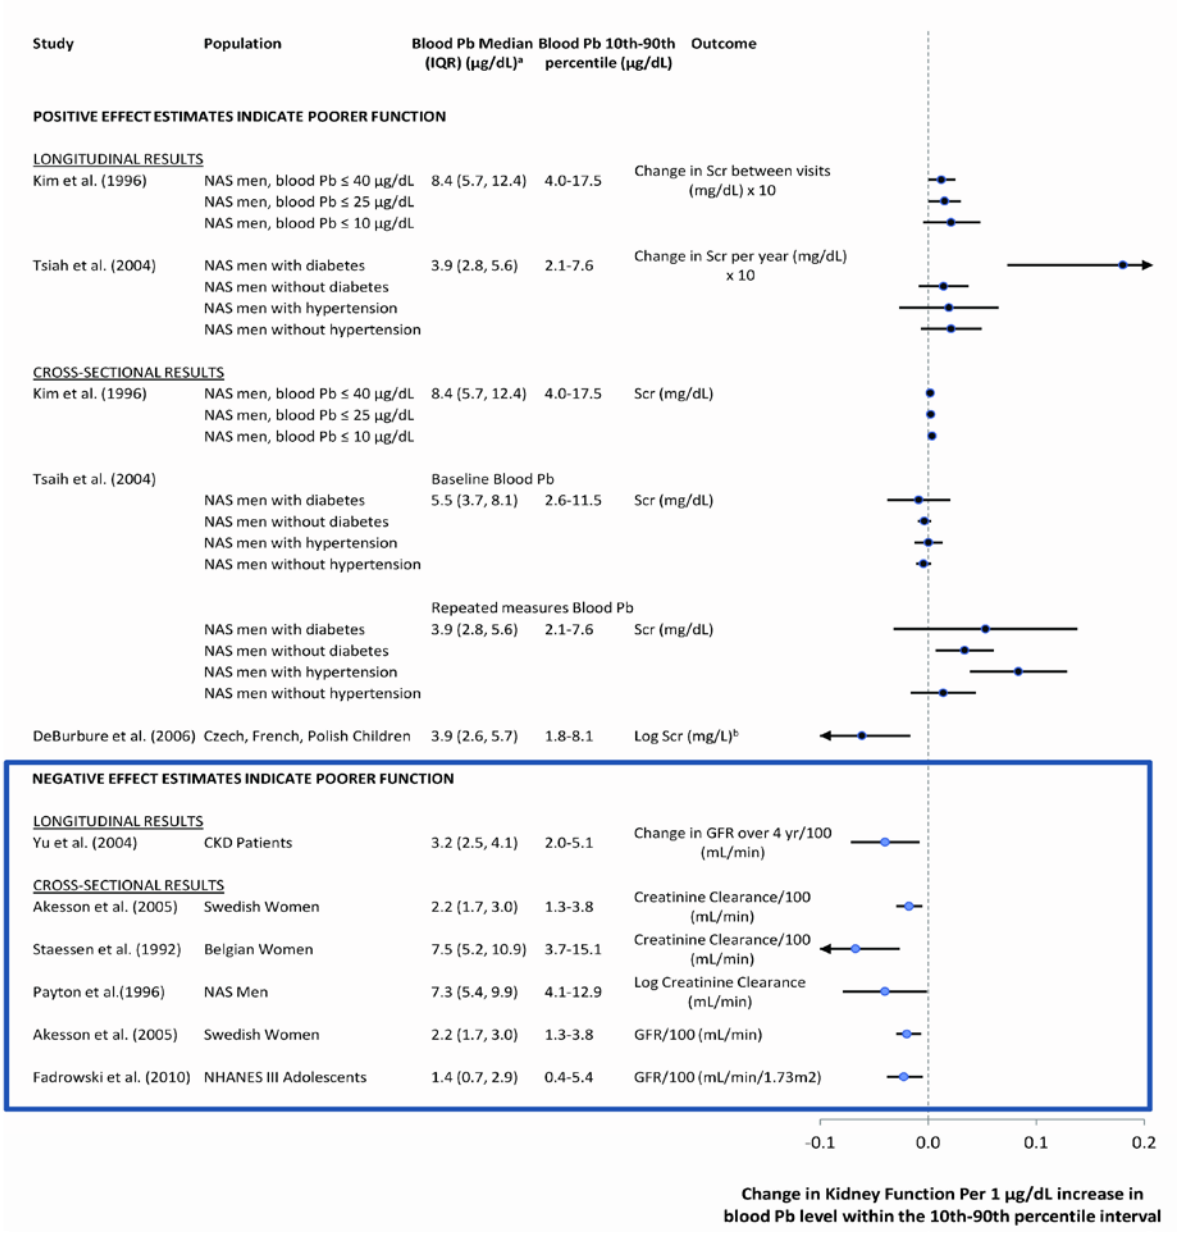
Multiple analyses assessing the kidney impact of Pb exposure have been conducted in the NAS population (Tsaih et al., 2004; Wu et al., 2003a; Kim et al., 1996; Payton et al., 1994). Participants in this study were originally recruited in the 1960s in the Greater Boston area. Inclusion criteria included male sex, age 21 to 80 years, and absence of chronic medical conditions. Longitudinal data contained in NAS publications remain essential, particularly in light of the dearth of prospective data on the kidney effects of Pb. The first of these included 459 men whose blood Pb levels from periodic

examinations, conducted every 3 to 5 years during 1979-1994, were estimated based on measurements in stored packed red blood cell samples adjusted for hematocrit level (Kim et al., 1996). Participants were randomly selected to be representative of the entire NAS population in terms of age and follow-up. Kidney function was assessed with serum creatinine. Data from four evaluations were available for the majority of participants. At baseline, mean (SD) age, blood Pb level, and serum creatinine, at baseline, were 56.9 (8.3) years, 9.9 (6.1) μg/dL, and 1.2 (0.2) mg/dL, respectively. In the longitudinal analysis, using random-effects modeling with repeated measures, ln-transformed blood Pb was associated with an increase in serum creatinine from the previous to current follow-up period in the 428 participants whose highest blood Pb level was ≤ 25 μg/dL (β= 0.027 mg/dL [95% CI: 0.0, 0.054] per unit increase in ln blood Pb); effect estimates in the entire group and subsets with different peak blood Pb levels (≤ 10 or 40 μg/dL) also were positive (and larger for blood Pb levels ≤ 10 μg/dL) but had p-values between 0.07 and 0.13.

This study made two other key contributions. In order to address the question of whether nephrotoxicity observed at current blood Pb levels is due to higher blood Pb levels from past exposure, these authors performed a sensitivity analysis in participants whose peak blood Pb levels, dating back to 1979, were ≤ 10 μg/dL. A statistically significant positive association between blood Pb and concurrent serum creatinine remained in a cross-sectional analysis. These authors also addressed reverse causality, which attributes increased blood Pb levels to lack of kidney excretion rather than as a causative factor for CKD, by showing in adjusted plots that the association between blood Pb and serum creatinine occurred over the entire serum creatinine range (0.7-2.1 mg/dL), including the normal range where reverse causality would not be expected.

Cortical and trabecular bone Pb measurements were obtained in addition to whole blood Pb in evaluations performed in the NAS between 1991 and 1995. Associations between baseline blood, tibia, and patella Pb and change in serum creatinine over an average of 6 years in 448 men were reported in a subsequent NAS publication (Tsaih et al., 2004). At baseline 6 and 26% of subjects had diabetes and hypertension, respectively. Mean blood Pb levels and serum creatinine decreased significantly over the follow-up period in the group. Baseline blood Pb level was not associated with change in creatinine in all participants. However, diabetes was observed to be an effect modifier of the relations of blood and tibia Pb with change in serum creatinine. Per unit increase in ln blood Pb, the increase in serum creatinine between follow-up periods was substantially stronger in diabetics (β = 0.076 mg/dL [95% CI: 0.031, 0.121]) compared to non-diabetics (β = 0.006 mg/dL [95% CI: -0.004, 0.016]). A similar relationship was observed for tibia Pb. An interaction was also observed between tibia Pb and hypertension, although it is possible that many of the 26 diabetics were also included in the hypertensive group and

were influential there as well. Reverse causality was addressed in a sensitivity analysis of participants whose serum creatinine was <1.5 mg/dL; the authors reported that longitudinal associations did not materially change.



[a]Blood Pb data are presented as median and (IQR) in µg/dL for blood Pb. For uniform presentation, median and IQR were estimated from the given distributional statistics by assuming normal distributions.

[b]The cross product of logged blood Pb and ranked urine Hg was included in the regression to model the interaction between these two variates. The significant hyperfilrative effect to these children could be due to a biphasic time course sometimes seen in early exposure.

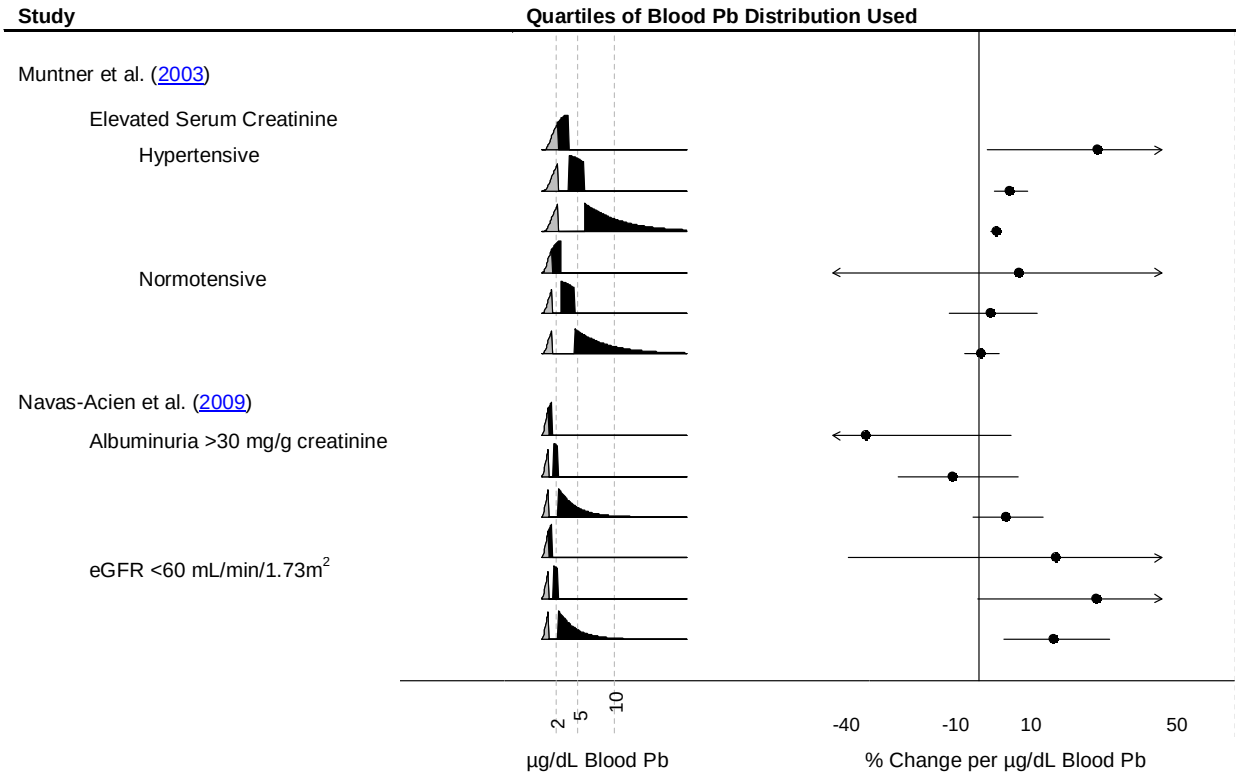
Note: Results are presented first for kidney function tests where an increase is considered impaired function (black circles) then for tests where a decrease is considered impaired function (blue circles, outlined in box). Within a category, results are presented first for longitudinal analyses followed by cross-sectional analyses. To compare results for linear and nonlinear modeling, effect estimates were standardized to a 1 µg/dL increase in blood Pb level within the 10th-90th percentile interval. Magnitudes of the effect should not be compared among different kidney metrics.

Figure 5-39 Kidney metric slopes for blood Pb or bone Pb.

The impact of Pb on the kidney has been examined in multiple NHANES datasets obtained over the last few decades (Figure 5-40 and Table 5-25). NHANES data analyses benefit from a number of strengths including large sample size, ability to adjust for numerous Pb risk factors, and the fact that the study population is representative of the U.S. non-institutionalized, civilian population. The results, covering different time frames, have been consistent in providing support for Pb as a CKD risk factor, including NHANES III, conducted from 1988-1994, in which adults with hypertension and diabetes were observed to be susceptible populations (Muntner et al., 2003) and NHANES 1999-2002 (Muntner et al., 2005). However, because the various NHANES analyses were cross-sectional in design, examining associations between concurrent measures of kidney function and blood Pb levels, a common limitation is the uncertainty regarding the magnitude, timing, frequency, and duration of Pb exposure that contributed to the observed associations.

A recent publication examined NHANES data collected from 1999 through 2006 (Navas-Acien et al., 2009). The geometric mean concurrent blood Pb level was 1.58 μg/dL in 14,778 adults aged ≥ 20 years. After adjustment for survey year, sociodemographic factors, CKD risk factors, and blood cadmium, the odds ratios for albuminuria (≥ 30 mg/g creatinine), reduced eGFR (<60 mL/min/1.73 m^2), and both albuminuria and reduced eGFR were 1.19 (95% CI: 0.96, 1.47), 1.56 (95% CI: 1.17, 2.08), and 2.39 (95% CI: 1.31, 4.37), respectively, comparing the highest (> 2.4 μg/dL) to the lowest (≤ 1.1 μg/dL) blood Pb quartiles. Thus, in the subset of the population with the most severe kidney disease (both reduced eGFR and albuminuria), the magnitude of association with concurrent blood Pb was greater. When blood cadmium was included as a covariate, blood Pb remained significantly associated. In fact, the most important contribution of this recent NHANES analysis was the evaluation of joint Pb and cadmium exposure (discussed in Section 5.5.4.1).

An important contribution of all NHANES publications is that they provide evidence that blood Pb remains associated with reduced kidney function (<60 mL/min/1.73 m^2 as estimated with the MDRD equation cross-sectionally) despite steadily declining blood Pb levels during the time periods covered. Additional studies in this category have also reported worse kidney function related to blood Pb levels (Lai et al., 2008a; Hernandez-Serrato et al., 2006; Goswami et al., 2005).



Note: These articles reported ORs of kidney function measures by grouping the population into quartiles of blood Pb and then comparing each group to the quartile with the lowest blood Pb (reference group). The blood Pb distribution of the examined group is shaded black and the reference group is shaded gray. To express these odds ratios in terms of blood Pb concentration, a log normal distribution was fit to the statistics presented and then the medians of each group were determined. The adjusted OR was the exponentiated quantity (log(OR) divided by the difference in the medians of the groups compared). The resulting odds ratio is presented in terms of percent change=100*(OR-1).

Patient Population Studies

CKD as defined by the National Kidney Foundation - Kidney Disease Outcomes Quality Initiative (NKF-K/DOQI) workgroup (National Kidney Foundation, 2002) is the presence of markers of kidney damage or GFR <60 mL/min/1.73 m^2 for ≥ 3 months. The MDRD equation is the most common one used in the eGFR determination for this definition. Notably, decreased GFR is not required for the first criterion and markers of kidney damage are not required for the second criterion.

Several key studies in CKD patients provide prospective data to evaluate the impact of baseline blood Pb level on CKD progression (kidney function decline) in patient populations (Table 5-26). Yu et al. (2004), discussed in the 2006 Pb AQCD, followed 121 patients over a four year period. Eligibility required well-controlled CKD with serum creatinine between 1.5 and 3.9 mg/dL. Importantly, EDTA-chelatable Pb <600 μg/72 h, a level below that traditionally thought to indicate risk for Pb-related nephrotoxicity, was required at baseline. Patients with potentially unstable kidney disease were excluded (i.e., due to systemic diseases such as diabetes). Mean blood Pb and EDTA-chelatable Pb levels were 4.2 μg/dL and 99.1 μg/72 hours, respectively. In a Cox multivariate regression analysis, chelatable Pb was significantly associated with overall risk for the primary endpoint (doubling of serum creatinine over the 4-year study period or need for hemodialysis). When the group was dichotomized by EDTA chelatable Pb level, Kaplan-Meier analysis demonstrated that significantly more patients (15/63) in the high-normal group (EDTA chelatable Pb level ≥ 80 but <600 μg/72 hours) reached the primary end point than did those in the lower EDTA chelatable Pb levels (<80 μg Pb/72 hours) group (2/58). Associations between baseline chelatable or blood Pb level and change in serial measurements of eGFR (estimated by the MDRD equation (Levey et al., 1999) were modeled separately using generalized estimating equations. Based on these models, a 10 μg higher chelatable Pb level or 1 μg/dL higher blood Pb level reduced the GFR by 1.3 and 4.0 mL/min/1.73 m^2, respectively, during the 4-year study period. Recent studies expanded the CKD patient populations in which this effect was observed to those with diabetic nephropathy (Lin et al., 2006a) and with the lowest blood Pb levels studied to date (Lin et al., 2006b). Results of these observational studies have been summarized (Weaver and Jaar, 2010).

Table 5-26 Patient population studies: kidney function decline

Study	n	Baseline mean (SD) blood Pb (μg/dL)	Baseline mean (SD) chelatable Pb (μg/72 hours)	Baseline mean (SD) eGFR (mL/min/1.73 m^2)	Years of follow-up	Decline in eGFR per 1 SD higher Pb dose at baseline per year	Comments
Lin et al. (2003)	202	5.3 (2.9)	104.5 (106.3)	41.6 (14.4)	2	0.16	Largest study to date
Yu et al. (2004)	121	4.2 (2.2)	99.1 (83.4)	36.0 (9.8)	4	2.7 (chelatable) 2.2 (blood Pb)	Longest follow-up; 1 μg/dL higher blood Pb, at baseline, associated with 4.0 mL/min/1.73 m^2 reduction in eGFR over 4 years
Lin et al. (2006a)	87	6.5 (3.4)	108.5 (53.8)	35.1 (9.0)	1	3.87	Type II diabetics with nephropathy
Lin et al. (2006b)	108	2.9 (1.4)[a]	40.2 (21.2) (all <80)	47.6 (9.8)	2	1.1	Lowest Pb exposed CKD patients

[a]Notably, mean blood Pb level in this study was below that observed in a recent large general population study of 50- to 70-year olds in Baltimore, MD (Martin et al., 2006).

A recent population-based case-control study examined occupational Pb exposure as a risk factor for severe CKD (Evans et al., 2010). The study included 926 cases with first time elevations of serum creatinine >3.4 mg/dL for men and >2.8 mg/dL for women and 998 population-based controls. Occupational Pb exposure was assessed using an expert rating method based on job histories. Eighty-one cases and 95 controls were judged to have had past occupational Pb exposure. Of those, 23 cases and 32 controls were thought to have been exposed to Pb levels ≥ 30 μg/m^3 (the current U.S. OSHA limit is 50 μg/m^3). In multivariable logistic regression modeling, the OR for CKD (adjusted for age, sex, smoking, alcohol consumption, diabetes, education, and BMI) was 0.97 (95% CI: 0.68, 1.38) in Pb-exposed compared to non-exposed participants. In analyses comparing low (≥ 3 to <10% of occupational exposure limit), medium (≥ 10 to < 30% of limit), and high (≥ 30% of limit) exposure groups, although ORs were elevated (statistically nonsignificant) in the medium exposure group compared to the never exposed group for average and lifetime cumulative exposure metrics, a monotonic increase in OR across exposure groups was not observed. In the low and high exposure groups, odds of CKD tended to be lower compared with the never exposed group. In addition, the CKD patients were followed prospectively for a mean of 2.5 years for the 70 Pb-exposed patients and 2.4 years for the 731 patients without past occupational Pb exposure. Mean eGFRs (using the MDRD equation) were 16.0 and 16.6 mL/min/1.73 m^2 in exposed and non-exposed patients, respectively, indicating severe disease in both groups. Using mixed-effects multivariable models, eGFRs declined by 4.27 and 3.39 mL/min/1.73 m^2/y in ever and most Pb-exposed CKD patients, respectively, compared with 4.55 mL/min/1.73 m^2/y in patients without occupational Pb exposure. Thus, the results overall did not provide strong evidence that Pb exposure was associated with renal effects.

Strengths noted by the authors included virtually complete case ascertainment and minimal loss to follow-up. Exposure assessment was listed as both a strength and a limitation. Expert rating methods are commonly used when biological monitoring is not an option and in case-control studies where many occupational exposures are considered. In Pb-kidney research, this approach is uncommon except in the case-control setting. However, given the challenges of interpreting blood Pb in dialysis patients (discussed below), this approach may have advantages in this study of such severe CKD. Other case-control studies examining occupational risk factors for CKD found Pb exposure to be a risk factor (Nuyts et al., 1995; Steenland et al., 1990). Nuyts et al. (1995) found adults with history of occupational Pb exposure to have elevated odds of CKD (OR for ever- versus never-exposed: 2.11 [95% CI: 1.23, 4.36]). The association was weaker in Steenland et al. (1990) (OR for ever- versus never-exposed: 1.73 [95% CI: 0.82, 3.65]). Regular moonshine consumption, also a potential source of Pb exposure, was a stronger risk factor for CKD (OR: 2.42 [95% CI: 1.10, 5.36]).

The prospective observational aspect of Evans et al. (2010) is similar in design to the work of Lin and colleagues but differs in several important respects. In Evans et al. (2010), only occupational Pb exposure was considered whereas the work in Taiwan excluded occupational exposure and used blood and chelatable Pb measures. In the past in developed countries, environmental exposures were substantial. For example, mean tibia Pb levels were 21.5 and 16.7 μg/g bone mineral, in environmentally-exposed 50- to 70-year-old African-Americans and whites, respectively, in Baltimore (Martin et al., 2006). In Korean Pb workers, mean baseline tibia Pb level was only twofold higher (35.0 μg/g) (Weaver et al., 2003a) which illustrates the substantial body burden in middle- and older-aged Americans from lifetime Pb exposure. Declines in blood Pb levels in Sweden have been reported and attributed to the leaded gasoline phase-out (Strömberg et al., 1995; Elinder et al., 1986), although blood Pb levels were lower than those noted during the U.S. phase-out. Finally, the severe degree of CKD among subjects in Evans et al. (2010) creates a survivor bias at enrollment and limits the eGFR decline possible during follow-up, thus limiting the ability to identify factors that influence that decline.

ESRD Patient Studies

End stage renal disease (ESRD) is a well-established public health concern, and is characterized by the use of dialysis to perform the normal functions of the kidney. Incidence and prevalence in the U.S. continue to increase resulting in rates that are the third highest among nations reporting such data (U.S. Renal Data System, 2009). Studies in patients with CKD requiring chronic hemodialysis (ESRD) have also been published in the past five years. A study of 271 adult patients on regular thrice weekly dialysis

reported much higher blood Pb levels than had been appreciated by the treating clinicians (Davenport et al., 2009). Blood Pb levels ranged from 3 to 36.9 μg/dL; 25.5% had levels >20 μg/dL, 59% had values of 10-20 μg/dL, and 15.5% were <10 μg/dL. Few details on the statistical analysis were provided which complicates interpretation of the findings. However, blood Pb was positively correlated with hemodialysis vintage (months on dialysis; Spearman r = 0.38, p <0.001); negatively correlated with urine output (r = -0.44, p <0.001) and higher in patients using single carbon filter and reverse osmosis water purification devices. Another recent publication reported higher Pb in dialysate than in the tap water used in its preparation (Chen et al., 2009a). A systematic review of a wide range of trace elements in hemodialysis patients reported higher Pb levels in patients compared to controls although the difference was not large (Tonelli et al., 2009). These data suggest that blood Pb monitoring in dialysis patients may be useful.

Interpretation of blood and bone Pb in patients on dialysis is challenging for several reasons. First, renal osteodystrophy, the bone disease related to kidney disease, may result in increased release of Pb from bone stores. Thus, interpretation of blood and even bone Pb levels may require adjustment with one or more of a range of osteoporosis variables. Secondly, as observed above (Davenport et al., 2009), residual kidney function may have a substantial impact on blood Pb levels in populations with such minimal excretion. Third, as illustrated in the studies cited above (Chen et al., 2009a; Davenport et al., 2009), water and concentrates used in dialysis may be variable sources of Pb. A recent study reported decreased blood Pb in post-dialysis compared to pre-dialysis samples (Kazi et al., 2008). Thus, substantial fluctuations in blood Pb are possible while on dialysis. Finally, anemia is common in CKD and Pb is stored in red blood cells. Thus, measurement of blood Pb in anemia may require adjustment for hemoglobin; no standardized approach to this currently exists.

Given these caveats, a pilot study observed higher median blood Pb levels in 55 African-American dialysis patients compared to 53 age- and sex-matched controls (6 and 3 μg/dL respectively; p <0.001) (Muntner et al., 2007). This study was unique in that tibia Pb levels were assessed. Median tibia Pb was higher in ESRD patients although the difference did not reach statistical significance (17 and 13 μg/g bone mineral, respectively [p = 0.13]). In order to determine the potential impact of renal osteodystrophy, median blood and tibia Pb levels in the dialysis patients were compared by levels of serum parathyroid hormone, calcium, phosphorus, and albumin and were not found to be significantly different (Ghosh-Narang et al., 2007). A study of 211 diabetic patients on hemodialysis (Lin et al., 2008) found parathyroid hormone and serum creatinine to be associated with blood Pb level in crude but not adjusted associations. In contrast, a study of 315 patients on chronic peritoneal dialysis observed parathyroid hormone to be positively correlated and residual renal function to be negatively

correlated with logarithmic-transformed blood Pb levels after adjustment (Lin et al., 2010). In the prospective portion of this study, blood Pb levels at baseline were categorized by tertile (range of 0.1 to 29.9 μg/dL with cut points of 5.62 and 8.66 μg/dL). Cox multivariate analysis, after adjustment for parathyroid hormone level, residual renal function, and 20 other variables, showed increased all-cause mortality in the middle (5.62-8.66 μg/dL) and highest (> 8.66 μg/dL) compared to the lowest (< 5.62 μg/dL) tertiles after 18 months of follow-up (hazard ratio= 2.1 [95% CI: 2.0, 2.2] and 3.3 [95% CI: 1.3, 13.5], respectively). A recent publication of an 18-month follow-up of 927 patients on maintenance hemodialysis also reported increased hazard ratios for all-cause (4.7 [95% CI: 1.9, 11.5]), cardiovascular-cause (9.7 [95% CI: 2.1, 23.3]), and infection-cause (5.4 [95% CI: 1.4, 20.8]) 18-month mortality in the highest (> 12.64 μg/dL) compared to the lowest tertile (< 8.51 μg/dL) of baseline blood Pb level, after adjustment for sex, urban residence, hemodialysis vintage, hemoglobin, serum albumin, and ferritin (Lin et al., 2011). Given other recent publications in hemodialysis patients by this group, it would be valuable to examine these risks after adjustment for hemoglobin A1C (Lin-Tan et al., 2007a), and blood cadmium (Yen et al., 2011; Hsu et al., 2009a).

Clinical Trials in Chronic Kidney Disease Patients

Randomized chelation trials in CKD patients, uncommon in nephrotoxicant research, provide unique information on the kidney impact of Pb. These studies have been performed by Lin and colleagues in Taiwan and involve similar study designs. Initially, patients are observed in order to compare CKD progression prior to chelation. Then, CKD patients whose diagnostic EDTA chelatable Pb levels are within certain ranges (generally 60-600 μg/72 hours and thus below the level commonly considered for chelation) are randomized. The treated group receives weekly chelation with 1 g EDTA intravenously for up to 3 months. The control group receives placebo infusions. In the follow-up period, chelation is repeated for defined indications such as increased serum creatinine or chelatable Pb levels above specified cut-offs. Placebo infusions are repeated in the controls as well. The results of the most recent of these trials are summarized in Table 5-27 below.

Table 5-27 Clinical randomized chelation trials in chronic kidney disease patients

Reference	Group	n	Baseline mean (SD) blood Pb (µg/dL)	Baseline mean (SD) chelatable Pb (µg/72 hr)	Baseline mean (SD) eGFR (mL/min/1.73 m^2)	Months of treatment/ follow-up	Change in eGFR per yr (mL/min/1.73 m^2)	Comments
Lin et al. (2003)	Chelated	32	6.1 (2.5)	150.9 (62.4)	32.0 (12.1)	27	+ 1.07	
	Control	32	5.9 (3.0)	144.5 (87.9)	31.5 (9.0)		- 2.7

	Control	16	3.0 (1.1)	47.1 (15.8)	42.6 (9.7)		-2.0	
Lin-Tan et al. (2007b)	Chelated	58	5.0 (2.2)	164.1 (111.1)	36.8 (12.7)	51	-0.3	Subjects without diabetes
	Control	58	5.1 (2.6)	151.5 (92.6)	36.0 (11.2)		-2.9	

[a]Notably, mean blood Pb level in this study was below that observed in a recent large general population study of 50- to 70-year olds in Baltimore, MD (Martin et al., 2006).

This study design requires replication in larger populations at multiple clinical centers. If confirmed, the effect may be due to removal of Pb. However, chelation may also have a direct beneficial effect on kidney function, regardless of Pb exposure. Antioxidant effects of $CaNa_2EDTA$ which may improve kidney function directly via improved blood flow to the kidneys have been reported (Saxena and Flora, 2004; Jacobsen et al., 2001). EDTA benefits in a Pb rodent model appeared to occur via reduced oxidation (Saxena and Flora, 2004). EDTA administration reduced kidney damage in a rat model of acute renal failure induced by ischemia (Foglieni et al., 2006). Similarly DMSA has been reported to prevent renal damage when co-administered during induction of nephrosclerosis in a nonPb-exposed rat model (Gonick et al., 1996). Benefits from chelation reported in rodent models of Pb-related nephrotoxicity (Sanchez-Fructuoso et al., 2002a; Sanchez-Fructuoso et al., 2002b; Khalil-Manesh et al., 1992b) did not appear to occur via reversal of structural damage (Khalil-Manesh et al., 1992b); again suggesting that improved hemodynamics from reduction of reactive oxidant species, which could be due to reduced Pb and/or directly to the chelating agent, may be a mechanism (Gonick et al., 1996). However, the most parsimonious explanation for the combination of the observational

and experimental chelation work of Lin and colleagues is that reduced Pb is the underlying reason.

The unique body of work in patient populations by Lin and co-workers, both observational and experimental, has numerous strengths including prospective study design, randomization, Pb assessment that includes estimates of the bioavailable dose, longitudinal statistical analysis, and control for multiple kidney risk factors. However, the generalizability of the results to broader populations is unknown. In addition, the association observed between Pb dose and decline in GFR has been variable; the annual decline in eGFR per standard deviation (SD) higher Pb dose at baseline was much lower in the 2003 study than in subsequent publications (Table 5-27 above). Small sample sizes and differences in renal diagnoses between groups may be factors in this variability. Additional research in large populations at multiple centers with assessment of neuropsychological as well as kidney outcomes is needed.

Occupational Studies

The vast majority of studies in the literature on the impact of Pb on the kidney have been conducted in the occupational setting. In general, study size and extent of statistical analysis are much more limited than those in general population studies. Publications in few populations have reported adjusted results in occupationally exposed workers in the five years since the 2006 Pb AQCD. In a two-year prospective cohort study, generalized estimating equations were used to model change in kidney function between each evaluation in relation to tibia Pb and concurrent change in blood Pb in 537 current and former Pb workers (Weaver et al., 2009). Tibia Pb was evaluated at the beginning of each follow-up period (yearly on average) and Pb biomarker levels were adjusted for baseline levels and other covariates. In males, serum creatinine decreased and calculated creatinine clearance increased over the course of the study; these changes were largest in participants whose blood Pb declined concurrently or whose tibia Pb was lower at the beginning of the follow-up interval. In females, decreasing serum creatinine was associated with declining blood Pb (as in males); however, increasing blood Pb was associated with a concurrent increase in serum creatinine. Women (25.9% of the study population) were older and more likely to be former Pb workers than were men which may have been important factors in the effect modification observed by sex.

Chia and colleagues observed a significant, positive association between concurrent blood Pb and urine NAG in linear regression models after adjustment for age, sex, race, exposure duration, ALAD G177C polymorphism and the interaction between ALAD genotype and blood Pb (Chia et al., 2006). Similar positive associations were observed between blood Pb and a wider range of EBE markers in models that adjusted for age, sex,

race, exposure duration, and the HpyCH4 ALAD polymorphism (Chia et al., 2005). Other studies published in the last 5 years also focused on ALAD polymorphisms but did not find effect modification to be in a consistent direction (Gao et al., 2010a; Wang et al., 2009a; Weaver et al., 2006; Weaver et al., 2005b). In adults with the ALAD2 genotype, Pb has been associated with better and poorer renal function in separate cohorts of Pb workers.

A study of 155 male workers reported significant, positive correlations between blood and urine Pb and urine NAG and albumin after controlling for age and job duration (Sun et al., 2008a). An important additional study that analyzed occupational Pb exposure is discussed below under patient population studies (Evans et al., 2010).

A few studies of occupationally-exposed adults have performed benchmark dose calculations for the effect of Pb on the kidney. Both used only EBE markers and found NAG to be the most sensitive outcome; reported lower confidence limits on the benchmark doses were 10.1 μg/dL (Sun et al., 2008a), and 25.3 μg/dL (Lin and Tai-yi, 2007).

A number of other publications in the five years since the 2006 Pb AQCD have reported significantly worse kidney outcomes in unadjusted analyses in occupationally-exposed adults compared to unexposed controls (Onuegbu et al., 2011; Patil et al., 2007) and/or significant correlations between higher levels of Pb biomarkers and worse kidney function (Alasia et al., 2010; Khan et al., 2008; Sun et al., 2008a; Garcon et al., 2007; Lin and Tai-yi, 2007; Alinovi et al., 2005). One small study found no significant differences (Orisakwe et al., 2007). In a study of 108 Pb workers with mean blood Pb level of 36.2 μg/dL, no significant correlations were observed between blood Pb concentration and GFR, creatinine clearance, uric acid clearance or uric acid excretion fraction (Karimooy et al., 2010). However, interpretation of this study is limited by the fact that "only 30 subjects had a correct 24 hours urine volume" and no methods are described for kidney outcome measurement or analysis.

Overall, the occupational literature published in the last five years on the kidney impact of Pb exposure has been more consistent in reporting statistically significant associations than were data reviewed for the 2006 Pb AQCD. This may reflect increased reliance on EBE markers as more sensitive outcome measures, publication bias, or multiple comparisons due to a greater number of outcomes assessed.

A small number of publications that include concentration-response information provides evidence of Pb-related nephrotoxicity in the occupational setting across the blood Pb ranges analyzed (Weaver et al., 2003a; Ehrlich et al., 1998). Data in 267 Korean Pb workers in the oldest age tertile (mean age = 52 years) did not provide evidence of a

threshold for a Pb effect on serum creatinine levels (added variable plot shown in Figure 5-41) (Weaver et al., 2003a). It is important to note the uncertainty regarding whether the concentration-response information provided in these studies applies to lower blood Pb levels or to populations with lower current environmental Pb exposures.

Note: Both the adjusted regression line (straight line) and the line estimated by the smoothing method of the S-PLUS statistical software function lowess (line with curves) are displayed. Both have been adjusted for covariates. For ease of interpretation, axes have been scaled, so that the plotted residuals are centered on the means, rather than zero.

Figure 5-41 Added variable plot of association between serum creatinine and blood Pb in 267 Korean Pb workers in the oldest age tertile.

A major challenge in interpretation of the occupational literature is the potential for Pb-related hyperfiltration. Hyperfiltration involves an initial increase in glomerular hypertension which results in increased GFR. If persistent, the risk for subsequent CKD increases. This pattern has been observed in diabetes, hypertension, and obesity (Nenov et al., 2000). As discussed in the 2006 Pb AQCD, findings consistent with hyperfiltration have been observed in occupational populations (Weaver et al., 2003a; Hsiao et al., 2001; Roels et al., 1994), a study of adults who were Pb poisoned as children (Hu, 1991), and a study in European children (De Burbure et al., 2006). Longitudinal data in Pb-exposed rodents provide evidence of a hyperfiltration pattern of increased, followed by decreased GFR, associated with Pb exposure and are critical in interpretation of the human Pb-kidney literature (Khalil-Manesh et al., 1992a). Pb could induce glomerular hypertension resulting in hyperfiltration by several mechanisms including increased ROS, changes in

eicosanoid levels, and/or an impact on the renin-angiotensin system (Vaziri, 2008b; Roels et al., 1994). Whether hyperfiltration contributes to pathology in humans is unclear; longitudinal studies are needed.

Regardless, significant findings could be obscured if opposite direction associations are present in different segments of the study population and interaction models are not performed to address this. In the Korean Pb workers (Weaver et al., 2003a; Weaver et al., 2003b), significant associations in opposite directions were observed only when relevant effect modifiers such as age or genetic variants in ALAD, VDR, and NOS were included in the model. This is a valid concern for risk assessment, since the factors involved in these inverse associations in Pb-exposed workers are not well defined at present.

5.5.2.3 Epidemiology in Children

Lead Nephrotoxicity in Children

Both the 2006 and 1986 Pb AQCDs noted that the degree of kidney pathology observed in adult survivors of untreated childhood Pb poisoning in the Queensland, Australia epidemic (Inglis et al., 1978) has not been observed in other studies of childhood Pb poisoning. Recent publications remain consistent with that conclusion; a recent study observed an impact of childhood Pb poisoning on IQ but not kidney outcomes (Coria et al., 2009). Chelation was raised as a potential explanation for this discrepancy in the 2006 Pb AQCD.

With declining Pb exposure levels, recent work has focused on studies in children with much lower blood Pb levels. However, insensitivity of the clinical kidney outcome (i.e., GFR) measures for early kidney damage is a particular problem in children who do not have many of the other kidney risk factors that adults do, such as hypertension and diabetes. As a result, such studies have utilized EBE markers. However, data to determine the predictive value of such biomarkers for subsequent kidney function decline in Pb exposed populations are extremely limited (Coratelli et al., 1988) and may pose particular challenges in children due to puberty-related biomarker changes (Sarasua et al., 2003). The few studies included the 2006 Pb AQCD that analyzed clinical kidney outcomes in children found associations with indicators of Pb exposure that were inconsistent in direction. Fels et al. (1998) found no difference in mean serum creatinine between 62 children living near Pb-producing factories and 50 control children living in communities without Pb emission sources. In a study of 200 Belgian adolescents aged 17 years, higher concurrent blood Pb level was associated with higher serum cystatin-C in 200 (De Burbure et al., 2006); however, among 300-600 European children (n varied by

outcome), higher concurrent blood Pb level was associated with lower serum creatinine and cystatin C (Staessen et al., 2001).

Recent studies of children with elevated Pb exposure did not consistently indicate that Pb exposure was associated with reduced kidney function. A study in 123 children of workers in Pakistani Pb smelters and battery recycling plants and 123 control children, ages 1-6 years, reported elevated blood Pb levels, serum creatinine and urea in children of Pb-exposed workers compared to controls (medians: 8.1 versus 6.7 µg/dL; 56 versus 52 µM; and 4,500 versus 4,300 µM, respectively ($p \leq 0.01$ for all) in unadjusted analyses (Khan et al., 2010a). Blood Pb levels were correlated with serum creatinine (Spearman r = 0.13; p = 0.05). However, a study of 77 participants, ages 10-25 years, who were previously Pb poisoned through contaminated flour and chelated, reported no difference in renal effects between children with blood Pb levels > 48 µg/dL and < 43 µg/dL although lower IQ was observed in the subset who were exposed before the age of six years (Coria et al., 2009).

One of the key gaps identified in the 2006 Pb AQCD was limited data in children and adolescents particularly with respect to GFR measures and in populations without the elevated Pb exposure associated with Pb poisoning, living near a Pb source, or having parents with occupational Pb exposures. A recently published NHANES analysis in adolescents begins to fill this gap (Fadrowski et al., 2010). Associations between concurrent blood Pb and kidney function were investigated in 769 adolescents aged 12-20 years in the U.S. NHANES III, conducted 1988-1994. Kidney function was assessed with two eGFR equations. One utilized serum cystatin C and the other used the more traditional marker, serum creatinine. Median concurrent blood Pb and cystatin C-based eGFR levels were 1.5 µg/dL and 112.9 mL/min/1.73 m^2, respectively. Cystatin C-based eGFR was lower (-6.6 mL/min/1.73 m^2 [95% CI: -0.7, -12.6]) in participants with blood Pb levels in the highest quartile (≥ 3.0 µg/dL) compared with those in the lowest (<1 µg/dL). A doubling of blood Pb level was associated with a -2.9 mL/min/1.73 m^2 (95% CI: -0.7, -5.0) lower eGFR. In contrast, the association between blood Pb and creatinine-based eGFR, although in the same direction, was not statistically significant. As these children were born between 1968 and 1982, some likely had higher Pb exposures in earlier childhood, although notably, not as high or as long in duration as did older adults examined in aforementioned studies. Nonetheless, in this study of NHANES adolescents, there also is uncertainty regarding the magnitude, timing, frequency, and duration of Pb exposure that contributed to the observed associations. Additional research in children is warranted, in particular studies with longitudinal follow-up, multiple outcome assessment methods, and examination of children born after Pb was banned from gasoline.

5.5.2.4 Associations between Lead Dose and New Kidney Outcome Measures

As noted above, in an effort to more accurately estimate kidney outcomes, new equations to estimate GFR based on serum creatinine have been developed, and the utility of other biomarkers, such as cystatin C, as well as equations based on them, are being studied. However, few publications have utilized these state-of-the-art techniques when evaluating associations between Pb or cadmium dose and renal function. In addition to the study in NHANES adolescents discussed above (Fadrowski et al., 2010), a cross-sectional study of Swedish women reported that higher concurrent blood Pb (median: 2.2 µg/dL) and cadmium (median: 0.38 µg/L) levels were associated with lower eGFR based on serum cystatin C alone (without age, sex, and race) after adjustment for socio-demographic and CKD risk factors (Akesson et al., 2005). Associations were comparable to those using creatinine clearance as the kidney outcome for Pb; however associations of cadmium dose measures were stronger for the cystatin C based outcome. Staessen et al. (2001) found a statistically significant association between concurrent blood Pb level and serum cystatin C in a cross-sectional study of adolescents; creatinine-based measures were not reported. However, in a cross-sectional study of European children, higher concurrent blood Pb levels were associated with lower serum cystatin C and creatinine; these inverse associations were attributed to hyperfiltration (De Burbure et al., 2006). A very recent publication compared associations of blood Pb and eGFR using the traditional MDRD equation to those with four new equations: CKD-EPI, and cystatin C single variable, multivariable, and combined creatinine/cystatin C, in 3,941 adults who participated in the 1999-2002 NHANES cystatin C subsample (Spector et al., 2011). Similar to the NHANES adolescent analysis, associations with the cystatin C outcomes were stronger. After multivariable adjustment, differences in mean eGFR for a doubling blood Pb were -1.9 (95% CI: -3.2, -0.7), -1.7 (95% CI: -3.0, -0.5), and -1.4 (95% CI: -2.3, -0.5) mL/min/1.73 m^2, using the cystatin C single variable, multivariable and combined creatinine/cystatin C equations, respectively, reflecting lower eGFR with increased blood Pb. The corresponding differences were -0.9 (95% CI: -1.9, 0.02) and -0.9 (95% CI: -1.8, 0.01) using the creatinine-based CKD-EPI and MDRD equations, respectively.

5.5.2.5 Reverse Causality

As discussed briefly above, reverse causality has been considered as an alternative hypothesis to explain associations observed between indicators of Pb exposure and renal dysfunction in adults. The reverse causality hypothesis attributes increased blood and bone Pb levels to reduced Pb excretion from nonPb-related causes rather then implicating Pb-related renal dysfunction as a contributing factor to CKD. The 2006 Pb AQCD

concluded that "reverse causality is not likely to be a major explanatory factor accounting for observed associations between Pb and renal dysfunction" (U.S. EPA, 2006b). The strongest evidence against reverse causality was provided by longitudinal studies in which associations between baseline measurements of Pb biomarkers and subsequent changes in renal function were demonstrated. In the NAS, baseline blood Pb levels were associated with subsequent declines in renal function over follow-up periods ranging from 3 to 6 years after adjustment for baseline renal function (Tsaih et al., 2004; Kim et al., 1996). Similar results were reported in studies of patients with renal disease (Yu et al., 2004; Lin et al., 2003). The longitudinal analyses in NAS studies also indicated that associations between blood Pb level and serum creatinine persisted in the lower range of serum creatinine levels, including those in the normal range (Tsaih et al., 2004; Kim et al., 1996). Thus, the association was not limited to the segment of the population with potentially clinically significant renal dysfunction in whom reduced Pb excretion would be more likely.

Additional support against reverse causality was provided by findings in Swedish women that both higher blood and urinary Pb were associated with lower creatinine clearance (Akesson et al., 2006; Akesson et al., 2005). If reverse causality were the more likely hypothesis for these associations, lower creatinine clearance would be associated with lower urinary Pb, which it is not. Among adults with chronic kidney disease, renal failure was not associated with increases in blood or bone Pb levels or chelatable Pb levels (Van De Vyver et al., 1988). Batuman et al. (1983) found that chelatable Pb levels were similar in adults with renal disease of unknown and known nonPb-related causes. Study had bone Pb levels (group means: 18 and 19 µg/g) in the range of those measured in recent epidemiologic studies. In summary, evidence that higher blood Pb levels are associated with subsequent declines in renal function from baseline levels, that associations persist among adults with normal renal function, and that renal failure does not increase Pb biomarker levels collectively do not support reverse causality and thus demonstrate that reverse causality does not provide a more suitable alternative hypothesis to explain the associations consistently observed between Pb biomarker levels and renal dysfunction.

5.5.3 Modes of Action for Lead-Induced Nephrotoxicity

5.5.3.1 Altered Uric Acid

Higher occupational Pb exposure or blood Pb levels have been linked to increased risk for both gout and kidney disease (Shadick et al., 2000; Batuman, 1993). Pb is thought to increase serum uric acid by decreasing its kidney excretion (Emmerson and Ravenscroft,

1975; Ball and Sorensen, 1969; Emmerson, 1965). Research during the past decade indicates that uric acid is nephrotoxic at lower levels than previously recognized (Johnson et al., 2003). Therefore, the 2006 Pb AQCD reviewed literature implicating increased uric acid as a mechanism for Pb-related nephrotoxicity (Weaver et al., 2005a; Shadick et al., 2000). However, this does not appear to be the only mechanism, since associations between blood Pb and serum creatinine have remained significant even after adjustment for uric acid (Weaver et al., 2005a). These mechanistic relations have more than just theoretical importance. Clinically relevant therapies may be possible since EDTA chelation has been reported to improve both kidney function and urate clearance in patients with kidney insufficiency and gout, even when EDTA-chelatable Pb body burdens were low (Lin et al., 2001).

Alterations in serum uric acid have been studied in animal models exposed to Pb. Conterato et al. (2007) followed various parameters of kidney function after single or multiple Pb injections in rats. The single dosing regimen consisted of a single i.p. injection of 25 or 50 mg/kg Pb-acetate, while the multiple injections involved once daily i.p. injection of either vehicle or Pb-acetate (5 or 25 mg/kg) for 30 days. Single and multiple injections at both dose levels increased plasma uric acid levels. Similarly, Abdel Moneim et al. (2011b) reported increased serum uric acid and urea levels after 5 days of Pb-acetate treatment (i.p. 20 mg/kg). In male rats exposed to Pb in drinking water from lactation to puberty (40 days) or post-puberty (65 days), Berrahal et al. (2011) found that plasma urea levels increased after 40 days of exposure (puberty blood Pb level of 12.7 µg/dL) but decreased after 65 days of Pb exposure (post-puberty blood Pb level of 7.5 µg/dL) (Table 5-23).

5.5.3.2 Oxidative Damage

A role for ROS in the pathogenesis of experimental Pb-induced hypertension and renal disease has been well characterized (Vaziri, 2008a, b; Vaziri and Khan, 2007). The production of oxidative stress following Pb exposure is detailed in respect to modes of action of Pb (Section 5.2.4). Past studies have shown that Pb treatment (single or three daily i.p. injections) can elevate kidney GST levels, affecting glutathione metabolism (Daggett et al., 1998; Moser et al., 1995; Oberley et al., 1995).

Animal studies continue to provide evidence for increased oxidative stress playing a role in the pathogenesis of Pb-induced renal toxicity. Increased ROS, serum NO, and renal NO were observed after Pb injections in rats (i.p. 20 mg/kg, 5 days) (Abdel Moneim et al., 2011b). Pb exposure to rat proximal tubular cells (0.5-1 µM) also increased ROS production, in a concentration-dependent manner (Wang et al., 2011b). Oxidative stress

was also demonstrated by increased lipid peroxidation (i.e., MDA) in serum and renal tissue after Pb exposure (Abdel Moneim et al., 2011b; Lodi et al., 2011; Wang et al., 2011b). Berrahal et al. (2011) reported increased MDA in Pb-exposed (50 ppm Pb-acetate pre- and post-natally) rat kidney relative to controls at both 40 (puberty; blood Pb 12.7 µg/dL) and 65 (post-puberty; blood Pb 7.5 µg/dL) days of age. In addition, total sulfhydryl groups were significantly decreased at 65 days. These increases in oxidative stress were accompanied by age-dependent Pb nephrotoxicity in male rats (Table 5-24).

Alterations in endogenous antioxidants and antioxidant enzymes that may lead to oxidative stress have also been reported after Pb exposure. Pb treatment decreased the activity of the renal antioxidant enzymes, CAT, SOD, GST, GPx, and GR (Abdel Moneim et al., 2011b) and protein levels of CAT and GSH (Lodi et al., 2011). Additionally, proteomic analysis of high-level Pb treated (1,500 ppm, 5 weeks; resulting in blood Pb level of 53.4 µg/dL) rat kidney identified decreased abundance of a rate-limiting enzyme in the synthesis of GSH (glutamate cysteine ligase) (Chen et al., 2011).

Conterato et al. (2007) examined the effect of Pb-acetate on the cytosolic thioredoxin reductase activity and oxidative stress parameters in rat kidneys. A single injection of Pb-acetate consisted of a single i.p. injection of 25 or 50 mg/kg Pb-acetate, while repeated injections consisted of one daily i.p. injection of Pb-acetate (5 or 25 mg/kg) for 30 days. Measured were thioredoxin reductase-1, a selenoprotein involved in many cellular redox processes, SOD, δ-ALAD, GST, GPx, non protein thiol groups (NPSH), CAT, as well as plasma creatinine, uric acid, and inorganic phosphate levels. The single injection at the 25 mg Pb dose level resulted in increased SOD and thioredoxin reductase-1 activity, while the 50 mg dose level increased CAT activity and inhibited δ-ALAD activity in the kidney. Repeated injections at the 5 mg dose level of Pb inhibited δ-ALAD and increased GST, NPSH, CAT, and thioredoxin reductase-1. Repeated injections at the 25-mg dose level reduced δ-ALAD but increased GST, NPSH, and plasma uric acid levels. No changes were observed in TBARS, GPx, creatinine or inorganic phosphate levels after either single or repeated injection dosing. As both dosing regimens increased thioredoxin reductase-1 activity, the authors suggest that this enzyme may be a sensitive indicator of renal changes with low dose Pb treatment.

Jurczuk et al. (2006) published a study of the involvement of some low molecular weight thiols in the peroxidative mechanisms of action of Pb in the rat kidney. Wistar rats were fed a diet containing 500 ppm Pb-acetate for a period of 12 weeks and were compared to a control group receiving distilled water for the same time period. GSH, metallothionein (MT), total and nonprotein SH groups (TSH and NPSH) were measured, as were the blood activity and urinary concentration of δ-ALA. The concentrations of GSH and NPSH were decreased by Pb administration, while MT concentration was unchanged. δ-

ALAD in blood was decreased, whereas urinary δ-ALA was increased by Pb administration. Negative correlations were found between the kidney GSH concentrations and previously reported concentrations of Pb and MDA in kidneys of these rats. It is apparent from graphical presentation of the data that GSH was reduced by more than 50% following Pb administration, while TSH was reduced by approximately 15%. No values for either blood or kidney Pb levels or kidney MDA were reported in this article. In 2007, the same authors (Jurczuk et al., 2007) reported on the renal concentrations of the antioxidants, vitamins C and E, in the kidneys of the same Pb-treated and control rats. Exposure to Pb significantly decreased vitamin E concentration by 13% and vitamin C concentration by 26%. The kidney concentration of vitamin C negatively correlated with MDA concentration. The authors concluded that vitamins E and C were involved in the mechanism of peroxidative action of Pb in the kidney, and their protective effect may be related to scavenging of free radicals.

Studies have used antioxidant compounds to investigate the role of oxidative stress in Pb-induced nephrotoxicity. Abdel Moneim et al. (2011b) reported that flaxseed oil treatment protected rats from Pb-induced (i.p. 20 mg/kg, 5 days) oxidative stress, inflammation, and apoptosis. However, the flaxseed oil also decreased the accumulation of Pb in renal tissue making it difficult to ascertain whether the protection was due to decreased oxidative stress or to altered Pb uptake kinetics.

El-Neweshy and El-Sayed (2011) studied the influence of vitamin C supplementation on Pb-induced histopathological alterations in male rats. Rats were given Pb-acetate, 20 mg/kg by intragastric feeding once daily for 60 days. Control rats were given 15 mg of sodium acetate per kg once daily, and an additional group was given Pb-acetate plus vitamin C (20 mg/kg every other day) 30 minutes before Pb feeding. Control rats showed normal histology, while Pb-treated rats exhibited karyomegaly with eosinophilic intranuclear inclusion bodies in the epithelial cells of the proximal tubules. Glomerular damage and tubular necrosis with invading inflammatory cells were also seen in Pb-treated animals. Among rats treated with Pb-acetate plus vitamin C, five exhibited relatively mild karyomegaly and eosinophilic intranuclear inclusion bodies of proximal tubules and an additional five rats were normal. Normal glomeruli were noted in all. Thus, vitamin C was shown to ameliorate the renal histopathological effects of Pb intoxication, however no measures of Pb accumulation were provided to clarify the mechanism of action of vitamin C.

Masso-Gonzalez and Antonio-Garcia (2009) studied the protective effect of natural antioxidants (zinc, vitamin A, vitamin C, vitamin E, and vitamin B6) against Pb-induced damage during pregnancy and lactation in rat pups. At weaning, pups were sacrificed and kidneys were analyzed. Pb-exposed pups had decreased body weights. Blood Pb levels

were 1.43 µg/dL in the control group, 22.8 µg/dL in the Pb group, 21.2 µg/dL in the Pb plus zinc plus vitamins group, and 0.98 µg/dL in the zinc plus vitamin group. The kidney TBARS were significantly elevated in Pb exposed pups, while treatment with vitamins and zinc returned TBARS to control levels. Kidney CAT activity was significantly increased above control with Pb treatment; however supplementation with zinc and vitamins reduced CAT activity toward normal. Pb exposure inhibited kidney Mn-dependent SOD but not Cu-Zn-dependent SOD activity. Thus, supplementation with zinc and vitamins during gestation and lactation was effective in attenuating the redox imbalance induced by developmental, chronic low-level Pb exposure, likely through the alteration of Pb accumulation.

Bravo et al. (2007) reported further that mycophenolate mofetil (an immunosuppressive agent used in renal transplantation which inhibits T and B cell proliferation) administration reduces renal inflammation, oxidative stress and hypertension in Pb-exposed rats. Thus, an inflammatory immune and oxidative stress component can be seen as contributing to Pb-induced renal effects and hypertension.

Although the majority of studies of the effects of Pb exposure have been conducted in male rats, a couple of studies have compared the response of male rats with female rats (Sobekova et al., 2009; Alghazal et al., 2008a). Sobekova et al. (2009) contrasted the activity response to Pb on the antioxidant enzymes, GPx and GR, and on TBARS in both male and female Wistar rats of equal age. Males weighing 412 ± 47 g and females weighing 290 ± 19 g were fed diets containing either 100 ppm or 1,000 ppm Pb-acetate for 18 weeks. In the male rats, kidney Pb content increased by 492% on the 100 ppm Pb diet and by 7,000% on the 1,000 ppm Pb diet. In the female rats, kidney Pb content increased by 410% on the 100 ppm Pb diet and by 23,000% on the 1,000 ppm Pb diet. There was virtually no change in GPx in the kidney of male rats given the 100 ppm Pb diet but there was a significant reduction in GPx in the female rats on both the 100 ppm diet and 1,000 ppm diet. In male rats, GR was increased from 182 units/gram of protein in control kidneys to 220 units on the 100 ppm Pb diet and 350 units on the 1,000 ppm diet. In female rats, kidney GR decreased from 242 units in control animals to 164 units in animals on the 100 ppm Pb diet and 190 units in animals on the 1,000 ppm diet. In male rats, kidney TBARS content increased from 7.5 units/gram protein to 10.0 units (1,000 ppm Pb diet group). In female rats, there was a reduction in TBARS from 14.4 units per gram protein to 10.0 units in rats on the 100 ppm Pb diet and to 11 units in rats on the 1,000 ppm Pb diet.

Alghazal et al. (2008a) compared the activity responses of the antioxidant enzyme, SOD and the detoxifying enzyme, GST, of the same rats exposed to 100 ppm or 1,000 ppm Pb-acetate for 18 weeks. Similar to the previous study, kidney TBARS were increased

only in male rats given the higher dose of Pb. Kidney SOD activity, on the other hand, was increased in both males and females at the higher dose of Pb, while GST activity was increased in kidney of males at the higher dose of Pb and decreased at the lower dose, but was decreased at both doses of Pb in females. Thus there were significant differences in the responses of male and female rats to Pb exposure. Differences may be accounted for in part due to the greater deposition of Pb in female rat kidneys. Another explanation, offered by the authors, is that male rats are known to metabolize some foreign compounds faster than do females, so the biological half-life of xenobiotics in the females may be longer.

5.5.3.3 Renal Gangliosides

Gangliosides are constituents of the plasma membrane that are important for control of renal GFR because they can act as receptors for various molecules and have been shown to take part in cell-cell interactions, cell adhesion, recognition and signal transduction. Aguilar et al. (2008) studied changes in renal gangliosides following Pb exposure (600 ppm Pb-acetate in drinking water for 4 months) in adult male Wistar rats. Pb exposure caused an increase in blood Pb from 2.1 to 35.9 µg/dL. There was no change in serum creatinine or in hemoglobin, but there was an increase in urinary δ-ALA. The following renal gangliosides were measured by immunohistochemistry and by thin layer chromatography: GM1, GM2, GM4, and 9-O-acetylated modified form of the GD3 ganglioside (9-O-Ac-GD3). The ganglioside pattern was mainly characterized by a decrease in the GM1 ganglioside as well as by a mild increase in GM4 and GM2 gangliosides, while the strongest alteration was observed in the 9-O-Ac-GD3, which was overexpressed. The latter was observed only in the glomerular zone. This was associated with a decrease in apoptotic glomerular cells, as assessed by the TUNEL assay. The authors hypothesized that the increase in GD3-O-acetylation could represent a strategy to attenuate the normal renal apoptotic process and therefore contribute to cell survival during Pb exposure.

5.5.3.4 Role of Metallothionein

Yu et al. (2009) described dichotomous effects of Pb-acetate on the expression of MT in the liver and kidney of mice. Male mice were i.p. injected with Pb-acetate in doses of 100, 200, and 300 µmol/kg and sacrificed 4, 8, and 24 hours after Pb treatment. Administration of Pb increased the levels of MT-1 mRNA in the liver and kidneys but increased MT protein only in the liver. Treatment of mouse PT cells in vitro with Pb also resulted in an increase in MT mRNA but little increase in MT protein. Thus, Pb appears

to exert a dual effect on MT expression in the kidney: enhancement of MT gene transcription but suppression of MT mRNA translation.

Zuo et al. (2009) examined the potential role of α-Synuclein (Scna) and MT in Pb-induced inclusion body formation. They used MT-I/II double knockout (MT-null) and parental wild type (WT) cell lines to explore the formation process of Pb-induced inclusion bodies. Unlike WT cells, MT-null cells did not form inclusion bodies after Pb exposure. Western blot of the cytosol showed that soluble MT protein in WT cells was lost during Pb exposure as inclusion bodies formed. However, transfection of MT-1 into MT-null cells allowed inclusion body formation after Pb exposure. As Scna is a protein with a natural tendency to aggregate into oligomers, Scna was measured in WT cells and MT-null cells after Pb exposure. Scna protein showed poor basal expression in MT-null cells, and Pb exposure increased Scna expression only in WT cells. MT transfection increased Scna transcript to WT levels. In both of these cell lines Pb-induced Scna expression rapidly increased and then decreased over 48 hours as Pb-induced inclusion bodies were formed. A direct interaction between Scna and MT was confirmed ex vivo by an antibody pull down assay, where the proteins co-precipitated with an antibody to MT. Pb exposure caused increased colocalization of MT and Scna proteins. In archival kidney samples of renal cortex from WT mice chronically treated with Pb, MT was localized to the surface of inclusion bodies. Thus, Scna may be a component of Pb-induced inclusion bodies and, with MT, may play a role in inclusion body formation.

5.5.4 Effects of Exposure to Lead Mixtures

The effect of Pb on other cations, specifically calcium, is well established in the kidney literature. Calcium-mediated processes involving receptors, transport proteins, and second messenger signaling among other endpoints have been shown to be significantly affected by Pb exposure. The disposition of Pb in the soft tissues (kidney and spleen) can change with exposure to Pb and other compounds. Pb plus Cd exposure changed Pb disposition with increased blood Pb (versus Pb alone group) and decreased metal concentration in the kidney and liver (versus Pb alone). An iron deficient diet significantly increased Pb deposition in adult animals (Hashmi et al., 1989), pregnant dams, and maternally-exposed fetuses (Singh et al., 1991). Dietary thiamine plus zinc slightly reduced blood and kidney Pb in exposed animals (Flora et al., 1989). Selenium, a cofactor for GPx, attenuated Pb-induced lipid peroxidation and abrogated the Pb-induced attenuation of GR and SOD. Concomitant exposure to the cations aluminum and Pb protected animals from ensuing nephropathy (Shakoor et al., 2000). In summary, Pb has been shown to affect processes mediated by endogenous divalent cations. In addition,

exposure to other metals or divalent cations can modulate Pb disposition and its effects in the body.

5.5.4.1 Lead and Cadmium

Cd shares many similarities with Pb; it has been shown to be a ubiquitous PT nephrotoxicant and accumulates in the body. Despite the similarities, few studies have evaluated associations between Cd exposure and CKD or the impact of joint exposure of Pb and Cd or other metals on CKD. As discussed in the 2006 Pb AQCD, environmental exposure to Cd, at levels common in the U.S. and other developed countries, has been shown to impact substantially associations between indicators of Pb exposure and the kidney EBE marker, NAG, even in the presence of occupational level Pb exposure. In an occupational study, mean NAG, although higher in the Pb-exposed worker group compared to controls, was correlated with urine Cd but not blood or tibia Pb (Roels et al., 1994). In another occupational population where both metals were significantly associated with NAG, a 0.5 μg/g creatinine increase in Cd had the same effect on NAG as did a 66.9 μg/g bone mineral increase in tibia Pb (Weaver et al., 2003a).

The 2006 Pb AQCD noted that data examining the concentration-response relation between environmental Cd and the kidney were too scarce to determine the impact of Cd exposure on relations between Pb exposure and other kidney outcomes. A recent publication in NHANES data collected from 1999 through 2006 addresses this need; (results pertaining solely to Pb were discussed in Section 5.5.2.2) (Navas-Acien et al., 2009). Geometric mean concurrent blood Cd level was 0.41 μg/L in 14,778 adults aged ≥ 20 years. After adjustment for survey year, sociodemographic factors, CKD risk factors, and blood Pb, the ORs for albuminuria (≥ 30 mg/g creatinine), reduced eGFR (<60 mL/min/1.73 m^2), and both albuminuria and reduced eGFR were 1.92 (95% CI: 1.53, 2.43), 1.32 (95% CI: 1.04, 1.68), and 2.91 (95% CI: 1.76, 4.81), respectively, comparing the highest with the lowest blood Cd quartiles. Both Pb and Cd remained significantly associated after adjustment for the other. Effect modification was not observed; however, ORs were higher for adults in the highest quartiles of both metals compared with the ORs for the highest quartiles of concurrent blood Cd or Pb alone (Table 5-25). Compared with adults with blood Cd levels ≤ 0.2 μg/L and blood Pb levels ≤ 1.1 μg/dL, adults with blood Cd levels > 0.6 μg/L and blood Pb levels > 2.4 μg/dL had ORs (95% CIs) of 2.34 (95% CI: 1.72, 3.18) for albuminuria, 1.98 (95% CI: 1.27, 3.10) for reduced eGFR, and 4.10 (95% CI: 1.58, 10.65) for albuminuria and reduced eGFR together. These findings are consistent with other recent publications (Akesson et al., 2005; Hellstrom et al., 2001), support consideration of both metals as independent CKD risk factors in the general

population, and provide novel evidence of increased risk in those with higher environmental exposure to both metals.

However, a very recent study suggests that interpretation of Cd associations with GFR measures may be much more complex. Conducted in Pb workers to address the fact that few studies have examined the impact of environmental Cd exposure in workers who are occupationally exposed to other nephrotoxicants such as Pb, the study assessed Cd dose with urine Cd, which is widely considered the optimal dose metric of cumulative Cd exposure. In 712 Pb workers, mean (SD) blood and tibia Pb, urine Cd, and eGFR using the MDRD equation were 23.1 (14.1) μg/dL, 26.6 (28.9) μg/g, 1.15 (0.66) μg/g creatinine, and 97.4 (19.2) mL/min/1.73m^2, respectively (Weaver et al., 2011). After adjustment for age, sex, BMI, urine creatinine, smoking, alcohol use, education, annual income, diastolic BP, current or former Pb worker job status, new or returning study participant, and blood and tibia Pb, higher urine Cd was associated with higher calculated creatinine clearance, eGFR (β = 8.7 mL/min/1.73 m^2 [95% CI: 5.4, 12.1] per unit increase in ln-transformed urine Cd) and ln-NAG, but lower serum creatinine. These unexpected paradoxical associations have been reported in a few other publications (De Burbure et al., 2006; Hotz et al., 1999) and have been observed in other populations. Potential explanations for these paradoxical results included a normal physiologic response in which urine Cd levels reflect renal filtration; the impact of adjustment for urine dilution with creatinine in models of kidney outcomes; and Cd-related hyperfiltration.

Wang et al. (2009c) studied the effects of Pb and/or Cd on oxidative damage to rat kidney cortex mitochondria. In this study young female Sprague Dawley rats were fed for 8 weeks with either Pb-acetate (300 ppm), Cd chloride (50 ppm), or Pb and Cd together in the same dosage. Lipid peroxidation was assessed as MDA content. Renal cortex pieces were also processed for ultrastructural analysis and for quantitative rtPCR to identify the mitochondrial damage and to quantify the relative expression levels of cytochrome oxidase subunits (COX-I/II/III). Cytochrome oxidase is the marker enzyme of mitochondrial function, and COX-I, II, and III are the three largest mitochondrially-encoded subunits which constitute the catalytic functional core of the COX holoenzyme. Mitochondria were altered by either Pb or Cd administration, but more strikingly by Pb plus Cd administration, as indicated by disruption and loss of mitochondrion cristae. Kidney cortex MDA levels were increased significantly by either Pb or Cd, given individually, but more so by Pb plus Cd. COX-I/II/III were all reduced by either Pb or Cd administration, but more prominently by Pb plus Cd administration. This study adds to knowledge of the synergistic effects of Pb and Cd on kidney mitochondria.

5.5.4.2 Lead, Cadmium, and Arsenic

Wang and Fowler (2008) present a general review of the roles of biomarkers in evaluating interactions among mixtures of Pb, Cd, and arsenic. Past studies have found that addition of Cd to treatment of rats with Pb or Pb and As significantly reduced the histological signs of renal toxicity from each element alone; on the other hand, animals exposed to Cd in addition to Pb or Pb and As showed an additive increase in the urinary excretion of porphyrins, indicating that, although measured tissue burdens of Pb were reduced, the biologically available fraction of Pb is actually increased (Mahaffey et al., 1981; Mahaffey and Fowler, 1977).

Stress proteins were examined after exposure to mixtures of Pb and other metals. Induction of MT was strongest in groups with Cd treatment. However, co-exposure to Pb and As induced higher levels of MT protein than did either Pb or As exposure alone in kidney tubule cells. Heat shock proteins (Hsps) are commonly altered with exposure to metal mixtures. A study found in vitro (low dose) and in vivo that Pb induced Hsps in a metal/metalloid-, concentration- and time-specific manner (Wang et al., 2005). Additive or more than additive interactions occurred among Pb, Cd and As under combined exposure conditions.

5.5.4.3 Lead and Zinc

Zinc has been investigated as a protective compound against the effects of Pb. Pb treatment (35 mg/kg i.p. for 3 days) caused a significant fall in hemoglobin content, significant increases in lipid peroxidation and decreased level of reduced glutathione in liver, together with diminished total protein content in liver and kidney. Co-treatment of Pb with zinc (10 mg/kg i.p.) or ascorbic acid (10, 20 and 30 mg/kg i.p.) showed a moderate therapeutic effect when administered individually, but more pronounced protective effects after combined therapy (Upadhyay et al., 2009).

Jamieson et al. (2008) studied the effect of dietary zinc content on renal Pb deposition. Weanling Sprague Dawley rats were assigned to marginal zinc (MZ, 8 mg Zn/kg diet), zinc adequate control (CT, 30 mg Zn/kg), zinc-adequate diet-restricted (30 mg Zn/kg), or supplemental zinc (SZn, 300 mg Zn/kg) groups, with or without Pb-acetate (200 ppm for 3 weeks). Pb exposure did not result in nephromegaly or histological alterations. The MZ rats had higher renal Pb (35%) and lower renal zinc (16%) concentrations than did CT rats. On the other hand, SZn was more protective than the CT diet was against renal Pb accumulation (33% lower). Standard procedures for indirect immunoperoxidase staining were used to determine MT localization in the kidney. Pb had no effect on MT staining

intensity, distribution, or relative protein amounts. Western blot analysis confirmed that MT levels were responsive to dietary zinc but not to Pb exposure.

5.5.4.4 Lead and Mercury

Stacchiotti et al. (2009) studied stress proteins and oxidative damage in a renal-derived cell line exposed to inorganic mercury and Pb. The time course of the expression of several Hsps, glucose-regulating proteins and MTs in a rat proximal tubular cell line (NRK-52E) exposed to subcytotoxic doses of inorganic mercury ($HgCl_2$, 1-40 μM) and Pb ($PbCl_2$, 2-500 μM) were analyzed. ROS and reactive nitrogen species (RNS) were detected by flow cytometric analysis. Endogenous total GSH content and the enzymatic activity of GST were determined in cell homogenates. Western blot analysis and immunohistochemistry were used for quantification of hsps and MTs. Reverse transcription PCR was used for quantification of metallothionein. The higher doses of mercury (20 μM and 40 μM) were shown to markedly inhibit growth of the cell line while the higher doses of Pb (60 μM to 500 μM) inhibited cell growth to a lesser degree. After 24 hours of exposure at 20 μM mercury, the cells presented abnormal size and pyknotic nuclei, swollen mitochondria and both apoptosis and overt necrosis. In the presence of 60 or 300 μM Pb, the cells lost cell-cell and cell-matrix contacts, showed a round size, irregular nuclear contour and often mitotic arrest, but no apoptosis or overt necrosis at 24 hours. Mercury induced a significant increase in both ROS and RNS, maximal RNS at 24 hours, and maximal ROS at 48 hours. Pb (60 or 300 μM) did not cause an increase in ROS or RNS beyond the levels measured in control cells. Total GSH significantly increased in cells grown in the presence of Pb; the effect was concentration-dependent and GSH reached its maximal value at a dose of 300 μM Pb. The effect of mercury was biphasic: 10 μM significantly enhanced GSH by 600%, while the amount of GSH detected after 20 μM mercury only increased by 50% compared to control levels. GST activity was enhanced by both Pb and mercury. Hsp25 and Hsp72 were up-regulated by mercury but there was no effect on Grp78 as compared to control. On the contrary, Pb treatment only upregulated Grp78. Mercury induced a time-dependent effect on MT mRNA expression, which reached its maximal value 3 hours after beginning treatment and reverted to control values at 24 hours. With Pb, on the other hand, mRNA transcription was concentration- and time-dependent. The transcripts remained overexpressed compared to controls up to 72 hours. The results of this study with regard to the Pb effect on MT synthesis clearly differ from those of Jamieson et al. (2008), which found no increase in MT following Pb exposure. This discrepancy remains to be clarified.

5.5.5 Impact of Treatment with Antioxidants on Renal Lead Accumulation and Pathology

5.5.5.1 Treatment with Antioxidants

Wang et al. (2010d) assessed the protective effect of N-acetylcysteine (NAC) on experimental chronic Pb nephrotoxicity in immature female rats. NAC is a potent oxygen free radical scavenger, a metal chelator, and the precursor to the antioxidant glutathione. Sprague-Dawley rats received Pb-acetate (300 ppm in drinking water) and/or NAC (100 mg/kg/day, by i.p. injection) for 8 weeks to investigate the protective effect of NAC on Pb-induced renal damage and oxidative stress. Serum and renal cortical Pb levels were markedly increased in the Pb-treated animals, but reduced in the Pb plus NAC treated animals. There were time-related increases in urinary alkaline phosphatase, urinary GGT, urinary NAG, urinary total protein, urinary β-2 microglobulin, and urinary microalbumin, which were all decreased by NAC. Serum urea nitrogen was significantly increased by Pb administration and reduced toward normal by Pb plus NAC. Alterations in proximal tubular structures were observed in most kidney samples from Pb-treated rats, but animals treated with combination Pb plus NAC showed well-preserved cell structures and organelles. Indices of oxidative stress (MDA, SOD, GSH, GPx, and CAT) were altered by Pb treatment and restored to or toward normal by Pb plus NAC treatment (MDA increased and the remainder decreased). Thus NAC was shown to have both an anti-oxidative and a chelator effect on Pb intoxication.

Saxena et al. (2005) investigated the beneficial role of monoesters of meso-2, 3-dimercaptosuccinic acid in the mobilization of Pb and recovery of tissue oxidative injury in rats. Dimercaptosuccinic acid (DMSA) is known as a Pb chelator and as an antioxidant by virtue of its possession of thiol groups. In this study, DMSA, and two of its analogues, monomethyl dimercaptosuccinic acid (MmDMSA) and mono-cyclohexyl dimercaptosuccinic acid (MchDMSA) were assessed for their capability to reduce Pb concentration in blood and soft tissues and to recover Pb-induced oxidative stress. Male Wistar rats were exposed to Pb-acetate (0.1% in drinking water) for 20 weeks. Rats were then treated orally once daily for five days with DMSA or its two analogues at doses up to 100 mg/kg. Exposure to Pb caused a rise in blood Pb levels to approximately 25 μg/dL. Exposure to Pb also caused a significant decrease in blood ALAD activity and GSH levels, accompanied by inhibition of kidney ALAD and an increase in δ-aminolevulinic acid synthetase (ALAS) activity in liver and kidneys. Pb exposure also resulted in increased blood and soft tissue (brain, liver, and kidney) Pb and TBARS levels and decreased GSH levels. These were restored by treatment with DMSA and its analogues, particularly MchDMSA.

Abdallah et al. (2010) examined the effect of Pb on coenzyme Q levels in rat tissues. Coenzyme Q acts as an electron and proton carrier in mitochondria and functions as an antioxidant in its reduced form (ubiquinol). Both coenzyme Q9 and coenzyme Q10 were measured in rat tissues as coenzyme Q9 is the predominant form found in the rat. Male albino rats were injected i.p. with Pb-acetate at a dose of 5 mg/kg daily for 6 weeks. No blood Pb levels were reported. TBARS were elevated above levels in controls in serum, liver, kidney and brain while non-protein sulfhydryl groups (indicative of GSH) were decreased in serum and kidney. Both oxidized and reduced coenzyme Q9 levels were significantly reduced in kidneys from Pb-treated rats as contrasted to controls (mean [SE]: respectively, 48.6 [5.6] versus 95.5 [10.1] nmol/g tissue for oxidized form and 35.4 [3.0] versus 61.4 [5.1] nmol/g tissue for reduced form). On the other hand, levels of oxidized and reduced coenzyme Q10 were unchanged. Thus, the reduced levels of coenzyme Q attributable to Pb exposure may be a factor in the diminished antioxidant defense mechanism.

El-Sokkary et al. (2005) evaluated the effect of melatonin against Pb-induced hepatic and renal toxicity in male rats. Melatonin is known to be efficacious as a free radical scavenger and indirect antioxidant. Three groups of animals were used: control, Pb-acetate-treated (100 ppm) and Pb-acetate and melatonin (10 mg/kg) given subcutaneously for 30 days. Lipid peroxidation was measured as the sum of MDA and 4-hydroxyalkenals (4-HAD). Pb increased kidney lipid peroxidation products, but these were reduced toward normal with melatonin co-treatment. Both SOD and GSH levels were reduced by Pb and were increased by melatonin. Histological section of kidneys of Pb-treated rats showed tubular degeneration with some apparently necrotic cells, while melatonin-treated rats demonstrated a near normal structure. The authors concluded that melatonin protected the liver and kidneys from the damaging effects of exposure to Pb through inhibition of lipid peroxidation and stimulation of endogenous antioxidative defense systems.

Ozsoy et al. (2010) studied the protective effects of L-carnitine on experimental Pb toxicity in rats. Female two month-old rats were fed 0.5 mg/kg Pb-acetate alone or with daily injections of 0.5 mg/kg L-carnitine for 60 days. Control animals were injected with physiological saline. Pb caused an increase in serum creatinine and histopathological changes in the kidney, consisting of tubule dilatation, degeneration and necrosis and interstitial inflammation. In the Pb plus L-carnitine group, serum creatinine was reduced to control values and the histopathological changes were reversed. Immunological staining indicated Cu/Zn-SOD stimulation by Pb feeding alone and reduction by L-carnitine co-treatment. The authors attributed the beneficial effects of L-carnitine to its antioxidant effect.

Reddy et al. (2010) treated Sprague-Dawley rats with 10 mg/kg/day of Pb-acetate and/or thiamine (25 mg/kg/day) for 7 weeks. Thiamine treatment normalized the Pb-induced alterations in blood ALAD activity and urinary NAG activity.

The effectiveness of various plant or bacterial extracts as antioxidants in the kidney was examined in a few studies. Kharoubi et al. (2008a) described the prophylactic effects of Wormwood (*Artemisia absinthium L.*) plant extracts on kidney function in Pb-exposed animals. Male Wistar rats were exposed to Pb-acetate (750 ppm in drinking water) for 11 weeks, and then received Wormwood extract (200 mg/kg) for 4 weeks. Significant differences in blood and urinary Pb concentration were observed between the Pb group and the Wormwood group (e.g., 55.6 µg/dL blood Pb versus 22.3 µg/dL, respectively). Pb induced lipid peroxidation (TBARS and protein carbonyls in the kidney), but these levels were reduced by Wormwood extract. Wormwood extract also attenuated the effects of Pb on renal function. These results indicated that Wormwood extract had significant antioxidant activity and protected the kidney from Pb-induced toxicity.

Jayakumar et al. (2009) evaluated the effect of a methanolic extract of the Indian herb, *Achyranthes aspera*, in preventing Pb-induced nephrotoxicity in rats. Male albino Wistar rats, received Pb-acetate (0.2% for 6 weeks) or Pb-acetate plus *A. aspera* (200 mg/kg for 6 weeks) simultaneously. *A. aspera* partially prevented the increases in kidney weight, BUN, serum uric acid, and serum creatinine caused by Pb administration. The levels of urinary marker enzymes, GGT, β-glucuronidase, NAG, Cathepsin D, and LDH, which were reduced by Pb administration, were increased to or toward normal by *A. aspera*. Kidney histology revealed that Pb-treated animals showed tubular damage, whereas the Pb plus *A. aspera*-treated animals showed a reduction in tubular damage.

El-Nekeety et al. (2009) evaluated the protective effect of an extract of the folk medicine plant *Aquilegia vulgaris* against Pb-acetate-induced oxidative stress in Sprague-Dawley rats. The experimental group was treated with 200 ppm Pb-acetate and/or 100 ppm of an extract of *A. vulgaris* for 2 weeks prior to Pb-acetate. Pb-acetate increased serum urea and decreased serum total protein and albumin. These changes were reversed by treatment with the extract. Histological examination of kidneys of rats treated with Pb showed tubular dilatation, interstitial inflammatory cells, hemorrhage, cellular debris, and hypercellularity in the glomerulus, with apoptotic nuclei in renal tubular epithelial cells. The rats treated simultaneously with Pb and the extract showed essentially normal renal tubules and glomeruli while rats treated with Pb and then the extract showed improvement in tubular structure, but interstitial fibrosis was still present. This experiment indicated that exposure to Pb generates free radicals, and that an extract of *A. vulgaris* resulted in restoration of the different parameters tested. The second experiment in this group was by Ponce-Canchihuaman et al. (2010) who evaluated the antioxidant

activity of the cyanobacterium *Spirulina maxima* against Pb-acetate-induced hyperlipidemia and oxidative damage in the liver and kidney of male rats. Male Wistar rats were treated with Pb-acetate by i.p. injection (25 mg/rat on a weekly basis for 3 weeks), and a 5% supplement of Spirulina was given in food. The findings in the kidney were similar to those in the liver (see Section 5.9.1). Thus, Pb-induced oxidative stress and renal damage can be attenuated by treatment with Spirulina extract.

Finally, there is a need to examine whether the chelator, $CaNa_2EDTA$, acts also as an antioxidant and promotes increased vasodilatation and subsequent increased renal blood flow by enhancing the delivery of NO. This question arose because of the observations of Lin et al. (2006b) that repeated injections of $CaNa_2EDTA$ lead to improvement in kidney function in patients with chronic renal failure, even in individuals with very low body Pb stores as indicated by EDTA mobilization tests (i.e., < 80 μg 72 hour urinary Pb excretion). Jacobsen et al. (2001) examined the anti-oxidative effects of Gallic acid, EDTA, and an emulsifier in mayonnaise enriched with 16% fish oil. EDTA was shown to be an efficient antioxidant in the fish oil enriched mayonnaise as it strongly inhibited the formation of free radicals and volatile oxidation compounds. The authors suggested that the antioxidative effect appears to be due to its ability to chelate free iron in egg yolk at the oil-water interface.

5.5.5.2 Treatment with Antioxidants plus Chelators

Santos et al. (2006a) assessed the potentiating effects of chelators (2,3-dimercaptopropanol [BAL], 2,3-dimercaptopropane-l-sulfonic acid [DMPS], and meso-2,3-dimercaptosuccinic acid [DMSA]) given simultaneously with Pb-acetate on δ-ALAD activity, both in vivo and ex vivo. Ex vivo, human blood was pre-incubated with BAL or DMSA (10 μM) or DMPS (1 μM) then Pb-acetate added to the reaction mixture. In vivo, mice were given daily injections of 50 mg/kg Pb-acetate for 15 days and then injected with 1/3 of LD50 of the chelating agents. In human blood, the inhibitory effect of Pb-acetate (1 and 100 μM) on δ-ALAD activity was markedly increased in the presence of BAL and DMPS, whereas DMSA ameliorated the enzyme inhibition caused by 1 μM Pb-acetate. In vivo, Pb-acetate inhibited δ-ALAD activity by 42%. Parallel to the ex vivo results, BAL and DMPS, but not DMSA, increased the inhibitory potency of Pb in blood. In the kidney, BAL and DMSA but not DMPS increased inhibitory activity. The authors conjectured that the chelators may deplete the cells of zinc, an essential element for δ-ALAD activity. These observed effects with chelators were supported by Bradberry and Vale (2009), Hamidinia et al. (2006), and Aslani et al. (2010) who found decreased kidney Pb content post-chelation.

5.5.6 Summary and Causal Determination

The 2006 Pb AQCD concluded that "in the general population, both circulating and cumulative Pb was found to be associated with a longitudinal decline in renal function," evidenced by increased serum creatinine and decreased creatinine clearance or eGFR over follow-up of 4 to 15 years in association with higher baseline blood and bone Pb levels (U.S. EPA, 2006b). Data in general and patient populations of adults provided consistent evidence of Pb-associated lower renal function in populations with mean concurrent or baseline blood Pb levels of 2-10 μg/dL (Akesson et al., 2005; Tsaih et al., 2004; Yu et al., 2004; Kim et al., 1996); associations with lower eGFR were observed in adults with hypertension with a mean concurrent blood Pb level of 4.2 μg/dL (Muntner et al., 2003). The conclusion from the 2006 Pb AQCD was substantiated by the coherence of effects observed across epidemiologic and toxicological studies. Both human and animal studies observed Pb-associated hyperfiltration. In animals during the first 3 months after Pb exposure, effects were characterized by increased GFR and increased kidney weight due to glomerular hypertrophy. However, exposure for 6 or 12 months resulted in decreased GFR, interstitial fibrosis, and kidney dysfunction. Additionally, toxicological studies found that early effects of Pb on tubular cells were generally reversible, but continued exposure resulted in chronic irreversible damage. Toxicological studies provided mechanistic evidence to support the biological plausibility of Pb-induced renal effects, including oxidative stress leading to $^{\bullet}$NO inactivation. Despite the strong body of evidence presented in the 2006 Pb AQCD, uncertainty remained on the contribution of past Pb exposures to associations observed in adults, the impact in children, and the implication of hyperfiltration.

Recent epidemiologic studies in adult general and patient populations continue to support Pb-related nephrotoxicity with consistently observed associations of blood and bone Pb levels with worse kidney function. These studies benefit from a number of strengths that vary by study but include comprehensive assessment of Pb dose with measurements of blood Pb, bioavailable Pb, and bone Pb as a biomarker of cumulative exposure; prospective study design; and statistical approaches that utilize a range of exposure and outcome measures, while adjusting for numerous potential confounding factors including age, race, sex, education, household income, smoking, alcohol use, cadmium exposure, and various health indicators such as diabetes, SBP, BMI, and history of cardiovascular disease. Large sample sizes provide strength to the general population studies. Re-examination of a study from the 2006 Pb AQCD provided data to conclude that a 10-fold increase in concurrent blood Pb (e.g., from 1 to 10 μg/dL) was associated with an 18 mL/min decrease in estimated creatinine clearance or a 25% decrease from the mean, and that an increase in blood Pb from the 5th to the 95th percentile (3.5 μg/dL) had the same negative impact on eGFR as did an increase of 4.7 years in age or 7 kg/m^2 in body mass

index (Akesson et al., 2005). At current blood Pb levels in the U.S. adult population, a downward shift in kidney function of the entire population due to Pb may not result in CKD in identifiable individuals; however, that segment of the population with the lowest kidney reserve may be at increased risk for CKD when Pb is combined with other kidney risk factors. For example, in adults with mean (concurrent or baseline measured 4-6 years before kidney function tests) blood Pb levels that are comparable to that of the general U.S. population (1.6 to 4.2 μg/dL), higher blood Pb level was found to be associated with clinically-relevant effects (e.g., eGFR < 60 mL/min/1.73 m^2, doubling of serum creatinine) (Fadrowski et al., 2010; Yu et al., 2004) and larger magnitudes of effect in potentially at-risk populations with cormorbidities for CKD such as diabetes mellitus (Tsaih et al., 2004) and hypertension (Tsaih et al., 2004; Muntner et al., 2003) or higher co-exposure to other environmental nephrotoxicants such as cadmium (Navas-Acien et al., 2009).

Recent NHANES analyses added to the evidence for Pb-associated lower renal function in populations with low concurrent mean blood Pb levels (< 2 μg/dL) (Fadrowski et al., 2010; Navas-Acien et al., 2009). However, because of uncertainties concerning the magnitude, timing, frequency, and duration of Pb exposure that contributed to the observed associations, it is difficult to assess whether a threshold exists for Pb-related renal effects.

Research in the occupational setting has traditionally been far less consistent than that in environmentally exposed populations (Section 5.5.2.2). A number of explanatory factors for this inconsistency, all due to limitations of the occupational literature, were discussed in the 2006 Pb AQCD. The observation of paradoxical or inverse associations (higher Pb dose with lower serum creatinine, and/or higher eGFR or calculated or measured creatinine clearance) in several of these studies reflects limitations inherent in the study design. Irrespective of the mechanism, these associations have risk assessment implications. If associations are in opposite directions in different subgroups of the population and the relevant effect modifier is not considered, null associations will be observed. For these reasons, nonsignificant associations or paradoxical associations in the occupational setting cannot be used as a rationale for discounting Pb-related nephrotoxicity at lower environmental levels.

Important data on the effects of Pb on the kidney in children were reported in a recent NHANES analysis in adolescents, ages 12-20 years, which observed an association between higher concurrent blood Pb (mean: 1.5 μg/dL) and lower cystatin C-based eGFR (Fadrowski et al., 2010). These findings are consistent with results from a rodent model study in which a low dose of Pb (50 ppm) administered from birth resulted in renal impairment (elevated serum creatinine as compared to control rats), but these

observations require confirmation by measurement of GFR and renal pathology (Berrahal et al., 2011). This recent epidemiologic study along with several previous studies that included children with higher Pb exposures (due to residence near sources, Pb poisoning, or parental occupational exposure) provide evidence that renal function in children may be affected by Pb exposure; however, additional research is warranted. It is important to recognize that the NHANES adolescents from Fadrowski et al. (2010) likely had higher Pb exposures earlier in childhood, thus, the magnitude, timing, frequency, and duration of Pb exposure contributing to the observed association is uncertain.

CKD results in substantial morbidity and mortality, and, even at earlier stages than those requiring kidney dialysis or transplantation, is an important risk factor for cardiac disease. As kidney dysfunction can increase BP and increased BP can lead to further damage to the kidneys, Pb-induced damage to either or both renal or cardiovascular systems may result in a cycle of further increased severity of disease. Pb exposure has been causally linked to both increased BP and other cardiovascular effects (Section 5.4). Interestingly, animal studies have shown Pb-induced vascular injury in the kidney was associated with increased glomerular sclerosis, tubulointerstitial injury, increased collagen staining, and an increase in macrophages associated with higher levels of MCP-1 mRNA. It is possible that the cardiovascular and renal effects of Pb observed are mechanistically linked and are contributing to the progression of the diseases.

Recently available animal toxicological studies strengthen the evidence regarding the modes of action for Pb exposure leading to renal alterations, including the influence of Pb-induced oxidative stress. The mode of action of Pb in the kidneys has been extended to the field of immunology, evidenced by observations that Pb exposure resulted in infiltration of lymphocytes and macrophages associated with increased expression of NF-κB in proximal tubules and infiltrating cells (Roncal et al., 2007). Additionally, recent findings expand on the evidence of acute effects of Pb, including mitochondrial dysfunction, renal cell apoptosis, and glomerular hypertrophy. These mechanisms are useful in understanding the occurrence of acute hyperfiltration followed by chronic kidney dysfunction. As indicated in Figure 5-38 and Table 5-22, studies found dysfunction in various kidney function measures, including urinary flow, ALP, microalbumin, and NAG in animals with blood Pb levels > 20 µg/dL (Wang et al., 2010d). Lower concentration Pb exposures and lower blood Pb levels in animals have not been examined widely.

In summary, new epidemiologic and toxicological studies evaluated in the current review support or expand upon the strong body of evidence presented in the 2006 Pb AQCD indicating that Pb exposure is associated with renal effects. The weight of epidemiologic evidence demonstrates consistently a relationship between higher blood Pb level and

kidney dysfunction (e.g., lower creatinine clearance, higher serum creatinine, and lower GFR) in nonoccupationally-exposed adults with mean concurrent or baseline blood Pb levels of 2-10 µg/dL. A few analyses find higher blood Pb levels to be associated with a greater longitudinal decrease in kidney function over time (4-15 years), suggesting that past Pb exposures may contribute to ongoing renal effects. The epidemiologic evidence is strengthened by associations between Pb biomarker levels and renal function that were observed after adjustment for multiple potential confounding factors such as age, sex, comorbid cardiovascular conditions, BMI, smoking, and alcohol use. Similar findings among adults with CKD indicate that in populations with pre-existing renal disease, Pb exposure may be associated with greater progression of disease. Because blood Pb level in nonoccupationally-exposed adults reflects both recent and past Pb exposures, the magnitude, timing, frequency, and duration of Pb exposure contributing to the observed associations is uncertain. Coherence for epidemiologic findings is provided by observations in animal models that Pb exposure for greater than 6 months decreases GFR and increases serum creatinine. The weight of evidence in animal studies indicates Pb-induced histopathological changes, including tubular atrophy and sclerosis. Overall, reduced renal function and increased kidney damage in animals are observed with chronic Pb (> 4 weeks) exposure that result in blood Pb levels > 20 µg/dL. By demonstrating Pb-induced renal oxidative stress, inflammation, mitochondrial dysfunction, apoptosis, and glomerular hypertrophy, toxicological studies provide biological plausibility for the associations observed in epidemiologic studies between blood Pb levels and kidney dysfunction. Collectively, the evidence integrated across epidemiologic and toxicological studies as well as across the spectrum of renal outcomes is sufficient to conclude that there is a causal relationship between Pb exposures and renal health effects.

5.6 Immune System Effects

5.6.1 Introduction

With respect to studies conducted in laboratory animal and in vitro models, the immune effects of Pb exposure have been extensively examined over several decades. Animal studies of the effects of Pb exposure on host resistance date back to the 1960s while those focusing on Pb-induced immune functional alterations, including developmental immunotoxicity, were first conducted during the 1970s. Despite this long history of research, Pb-associated immune effects in animals with blood Pb levels in the range of current U.S. population levels (i.e., <10 µg/dL), particularly early in life, have been observed only relatively recently within the last 10-15 years (Dietert and McCabe, 2007).

Over the last 10-15 years, advances in the understanding of Pb-associated changes in immunological parameters in humans have substantiated the immune effects of Pb.

The 2006 Pb AQCD presented consistent evidence for immune system effects associated with Pb exposure (U.S. EPA, 2006b). Rather than producing overt cytotoxicity or pathology, Pb exposure was found to be associated with alterations in several subclinical parameters related to cellular and humoral immunity (Figure 5-42). These conclusions were based most heavily on toxicological evidence in animals and in vitro models for the direct effects of Pb exposure in inducing changes in a wide spectrum of immune outcomes, but principally, a shift away from T-derived lymphocyte helper (Th)1 cytokines toward Th2 cytokines, suppression of Th1-dependent delayed type hypersensitivity (DTH), elevation in Th2-driven immunoglobulin E (IgE), and modulation of macrophages into a hyperinflammatory phenotype. Relatively fewer studies were available in humans and for fewer immune-related endpoints. A majority of studies in humans were conducted in Pb-exposed male workers, and while a larger number of immune outcomes were examined, the most consistent evidence comprised effects on neutrophil functionality. In a smaller body of studies of humans without occupational exposures, the weight of evidence indicated associations of higher blood Pb levels with lower abundance of T lymphocyte cells and, in concordance with toxicological studies, higher IgE levels in children. Due to limited examination, the immune effects of Pb exposure in adults without occupational exposures were not well characterized.

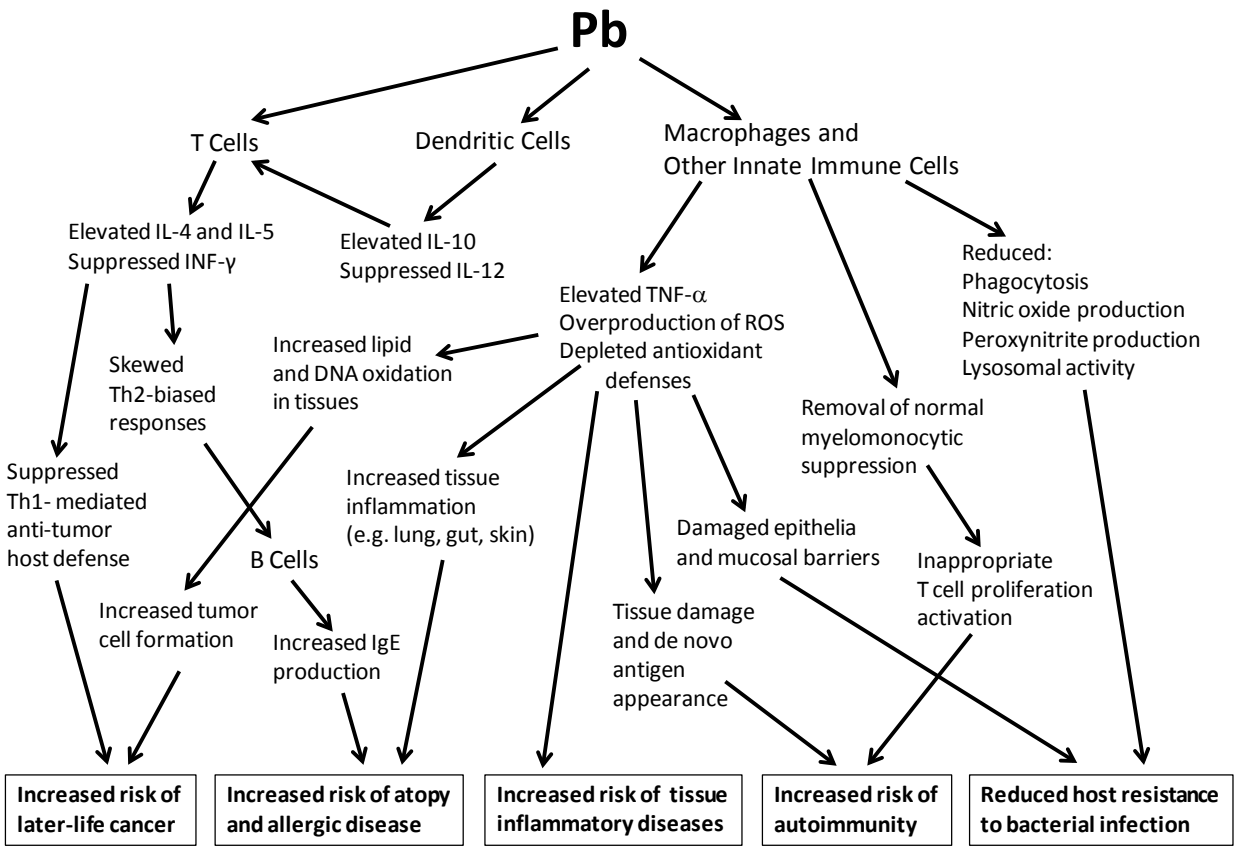

Figure 5-42 Immunological pathways by which Pb exposure may increase risk of immune-related diseases.

The pathways by which Pb exposure may alter immune cell function and consequently increase the risk of immune-related diseases are presented in Figure 5-42. Both toxicological and epidemiologic studies of children indicated Pb exposure effects on T cells. A large body of toxicological evidence demonstrated Pb-induced effects on macrophages. Neutrophil functionality was found to be reduced with higher Pb exposure, based on studies of Pb-exposed workers with mean blood Pb levels > 40 µg/dL. Alterations in immune cells can lead to changes in cell-to-cell interactions, multiple signaling pathways, and inflammation that affect both innate and acquired immunity, that in turn, influence the risk of developing infectious, allergic and autoimmune diseases as well as exacerbating inflammatory responses in other organ systems. Studies conducted in animal and in vitro models provided consistent evidence for Pb exposure inducing effects on the range of immune effects presented in this continuum. Among the hallmarks reported for Pb-induced changes in functional pathways were: (1) a suppression of T-derived lymphocyte helper (Th)1-driven cell-mediated immunity (as measured by a DTH response); (2) an increase in Th2-driven IgE antibody and Th2 cytokine production; and

(3) a pro-inflammatory shift in macrophage function. The latter was characterized by increased production of reactive oxygen species (ROS), prostaglandin E_2 (PGE_2), and inflammatory cytokines such as tumor necrosis factor-*αlpha* (TNF-α) and interleukin (IL)-6 and decreased production of IL-12 and nitric oxide (NO). While epidemiologic studies did not provide evidence for this full spectrum of immune effects, a shift to a Th2 phenotype was indicated by associations observed between higher blood Pb level and higher serum IgE levels in children.

Reflecting an inhibition of Th1 activity, toxicological evidence presented in the 2006 Pb AQCD linked Pb exposure of animals to impaired host resistance to bacteria (U.S. EPA, 2006b). Indicating a hyperinflammatory state and local tissue damage, a few available toxicological studies found Pb exposure-induced generation of autoantibodies, suggesting an elevated risk of autoimmune reactions. Additionally, the shift toward a Th2 response suggested that Pb could elevate the risk of atopy and allergic responses. While toxicological evidence for Pb-induced Th2 activity, elevated IgE, and inflammation supported the biological plausibility of such effects, epidemiologic evidence was too sparse to draw conclusions regarding associations between blood Pb levels and these broader indicators of immune dysfunction in humans.

Changes in the spectrum of immune endpoints were associated with a wide range of blood Pb levels. Several toxicological studies found blood Pb levels in the range of 7-100 µg/dL to be associated with juvenile and/or adult immune effects (e.g., suppressed DTH, elevated IgE, changes in cytokine levels). Most epidemiologic studies examined and found lower T cell abundance and higher serum IgE levels in association with population mean (or quantiles) concurrent blood Pb levels > 10 µg/dL.

With respect to critical lifestages of Pb exposure, animal studies provided strong evidence for immune effects induced by prenatal Pb exposures and by postnatal exposures in adult animals. There was uncertainty regarding critical lifestages of Pb exposure in humans as epidemiologic studies of children primarily were cross-sectional in design and examined concurrent blood Pb levels. Several other limitations of epidemiologic studies were noted, including small sample sizes; inconsistent adjustment for potential confounders such as age, sex, smoking, and comorbid conditions; and reliance on comparisons of immune endpoints among groups with different blood Pb levels, which provided limited information on the concentration-response function.

Collectively, the small numbers of toxicological and epidemiologic studies published since the 2006 Pb AQCD supported the previous findings of Pb-associated immune effects. Epidemiologic studies supported previous findings in children and provided new evidence for effects in nonoccupationally-exposed adults. Recent studies also expanded on the array of immunological parameters affected by Pb exposure as presented in Figure

5-42. For example, a new toxicological study indicated that Pb may modulate the function of dendritic cells. Results from new toxicological and epidemiologic studies strengthened the link between Pb-associated effects on immune cells and immune- and inflammatory-based diseases by providing evidence for changes in intermediary signaling and inflammatory pathways (Figure 5-42). Several new epidemiologic studies examined signaling molecules such as pro-inflammatory cytokines and NO to produce findings parallel with toxicological studies. New toxicological studies expanded knowledge of the broader role of Pb-associated immune modulation in mediating Pb effects in nonlymphoid tissues (e.g., in the nervous, reproductive, and respiratory systems). Although primarily cross-sectional in design, recent epidemiologic studies improved on the design of earlier studies through greater examination of children and adults with blood Pb levels more comparable to contemporary levels in the U.S. population and greater consideration of confounding by age, sex, smoking, comorbid conditions, and SES-related variables.

5.6.2 Cell-Mediated Immunity

5.6.2.1 T Cells

A majority of the evidence indicating effects of Pb exposure on T cells was provided by older toxicological and epidemiologic studies reviewed in the 2006 Pb AQCD (U.S. EPA, 2006b). Toxicological studies demonstrated Pb exposure-induced shifts in the partitioning of CD4+ (T helper) cell populations to favor Th2 cells (10-100 µM in vitro) and the production of Th2 cytokines and to suppress production of Th1 cytokines (wide range of Pb exposures) (Section 5.6.5.4). Previous epidemiologic findings were limited largely to associations between higher concurrent blood Pb level and lower T cell abundance in children.

Consistent with previous epidemiologic findings, in a recent study of 7 week-old Wistar rats administered 200 ppm Pb-acetate, the percentages of CD4+ and CD8+ cytotoxic T cells were decreased (with CD4-CD8- cells elevated) in the submaxillary lymph nodes, but only with i.p. Pb dosing ($p < 0.05$) and not oral exposure (200 ppm Pb-acetate both routes of administration) (Teijon et al., 2010). Limited recent toxicological investigation added mechanistic information by indicating that Pb may induce a shift to Th2 responses via T cell-dependent and -independent pathways. Previously, in cultures of human CD4+ T cells, Pb (1 µM, 30 minutes) was shown to activate transcription factor NF-κB (regulates T cell activation) (Pyatt et al., 1996) and to increase, in a concentration-dependent manner (10 and 50 µM $PbCl_2$, 24 hours), the expression of MHC class II

surface antigens (e.g., HLA-DR), which mediate the CD4+ response to exogenous antigens (Guo et al., 1996b). Recent studies examined higher Pb exposure concentrations than did previous studies. Heo et al. (2007) recently showed that Pb (25 µM) blocked production of the Th1 cytokine interferon-γ (IFN-γ) in cultures of stimulated mouse T cells not by affecting gene expression but by suppressing translation of the protein. This blockage was rescued with the addition of IL-12, which promotes Th1 activity. These results demonstrated a T cell-dependent pathway to skewing toward Th2 responses. However, Pb was able to decrease the IFN-γ to IL-4 ratio (indicating a shift to Th2) in the absence of STAT6, the preferential signaling pathway for T cells. Thus, Pb also was found to skew toward Th2 responses via a T cell-independent pathway. Similar observations were made in vivo by Kasten-Jolly et al. (2010). In this study, developmental Pb exposure of mice (100 µM Pb-acetate in drinking water of dams from GD8 to PND21, resulting in pup blood Pb levels of 10-30 µg/dL) induced gene expression of IL-4 and suppressed production of IFN-γ in splenic cells. These changes occurred in the absence of STAT4 or STAT6 and occurred with concomitant increases in adenylate cyclase 8 and phosphatidylinositol 3-kinase, adding to the evidence that Pb may promote Th2 activity via T cell-independent pathways.

While a few available recent epidemiologic studies found associations of blood Pb levels with lower levels of Th1 cytokines and higher levels of Th2 cytokines in humans (Section 5.6.5.4), the extant evidence for effects on T cells in humans is derived largely from older studies describing differences in the abundance of several T cell subtypes that mediate acquired immunity responses to antigens. In most studies of children, higher blood Pb levels were associated with lower T cell abundance, primarily CD3+ cells. Such associations were observed in studies that adjusted for potential confounding factors (as described below) and studies that compared mean cell abundances among groups with different blood Pb levels. Blood Pb level was less consistently associated with lower abundance of other T cell subtypes such as CD4+ and CD8+.

The weight of evidence supported lower T cell abundance in association with concurrent blood Pb level and in groups of children with levels > 10 µg/dL (Zhao et al., 2004; Sarasua et al., 2000; Lutz et al., 1999). Associations were less consistent in comparisons of children with lower blood Pb levels. In analyses of 331 children in Germany, Karmaus et al. (2005) found that children (ages 7-10 years) with concurrent blood Pb levels 2.2-2.8 µg/dL (2nd quartile) had a 9 to 11% lower abundance of several T cell subtypes ($p < 0.05$, t-test) compared with children with blood Pb levels < 2.2 µg/dL (lowest quartile). Unlike other studies in children, Karmaus et al. (2005) considered potential confounding by adjusting for sex, age, number of infections in the past 12 months, passive smoke exposure, serum lipids, and serum organochlorine levels. Other studies that examined

blood Pb levels < 10 µg/dL (population mean < 2 µg/dL or quantile 5-9 µg/dL) did not find associations with T cell abundance (Hegazy et al., 2011; Belles-Isles et al., 2002).

Another study of U.S. (multiple unspecified locations) children that considered confounding also found an association between higher concurrent blood Pb level and lower T cell abundance; however, it was limited to the youngest subjects (Sarasua et al., 2000). Among 241 children 6-35 months in age, a 1 µg/dL higher blood Pb level was associated with a 0.18% (95% CI: -0.34, -0.02) lower CD3+ cell count, a 0.10% (95% CI: -0.24, 0.04) lower CD4+ cell count, and a 0.04% (95% CI: -0.15, 0.07) lower CD8+ cell count, adjusting for city of residence, age, and sex. In older age groups (36-71 months, 6-15 years), many effect estimates were positive. Analysis of blood Pb level categories indicated that associations were driven by lower T cell abundance (3-6%) among children 6-35 months in age with blood Pb levels > 15 µg/dL. It is important to note that 76% of subjects lived near a Pb smelting operation. These subjects living near Pb sources likely had higher blood Pb levels and may have driven the observed associations. Neither Karmaus et al. (2005) nor Sarasua et al. (2000) found a monotonic decrease in T cell abundance across blood Pb level groups. Neither of these studies adjusted for SES, which has been associated with blood Pb levels and immune-related conditions such as asthma, allergy, and viral infections. However, it is difficult to assess the potential for confounding by SES as neither study reported the SES characteristics of the study population.

In the limited investigation of nonoccupationally-exposed adults, higher concurrent blood Pb levels were associated with higher T cell abundance (Boscolo et al., 2000; Sarasua et al., 2000; Boscolo et al., 1999); however, occupational studies conducted in the U.S. and Asia did not find Pb-exposed workers consistently to have lower or higher abundance of T cells (Mishra et al., 2010; Pinkerton et al., 1998; Yucesoy et al., 1997b; Undeger et al., 1996; Fischbein et al., 1993). Some studies found that compared with unexposed controls, Pb-exposed workers had a lower ratio of CD4+/CD8+ cells (Mishra et al., 2010; Fischbein et al., 1993). In particular, Fischbein et al. (1993) found this lower ratio in New York area firearms instructors with a relatively lower mean blood Pb level of 14.6 µg/dL and after adjusting for age and smoking. Changes in the CD4+/CD8+ ratio have not been examined in populations with lower blood Pb levels.

Although several epidemiologic studies have found lower T cell abundance in association with higher blood Pb levels, after adjusting for a range of potential confounding factors, it is not clear what effects these small magnitudes of change may have on the cell-to-cell interactions that mediate downstream acquired immune responses. In children, groups with higher blood Pb level had lower CD3+ cell abundance that ranged between 1 and 9%. Larger decreases (20-35%) were observed in studies of occupationally-exposed

males with higher blood Pb levels than those found in the general U.S. population (means 15 and 75 µg/dL) (Undeger et al., 1996; Fischbein et al., 1993).

In summary, a majority of the evidence indicating effects of Pb exosure on T cells was provided by previous toxicological and epidemiologic studies reviewed in the 2006 Pb AQCD. Previous toxicological studies demonstrated Pb-induced expansion of Th2 cells and increased Th2 cytokine production. A small number of new toxicological studies expanded the evidence by describing that Pb-induced Th2 skewing may occur via T cell-dependent pathways (Heo et al., 2007) and -independent pathways (Kasten-Jolly et al., 2010; Heo et al., 2007). Previous studies did not provide consistent evidence that higher blood Pb levels or Pb exposure was associated with lower T cell abundance in nonoccupationally-exposed or occupationally-exposed adults, respectively. A new study of children did not find children with higher blood Pb level to have lower T cell abundance (Hegazy et al., 2011). Epidemiologic findings were limited largely to associations between higher concurrent blood Pb level (> 10 µg/dL) and lower T cell abundance observed in previous studies of children (Karmaus et al., 2005; Zhao et al., 2004; Sarasua et al., 2000; Lutz et al., 1999).

5.6.2.2 Lymphocyte Activation

A majority of the evidence indicating that Pb exposure stimulates lymphocyte activation is provided by previous toxicological studies in which exposures to high concentrations of Pb (10-100 µM) induced an expansion of alloreactive B and T lymphocytes (U.S. EPA, 2006b). Lymphocyte activation occurs as a result of reversing the normal suppression that is mediated by a macrophage-like subpopulation. In the limited recent investigation of Pb-induced lymphocyte activation, toxicological studies characterized potential mechanisms underlying this effect. Gao et al. (2007) described a potential role for dendritic cells. Dendritic cells that matured in the presence of 25 µM $PbCl_2$ promoted enhanced alloreactive T cell proliferation compared to control dendritic cells. In addition, using the local lymph node assay (LLNA), Carey et al. (2006) found that $PbCl_2$ (injection doses 25-50 µg) was able to provide a costimulatory signal to antigens that could activate T cells in adult female mice. The exact mechanistic basis for this is not known. As discussed in Section 5.6.5.2, changes in NO production appear to be involved in Pb-induced lymphocyte activation (Farrer et al., 2008).

The available epidemiologic evidence for Pb-associated lymphocyte activation was provided by a small number of previous studies in children and nonoccupationally-exposed adults. Instead of directly measuring lymphocyte proliferation, these studies provided indirect evidence by measuring the abundance of cells that expressed HLA-DR,

an indicator of activated cells. It is important to note that HLA-DR+ cells also may indicate the presence of activated monocytes. Further, these studies did not adjust extensively for potential confounding. In the only study of children (ages 9 months-6 years, Missouri), the mean percentage of HLA-DR+ cells was approximately 2-fold higher ($p > 0.05$, Kruskal-Wallis) in the 19 children with concurrent blood Pb levels 15-19 µg/dL than in children with blood Pb levels 10-14 µg/dL ($n = 61$) or < 10 µg/dL ($n = 178$) after adjusting for age (Lutz et al., 1999). However, activated cells were not elevated in children with blood Pb levels 20-44 µg/dL. Studies of nonoccupationally-exposed adults in Italy found that concurrent blood Pb level was correlated positively with the percentage of HLA-DR expressing cells in men with and without allergies (Spearman $r = 0.51$, $p < 0.002$, $n = 17$ each, median blood Pb level both groups combined: 11 µg/dL) (Boscolo et al., 1999) but only in women without allergies (Spearman $r = 0.44$, $p < 0.05$, $n = 25$, median blood Pb level: 5.5 µg/dL) (Boscolo et al., 2000).

Comparisons of Pb-exposed workers and unexposed controls indicated similar levels of lymphocyte proliferation (≤ 1% difference) between groups (Queiroz et al., 1994b; Cohen et al., 1989) or lower lymphocyte proliferation among Pb-exposed workers (8-25%) (Mishra et al., 2003; Fischbein et al., 1993; Alomran and Shleamoon, 1988; Kimber et al., 1986) Toxicological studies have demonstrated the selective expansion of Th2 cells and suppression of Th1 cells (U.S. EPA, 2006b). Therefore, the differential activation of specific subtypes may not be discernable in epidemiologic studies that measure overall lymphocyte proliferation. Additionally, because occupational studies did not provide concentration-response information, it is difficult to infer whether findings apply to populations with lower blood Pb levels. Toxicological studies also did not provide information on Pb-induced lymphocyte activation at exposure concentrations relevant to humans without occupational Pb exposures.

5.6.2.3 Delayed-type Hypersensitivity

Although recent investigation was limited, a large body of previous toxicological studies reviewed in the 2006 Pb AQCD (U.S. EPA, 2006b) and recent reviews (Mishra, 2009; Dietert and McCabe, 2007) identified a suppressed DTH response as one of the most consistently observed and well-documented immunomodulatory effects of Pb exposure in animal models. A new study indicated that this effect may be mediated by dendritic cells. The DTH assay is commonly used to assess the T cell-mediated adaptive immune response, i.e., induration and erythema resulting from the activation of T cells and recruitment of monocytes to the site of antigen deposition. The DTH response is largely Th1-dependent in that Th1 cytokines drive the production of antigen-specific T cells

directed against the antigen (sensitizing phase) and the recruitment of antigen-specific T cells and monocytes to the site of antigen deposition (elicitation phase).

Previous toxicological studies demonstrated suppressed DTH responses in animals after gestational (Chen et al., 2004; Bunn et al., 2001a; Bunn et al., 2001b, c; Lee et al., 2001b; Chen et al., 1999; Miller et al., 1998; Faith et al., 1979) and postnatal (McCabe et al., 1999; Laschi-Loquerie et al., 1984; Muller et al., 1977) Pb exposures. Blood Pb level data were not available in all studies; however, DTH was suppressed in animals with a wide range of blood Pb levels (11 to > 100 µg/dL), with the associations of DTH with lower blood Pb levels occurring as a result of gestational exposure.

In some studies that examined Pb exposures at multiple stages of gestation, exposures later in gestation suppressed DTH in animals (Bunn et al., 2001c; Lee et al., 2001b). These latter findings may reflect the status of thymus and T cell development. A recent study contributed to the robust evidence by indicating a role for dendritic cells in the Pb-induced suppression of the DTH response. Gao et al. (2007) exposed bone marrow-derived dendritic cells in vitro to $PbCl_2$ (25 µM, 10 days) then the antigen ovalbumin (OVA) and injected the cells into naïve adult mice. Mice treated with Pb-exposed dendritic cells had a diminished OVA-specific DTH footpad response compared with mice treated with non Pb-exposed dendritic cells.

The capability of Pb to suppress the DTH response is strongly supported by mechanistic studies in which Pb suppresses Th1 cytokine production (Section 5.6.5.4). In some animal studies, the suppressed DTH response was accompanied by a decreased production of IFN-γ (Lee et al., 2001b; Chen et al., 1999), which is the primary cytokine that stimulates recruitment of macrophages, a key component of the DTH response. Observations of a concomitant decrease in IFN-γ further link Pb-induced inhibition of Th1 functional activities with suppression of the DTH response. Further, coherence is provided by associations observed between Pb exposure or blood Pb levels and other responses in animals related to the inhibition of Th1-driven adaptive immune responses, including decreased host resistance (Section 5.6.4.1).

5.6.2.4 Macrophages and Monocytes

As reported in the 2006 Pb AQCD, based on a large body of toxicological evidence, Pb-induced promotion of a hyperinflammatory phenotype in macrophages was considered to be a hallmark of Pb-associated immune effects (U.S. EPA, 2006b). Pb-induced hyperinflammation was indicated by the enhanced production of ROS, suppressed production of NO, enhanced production of TNF-α, excessive metabolism of arachidonic acid into immunosuppressive metabolites (e.g., PGE_2), impaired growth and

differentiation of cells, and potentially altered receptor expression [e.g., toll-like receptors]). Several of these findings are described in detail in Sections 5.6.5.2 and 5.6.5.4. Because macrophages are major resident populations in most tissues and organs and also are highly mobile in response to microbial signals and tissue alterations, their functional impairment in response to Pb exposure may serve as a link between Pb-induced immune effects and impaired host defense, tissue integrity, and organ homeostasis in numerous physiological systems (Section 5.6.4.5). A small number of available recent studies continue to support previous findings. A study in Pb-treated (40 ppm by oral gavage, once daily for 40 days) adult mice reported decreased macrophage yield and viability, and phagocytic index in the kidney (Lodi et al., 2011). In addition, several studies reinforced the effect of Pb exposure to alter a broad spectrum of functional alterations in human monocytes (the blood form of macrophages) or mouse macrophages in vitro (Khan et al., 2011; Bussolaro et al., 2008; Mishra et al., 2006a). In particular, Bussolaro et al. (2008) found reduced phagocytic activity with a relatively low concentration of Pb exposure (0.2 µM Pb nitrate, 72 hours). Khan et al. (2011) found that exposure of human monocytes to 25-100 µM Pb-acetate for 3-6 hours induced increases in the pro-inflammatory cytokine TNF-α. Mishra et al. (2006a) found that 100 ppm Pb-acetate suppressed lipopolysaccharide (LPS)-induced NO production.

Epidemiologic studies have not widely examined the effects of Pb exposure on altered macrophage functional activity in humans, and the indices of macrophage function have varied among the few available studies. Pineda-Zavaleta et al. (2004) was unique in examining the hyperinflammatory state specifically in macrophages, albeit in relation to blood Pb levels higher than those in the current U.S. population (range of blood Pb levels: 3.5-47.5 µg/dL). This study included children in Lagunera, Mexico, attending schools at varying distances from an active Pb smelter. Consistent with the large body of toxicological evidence, higher concurrent blood Pb level was associated with lower NO production and higher superoxide anion production in macrophages isolated from child sera (Section 5.6.5.2). Model covariates included sex, age, and presence of allergies.

Other studies in humans examined occupationally-exposed adults and did not find a clear association between concurrent measurements of blood Pb level and macrophage abundance. Adjusting for age, race, smoking, and workshift, Pinkerton et al. (1998) found a lower abundance of monocytes among 145 U.S. Pb smelter workers with a mean blood Pb level of 39 µg/dL (7.8%) than among 84 unexposed controls with a mean blood Pb level of <2 µg/dL (8.5%) ($p = 0.03$). Conterato et al. (In Press) examined a group of male Pb-exposed painters with blood Pb levels ranging between 1.4 and 14.0 µg/dL (mean: 5.4 µg/dL), lower than those in other occupational studies. The mean level and percentage of monocytes in the 50 painters were similar to those in the 36 controls (mean blood Pb level: 1.5 µg/dL) and in the 23 battery workers with much higher blood Pb

levels (mean: 50 µg/dL). Fischbein et al. (1993) found lower ($p < 0.001$) abundance of HLA-DR+ cells in two groups of New York metropolitan area firearms instructors with mean blood Pb levels of 14.6 µg/dL (n = 36, 8.8%) and 31.4 µg/dL (n = 15, 8.7%) than among the 36 unexposed controls (15.2%). HLA-DR+ is an indicator of activated functional state of antigen presenting cells (APCs, e.g., macrophages, dendritic cells, T cells) and is upregulated in response to cell signaling. While this study did not provide direct evidence for Pb effects on macrophages, the investigators cited previous observations that 70% of monocytes express HLA-DR antigen compared with 15% of lymphocytes to suggest that the reduced expression of HLA-DR antigen in Pb-exposed workers was due primarily to a reduction in activated monocytes.

In summary, a small body of new in vitro studies (Khan et al., 2011; Bussolaro et al., 2008; Mishra et al., 2006a) adds to the extensive base toxicological evidence indicating that Pb exposure decreases functionality of macrophages and promotes a hyperinflammatory phenotype. The sparse epidemiologic data are provided primarily by older studies and are not conclusive. Whereas an association between blood Pb level and a hyperinflammatory state of macrophages was observed in a previous study of children (Pineda-Zavaleta et al., 2004), studies of occupationally-exposed adults did not clearly indicate Pb exposure effects on macrophages. A new study did not find large differences in monocyte abundance between Pb-exposed workers and unexposed controls (Conterato et al., In Press).

5.6.2.5 Neutrophils

In the 2006 Pb AQCD, Pb exposure was not judged to have strong effects on neutrophils (U.S. EPA, 2006b). This conclusion was based on the relatively limited available toxicological evidence as compared with that for effects on other immune cells. However, the modulation of neutrophil activity may have important consequences on the dysregulation of inflammation and ability of organisms to respond to infectious agents. Studies of cultured human polymorphonuclear cells (PMNs) (Governa et al., 1987) and occupationally-exposed adults (Queiroz et al., 1994a; Queiroz et al., 1993; Valentino et al., 1991; Bergeret et al., 1990) found Pb-associated reductions in PMN functionality, as indicated by reduced chemotactic response, phagocytic activity, respiratory oxidative burst activity, or reduced ability to kill ingested antigen. Important limitations to applying epidemiologic findings broadly include male-only study populations, the relatively high blood Pb levels of workers (range of mean levels: 33.1-71 µg/dL), lack of concentration-response information for associations between blood Pb level and neutrophil function, and lack of consideration of potential confounding factors.

Instead of examining neutrophil functional activities, a few available recent studies of animals and occupationally-exposed adults examined the effects of Pb exposure on neutrophil counts, an increase in which has been interpreted by some investigators to be a compensatory response to Pb-induced impairment in neutrophil chemotactic activity and a hyperinflammatory response. In male rats with Pb spheres implanted in their brains, neutrophils were a major responding cell (Kibayashi et al., 2010). Compared with rats implanted with glass spheres, rats with Pb spheres had greater neutrophil infiltration with inflammatory-related damage that included apoptosis and indications of neurodegeneration. It is important to acknowledge the uncertain relevance of these findings to those expected from typical routes of Pb exposure in humans.

In a group of 68 ceramic, Pb recycling, or bullet manufacturing workers and 50 controls selected among food plant workers, DiLorenzo et al. (2006) provided information on the concentration-response relationship and adjusted for potential confounding variables. Among all subjects, a 1 µg/dL higher concurrent blood Pb level was associated with a 21.8 cells/µL (95% CI: 11.2, 32.4 cells/µL) higher absolute neutrophil count (ANC) adjusted for age, BMI, and smoking status. The geometric mean (range) of concurrent blood Pb levels was 20.5 µg/dL (range: 3.2 to 120 µg/dL) among workers and 3.5 µg/dL (range: 1 to 11 µg/dL) among controls. Eight workers described to have medium to high Pb exposures (exact blood Pb levels not reported), but no controls had neutrophilia (n >7,500 cells/mm^3), suggesting that chronic, higher-level Pb exposures can lead to a biologically meaningful excess of circulating neutrophils. Additionally, in analyses comparing three blood Pb level groups, controls, workers with blood Pb levels ≤ 30 µg/dL, and workers with blood Pb levels >30 µg/dL, ANC was observed to increase monotonically across increasing blood Pb groups, supporting a blood Pb concentration-dependent relationship. When the three blood Pb groups were further stratified by current smoking, two-way ANOVA indicated an interaction between concurrent blood Pb level and current smoking. Higher blood Pb level was associated with higher ANC only in current smokers. Among nonsmokers, ANCs were similar across blood Pb groups. In contrast, Conterato et al. (In Press) found lower neutrophil concentrations among two groups of Pb-exposed male workers with mean concurrent blood Pb levels of 50.0 and 5.4 µg/dL than among controls with a mean blood Pb level of 1.5 µg/dL. Pb-exposed workers did not consistently have higher levels of other immune cells such as eosinophils, basophils, monocytes, or total lymphocytes either.

Additional evidence for the effects of Pb exposure on neutrophils is provided by findings that blood Pb level is associated with mediators of neutrophil proliferation, survival, maturation, and functional activation. These mediators include cytokines such as TNF-α (Section 5.6.5.4) and complement. The complement system is a component of the innate immune system that controls various cell-mediated immune responses such as

chemotaxis of macrophages and neutrophils and phagocytosis of antigens. The effects of Pb exposure on complement have not been widely examined; however the limited data suggest Pb may suppress complement activity. Both Ewers et al. (1982) and Undeger et al. (1996) measured lower serum complement C3 protein among Pb-exposed workers compared with unexposed controls, with Ewers et al. (1982) additionally observing an association between higher concurrent blood Pb level and lower C3 in a regression analysis combining Pb-exposed workers and controls. However, the broad applicability of these findings may be limited due to the high blood Pb levels in these occupationally-exposed groups (range of blood Pb levels: 18.6-85.2 µg/dL and 38-100 µg/dL, respectively) and by the lack of adjustment for potential confounding variables.

In summary, a majority of evidence indicating the effects of Pb exposure on neutrophils was provided by previous studies that found that compared with unexposed controls, Pb-exposed workers had lower neutrophil functionality (Queiroz et al., 1994a; Queiroz et al., 1993; Valentino et al., 1991; Bergeret et al., 1990) and lower complement, which is a mediator of phagocyte functionality (Undeger et al., 1996; Ewers et al., 1982). In the limited new epidemiologic investigation that examined neutrophil abundance, studies did not conclusively find Pb-exposed workers to have higher or lower neutrophil abundance. Overall, the epidemiologic evidence is limited by the high blood Pb levels (range of mean levels: 33.1 to 71 µg/dL) with which neutrophil functionality was observed to be decreased and the lack of consideration of potential confounding.

5.6.2.6 Dendritic Cells

Since the publication of the 2006 Pb AQCD, new results (from both an ex vivo and in vitro models) suggest that the effects of Pb exposure on suppressing Th1 activity and promoting Th2 activity may be a consequence of the direct action of Pb on the function of dendritic cells (a major APC). Prior research on the effects of Pb in favoring Th2 over Th1 activity emphasized the direct measurement of Th1 versus Th2 T-cell populations and cytokine profiles. But new research techniques have been developed (Gao and Lawrence, 2010) that provide an opportunity to look upstream at how dendritic cells may be involved in mediating the effects of Pb on acquired immunity. Gao et al. (2007) used bone marrow cultures exposed to Pb to examine the impact of Pb on dendritic cell maturation and function. $PbCl_2$ (25 µM, 10 days) was found to alter the course of dendritic cell maturation by changing the ratio of cell surface markers, such as the CD86/CD80 ratio, that promote Th2 cell development. Additionally, upon activation with LPS, Pb-matured dendritic cells produced less IL-6, TNF-α, and IL-12 (stimulates growth and differentiation of T cells) than did control cells but the same amount of IL-10 (inhibits production of Th1 cytokines). The effect of Pb in altering the cytokine

expression profile of dendritic cells, in particular, the lower IL-12/IL-10 ratio, may serve as an important signal to shift naïve T cell populations toward a Th2 phenotype. Strengthening the role of dendritic cells in mediating Pb immune effects were ex vivo results from the same study which showed that Pb-naïve adult BALB/c mice implanted with Pb-exposed dendritic cells were skewed toward Th2 activity as indicated by inhibited DTH (Section 5.6.2.3) and IgG2a antibody (Section 5.6.3) responses (Gao et al., 2007).

5.6.2.7 Natural Killer Cells

Based mostly on epidemiologic studies, previous and recent evidence does not clearly indicate that the innate immune natural killer (NK) cells are affected to a large extent by Pb exposure. In previous studies of nonoccupationally-exposed adults in Italy, concurrent blood Pb levels were correlated with NK cell abundance among men with and without allergy (Spearman $r = 0.49$, $p \sim 0.05$, $n = 17$ each, median blood Pb level both groups combined: 11 µg/dL) (Boscolo et al., 1999) and women without allergies (Spearman $r = 0.44$, $p < 0.05$) (Boscolo et al., 2000) In a study of children from St. Lawrence River communities in Quebec, Canada, cord blood Pb level was not significantly associated with cord blood NK cell abundance (quantitative results not reported (Belles-Isles et al., 2002). Similar means of NK cell abundance or functional activity were observed in Pb-exposed workers and unexposed controls (García-Lestón et al., 2011; Mishra et al., 2003; Pinkerton et al., 1998; Yucesoy et al., 1997b; Undeger et al., 1996; Fischbein et al., 1993; Kimber et al., 1986). The lack of evidence for a strong effect on NK cells is underscored by epidemiologic observations within individual studies that blood Pb levels are associated with T cell abundance but are not associated with NK cell abundance or their level of functional activity (Karmaus et al., 2005; Sarasua et al., 2000; Pinkerton et al., 1998). Consistent with the epidemiologic evidence, toxicological evidence is not conclusive. In a recent in vitro study comparing the toxicities of metals for different populations of immune cells, Fortier et al. (2008) found that $PbCl_2$ (7.5-20.7 µg/dL) did not affect NK cytotoxicity compared with the DMSO vehicle. However, $PbCl_2$ was not found to affect other immune parameters (e.g., monocyte phagocytic activity or lymphocyte proliferation) either. A recent study did show a decrease in NK cell activity in mice albeit with high-level Pb exposure (1,300 ppm Pb-acetate in drinking water, 10 days, blood Pb level ~100 µg/dL) (Queiroz et al., 2011).

5.6.3 Humoral Immunity

The 2006 Pb AQCD described another hallmark effect of Pb on the immune system to be an enhanced humoral immune response as characterized by increased production of IgE antibodies (U.S. EPA, 2006b). Several previous toxicological and epidemiologic studies (Table 5-28) demonstrated Pb-associated increases in IgE production, which is strongly implicated in mediating allergic responses and inflammation in allergic asthma. In studies of juvenile rodents, Pb exposures (Pb-acetate) through drinking water from gestation through lactation induced concomitant increases in IgE and IL-4 production (a Th2 cytokine) by T cells (Snyder et al., 2000; Chen et al., 1999), consistent with the hypothesis that Th2-mediated mechanisms can induce class switching of B cells to produce IgE. Evidence from both earlier toxicological and epidemiologic studies (Table 5-28) did not consistently indicate that Pb exposure was associated with changes in other classes of Igs including IgG, IgM, and IgA. Previous epidemiologic studies of children (Table 5-28) and adults [Table 5-28 with group comparisons and (Boscolo et al., 2000; Boscolo et al., 1999) with correlation analyses] did not find a consistent association between blood Pb level and the abundance of B cells, which produce IgE and other antibodies.

Although previous evidence for effects on Ig classes other than IgE was inconsistent, a small number of available new toxicological studies found Pb-induced increases in IgG and pointed to a role for T cell-mediated mechanisms in Pb-induced activation of B cells and production of Ig antibodies. Important limitations of this evidence include high Pb exposures tested and use of injection routes of exposure that may have little relevance to human routes of exposure. Fernandez-Cabezudo et al. (2007) reported evidence for a subtle shift toward a Th2 immune response following *Salmonella* infection in mice exposed to high concentrations of Pb-acetate (5,000-10,000 µM, 16 weeks, resulting in blood Pb levels of 20.5-106 µg/dL). Serum levels of *Salmonella*-specific IgG1 antibodies were increased in the Pb-exposed mice compared to controls, whereas IgG2a levels were increased in control but not Pb-exposed mice following infection. The impaired Th1 and enhanced Th2 response also was evident by the decreased secretion of IL-12 and increased production of IL-4 by spleen cells taken from Pb-exposed (blood Pb levels > 20.5 µg/dL) mice (Fernandez-Cabezudo et al., 2007).

In a highly-specialized strain of knockout adult mice lacking the ability to produce IFN-γ, i.p. injection with 50 µg $PbCl_2$ increased the IgG2a/IgG1 ratio (Gao et al., 2006). This result was surprising given evidence that IFN-γ usually directs secretion of IgG2a; however, the authors suggested that in these knockout mice, Pb may initiate a Th1 response via an IFN-γ independent pathway to enhance IgG2a production. Other animal studies that administered Pb via the i.p., found Pb-induced humoral responses to

mediated preferentially via Th2 mechanisms. Carey et al. (2006) treated BALB/c mice with subsensitizing doses of a T cell-independent (Trinitrophenyl-Ficoll [TNP-Ficoll]) or T cell-dependent (TNP-ovalbumin [TNP-OVA]) hapten-protein conjugate with or without co-exposure to $PbCl_2$. Seven days later, investigators examined the effects of Pb on the LLNA response to TNP-Ficoll or TNP-OVA. A bolus injection of $PbCl_2$ (25-50 µg) increased the numbers of T and B cells in the lymph node against both TNP-Ficoll and TNP-OVA. Further, in a concentration-dependent manner, Pb induced statistically significant elevations of IgM-, IgG2a-, and IgG1-producing cells in the lymph node. While the increase in IgM-producing cells against TNP-Ficoll indicated a T-cell independent mechanism, the increases in IgG2a- and IgG1-producing cells against both antigens indicated a Th1- and Th2-mediated mechanism, respectively. Despite finding increases in both IgG1- and IgG2a-producing cells, the authors concluded that Pb skewed the response toward Th2 and had considerable potential for promoting allergic sensitization against T-dependent antigens.

In a recent microarray study in BALB/c mice, Kasten-Jolly et al. (2010) found that early-life Pb exposure (100 µM Pb-acetate in drinking water of dams from GD8 to PND21, resulting in pup blood Pb levels 10-30 µg/dL) produced statistically significant increases in the expression of genes encoding Ig antibodies or those involved in B lymphocyte function and activation. These genes included those for the heavy chain of IgM, IL-4, IL-7 and IL-7 receptor, IL-21, RAG-2, CD antigen 27, B-cell leukemia/lymphoma 6, RNA binding motif protein 24, Histocompatibility class II antigen A (beta 1), Notch gene homolog 2, and histone deacetylase 7A.

In epidemiologic studies, several of which are new, associations between biomarkers of Pb exposure and serum IgE level were demonstrated primarily in children, although a monotonic dose-dependent increase was not consistently observed (Hegazy et al., 2011; Hon et al., 2010; Hon et al., 2009; Karmaus et al., 2005; Annesi-Maesano et al., 2003; Sun et al., 2003; Lutz et al., 1999) (Table 5-28). Karmaus et al. (2005) had the most extensive adjustment for potential confounding factors and examined differences with lower blood Pb levels. Compared with children with concurrent blood Pb level <2.2 µg/dL (quartile 1), children with blood Pb levels 2.84-3.41 µg/dL (quartile 3) and >3.4 µg/dL (quartile 4) had 28% higher serum IgE levels ($p = 0.03$, F-test). These differences were observed after the adjustment for potential confounding by age, biomarkers of various organochlorine exposures, number of infections in the previous 12 months, serum lipids, and passive smoke exposure. Similar differences in IgE count on basophils were not observed among the blood Pb quartiles; however, it is important to note that although serum IgE and basophil-bound IgE have been correlated in adults (Malveaux et al., 1978; Conroy et al., 1977), little data are available in children (Dehlink et al., 2010). A recent study in children found that serum IgE levels were not correlated

with basophil-bound IgE but correlated (Spearman r = -0.003) with other IgE receptor-expressing cells such as dendritic cells and monocytes (Spearman r = 0.43 to 0.65, $p < 0.05$) (Dehlink et al., 2010). The number of IgE-bound basophils also has been found to be highly variable across individuals, particularly children (Hausmann et al., 2011; Dehlink et al., 2010). Thus, it is not unexpected that higher blood Pb level was associated with higher serum IgE but not basophil-bound IgE counts in Karmaus et al. (2005). In this study, blood Pb level was not associated with serum levels of IgG, IgA, and IgM or B cell abundance. Lutz et al. (1999) found higher serum IgE in children after adjusting for age, albeit with concurrent blood Pb levels > 10 µg/dL.

Recent studies in children also reported associations between concurrent blood Pb level and elevated serum IgE but did not adjust for potential confounding variables (Hegazy et al., 2011; Hon et al., 2010; Hon et al., 2009). The studies by Hon and colleagues (2010; 2009) demonstrated associations in children with low blood Pb levels (range: 1.4-6.0 µg/dL) and found that blood Pb level was correlated with both serum IgE and atopic dermatitis, a condition commonly characterized by elevated IgE levels.

[a]IgE data are presented as IU/mL. (In parentheses are the ratio of IgE in the higher blood Pb group to IgE in the lowest blood Pb group.)

[b]Other Ig data are presented as mg/dL unless otherwise specified.

[c]B cell data are presented as the percentage of B cells among all lymphocytes unless otherwise specified. (In parentheses are the ratio of B cells in the higher blood Pb group to B cells in the lowest blood Pb group.)

[d]p <0.05 for group differences.

[e]Data represent the number of cells/µL serum.

[f]Data are presented as IU/mL.

Sarasua et al. (2000) found associations of higher concurrent blood Pb level with higher IgA, IgG, and IgM in U.S. children. Blood Pb level was associated with higher levels of all three Igs (0.8 [95% CI: 0.2, 1.4], 4.8 [95% CI: 1.2, 8.4], and 1.0 [95% CI: 0.1, 1.9] mg/dL higher IgA, IgG, and IgM, respectively, per 1 µg/dL higher blood Pb level, adjusted for age, sex, and location) in the youngest age group (6-35 months) but not in older age groups (36-71 months, 6-15 years, 16-75 years), suggesting elevated risk in very young children. Among infants aged 6-35 months with concurrent blood Pb levels ≥ 15 µg/dL, serum levels of all three examined Igs were elevated over levels measured in infants with blood Pb levels < 5 µg/dL. In this study, IgE was not examined.

While most epidemiologic studies examined concurrent blood Pb levels, some studies indicated that prenatal Pb exposure may impact Ig levels in newborns (Annesi-Maesano et al., 2003; Belles-Isles et al., 2002). These studies also pointed to an increased risk in infants; however, important limitations of these studies are the lack of extensive consideration of potential confounding variables. Belles-Isles (2002) examined newborns in St. Lawrence River communities in Quebec, Canada and found an association between

higher cord blood Pb level and higher cord serum IgG in a regression analysis adjusted for prenatal smoke exposure. Annesi-Maesano et al. (2003) found that infant hair Pb level but not cord or placental Pb level was associated with cord serum IgE in newborns in Paris. From these findings, the authors inferred a stronger effect of Pb exposure integrated over the entire gestational period compared to exposures closer to birth. Cotinine was not associated significantly with Pb biomarker levels or with IgE. The magnitude of association was larger in the subgroup of infants with mothers without allergies (Spearman $r = 0.21$, $p < 0.01$ in infants with mothers without allergies versus $r = 0.12$ in infants with mothers with allergies, pointing to the possible masking of a blood Pb association with IgE by the stronger association of family history of allergy.

Associations between blood Pb level and IgE also were reported in studies of adults, without (Pizent et al., 2008) and with occupational Pb exposure (Heo et al., 2004). In a study of urban adults aged 19 to 67 years and of similar SES (i.e., white-collar office workers) in Zagreb, Croatia, a statistically significant association between higher concurrent blood Pb level and higher IgE was found in women but not men (Pizent et al., 2008). Several covariates were considered in a stepwise multiple regression, including age, smoking intensity, and alcohol consumption. Among women not on hormone replacement therapy or oral contraceptives, a 1 µg/dL higher blood Pb level was associated with a 0.60 higher log of IgE (95% CI: 0.58, 1.18). Concurrent blood Pb levels were low in these women who were aged 19-67 years (mean: 2.16 µg/dL, range 0.56-7.35 µg/dL); however, due to the cross-sectional nature of this study, it is difficult to characterize the timing, level, frequency, and duration of Pb exposure that contributed to the observed association. Because of likely higher past Pb exposures of adults and the mobilization of Pb from bone to blood, the associations may reflect effects of higher past Pb exposures. Investigators did not report an effect estimate in men because it did not attain statistical significance. Without quantitative results, it was difficult to ascertain whether there was suggestion of association in men but insufficient power to indicate statistical significance due to the smaller number of men examined (50 men versus 166 females). Another study of 34 men in Italy also did not report quantitative results but indicated a lack of statistically significant correlation between blood Pb level and IgE in men (Boscolo et al., 1999).

A majority of the epidemiologic evidence for the effects of Pb on IgA, IgG, and IgM levels is provided by previous studies of Pb-exposed workers (Anetor and Adeniyi, 1998; Pinkerton et al., 1998; Undeger et al., 1996; Queiroz et al., 1994b; Alomran and Shleamoon, 1988; Kimber et al., 1986; Ewers et al., 1982). Consistent with the collective body of toxicological findings for these other Ig classes, epidemiologic evidence is mixed, with studies reporting higher, lower, and similar Ig levels in Pb-exposed workers compared with unexposed controls. Some studies reporting lower Ig levels in Pb-exposed

workers included workers with the highest mean blood Pb levels (> 50 µg/dL) (Anetor and Adeniyi, 1998; Undeger et al., 1996). The lack of rigorous statistical analyses in occupational studies precludes characterization of the factors that may contribute to inconsistent associations.

In summary, a majority of the evidence for Pb exposure affecting humoral immunity is provided by previous toxicological and epidemiologic studies that found Pb-associated increases in IgE. Previous toxicological studies provided evidence for the independent effects of Pb exposure increasing IgE levels. A few available recent epidemiologic studies add to the large body of extant evidence supporting associations between higher concurrent blood Pb level and higher IgE levels in children; however, they did not adjust for potential confounding variables (Hegazy et al., 2011; Hon et al., 2010; Hon et al., 2009). Collectively, epidemiologic evidence indicates higher IgE in children with concurrent blood Pb levels > 10 µg/dL. The epidemiologic evidence in children equally comprises studies that did not and did adjust for potential confounding. Studies that adjusted for potential confounding varied in the number and the specific variables included as model covariates (Table 5-28) but were consistent in finding an association between blood Pb and IgE. None of the studies in children adjusted for SES or allergen exposure. Lower SES, which may indicate poorer housing conditions, is associated with higher exposures to Pb as well as cockroach, rodent, and other allergens. Allergen exposure and lower SES are associated with higher IgE and IgE-related conditions such as allergies and asthma (Bryant-Stephens, 2009; Dowd and Aiello, 2009; Aligne et al., 2000). Studies generally did not provide detailed demographic or residential information to assess whether SES and/or allergen exposure potentially confounded the observed associations between blood Pb level and IgE. Thus, uncertainty remains as to the extent to which blood Pb-IgE associations in children are confounded by unmeasured SES and/or allergen exposure. Evidence in adults is limited and thus, inconclusive. A new study of environmentally-exposed adults found an association between concurrent blood Pb level and IgE in women (Pizent et al., 2008). Evidence integrated across toxicological and epidemiologic studies does not consistently indicate that Pb exposure affects other classes of Igs; however, a few new toxicological studies found Pb-induced increases in IgG (Fernandez-Cabezudo et al., 2007; Gao et al., 2006) or increases in the expression of genes encoding Ig antibodies (Kasten-Jolly et al., 2010).

5.6.4 Immune-based Diseases

5.6.4.1 Host Resistance

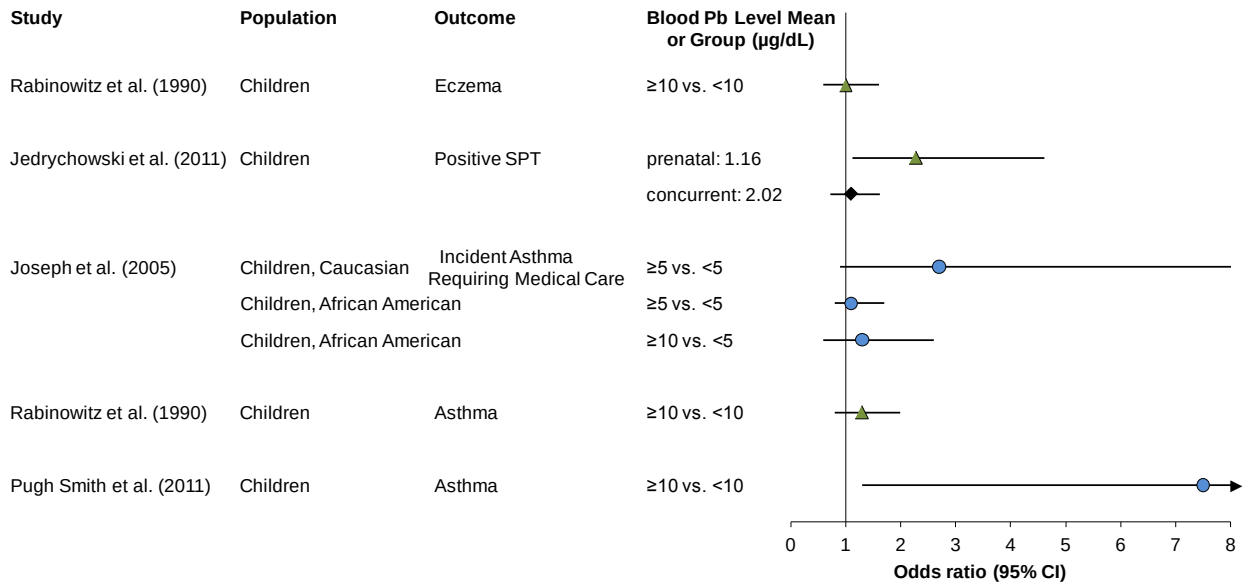
The capability of Pb to reduce host resistance of animals to bacteria has been known for almost 40 years and was supported by several animal studies described in the 2006 Pb AQCD (U.S. EPA, 2006b). A recent animal study provided supporting evidence for such an effect. Biological plausibility for these findings has been provided by observations that Pb affects mechanisms underlying diminished host resistance, e.g., suppressed Th1-driven acquired immune responses and increased inflammatory responses in target tissue resulting in further damage to host protective barriers. Host resistance to bacteria such as *Listeria* requires effective Th1-driven responses including the production of IL-12 and IFN-γ (Lara-Tejero and Pamer, 2004) and these have been found to be inhibited by Pb exposure. The lack of IFN-γ can inhibit appropriate and timely macrophage activation. Nitric oxide is produced by macrophages during cellular activation and plays a role in host defense against bacterial infection (U.S. EPA, 2006b), and NO production also has been found to be suppressed by Pb exposure. A recent animal study characterized a potential mechanism by which Pb may impact both innate immune cells and natural host defense barriers. Kasten-Jolly et al. (2010) showed that developmental exposure of mice to Pb (100 µM Pb-acetate in drinking water of dams from GD8 to PND21, resulting in pup blood Pb levels of 10-30 µg/dL) resulted in an upregulation of splenic RNA of caspase-12, a cysteine protease that inhibits the clearance of bacteria both systemically and in the gut mucosa (Saleh et al., 2006).

In the few available epidemiologic studies, a range of indicators of Pb exposure (i.e., cord blood Pb, concurrent blood Pb, Pb content in total deposition samples, Pb content in lichen) were associated with viral and bacterial infections in children. Collectively, study limitations, including lack of consideration for potential confounding variables (Karmaus et al., 2005; Rabinowitz et al., 1990), lack of statistical analysis (Karmaus et al., 2005), and ecological design (Carreras et al., 2009), limit the ability to draw inferences regarding the effects of Pb exposure on viral or bacterial infections in children. Similar to these studies in children, an occupational study finding higher frequency of self-reported colds or influenza among Pb battery or smelter plant workers with higher blood Pb levels than among unexposed controls is limited by a lack of statistical analysis (Ewers et al., 1982). Studies that address the aforementioned limitations are needed to characterize the relationship between Pb exposure and resistance to bacterial and viral infection in humans.

With limited investigation, the effect of Pb on host resistance to parasitic agents is unclear. The 2006 Pb ACQD described a study in which high-level Pb-exposed (≥ 10 µM) mouse macrophages had diminished ability to kill *Leishmania enrietti* parasites (Mauel et al., 1989). However, given the well-characterized effect of Pb in promoting Th2 activity, it is plausible for Pb to enhance host resistance to parasites that require robust Th2 responses (e.g., helminths) (U.S. EPA, 2006b). In a recent study, high-level Pb exposure (≥ 10 µM) enhanced host resistance to malaria (Koka et al., 2007). However, this was attributed to the capability of Pb to induce eryptosis and the rapid removal of malaria-infected erythrocytes and not to Pb-induced alterations in immune function. Nriagu et al. (2008) also reported that higher blood Pb level was associated with lower malaria prevalence among children (ages 2-9 years) from three Nigerian cities. A majority of children (75%) had blood Pb levels below 10 µg/dL. The association persisted after adjusting for age, sex, number of siblings, and other comorbidities such as headaches, depressed mood, and irritability.

5.6.4.2 Asthma and Allergy

Toxicological evidence and to a relatively limited extent, epidemiologic evidence, have supported the effects of Pb exposure on multiple immune parameters, including elevated production of Th2 cytokines such as IL-4, increased IgE antibody production (Table 5-24), and increased inflammation. These are well-recognized pathways in the development and exacerbation of allergy and allergic disease, including asthma. This mechanistic evidence is coherent with a small body of epidemiologic studies that found associations of blood Pb levels with asthma or allergy in children (Figure 5-43 and Table 5-29). Children examined in these studies encompassed a wide range of ages (i.e., less than 1 year to 12 years) and across studies, blood Pb was measured during different lifestages. This body of evidence in children included large studies with multivariate analyses and studies with prospective follow-up of subjects in which disease occurrence was ascertained after the measurement of blood Pb levels.



Note: Results are organized by endpoint and for asthma in order of increasing blood Pb level. For analyses with blood Pb level as a continuous variable, odds ratios are standardized to a 1 µg/dL increase in blood Pb level. SPT = skin prick test, BR = bronchial responsiveness. Black diamond represents associations with concurrent blood Pb levels, green triangles represent associations with prenatal (cord) blood Pb levels, and blue circles represent associations with blood Pb levels measured in childhood up to 12 months prior to outcome assessment.

Figure 5-43 Associations of blood Pb levels with asthma- and allergy-related conditions in children.

Table 5-29 Additional characteristics and quantitative results for studies presented in Figure 5-43

Study	Population/Location	Blood Pb Level Data (µg/dL)	Statistical Analysis	Outcome	Odds Ratio (95% CI)[a]
Rabinowitz et al. (1990)	1,768 children followed from birth to unspecified age Boston area, MA	Prenatal (cord) ≥ 10 vs. <10[a]	Logistic regression with no additional covariates included in model	Eczema	1.0 (0.6, 1.6)
Jedrychowski et al. (2011)	224 children followed prenatally to age 5 yr Krakow, Poland	Prenatal (cord): GM: 1.16 (95% CI: 1.12, 1.22) Concurrent: GM: 2.02 (95% CI: 1.95, 2.12)	Logistic regression adjusted for sex, parity, maternal age, maternal education, maternal atopy, maternal smoking	Positive SPT	2.3 (1.1, 4.6)[b] 1.1 (0.7, 1.6)[b]
Joseph et al. (2005)	4,634 children, ages 1-3 yr followed prospectively for 12 months Southeastern MI	Measured up to 12 mos before outcome Caucasian ≥ 5 vs. Caucasian <5[c] African American ≥ 5 vs. African American <5[c] African American ≥ 10 vs. African American <5[c]	Logistic regression adjusted for sex, birth weight, and annual income	Incident asthma requiring medical care	 2.7 (0.9, 8.1) 1.1 (0.8, 1.7) 1.3 (0.6, 2.6)
Rabinowitz et al. (1990)	1,768 children followed from birth to unspecified age Boston area, MA	Prenatal (cord blood) ≥ 10 vs. <10[a]	Logistic regression with no additional covariates included in model	Prevalent asthma	1.3 (0.8, 2.0)
Pugh Smith and Nriagu (2011)	356 children, ages 0-12 yr Saginaw, MI	Levels ascertained from statewide database, timing unreported but varied among subjects ≥ 10 vs. <10[a]	Logistic regression adjusted for age, sex, number of stories in unit, cat in home, dog in home, cockroach problem, number of persons in home, household smoking, clutter, candles/incense, type of cooking stove, main heating source, months of residency, housing tenure, type of air conditioning, peeling paint, ceiling/wall damage, age of housing, water dampness/mold/mildew	Prevalent asthma	7.5 (1.3, 42.9)

GM = geometric mean, SPT = skin prick test.

[a]Odds ratio in children with blood Pb level ≥ 10 µg/dL with children with blood Pb level <10 µg/dL serving as the reference group

[b]Odds ratio presented per 1 µg/dL increase in blood Pb level.

[c]Relative risk in each specified subgroup with children with blood Pb level <5 µg/dL serving as the reference group.

In a study of 4,634 children in southeastern Michigan, blood Pb levels were measured at ages 1 to 3 years, up to 12 months prior to asthma assessment. In analyses that controlled for annual income, birth weight, and sex, an elevated risk of incident asthma requiring a doctor visit or medication (indicator of severe asthma) was reported in association with blood Pb levels ≥ 5 µg/dL among Caucasian children (relative risk [RR]: 2.7 [95% CI: 0.9, 8.1] compared with Caucasian children with blood Pb levels < 5 µg/dL) (Joseph et al., 2005) (Figure 5-43 and Table 5-29). In analyses restricted to African Americans, children with blood Pb levels ≥ 10 µg/dL had an elevated risk of asthma requiring medical care (RR: 1.3 [95% CI: 0.6, 2.6] compared with children with blood Pb level < 5 µg/dL) (Figure 5-43 and Table 5-29). In analyses that used Caucasian children with blood Pb level <5 µg/dL as the reference group, blood Pb level was associated with increased risk of asthma requiring medical care among African American children in all blood Pb level categories. Collectively, the results indicated a stronger association with race/ethnicity than with blood Pb level. It is important to recognize the small numbers of

children with asthma requiring medical care in the high blood Pb level categories, which likely accounted for the wide 95% CIs (5 Caucasian children with blood Pb ≥ 5 µg/dL and 9 African American children with blood Pb level ≥ 10 µg/dL).

Consistent with Joseph et al. (2005), a recent cross-sectional study conducted in Saginaw, Michigan found a higher prevalence of asthma in children (ages ≤ 12 years) with blood Pb levels ≥ 10 µg/dL (Pugh Smith and Nriagu, 2011). Of the 356 children randomly selected from a statewide surveillance database of blood Pb measurements, 78% were African American. This study had greater power than did Joseph et al. (2005) due to the larger percentage of children with blood Pb levels ≥ 10 µg/dL (18.6%). Compared with children with initial blood Pb levels < 10 µg/dL, children with initial blood Pb levels ≥ 10 µg/dL had a higher odds of having a doctor diagnosis of asthma within the past 12 months (OR: 7.5 [95% CI: 1.3, 42.9]). A strength of this study was the adjustment for a large number of potential confounding variables such as age, sex, pets in the home, housing characteristics, and household smoking. However, because children were identified from a statewide database of initial blood Pb measurements collected at unspecified ages, the timing of blood Pb varied among children. In a study that did not consider potential confounding variables, Rabinowitz et al. (1990) reported an increased risk of asthma in children (age of assessment not reported) in association with cord blood Pb levels > 10 µg/dL relative to cord blood Pb levels ≤ 10 µg/dL (Figure 5-43 and Table 5-29).

While the aforementioned studies examined blood Pb levels measured at a single point in time, a recent prospective birth cohort study compared associations of prenatal (cord and maternal) and concurrent blood Pb levels with risk of allergic sensitization at age 5 years (Jedrychowski et al., 2011). Cord and prenatal maternal blood Pb level were associated with greater risk of positive skin prick test (SPT) to dust mite, dog, or cat allergen than was child concurrent blood Pb level (Figure 5-43 and Table 5-29). For prenatal Pb biomarkers, similar effect estimates were obtained before and after adjusting for sex, parity, maternal age, maternal education, maternal atopy, and environmental tobacco smoke exposure. Cord and concurrent blood Pb levels were weakly correlated (r = 0.29), providing support for an independent association for prenatal Pb biomarkers. The independent effects of Pb also were substantiated by observations that indicators of other exposures, including blood levels of mercury, polycyclic aromatic hydrocarbon DNA adducts, and residential levels of dust mite or pet allergen were associated with lower risks of SPT than was blood Pb level. While associations were observed with relatively low cord blood Pb levels (geometric mean: 1.16 µg/dL [95% CI: 0.12, 1.22]), it is uncertain the extent to which higher past Pb exposures of the mothers may have influenced their pregnancy blood Pb levels and newborn cord blood Pb levels. Among children approximately age 10 years in Hong Kong, Hon et al. (2010; 2009) found

correlations between low concurrent blood Pb levels (population means < 2 µg/dL) and severity of atopic dermatitis (Spearman r = 0.46, p <0.001 and r = 0.33, p <0.005), another inflammatory condition commonly related to elevated IgE levels. Neither analysis considered potential confounding variables.

Among the studies in children that found associations of blood Pb level with asthma and allergy-related outcomes, several adjusted for potential confounding by SES-related variables. Joseph et al. (2005) adjusted for annual income. Pugh Smith et al. (2011), who examined a primarily low SES population of children in Michigan, adjusted for various factors associated with SES, including multiple indices of housing condition, and presence of pets and cockroaches in the home, which are indicators of allergens in the home. Jedrychowski et al. (2011) adjusted for maternal education, and found similar magnitudes of association between cord blood Pb level (and positive SPT) as those in the unadjusted analysis. Further, residential levels of dust mite or pet allergen were associated with lower risks of SPT than was blood Pb level. Thus, while SES and/or allergen exposure has been associated with both Pb exposure and asthma and allergy in children (Bryant-Stephens, 2009; Dowd and Aiello, 2009; Aligne et al., 2000), these collective findings in different populations do not demonstrate that confounding by SES and/or allergen exposure fully accounts for the associations observed between blood Pb levels and asthma and allergy. As allergic sensitization, asthma, and elevated IgE have been correlated in children, the evidence of association of blood Pb level with asthma and allergy after adjusting for SES, housing conditions, and allergen exposures, may provide support for the associations observed between higher blood Pb and higher IgE in children (Section 5.6.3).

Studies in nonoccupationally-exposed adults did not find associations of biomarkers of Pb exposure with asthma or allergy (Pizent et al., 2008; Mendy et al., In Press). The largest of these studies was a U.S. NHANES 2007-2008 analysis of adults ages 20 years and older, in which urinary Pb level was not associated with an increase in asthma (OR: 0.72 [95% CI: 0.46, 1.12] per 1 µg/g increase in creatinine-adjusted urine) (Mendy et al., In Press). The results did not provide strong evidence that urinary Pb level was associated with other respiratory conditions such as emphysema or chronic bronchitis either. In a study of 216 adults without occupational Pb exposures, Pizent et al. (2008) found that among women, the association between concurrent blood Pb level and serum IgE was statistically significant, whereas the association with positive SPT to common inhaled allergens was not. Among men, higher concurrent blood Pb level was associated with lower odds of positive SPT (OR: 0.92 [95% CI: 0.86, 0.98] but was not statistically significantly associated with IgE. These findings appeared to be discordant because an increase in IgE commonly mediates the acute inflammatory response to allergens. However, the interpretation of the findings is difficult because only statistically

significant effect estimates were reported; thus it is not known whether odds ratios were in the same direction for SPT and IgE. Bener et al. (2001b) found higher prevalence of asthma and allergy-related conditions such as rhinitis and dermatitis among Pb industrial workers than among control subjects; however, the blood Pb levels in both the Pb-exposed group and the control group (geometric means: 77.5 and 19.8 µg/dL, respectively) were higher than those in the current U.S. general adult population.

In summary, an available recent epidemiologic study added evidence for associations between blood Pb level and asthma in children (Pugh Smith and Nriagu, 2011), and a few recent studies provided new evidence for associations with allergic conditions in children (Jedrychowski et al., 2011; 2010; Hon et al., 2009). This epidemiologic evidence was strengthened by several observations that associations were robust to the adjustment of multiple potential confounding factors, in particular, SES and allergen exposures. Because of the heterogeneity in the relatively small body of evidence, it was difficult to identify whether the strength of association with asthma and allergy differed by age of children, lifestage of blood Pb measurement (prenatal, sometime in childhood prior to outcome assessment, concurrent), or level of blood Pb. The epidemiologic evidence for associations of blood Pb level with asthma and allergy is well supported by toxicological and epidemiologic evidence indicating Pb effects on increasing IgE (Section 5.6.3), Th2 cytokines (Section 5.6.5.4), and inflammation (Section 5.6.5.1). In the few recent studies that investigated nonoccupationally-exposed adults, Pb biomarker levels were not associated significantly with greater asthma or allergy (Pizent et al., 2008; Mendy et al., In Press).

5.6.4.3 Other Respiratory Effects

The respiratory effects of Pb have been examined primarily in a small number of recent epidemiologic studies of nonoccupationally-exposed adults, and as with evidence for asthma, evidence for Pb-associated respiratory effects in adults is weak. Increased bronchial responsiveness (BR) is a characteristic feature of asthma and other respiratory diseases and can result from the activation of innate immune responses and increased airway inflammation. In a study of 525 middle-aged adults in Seoul, Korea, Min et al. (2008a) found an association between concurrent blood Pb level and BR. A 1 µg/dL higher concurrent blood Pb level was associated with a higher BR index (log [% decline in forced expiratory volume in 1 second (FEV_1)/log of final methacholine concentration in mg/dL]) of 0.018 (95% CI: 0.004, 0.03), adjusting for age, sex, height, smoking, lung function, and asthma diagnosis (Min et al., 2008a). The concurrent blood Pb levels in these adults were low (mean [SD]: 2.90 [1.59] µg/dL); however, it is uncertain what timing, level, frequency, and duration of Pb exposures contributed to the observed

association. In contrast to Min et al. (2008a), Pizent et al. (2008) found that higher concurrent blood Pb level was associated with lower BR in men (2.4% decrease [95% CI: -4.2, -0.52%] in percent change FEV_1 post-histamine challenge per 1 µg/dL increase in blood Pb level). Although this finding was not discussed in details by investigators, it was consistent with the observation that higher blood Pb level was associated with lower odds of positive SPT among men in this study.

In studies of male Pb workers, Pb-associated respiratory effects were not clearly indicated. None of the studies directly examined associations between blood Pb levels and lung function. In bus drivers in Hong Kong, China, (Jones et al., 2008; Jones et al., 2006), drivers of non-air conditioned buses had lower exposures to PM_{10}, lower blood Pb levels (mean 3.7 µg/dL versus 5.0 µg/dL in air conditioned buses) but lower indices of lung function than did drivers of air conditioned buses (Jones et al., 2006). In this study, the authors attributed the slightly higher blood Pb levels of air conditioned bus drivers to the poor efficiency in the filters and higher PM_{10} levels measured on those buses versus the non-air conditioned buses. In a comparison of roadside vendors and adjacent shopkeepers, blood Pb levels and various lung function parameters were similar between groups (Jones et al., 2008). Pb industrial workers in the United Arab Emirates had higher prevalence of respiratory symptoms such as cough, phlegm, shortness of breath, and wheeze than did unexposed controls (Bener et al., 2001b). Blood Pb levels in both the Pb-exposed group and the control group (geometric means: 77.5 and 19.8 µg/dL, respectively) were higher than those in the current U.S. adult general population, and the analysis did not consider potential confounding variables.

Toxicological evidence for Pb-associated respiratory effects is provided by observations that exposure to Pb-containing PM induces a range of inflammatory-related effects in the airways of animals and in cultured airway cells (Section 5.6.6). Specific effects on the lung also were demonstrated in a recent study of rats injected with Pb-acetate (25 mg/kg, 3 consecutive days, resulting in 2.1 µg/dL blood Pb) (Kaczynska et al., 2011). Pb-treated rats exhibited ultrastructural changes in lung tissue, including substantial pulmonary fibrosis containing numerous lipofibroblasts, collagens, and elastin filaments in the interstitium. Mast cells also were present in the interstitium following Pb exposure. Pulmonary inflammation was observed, evidenced by the increased recruitment of monocytes and thrombocytes inside the capillary vessels and increased macrophage accumulation in the alveolar space. Evidence of damaged surfactant lining and destruction of the laminae inside lamellar bodies of epithelial type II cells also was observed. While the observed pulmonary histological changes have been linked with functional pulmonary decrements in other studies (unrelated to Pb exposure), they were observed with injected Pb. It is not clear whether routes of Pb exposure more relevant to those in humans would result in similar effects.

5.6.4.4 Autoimmunity

Evidence for the effects of Pb on increasing the risk of autoimmunity is provided primarily by a small number of older toxicological studies reviewed in the 2006 Pb AQCD in which Pb exposure of animals (pre- and postnatal) was associated with the generation of autoantibodies (Hudson et al., 2003; Bunn et al., 2000; El-Fawal et al., 1999; Waterman et al., 1994). Whereas some evidence linked this risk of autoimmunity to a shift toward Th2 responses, other evidence pointed to a shift toward Th1 responses. While recent studies did not examine Pb-induced production of autoantibodies, some provided indirect evidence by indicating that the changes induced by Pb had broader implications for increasing risk of autoimmunity. For example, Kasten-Jolly et al. (2010) examined the impact of developmental (100 µM Pb-acetate in drinking water of dams from GD8 to PND21, resulting in pup blood Pb levels 10-30 µg/dL) Pb exposure of mice on changes in gene expression in the spleen. Investigators found that Pb upregulated digestive and catabolizing enzymes that could lead to the generation of self-peptides, which in conjunction with other Pb-induced immunomodulatory effects, had the potential to induce the generation of autoantibodies. In Carey et al. (2006), the activation of neoantigen-specific T cells in $PbCl_2$-treated adult mice (25-50 µg i.p.) also indicated the potential for autoantibody generation. Evidence of Pb-associated autoimmune responses in humans is limited to an older study of male Pb battery workers with blood Pb levels ranging from 10 to 40 µg/dL (El-Fawal et al., 1999). In this study, the Pb-exposed workers had higher levels of IgM and IgG autoantibodies to neural proteins compared with unexposed controls (blood Pb levels not reported) (El-Fawal et al., 1999). Pb also was found to modify neural proteins in rats (Waterman et al., 1994). The generation of self-peptides and modification of proteins can result in formation of neoantigens, thereby increasing the risk of autoimmune reactions.

5.6.4.5 Specialized Cells in Other Tissues

As discussed in Section 5.6.2.4, Pb exposure consistently has been found to alter the function of macrophages. Nonlymphoid tissues also contain specialized macrophages whose altered function can contribute to organ/tissue dysfunction, cell death, tissue pathology and tissue-specific autoimmune reactions. Among the specialized macrophages are microglia and astrocytes in the brain, Kupffer cells in the liver, alveolar macrophages in the lung, keratinocytes and Langerhans cells in the skin, osteoclasts in the bone, and preadipocytes in adipose tissue. The evidence demonstrating the effects of Pb on specialized macrophages, which was provided by recent toxicological studies, is important as it demonstrates the contribution of immune dysfunction to the effects of Pb on dysfunction in nonlymphoid tissues (Figure 5-44). Because these specialized cells are

not always recognized as macrophages, the resulting diseases and conditions are not always recognized as being linked with Pb-induced immune dysfunction. It is important to note that in this small body of available studies, several studies treated animals by Pb injection, and it is unclear whether the effects would be observed with routes of exposure that are more relevant for humans.

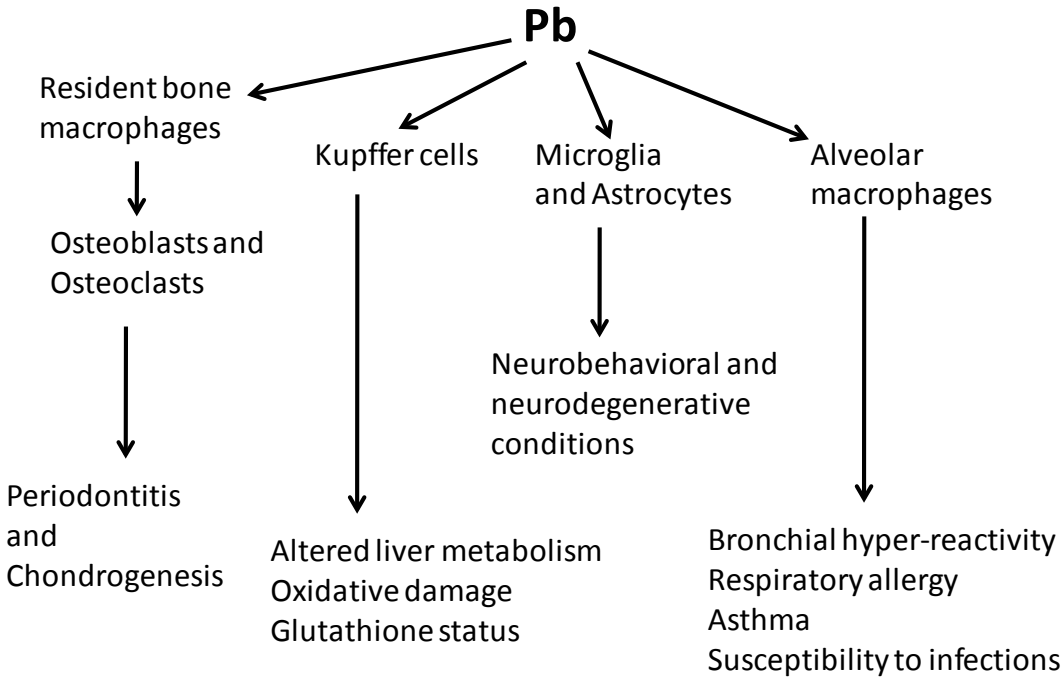


Figure 5-44 Specialized macrophages in nonlymphoid tissue may serve as a link between Pb exposure and disease in multiple organ systems.

Fan et al. (2009b) reported that Kupffer cells undergo significant changes in phenotypic expression (e.g., CD68 and ferritin light chain), organization, and functional activity connected to Pb-induced apoptosis in the liver. Dosing of juvenile Wistar rats with Pb injections (15 mg/kg of Pb-acetate daily for 2 weeks, resulting in a mean blood Pb level of 30 µg/dL) during early postnatal maturation was observed to produce chronic glial activation, increase pro-inflammatory cytokines, and increase neurodegeneration, as indicated by an increase in GFAP, increase in IL-1β, TNF-α and IL-6 cytokines, and a decrease in synaptophysin (component of presynaptic vesicles), respectively, in brain tissue (Struzynska et al., 2007). In bone, osteoclasts regulate osteoblast function (Chang et al., 2008a), and osteoblasts have been shown to be affected by Pb exposure. Effects on these cell types can contribute to later life diseases such as arthritis [reviewed in Zoeger et al. (2006)]. Pb-induced elevation of TGF-β production was found to be involved in

chondrogenesis in bone (Zuscik et al., 2007). Kaczynska et al. (2011) reported effects on alveolar macrophages after Pb treatment (i.p. 25 mg/kg, 3 days, resulting in blood Pb levels of 2.1 µg/dL) in rats. Macrophage recruitment increased, and this macrophage infiltration limited air space available to gas exchange and contained parts of phagocytized surfactant and alveolar lining.

Resident immune cells in reproductive organs have been shown to be affected by Pb exposure. Pace et al. (2005) reported that Pb exposure in mice contributed to poor reproductive performance that was concomitant with altered homeostasis of the testicular macrophage population in that organ. The authors proposed that increased oxidative damage and apoptosis among these macrophages and reduced potential to maintain organ homeostasis contributed to the observed pattern of male sterility.

5.6.4.6 Tumors

While toxicological evidence indicates that high concentration Pb exposures directly promote tumor formation or induce mutagenesis and genotoxicity (Section 5.10), evidence for involvement of the immune system is limited. Kerkvliet and Baecher-Steppan (1982) observed that male C57Bl/6 mice exposed to 130 and 1,300 ppm of Pb-acetate in drinking water had enhanced moloney sarcoma virus-induced tumor growth compared with control animals. The findings indicated that Pb-induced immunomodulation affecting tumors likely resulted from a combination of suppressed Th1 responses and increased inflammation leading to excessive release of ROS into tissues. The promotion of cancer is a relatively common outcome in chemical-induced immunotoxicology, particularly when early life exposures are involved (Dietert, 2011).

5.6.5 Modes of Action for Lead Immune Effects

5.6.5.1 Inflammation

The 2006 Pb AQCD indicated that misregulated inflammation represents one of the major immune-related effects of Pb and a major mode of action for Pb effects in multiple organ systems such as the liver, kidney, and vasculature (Section 5.2.5). In the 2006 Pb AQCD, several lines of toxicological evidence demonstrated Pb-induced inflammation: Pb-induced increases in PGE_2 and ROS (Section 5.6.5.2) and increases in pro-inflammatory cytokines (Section 5.6.5.4), both of which promote a hyperinflammatory phenotype in immune cells. As described in sections that follow, these findings are

corroborated by a small number of available recent toxicological studies. A few available recent epidemiologic studies provided new evidence of Pb-associated inflammation, as indicated by associations of blood Pb levels with pro-inflammatory cytokines and other nonspecific indicators of inflammation.

Enhanced inflammation and tissue damage occurs through the modulation of inflammatory cell function and production of pro-inflammatory cytokines and metabolites. It is important to note that while inflammation can mediate immune-related conditions such as asthma, respiratory infections, and BR, inflammation can exacerbate disease and damage in almost any organ given the distribution of immune cells as both permanent residents and infiltrating cell populations. Among the problems presented by this immunomodulation are the overproduction of ROS and an apparent depletion of antioxidant protective enzymes and factors (e.g., selenium). For example, toxicological studies have found that Pb-induced inflammatory damage involves the depletion of antioxidants such as glutathione and catalase (Lodi et al., 2011; Chetty et al., 2005). While several processes have been proposed to explain the mechanisms of Pb-induced oxidative damage, the exact combination of processes involved remains to be determined (Section 5.2.4).

In epidemiologic studies, Pb-associated changes in pro-inflammatory cell function (Section 5.6.2) and cytokine production (Section 5.6.5.4) have been found in the cumulative body of evidence. A few recent epidemiologic studies added to this evidence with observations of associations between blood Pb level and other nonspecific indicators of inflammation that may be related to multisystemic effects as have been demonstrated in animal and in vitro studies. Using 1999-2004 NHANES data, Songdej et al. (2010) examined the relationship between concurrent blood Pb levels and the inflammation markers, C-reactive protein (CRP), fibrinogen, and white blood cell (WBC) count in adults 40 years of age or older. Adjusting for age, sex, race/ethnicity, education, income, BMI, physical activity, smoking status, diabetes status, inflammatory disease status, and cardiovascular disease status, investigators found larger magnitudes of association between blood Pb and inflammation in men compared with women. Among women, most ORs for associations between quintiles of blood Pb level and tertiles of CRP, fibrinogen, and WBC count were less than 1.0 whereas corresponding ORs in men tended to be greater than 1.0 but were not always statistically significant. For example, compared with men with concurrent blood Pb levels less than 1.16 µg/dL, men with blood Pb levels of 1.16-<1.63 µg/dL, 1.63-<2.17, 2.17-<3.09 µg/dL, and ≥ 3.09 µg/dL had elevated odds of elevated CRP (OR [95% CI]: 2.22 [1.14, 4.32], 1.67 [0.85, 3.28], 2.12 [1.07, 4.21], and 2.85 [1.49, 5.45], respectively). For all inflammation markers, although the OR was highest in the highest quintile of blood Pb level (≥ 3.09 µg/dL), monotonic concentration-dependent increases were not observed.

Consistent with these findings, among men in Incheon, Korea without occupational Pb exposures, Kim et al. (2007) reported associations of higher concurrent blood Pb level with higher levels of WBCs and IL-6. Larger effects were estimated for men in the upper two quartiles of blood Pb levels, 2.51-10.47 µg/dL than for the full range of blood Pb levels. The findings are consistent with Pb effects on promoting a Th2 phenotype. Th2 cells produce IL-6 which is the primary stimulus for expression of CRP and fibrinogen (Hage and Szalai, 2007; Fuller and Zhang, 2001). Despite the low concurrent blood Pb level of adults in these aforementioned studies, it is important to acknowledge that the relative contributions of recent versus past Pb exposures to the associations observed with concurrent blood Pb levels are not delineated.

In a genome-wide association study that included 37 children with autism and 15 children without autism (ages 2-5 years; blood Pb level range: 0.37 to 5.2 µg/dL) in California, in models that included age, sex, and autism diagnosis, concurrent blood Pb level was associated with the expression of several genes related to immune function and inflammation, including human leukocyte antigen genes (HLA-DRB) and MHC Class II-associated invariant chain CD74 (involved in antigen presentation) (Tian et al., 2011). Although blood Pb levels were similar between children with and without autism and correlations were observed in both groups, they were in opposite directions (positive among children with autism and negative among children without autism). Pb has been shown to increase MHC molecule surface expression in mouse and human HLA antigen presenting cells (Guo et al., 1996a; McCabe and Lawrence, 1991); however, additional larger studies with a priori hypotheses regarding specific indices of inflammation are warranted to characterize Pb-associated changes in inflammation in children.

5.6.5.2 Increased Prostaglandin E_2 and Decreased Nitric Oxide

Consistent with the large body of evidence presented in the 2006 Pb AQCD (U.S. EPA, 2006b), a small number of available recent studies continued to indicate that Pb exposure alters the levels of signaling molecules such as PGE_2 and NO. Collectively, the weight of evidence was provided by toxicological studies. These signaling molecules are involved in mediating inflammation and host resistance (Figure 5-42). A recent in vitro study with human neuroblastoma cells found increases in PGE_2 with lower Pb concentrations (0.01-1 µM) than those previously reported (Chetty et al., 2005). A large body of evidence reviewed in the 2006 Pb AQCD demonstrated a Pb-associated decreased production of NO by macrophages [see 2006 Annex Table AX5.9.6 (U.S. EPA, 2006h)].

In adult animal models, decreases in NO were observed with short-term exposures (hours to days) to a wide range of Pb concentrations. Decreases in NO can impact not only

innate host defenses, but also, acquired immunity. In a recent study, Farrer et al. (2008) found that high-level Pb glutamate exposure (5 µM) of lymphocyte cultures led to decreased NO production, decreased inducible NO synthase function in myeloid cells, but no change in its gene expression. Additionally, Pb abrogated the myeloid cell (CD11b+)-mediated suppression of CD4+ T cell proliferation. Together, these findings indicated that Pb may indirectly enhance T cell proliferation through its effect on decreasing NO production. Combined with the observation that Pb can alter antigen processing (Farrer et al., 2005) and, hence, the quality and magnitude of the acquired immune response signal against pathogenic challenge, evidence indicated that multiple arms of the host defense against infectious challenge can be compromised. The loss of NO production in innate immune cells such as macrophages would be expected to affect other physiological systems (e.g., neurological, cardiovascular, endocrine) that require NO signaling cascades.

Relative to studies in animal and in vitro models, fewer epidemiologic studies have examined the effects of Pb on signaling molecules; however the limited data supported associations of blood Pb level with suppressed NO production (Barbosa et al., 2006a; Pineda-Zavaleta et al., 2004) and increased ROS production (Pineda-Zavaleta et al., 2004) in populations living near Pb sources. In a previous study of children in Mexico, with increasing residential proximity to the Pb smelter, mean concurrent blood Pb levels increased (7.02 to 20.6 to 30.38 µg/dL) as did superoxide anion release from macrophages (directly activated by IFN-γ/LPS) isolated from children (Pineda-Zavaleta et al., 2004). NO release from macrophages (indirectly activated by phytohemagglutinin, PHA) was lower with higher blood Pb levels. After adjusting for age and sex, a 1 µg/dL higher blood Pb level was associated with a higher level of superoxide anion of 0.00389 (95% CI: 0.00031, 0.00748) µmol/mg protein and a lower level of NO of 0.00089 (95% CI: -0.0017, -0.00005) nmol/µg protein. Because PHA activates macrophages indirectly through the activation of lymphocytes and IFN-γ directly activates macrophages, these results indicated that Pb suppressed T cell-mediated macrophage activation and stimulated cytokine-induced macrophage activation. Group-level comparisons indicated that associations likely were driven by changes observed in the group of children living in closest proximity to the smelter who had blood Pb levels 10.31-47.49 µg/dL. Results also demonstrated a larger magnitude of association between blood Pb levels and superoxide anion release in males. Although not described in detail, higher blood Pb level was not associated with lower NO in girls. Barbosa et al. (2006a) also observed an association between higher blood Pb level and lower plasma NO in a group of adults in Sao Paolo, Brazil residing near a closed battery plant, particularly among adults with the TC or CC eNOS genotype ($r = 0.23$, $p = 0.048$) which is associated with reduced promoter activity and potentially reduced gene expression. Quantitative results were not reported for analysis of all adults combined or adults with the TT genotype, but p-values were greater

than 0.05. Because NO was measured in plasma, it was not possible to identify immune cells as the specific sources of NO.

Studies of occupationally-exposed adults provided less clear indication of associations of blood Pb level with NO and ROS. Despite large differences in blood Pb levels between 30 male Pb recycling plant workers (mean: 106 µg/dL) and 27 unexposed controls (mean: 4.5 µg/dL), levels of ROS released from neutrophils (indicators of respiratory burst) were similar between groups (Mishra et al., 2006a). In a study of male foundry workers (mean blood Pb level: 21.7 µg/dL), pottery workers (mean blood Pb level: 9.7 µg/dL), and unexposed workers (mean blood Pb level: 3.9 µg/dL), Valentino et al. (2007) found similar plasma NO levels in controls compared with Pb-exposed workers. Also, although quantitative results were not reported, blood Pb level was reported not to be correlated with NO.

5.6.5.3 Cellular Death (Apoptosis, Necrosis)

The 2006 Pb AQCD reviewed a small number of toxicological studies in which Pb exposure had contrasting effects on the apoptosis of macrophages. Since then, a few available recent toxicological studies found that Pb exposure induces apoptosis or mediators of apoptosis in immune cells. In a study in mice, Bishayi and Sengupta (2006) found that Pb treatment of adult mice (10 mg/kg, i.p.) elevated DNA fragmentation in splenic macrophages. Using mouse resident peritoneal macrophages, Gargioni et al. (2006) found that 20 and 40 µM Pb nitrate induced both necrosis and apoptosis in vitro. While the exact pathways involved were not determined, the authors concluded that activation of the Bax pro-apoptotic protein was not the key effect of Pb on inducing macrophage apoptosis. In an in vivo study in 3 week-old mice, Xu et al. (2008) found that a 4-week administration of Pb-acetate (50-100 mg/kg, oral) significantly elevated both ROS and malondialdehyde (an indicator of ROS-induced peroxidation) levels in peripheral blood lymphocytes. Pb also induced DNA damage (determined by the comet assay), which was accompanied by elevations in p53 and Bax expression with no change in Bcl-2 expression (creating a Bax/Bcl-2 imbalance). The authors proposed that oxidative stress was a likely route to Pb-induced apoptosis and tumorigenesis. Because of the high Pb concentrations administered and systemic administration of Pb employed, other studies are warranted to examine whether apoptosis of macrophages represent a mode of action relevant to human Pb exposures.

5.6.5.4 Cytokine Production

The 2006 Pb AQCD presented a large body of toxicological evidence that clearly demonstrated Pb-induced changes in cytokine production in vivo and in vitro (U.S. EPA, 2006b). Previous toxicological studies indicated that Pb affects immune cytokine production via action on T cells and macrophages. The combination of cytokine changes induced by Pb in multiple cell types can create a hyperinflammatory state among innate immune cells to skew acquired immunity responses away from Th1 responses and toward Th2 responses. As illustrated in Figure 5-42, downstream effects include altered IgE production, ROS production, and inflammation. In support of a Pb-induced skew toward Th2 responses, several studies in rats, mice, and chickens found that pre- and postnatal Pb exposure suppressed the production of Th1 cytokine IFN-γ and/or increased production of Th2 cytokines such as IL-4 [Table 5-7 of the 2006 Pb AQCD (U.S. EPA, 2006g)]. Recent toxicological studies continued to find such Pb-induced changes in cytokine production, and a study provided new evidence that Th2 skewing may be mediated via effects on dendritic cells.

Cheng et al. (2006) found that Pb exposure affected TNF-α production in vitro in A/J mice macrophages by affecting the mitogen-activated protein kinase (MAPK) signaling pathway. Pb-acetate (10 µM) co-administered with LPS stimulated the phosphorylation of p42/44 MAPK and TNF-α expression (Cheng et al., 2006). Blocking protein kinase C or MAPK reduced TNF-α production of macrophages in vitro, which in turn, protected against Pb + LPS-induced liver injury in vivo. Thus, Pb exposure may induce local tissue damage through the modulation of immune responses. These findings were consistent with those from recent studies. Gao et al. (2007) showed that treatment of mouse dendritic cells with 25 µM $PbCl_2$ produced an increased phosphorylation of the Erk/MAPK signaling molecule, and Khan et al. (2011) showed that monocytes treated with 25-50 µM Pb-acetate increased TNF-α through ERK1/2 and p38 signaling.

In an in vivo study conducted across a lifetime (developmental through adulthood) in Swiss mice (females and males) using a broad range of dietary Pb concentrations, Iavicoli et al. (2006a) found a nonlinear hierarchical cytokine response. At the lowest dietary Pb concentration (0.11 ppm Pb-acetate, resulting in blood Pb level: 1.6 µg/dL), IL-2 and IFN-γ were decreased compared to those in the controls (0.02 ppm Pb-acetate, resulting in blood Pb level: 0.8 µg/dL), indicating a suppressed Th1 response. As dietary Pb exposure increased (resulting in blood Pb levels 12-61 µg/dL), a Th2 phenotype was observed with suppressed IFN-γ and IL-2 and elevated IL-4 production. These findings support the notion that the immune system is differentially modulated by low-level versus high-level Pb exposures. Other studies found variable Pb-induced changes in IL-2, with no change or elevated production, depending upon the protocol used. Recently, Gao et al.

(2007) found that Pb-treated dendritic cells (25 µM) promoted a slight but statistically significant increase in IL-2 production (quantitative results not reported) among lymphocytes.

In vitro studies also reported a Pb-induced shift to production of Th2 cytokines. In conjunction with other indicators of Th2 skewing described in Sections 5.6.2.3, 5.6.2.6, and 5.6.3, Gao et al. (2007) observed that 25 µM Pb elevated the production of Th2 cytokines such as IL-4, IL-5 and IL-6 in dendritic cells. In cultures of human PMNs activated with *Salmonella enteritidis* or with monoclonal antibodies of CD3, CD28, and CD40, Pb-acetate concentrations of 0.15 µg/dL and higher suppressed expression of Th1 cytokines, IFN-γ, IL-1β, and TNF-α, and increased secretion of Th2 cytokines, IL-5, IL-6, and IL-10 (Hemdan et al., 2005).

Consistent with toxicological studies, a few available epidemiologic studies also found higher concurrent blood Pb levels in children and occupationally-exposed adults to be associated with a shift toward production of Th2 cytokines relative to Th1 cytokines. The evidence in children was based on comparisons of serum cytokine levels among groups with different blood Pb levels without consideration of potential confounding factors. Among children ages 9 months to 6 years in Missouri, Lutz et al. (1999) found that children with concurrent blood Pb levels 15-19 µg/dL had higher serum levels of IL-4 ($p = 0.08$, Kruskal Wallis) and IgE (Section 5.6.3) than did children with lower blood Pb levels. However, IL-4 levels in children with blood Pb levels 20-44 µg/dL were lower than those in children with blood Pb levels < 15 µg/dL. The elevated IL-4 and IgE in children with blood Pb levels 15-19 µg/dL were consistent with the mode of action for IL-4 to activate B cells to induce B cell class switching to IgE. In another study of children in grades 5 and 6 in Taiwan, investigators did not group children by blood Pb levels but by potential for Pb exposures due to age of home and location of residence (Hsiao et al.). Concurrent blood Pb levels did not differ by residence in old versus new homes or by urban versus rural residence (means: 3.2-3.8 µg/dL) but were higher among children living near an oil refinery, in particular, among children with known respiratory allergies (mean: 8.8 µg/dL). This latter group of children also had the lowest serum levels of IFN-γ (45-fold) and highest levels of IL-4 (6-fold) (lower $p < 0.05$ for comparisons with any subgroup). There was no direct comparison of cytokine levels between blood Pb level groups in the population overall; however, cytokine levels were similar between healthy and allergy groups in the other Pb source groups that had similar blood Pb levels ($p > 0.05$ for comparisons with any subgroup). Thus, the differences in cytokine levels between healthy and allergic children living near the oil refinery may have been influenced by differences in their blood Pb levels.

Evidence of association between blood Pb levels and cytokine levels in nonoccupationally-exposed adults was equivocal. Among adult university students in Incheon, Korea, Kim et al. (2007) found associations of concurrent blood Pb level with serum levels of TNF-α and IL-6 that were larger among males in the upper two quartiles of blood Pb levels, 2.51-10.47 µg/dL. Notably, the relative contributions of recent versus past Pb exposures to these associations are not known. In models that adjusted for age, BMI, and smoking status, a 1 µg/dL higher blood Pb level was associated with a 0.75 (95% CI: 0.14, 1.36) pg/mL higher TNF-α and a 0.18 (95% CI: -0.02, 0.38) pg/mL higher IL-6. The association between levels of blood Pb and plasma TNF-α was greater among men who were GSTM1 null (1.14 [95% CI: 0.20, 2.10] pg/mL higher per 1 µg/dL higher blood Pb level) than men who were GSTM1 sufficient (0.12 [95% CI: -0.43, 0.67] pg/mL). Blood Pb also was associated with a larger increase in TNF-α among men who had the TNF-α GG genotype (0.80 [95% CI: 0.15, 1.45] pg/mL higher per 1 µg/dL higher blood Pb level) than men who had the GA or AA genotype (-0.21 [95% CI: -1.1, 0.71] pg/mL). For the association between blood Pb level and plasma IL-6, the effect estimate was slightly elevated in TNF-α GG genotype but not elevated in the GSTM1 positive group. The effects of Pb on several physiological systems have been hypothesized to be mediated by the generation of ROS (Daggett et al., 1998). Thus, it is biologically plausible that the null variant of GSTM1, which is associated with reduced elimination of ROS, may increase the risk of Pb-associated immune effects. The results for the TNF-α polymorphism were difficult to interpret. The GG genotype is associated with lower expression of TNF-α, and the literature is mixed with respect to which variant increases risk of inflammation-related conditions. Among adults in Italy, concurrent blood Pb levels were not statistically significantly correlated with either Th2 or Th1 cytokine levels in men (Boscolo et al., 1999) or women (Boscolo et al., 2000) (quantitative results not reported).

Results from studies of occupationally-exposed adults also suggested that Pb exposure may be associated with decreases in Th1 cytokines and increases in Th2 cytokines; however, analysis were mostly limited to comparisons of mean cytokine levels among different blood Pb groups or Pb exposure groups (Di Lorenzo et al., 2007; Valentino et al., 2007; Yucesoy et al., 1997a) that did not consider potential confounding variables. The exception was a study of male foundry workers, pottery workers, and unexposed workers (Valentino et al., 2007). Multiple regression analyses were performed with age, BMI, smoking, and alcohol consumption included as covariates; however, regression coefficients describing the concentration-response functions were not reported. Pb-exposed workers had higher IL-10 and TNF-α (ANOVA, $p < 0.05$). Levels of IL-2, IL-6, and IL-10 also increased from the lowest to highest blood Pb group (ANOVA, $p > 0.05$). In contrast with most other studies, both exposed worker groups had lower IL-4 levels compared with controls (ANOVA, $p > 0.05$). In a similar analysis, DiLorenzo et al.

(2007) separated exposed workers into intermediate (9.1-29.4 µg/dL) and high (29.4-81.1 µg/dL) blood Pb level groups, with unexposed workers comprising the low exposure group (blood Pb levels 1-11 µg/dL). Mean TNF-α levels showed a monotonic increase from the low to high blood Pb level group. Results also indicated a potential interaction between blood Pb level and smoking. Among current smokers, a 12- to 16-fold difference in TNF-α levels was observed among blood Pb groups. Among nonsmokers, the differences were less than two fold. In Yucesoy et al. (1997a), levels of the Th1 cytokines, IL-1β and IFN-γ, were lower in workers than in controls.

In summary, a large body of previous toxicological evidence clearly demonstrated Pb-induced increases in Th2 cytokines and decreases in Th1 cytokines. Several recent toxicological studies added to this evidence by showing Pb-induced increases in TNF-α that were mediated by MAPK signaling pathways (Khan et al., 2011; Gao et al., 2007; Cheng et al., 2006; Iavicoli et al., 2006a; Hemdan et al., 2005), and demonstrating Pb-induced increases in cytokine production in dendritic cells (Gao et al., 2007). The collective epidemiologic evidence is sparse; however, in the few available new studies, higher concurrent blood Pb level was associated with higher levels of various pro-inflammatory cytokines in children, nonoccupationally-exposed adults, and occupationally-exposed adults. The recent epidemiologic study of children in Taiwan found an association between higher IL-4 levels in children with higher blood Pb levels (Hsiao et al.), similar to a previous study of children in Missouri (Lutz et al., 1999). Neither study of children considered potential confounding variables. In contrast to previous studies, a recent study in nonoccupationally-exposed adults found associations between higher concurrent blood Pb level and higher TNF-α and IL-6 cytokine levels in men in Korea (Kim et al., 2007). Recent studies of occupationally-exposed adults added to the evidence for higher levels of several cytokines among Pb-exposed workers compared to unexposed controls (Di Lorenzo et al., 2007; Valentino et al., 2007). Due to the limited investigation, it is difficult to draw conclusions about the effects of Pb exposure on cytokine levels in any particular group in the human population.

5.6.6 Air-Lead Studies

Although comprising a smaller body of evidence than do immune studies of Pb biomarkers, several recent studies used Pb measured in PM_{10} and $PM_{2.5}$ air samples to represent Pb exposures. Some studies analyzed the Pb component individually, whereas others analyzed Pb as part of a group of correlated components using source apportionment techniques or principal component analysis. In concordance with blood Pb studies, recent time-series epidemiologic studies that examined ambient air Pb-PM concentrations found associations with respiratory morbidity in children (Gent et al.,

2009; Hong et al., 2007b). Adjusting for season, day of week, and date, Gent et al. (2009) found that an increase in lag 0-2 average Pb-$PM_{2.5}$ was associated with elevated odds of wheeze (OR: 1.03, p = 0.13 per 5 ng/m^3 increase in Pb $PM_{2.5}$), shortness of breath (OR = 1.12, p = 0.01), and fast-acting inhaler use (OR: 1.04, p = 0.10) among children with asthma (ages 4-12 years), followed for 1 year during 2000-2003. Among children in Korea (grades 3-6), a 1 log increase in lag 1 Pb PM_{10} was associated with a -6.83 L/min decrease (p < 0.01) in morning peak expiratory flow and a −6.37 L/min decrease (p < 0.01) in daily average peak expiratory flow adjusting for age, sex, height, weight, smoking exposure, and meteorological factors (Hong et al., 2007b). Older and recent toxicological studies also found Pb-containing CAPs to induce pulmonary inflammation. Uzu et al. (2011) specifically tested particles emitted at a Pb recycling plant and found that these Pb-rich particles increased the release of the cytokine granulocyte-macrophage colony-stimulating factor from human epithelial cells. Other toxicological studies found pulmonary inflammation induced by CAPs in which Pb was one of numerous components (Wei et al., 2011; Duvall et al., 2008; Godleski et al., 2002; Saldiva et al., 2002). As with blood Pb, epidemiologic studies did not consistently find associations of ambient air Pb-PM concentrations with respiratory-related hospitalizations or mortality in older adults. Both studies adjusted for meteorological factors and for temporal trends. Among adults ages 65 years and older in 6 California counties, a 4 ng/m^3 increase in lag 3 Pb-$PM_{2.5}$ was associated with an increased relative risk of respiratory mortality all year of 1.01 (95% CI: 0.99, 1.03) and during summer months (quantitative results not reported) (Ostro et al., 2007). However, among adults ages 65 years and older in 106 U.S counties, Bell et al. (2009) found that an increase in lag 0 Pb-$PM_{2.5}$ was associated with a decrease in respiratory hospital admissions. The 95% CI was wide, indicating lack of precision in effect estimate.

Although limited available recent findings suggest a relationship between respiratory effects in children and short-term (over several days) changes in ambient air Pb-PM concentrations, it is important to note uncertainties that limit the ability to draw conclusions regarding airborne Pb exposure. Size distribution data for Pb-PM are relatively limited, so it is difficult to assess the representativeness of these concentrations to population exposure (Section 3.5.3). Moreover, data on the relationship between blood Pb and air Pb are relatively limited (see Section 4.5.1) and do not characterize relationships of varying Pb-PM size distribution with blood Pb level. In several air-Pb studies, other PM components such as elemental carbon (EC), copper (Cu), and zinc (Zn) also were associated with respiratory effects. In the absence of detailed data on correlations among all PM components, measurements on other co-occurring ambient pollutants, or results adjusted for copollutants, it is difficult to exclude confounding by ambient air exposures to other PM components or ambient pollutants. In several studies that analyzed PM component mixtures, of which Pb particles comprised one component,

it is not possible to attribute the observed associations or lack of associations specifically to Pb (Sarnat et al., 2008; Andersen et al., 2007; Veranth et al., 2006; Maciejczyk and Chen, 2005).

5.6.7 Immune Effects of Lead within Mixtures

Several toxicological studies published since the 2006 Pb AQCD examined immune effects resulting from exposures to metal mixtures. Some studies indicated that immune effects may be observed with lower levels of Pb exposure when they occur in conjunction with other metals. In a study of mice treated with Pb-acetate (10 mg/kg i.p. injection by weight, daily for 15 days), As (0.5 mg/kg i.p. injection by weight, daily for 15 days), or both, Bishayi and Sengupta (2006) reported a greater than additive effect of co-administered Pb and As on macrophages in decreasing bacterial resistance, myeloperoxidase (MPO) release, and NO production. Investigators assessed the Pb-As interaction on MPO release using the multivariate ANOVA and constructing an isobologram by running an ordinary least squares regression between effects (% MPO release) and dose levels of metals (single and multimetal) in log-linear form.

Epidemiologic studies have not widely examined interactions between Pb and other metals. However, consistent with Bishayi and Sengupta (2006), Pineda-Zavaleta et al. (2004) (Section 5.6.5.2) found interactions between Pb and As among children in Mexico aged 6-11 years. Contamination of drinking water by both Pb and As was a concern in the study area; however, urinary As levels were higher in children who had lower blood Pb levels. In multiple regression analyses, urinary As was associated with lower NO release from macrophages (similar to blood Pb). An interaction was observed between Pb and As, which indicated that high internal doses of both metals were associated with a larger decrease in NO than was either metal alone (p for interaction = 0.037). Urinary As was associated with lower superoxide anion release (opposite direction of Pb). The interaction between Pb and As indicated that higher internal doses of both Pb and As were associated with a larger increase in superoxide anion than was blood Pb level alone (p for interaction = 0.042). Due to the high blood Pb in these children (means in three groups at varying distances from a Pb smelter: 7, 20.6, 30.4 µg/dL), it is not clear whether these relationships would apply to children with lower blood Pb levels.

Results from Institoris et al. (2006) indicated that metal co-exposures potentiated the effects of Pb. Lymph node weight decreased with exposure of 4 week-old rats to 20 mg/kg Pb-acetate by drinking water plus a second metal (Cd or Hg) but not with 20 mg/kg of Pb alone. In contrast with the aforementioned studies, Fortier et al. (2008) did not find Hg co-exposure to increase the effects of Pb. $PbCl_2$-exposed (7.5-20.7 µg/dL)

human leukocytes did not have alterations in lymphocyte proliferation, monocytic phagocytic activity, or NK cell activity. The combination of 20.7 µg/dL $PbCl_2$ plus 12.0 µg/dL methylmercuric chloride (MeHgCl) decreased lymphocyte proliferation; however, these effects were attributed to MeHgCl, which had a stronger suppressive effect independently. Other toxicological studies found immune effects of multiple metal mixtures that included Pb (e.g., decreased antibody titers, increased neutrophil counts) (Jadhav et al., 2007; Massadeh et al., 2007) but did not test each metal individually. Thus, it cannot be ascertained whether findings are due to interactions between Pb and other components within the mixture. Overall, results indicated that exposures to Pb-containing metal mixtures are associated with immune effects. Moreover, several studies found an interaction between Pb and metals such as As, Cd, and Hg, suggesting that a threshold for producing Pb-induced immune effects may be lower if additional metals are present.

5.6.8 Summary and Causal Determination

The collective body of evidence demonstrates that Pb exposure is associated with immune effects. The evidence indicates that rather than resulting in overt cytotoxicity to lymphoid tissues, Pb exposure is associated predominantly with subtle changes in a spectrum of cellular and humoral immune responses, most notably, altered function of T lymphocytes and macrophages, suppression of the DTH response and resistance to bacterial infection, increased IgE production, changes in cytokine production, and inflammation. The strength of evidence for Pb-associated immune effects is derived not only from the consistency of findings within particular endpoints but also from the coherence of findings among the spectrum of immune changes operating within the same pathway. In particular, the evidence integrated across the examined spectrum of immune outcomes clearly indicates that the prominent immune effect of Pb exposure is to shift responses from a Th1 phenotype toward a Th2 phenotype.

The weight of evidence is provided largely by an extensive body of animal studies characterizing effects on the broad range of immune endpoints as described above. Comprising a smaller body of evidence, epidemiologic studies in children are consistent with toxicological studies in reporting associations of blood Pb levels with indicators of increased Th2 activity, principally, higher levels of IgE, asthma, and allergy in children. Across outcomes, because most studies examined concurrent blood Pb levels, there is uncertainty regarding the critical timing, frequency, duration, and level of Pb exposures in children that contributed to observed associations. In toxicological studies, the shift to a Th2 phenotype is well characterized by observations that Pb exposures suppress the production of Th1 cytokines (e.g., IFN-γ) and increase production of Th2 cytokines (e.g., IL-4) (Section 5.6.5.4). In animal studies, the shift to Th2 cytokine production was

observed in juvenile animals with prenatal Pb exposures and in adult animals with long-term (> 4 weeks) Pb exposures [Table 5-7 in the 2006 Pb AQCD (U.S. EPA, 2006g)]. Blood Pb levels of animals were reported infrequently, and a wide range of Pb exposures was found to induce changes in cytokine levels. In a recent study, lifetime Pb exposure that resulted in blood Pb levels between 2-3 µg/dL suppressed Th1 cytokine production in adult mice (Iavicoli et al., 2006a). A few available epidemiologic studies in children (Hsiao et al., 2001; Lutz et al., 1999) found higher levels of IL-4, a Th2 cytokine, in groups of children with higher concurrent blood Pb levels (e.g., mean 8.8 µg/dL or range 15-19 µg/dL, respectively); however, these studies are limited by their lack of consideration of potential confounding variables and lack of information on the concentration-response function.

Coherence for a Pb-associated skewed ratio of cytokine production is provided by evidence demonstrating Pb-induced activation of T cells in animals, with recent studies describing mechanisms underlying T cell activation (Sections 5.6.2.1 and 5.6.2.2). A recent toxicological study expanded the extant evidence by showing in vivo and in vitro that Pb may promote Th2 responses by directly increasing production of Th2 cytokines in dendritic cells, the major effector in antigen response (Gao et al., 2007). Pb-induced T cell activation also is indicated by a relatively small body of evidence for prenatal and postnatal Pb exposures of animals resulting in the generation of autoantibodies in response to new antigens. These findings suggest that Pb exposure may increase the risk of developing autoimmune conditions (Section 5.6.4.4). In epidemiologic studies, evidence for the effects of Pb on T cells comprised associations of concurrent blood Pb levels > 10 µg/dL in children with lower T cell abundance, in particular CD3+ cells. However, the functional relevance of these changes is unclear.

In addition to T cell responses, a prominent effect of Pb exposure, as demonstrated in an extensive historical toxicological evidence base, was the induction of macrophages into a hyperinflammatory state as characterized by enhanced production of ROS, suppressed production of NO, enhanced production of TNF-α, and excessive metabolism of arachidonic acid into immunosuppressive metabolites (e.g., PGE_2). Consistent with these observations, a previous epidemiologic study examined and found greater release of ROS and lower release of NO from macrophages, primarily in children with concurrent blood Pb levels 10.31-47.49 µg/dL (Pineda-Zavaleta et al., 2004). Misregulated inflammation represents one of the major modes of action for Pb-induced immune effects. Toxicological studies provide evidence for the modulation of inflammatory cell function, production of pro-inflammatory cytokines and metabolites, enhanced inflammatory chemical messengers, and pro-inflammatory signaling cascades. In addition to the associations reported with IL-4, epidemiologic evidence for Pb effects on inflammation is limited to a few recent studies in nonoccupationally-exposed adults in which concurrent

blood Pb level was associated with other indicators of inflammation such as CRP (Songdej et al., 2010) and IL-6 (Kim et al., 2007). The studies commonly adjusted for potential confounding by age, sex, BMI, and smoking status. However, because only concurrent blood Pb levels were examined, there is uncertainty regarding the magnitude, timing, frequency, and duration of Pb exposures that contributed to the observed associations.

The toxicological evidence for Pb-induced production of Th2 cytokines provides biological plausibility for the evidence linking Pb exposure with elevated IgE levels. An increase in IL-4 from activated Th2 cells induces differentiation of B cells into antibody-producing cells, thereby amplifying B cell expansion to secrete IgE, IgA, and IgG. Animal studies describe Pb-induced (resulting in blood Pb levels 10-30 µg/dL) increases in IgE (Snyder et al., 2000; Miller et al., 1998; Heo et al., 1996). Additionally, epidemiologic studies in children consistently demonstrated associations between higher concurrent blood Pb levels and higher in serum IgE (Section 5.6.3). While most studies found elevated IgE in groups of children with blood Pb levels > 10 µg/dL, Karmaus et al. (2005) found higher serum in IgE in children with blood Pb levels 2.8-3.4 µg/dL compared with children with lower blood Pb levels. A few studies considered potential confounding by factors such as age (Karmaus et al., 2005; Lutz et al., 1999), smoking exposure, serum lipids, organochlorine biomarkers, and number of previous infections (Karmaus et al., 2005) but not SES or allergen exposure. It is important to acknowledge the extensive evidence in animals for Pb-induced increases in IgE that is not subject to confounding by SES. Additional support for effects on IgE is provided by toxicological evidence for Pb-induced increases in Th2 cytokines. Epidemiologic studies did not find blood Pb level to be associated consistently with B cell abundance.

The toxicological evidence for Pb-induced suppression of Th1 cytokine production is coherent with historical observations in animals that Pb exposure decreases responses to antigens and bacterial infection (U.S. EPA, 2006b). Toxicological studies provide clear, consistent evidence that prenatal and postnatal Pb exposure of animals (resulting in blood Pb levels 11->100 µg/dL) suppresses the DTH response to antigens (Section 5.6.2.3), and a recent in vitro study indicates such effects may be mediated by dendritic cells (Gao et al., 2007). Recent toxicological studies provided additional support for Pb-induced decreased host resistance by demonstrating that Pb exposure impairs phagocytic and chemotactic activity of macrophages (Lodi et al., 2011; Bussolaro et al., 2008). These observations reflect suppressed Th1 activity given the role of Th1-dependent IFN-γ in enhancing the killing capacity of macrophages. Epidemiologic evidence for Pb-associated diminished response to bacterial infection is limited to previous observations of reduced neutrophil functionality in Pb-exposed workers with mean blood Pb levels > 30 µg/dL. While a few previous epidemiologic studies in children found higher prevalence of

respiratory infections in children with higher blood Pb levels (Karmaus et al., 2005; Rabinowitz et al., 1990), the findings are limited by the weak statistical methods of studies and the lack of consideration of potential confounding variables.

The effects of Pb exposure on macrophages also suggest a role for the immune system in mediating Pb-associated effects in multiple other physiological systems. A small body of new toxicological studies indicated Pb-induced changes in specialized macrophages in nonlymphoid tissue such as alveolar macrophages, testicular macrophages, and brain microglia (Section 5.6.4.5); however, these studies primarily used the i.p. route to administer Pb. Thus, the relevancy of observations to those expected from typical routes of human exposure is not clear.

Th2-dependent increases in IgE mediate type 1 hypersensitivity resulting in various allergic conditions and asthma. Observations of Pb-associated increases in Th2 cytokines and circulating IgE levels provide biological plausibility for the small body of available epidemiologic evidence indicating associations of blood Pb levels with asthma and allergic conditions in children (Jedrychowski et al., 2011; Pugh Smith and Nriagu, 2011; Joseph et al., 2005). Several of these studies considered a larger set of potential confounding variables than did studies of IgE in children. While the set of particular factors varied among studies, studies frequently considered SES indicators and/or residential allergen measurement. Low SES has been associated with higher blood Pb levels, poorer housing conditions, higher exposures to mouse and cockroach allergen, and with conditions such as asthma and allergy. Jedrychowski et al. (2011) found similar magnitudes of association between cord blood Pb level and cord blood IgE in models that did and did not adjust for potential confounding variables, including maternal education. Studies examining cognitive effects in children also found that associations with blood Pb levels with and without adjustment for SES-related variables (Section 5.3). Pugh Smith et al. (2011) and Jedrychowski et al. (2011) also indicated lack of confounding by allergen exposures and other indicators of housing condition by their inclusion as model covariates or analysis of their independent associations with outcomes. The robust association between blood Pb level and allergic sensitization (which indicates elevated allergen-specific IgE) observed in Jedrychowski et al. (2011), provides support for the associations observed between blood Pb and IgE, in children, in which confounding by SES and allergen was not considered. Collectively, these findings do not indicate that confounding by SES or allergen exposure alone accounts for associations observed between blood Pb levels and immune effects in children. This evidence for associations of blood Pb level with clinical conditions such as asthma, allergic sensitization, and allergic diseases in children expanded by results from recent studies also supports the public health significance for Pb-associated immune effects.

With respect to lifestages of Pb exposure, animal studies found that gestational Pb exposures, encompassing a wide range of concentrations, affected endpoints such as IgE, cytokine levels, and DTH but also found postnatal short-term (multiple days) long-term (multiple weeks) Pb exposures to affect cytokine levels in adult animals. The blood Pb levels and Pb exposure lifestage, magnitude, frequency, and duration associated with immune effects are not well characterized in humans. Several epidemiologic studies examined associations (of IgE, asthma, and allergy) with concurrent blood Pb levels of children > 10 µg/dL. A few studies found cord blood or newborn hair Pb levels to be associated with endpoints such as Ig levels (Annesi-Maesano et al., 2003; Belles-Isles et al., 2002) and allergic sensitization (Jedrychowski et al., 2011). The small body of epidemiologic studies of nonoccupationally-exposed adults examined different endpoints and found associations with concurrent blood Pb levels, which are influenced by current Pb exposures as well as cumulative Pb stores in bone.

In summary, recent toxicological and epidemiologic studies support the strong body of evidence presented in the 2006 Pb AQCD that Pb exposure is associated with a broad spectrum of changes in both cell-mediated and humoral immunity that cumulatively promote a Th2 phenotype and hyperinflammatory state. The principal findings are Pb-induced increased production of Th2 cytokines, suppressed production of Th1 cytokines, increased inflammation, and elevated IgE, with the weight of evidence provided by toxicological studies. Collectively, these findings are coherent with the observed effects of Pb exposure on decreasing responses to antigens (e.g., DTH, bacterial resistance) in animals. Both toxicological and epidemiologic studies in children provide evidence for Pb-associated increases in IgE. The toxicological and epidemiologic findings for Th2 cytokines, IgE, and inflammation provide biological plausibility for associations observed for blood Pb levels with asthma and allergic conditions in children. Associations with asthma and allergy were observed after considering potential confounding by several factors, including, SES and allergen exposure. Animal studies found a range of immune effects with prenatal exposure in juvenile animals and long-term postnatal (> 4 weeks) Pb exposures in adult animals. The blood Pb levels and Pb exposure lifestage, magnitude, frequency, and duration associated with immune effects are not well characterized in children or adults. Epidemiologic studies of children and adults primarily examined concurrent blood Pb levels. Little information was provided on concentration-response functions. In epidemiologic studies, higher IgE and higher asthma prevalence were examined and found in children with blood Pb levels > 10 µg/dL. In the large body of studies of adults (mostly males) with occupational Pb exposures, the most consistent findings were decreased neutrophil functionality in workers with mean blood Pb levels 21-71 µg/dL. Recent epidemiologic studies provided new evidence in adults without occupational Pb exposures; however, each examined a different immune endpoint, for example, IgE, eNO, IL-6. These endpoints were associated with concurrent

blood Pb levels in populations of adults with mean blood Pb levels of 1.9-7 µg/dL; however, there is uncertainty regarding the contributions of current Pb exposures and cumulative Pb stores in bone. The consistency and coherence of findings across the continuum of related immune parameters that demonstrate a stimulation of Th2 responses in toxicological studies combined with the supporting epidemiologic evidence in children are sufficient to conclude that there is a causal relationship between Pb exposures and immune system effects.

5.7 Effects on Heme Synthesis and Red Blood Cell Function

5.7.1 Summary of Findings from 2006 Pb AQCD

The 2006 Pb AQCD reported that Pb affects developing red blood cells (RBCs) in children and occupationally exposed adults as noted by anemia observed with blood Pb > 40 µg/dL. Pb-induced anemia is thought to occur due to decreased RBC life span and effects on hemoglobin (Hb) synthesis. The exact mechanism for these effects was not known, although Pb-induced changes on iron uptake or inhibition of enzymes in the heme synthetic pathway may be responsible.

The 2006 Pb AQCD indicated that Pb crosses RBC membranes through passive (i.e., energy-independent) carrier-mediated mechanisms including a vanadate-sensitive Ca^{2+} pump. Once Pb enters the cells, it is predominantly found in protein-bound form, with Hb and aminolevulinic acid dehydratase (ALAD) both identified as targets. Pb poisoning (blood Pb levels > 100 µg/dL) was found to decrease RBC survival in laboratory animals, as well as alter RBC mobility and morphology, although the precise mechanisms by which it does so are not known. Pb exposure has been found to significantly decrease several hematological parameters including Hb, hematocrit (Hct), mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC). Pb has also been observed to exert multiple effects on RBC membranes, including altered microviscosity and fluidity, decreased sialic acid content, decreased lamellar organization, decreased lipid resistance to oxidation (possibly mediated by perturbations in RBC membrane lipid profiles), and increased permeability. These alterations to RBC membranes potentially lead to RBC fragility, abnormal cellular function, RBC destruction, and ultimately anemic conditions. Pb exposure also has been shown to result in increased activation of RBC scramblase, an enzyme responsible for the expression of phosphotidylserine (PS) on RBC membranes. This expression of PS decreases the life span of RBCs via phagocytosis by macrophages. Pb exposure has been observed to alter the phosphorylation profiles of membrane

proteins, which may influence the activity of membrane enzymes and the functioning of receptors and channels located on the membrane.

The 2006 Pb AQCD reported that Pb affects heme synthesis through the inhibition of multiple key enzymes, most notably ALAD, the enzyme that catalyzes the second, rate-limiting step in heme biosynthesis (Figure 5-45 presents a schematic representation of the heme biosynthetic pathway). The 2006 Pb AQCD further reported that decreased RBC ALAD activity is the most sensitive measure of human Pb exposure, in that measurement of ALAD activity is correlated with blood Pb levels. Concentration-response changes in the ratio of activated/nonactivated ALAD activity in avian RBCs was observed to be not dependent on the method of Pb administration. The inhibition of the ALAD enzyme was observed in RBCs from multiple species, including birds, Cynomolgous monkeys, and humans. Pb was also observed to inhibit other enzymes responsible for heme biosynthesis, including ferrochelatase, porphobilinogen (PBG) deaminase, and coproporphyrinogen oxidase. Pb also potentially alters heme biosynthesis through inhibition of transferrin (TF) endocytosis and iron transport.

Pb has been found to alter RBC energy metabolism through inhibition of enzymes involved in anaerobic glycolysis and the pentose phosphate pathway. Pb was also found to inhibit pyrimidine 5'-nucleotidase (P5N) activity and the 2006 Pb AQCD indicated that this might be another possible biomarker of Pb exposure. Inhibition of P5N results in an intracellular increase in pyrimidine nucleotides leading to hemolysis and potentially ultimately resulting in anemic conditions. The 2006 Pb AQCD indicated that perturbations in RBC energy metabolism may be related to significant decreases in levels of nucleotide pools, including nicotinamide adenine nucleotide (NAD), possibly due to decreased NAD synthase activity, and nicotinamide adenine nucleotide phosphate (NADP) accompanying significant increases in purine degradation products.

Pb was found to alter the activity of membrane-bound ion pumps. Potassium (K^+) permeability was found to be increased by Pb due to altered sensitivity of the membrane calcium (Ca^{2+})-binding site that caused selective efflux of K^+ ions from the RBC membrane. Inhibition of RBC sodium (Na^+)-K^+ adenosine triphosphate synthase (ATPase), acetylcholinesterase (ACh), and NADH dehydrogenase was also observed. In human RBCs, Na^+-K^+ ATPase activity was more sensitive to Pb exposure than were Ca^{2+} or magnesium (Mg^{2+}) ATPases.

The 2006 Pb AQCD identified oxidative stress as an important potential mechanism of action by which Pb exposure induced effects on RBCs. Increased lipid peroxidation and inhibition of antioxidant enzymes (e.g., superoxide dismutase [SOD], catalase [CAT]) were observed following exposure to Pb.

5.7.2 Red Blood Cell Functions

As stated in the 2006 Pb AQCD, Pb poisoning has been associated with anemia resulting from shortened RBC life span and Pb effects on Hb synthesis. As of 2006, the mechanism for this was not clear, but it was determined not to be due to iron deficiency, which can be found to occur independently of Pb exposure. However, Zimmerman et al. (2006) found that blood Pb levels were statistically significantly lower in non- or mildly anemic, iron-deficient 5- to 9-year old children in India fed an iron-fortified diet for 30 weeks compared to 14 weeks (mean [range]: 8.1 [3.1-219] µg/dL versus 12.1 [3.7-26.8] µg/dL; $p < 0.02$); blood Pb levels were not lower in children receiving the no iron diet for 30 weeks compared to 14 weeks (mean [range]: 10.2 [4.4-25.3] µg/dL versus 12.0 [3.8-25.5] µg/dL). Although a number of epidemiologic studies find decreases in RBCs and/or Hct levels associated with blood Pb, it is not known whether this is due to reduced cell survival or a decrease in RBC cell production. However, decreased RBC survival and hematopoiesis can be expected to occur simultaneously, and any effect on RBC numbers is likely a combination of the two modes of action.

5.7.2.1 Pb Uptake, Binding, and Transport into Red Blood Cells

The 2006 Pb AQCD reported that Pb uptake into human RBCs occurs via passive anion transport mechanisms. Although Pb can passively cross the membrane in both directions, little of the Pb is found to leave the cell after entry. Simons (1993b) found that in vitro uptake of ^{203}Pb (1-10 µM) occurred via an anion exchanger while the efflux occurred via a vanadate-sensitive pathway. After entry into the RBC, radioactive Pb was found to partition with Hb at a ratio estimated to be about 6000:1 bound to unbound (Simons, 1986). However, Bergdahl et al. (1997a) suggested that ALAD was the primary Pb binding protein and not Hb. The 2006 Pb AQCD also reported that the majority (approximately 98%) of Pb accumulates in RBC cytoplasm bound to protein and only about 2% is found in the membrane. This is related to the high ratio of Pb in RBCs compared to plasma Pb. Further information on Pb binding and transport in blood can be found in the kinetics section of 0 (Section 4.2).

Although no studies were indentified that examined transport of Pb into RBCs, Lind et al. (2009) recently observed that several zinc (Zn) ionophores (8-hydroxyquinoline derivatives and Zn and Na pyrithione) were able to effectively transport Pb out of RBCs into the extracellular space.

5.7.2.2 Red Blood Cell Survival, Mobility, and Membrane Integrity

Although Pb exposure has been consistently shown to shorten the RBC life span and alter RBC mobility, as of the 2006 Pb AQCD the mechanism of this was not well understood. While the mechanism is still not fully understood, there has been some indication for a role of free Ca^{2+}. There are also newer studies that examine the relationship between Pb and RBC survival, mobility, and membrane integrity. Occupational studies investigating severely Pb-intoxicated worker populations (mean blood Pb > 28 µg/dL) observed increased intracellular RBC free calcium levels ($[Ca^{2+}]_i$) and decreased RBC membrane Ca^{2+}-Mg^{2+}-ATPase activity in workers compared with unexposed controls (Abam et al., 2008; Quintanar-Escorza et al., 2007). $[Ca^{2+}]_i$ levels were highly correlated with blood Pb levels even among unexposed control populations with blood Pb levels < 10 µg/dL (mean 9.9 ± 2 µg/dL) (Quintanar-Escorza et al., 2007). Changes in $[Ca^{2+}]_i$ were associated with increased fragility of the RBCs and dramatic morphological alterations, including the increased presence of echinocytes (cells without normal biconcave shape) and crenocytes (speculated cells) in Pb-exposed workers.

Similar to the associations observed in Quintanar-Escorza et al. (2007), concentration-dependent effects were observed when RBCs from healthy human volunteers were incubated in vitro with Pb nitrate at physiologically-relevant concentrations. $[Ca^{2+}]_i$ increased in a concentration-dependent manner when RBCs were exposed to 0.2 or 0.4 µM Pb nitrate for 24 or 120 hours (0.4 µM Pb nitrate roughly approximates 10 µg/dL Pb, although concentrations in exposure media are not directly comparable to blood Pb levels) (Quintanar-Escorza et al., 2010). $[Ca^{2+}]_i$ levels were further increased at higher, less physiologically-relevant concentrations (i.e., 2-6 µM Pb nitrate). The increase in $[Ca^{2+}]_i$ levels was observed to be related to increased Ca^{2+} influx: RBCs exposed to 0.4 µM Pb nitrate for 24 hours incorporated twice as much Ca^{2+} as controls did, whereas exposure for 120 hours resulted in a fourfold increase. Concomitant to increased influx of Ca^{2+}, efflux of Ca^{2+} was observed due to reduced Ca^{2+}-Mg^{2+} ATPase activity; exposure to 0.4 µM Pb nitrate for 24 or 120 hours reduced activity by 33% and 83%, respectively, compared to controls. As was observed among severely Pb-intoxicated workers, changes in $[Ca^{2+}]_i$ were associated with increased fragility of the RBCs (measured as increased hemolysis) and dramatic morphological alterations, including the increased presence of echinocytes (cells without normal biconcave shape) and crenocytes (speculated cells) following exposure to 0.4 µM Pb nitrate. Similarly, Ciubar et al. (2007) found that RBC morphology was disrupted, with ≥ 50% RBCs having lost the typical discocytic morphology and displaying moderate to severe echinocytosis following exposure to Pb nitrate concentrations of 0.5 µM or higher for 24 hours at 37 °C. Exposure of RBCs to higher concentrations (concentrations not stated) of Pb nitrate resulted in cell shrinkage. Ademuyiwa et al. (2009) observed that the cholesterol content of RBC plasma

membranes, but not the phospholipid content, was statistically significantly higher in rats exposed to 200 ppm Pb-acetate (resulting in mean [SD] blood Pb: 40.63 [9.21] µg/dL) for three months through drinking water compared to controls. Further, the cholesterol/phospholipid ratio was increased in the Pb-exposed rats with increased cholesterol, indicating that RBC membrane fluidity was decreased.

A number of studies have investigated the effect of occupational exposure to Pb on various inter-connected and related hematological parameters. Most occupationally-exposed cohorts represent populations highly exposed to Pb, with mean blood Pb levels ranging from 26-74 µg/dL. Although effects observed within these cohorts may not be generalizable to the population as a whole, they are useful in demonstrating consistent effects on a number of hematological parameters, including Hb, MCV, MCH, MCHC, total RBCs, and packed cell volume (PCV) (Khan et al., 2008; Patil et al., 2006a; Patil et al., 2006b; Karita et al., 2005). Additionally, these studies were cross-sectional in design; thus, there is uncertainty regarding the magnitude, timing, frequency, and duration of Pb exposure that contributed to the observed observations. Workers occupationally exposed to Pb may also have been co-exposed to other contaminants than can affect the hematological system although the potential for co-exposure was not assessed in most studies. A few occupational studies did investigate the effect of moderate occupational Pb exposure on hematological parameters. Ukaejiofo et al. (2009) studied the hematological effects of Pb in 81 male subjects moderately exposed to Pb at three different manufacturing companies in Nigeria for durations between six months and 20 years. Two control groups were used for comparison (30 individuals from the same industries not involved in handling Pb and 20 individuals from the same locality but not involved in Pb handling). The exposed individuals had a mean blood Pb level of 7.00 µg/dL compared to 3 µg/dL in controls drawn from industries not involved in Pb handling (control group I) and 2 µg/dL in controls drawn from the general population (control group II) ($p < 0.05$). Pb-exposed workers had significantly reduced Hb and PCV levels and increased percentage of reticulocytes. Although the differences were statistically significant between the exposed and control subjects, the study authors state that the levels in the exposed subjects were at the lower range of normal for Nigerians. The percent cell lysis did not differ between controls and exposed workers; however, when workers and controls were stratified by age, there was a significant increase in cell lysis in workers under age 30 compared to similarly aged controls in group II ($p < 0.01$). Conterato et al. (In Press) investigated hematological parameters in automotive painters exposed to Pb in Brazil. Exposed painters had a mean [SEM] blood Pb concentration of 5.4 [0.4] µg/dL compared to 1.5 [0.1] µg/dL in controls. The mean [SEM] duration of exposure to Pb in painters was 133.9 [14.5] months, whereas the controls were not occupationally exposed to Pb. Although hematocrit, hemoglobin concentration, and the number of RBCs were statistically significantly decreased in painters compared to controls, they were not

correlated with blood Pb levels. These parameters were correlated with blood Cd levels which were also statistically significantly elevated in painters compared to controls (mean [SEM]: 1.606 [0.074] versus 0.003 [0.001] µg/dL). MCHC and RBC distribution width (a measure of the variability of RBC widths) were correlated ($r = 0.23$ and 0.44, respectively; $p < 0.05$) with blood Pb although these measures were not statistically different in painters compared to controls. In an investigation of petrol workers in Sarajevo, Yugoslavia, examinations on hematological parameters were performed on the same population five years apart, in 2003 and 2008. Workers (mean [SD] duration of exposure: 12.1 [9.1] years) had increased blood Pb (mean: 5.96 µg/dL) in 2008 compared to 2003 (mean: 4.07 µg/dL; mean [SD] duration of exposure: 10.4 [5.5]) (Cabaravdic et al., 2010). In 2008, levels of MCH and MCHC were significantly decreased from levels in 2003, whereas RBC numbers, Hb, Hct, and MCV were elevated. Positive correlations were observed in all subjects between blood Pb and RBC count, Hb, and MCH ($r = 0.241$, 0.201, and 0.213, respectively; $p < 0.05$). Taken together, the above occupational studies provide consistent evidence that very high (blood Pb > 26 µg/dL) and moderate (blood Pb ~ 5.5-7.0 µg/dL) occupational exposure to Pb reduces the number of RBCs in circulation. Although this decrease in RBCs observed in highly exposed worker cohorts may be explained by both decreased cell survival and/or disruption of hematopoiesis, the observation of increased reticulocytes in Ukaejiofo et al. (2009) seems to represent compensation for decreased RBC survival due to Pb exposure. In a non-occupational study, the associations between blood Pb levels, calcium, iron, and hemoglobin were investigated in 55 pregnant Brazilian women (21.9% 14-19 years old, 74.5% 20-34 years olds, and 3.6% ≥ 35 years old) (Zentner et al., 2008). The majority of women (across all age groups) had concurrent blood Pb levels below 5 µg/dL (58.2%), although the mean blood Pb level was not reported; only 5.4% of women had blood Pb levels above 10 µg/dL. The vast majority of women (78.2%) were also observed to have adequate levels of hemoglobin (≥ 11 g/dL). In a multiple linear regression model, blood Pb was observed to be negatively correlated with hemoglobin ($\beta = -0.359$ g/dL).

Studies in children were generally supportive of effects on hematological parameters (e.g., Hb, MCV, MCH) observed in occupational adult populations. In two cross-sectional studies of children measuring blood hemoglobin as the independent variable, blood Pb levels were observed to decrease with increasing blood Hb. Riddell et al. (2007) found that 21% of children 6 months to 5 years of age living in rural Philippines had concurrent blood Pb levels greater than 10 µg/dL (total population mean: 6.9 µg/dL). Hb levels were inversely related to blood Pb, with a decrease of 3% blood Pb associated with every 1 g/dL increase in Hb. Similarly, in children aged 6-36 months (n = 222) living in Montevideo, Uruguay, 32.9% of children had blood Pb greater than 10 µg/dL (population mean [SD]: 9.0 [6.0] µg/dL) (Queirolo et al., 2010). The mean [SD] Hb concentration was 10.5 [1.5] g/dL, and 44.1% of children were diagnosed as anemic (Hb < 10.5 g/dL).

Blood Pb levels were higher in anemic children compared to non-anemic (mean [SD]: 10.4 [6.8] versus 7.9 [5.1] µg/dL), and in bivariate regression models, blood Pb decreased 0.65 µg/dL for every 1 g/dL increase in Hb. In children younger than 18 months of age, blood Pb was, on average, 3.5 ± 1.1 µg/dL higher in anemic children. In children aged 5-9 years (n = 189) living in Cartegena, Columbia, a smaller percentage (4.7%) of children had blood Pb > 10 µg/dL (mean [SD]: 5.49 [0.23] µg/dL). The only hematological parameters that fell outside of their reference values were MCV and MCH, which were negatively correlated with blood Pb (r = -0.159 [p = 0.029] and -0.171 [p = 0.019], respectively) (Olivero-Verbel et al., 2007). RBC count, which was not observed to differ from reference values, was positively correlated with blood Pb level (r = 0.208, p = 0.004). Ahamed et al. (2006) studied 39 male urban adolescents in India who were separated into groups according to their blood Pb level (group 1: <10 µg/dL [mean 7.4 µg/dL], group 2: >10 µg/dL [mean 13.27 µg/dL]). Although the groups were similar in age (mean [SD]: 16.59 [0.91] versus 16.76 [0.90] years, respectively), height, weight, and body mass index, group 2 had a significantly lower PCV compared to group 1. In a related study, Ahamed et al. (2007) investigated the relationship between blood Pb, anemia, and other hematological parameters in urban children in India (n = 75). Children were split into two groups as above: group 1 had blood Pb <10 µg/dL (mean [SD]: 6.89 [2.44] µg/dL, n = 19), whereas group 2 had blood Pb >10 µg/dL (mean [SD]: 21.86 [7.58] µg/dL, n = 56). As with the earlier study, ages were similar between the two groups: mean [SD]: 4.68 [1.49] and 4.11 [1.77] years, respectively. Hb and Hct were significantly decreased in group 2, compared to group 1, and children in group 2 had an increased odds of anemia (OR: 2.87 [95% CI: 1.60, 2.87]) compared to group 1 after adjustment for age, sex, and area of residence. Similarly, in a study of 340 children (aged 1-5 years) from Karachi, Pakistan, mildly and severely anemic children (mean [SD] Hb levels: 8.9 [0.9] and 7.4 [0.5] g/dL, respectively) had higher blood Pb levels compared to non-anemic children (mean [SD] Hb: 12.1 [1.3] g/dL). Mean [SD] blood Pb levels in the mildly anemic, severely anemic, and nonanemic children were 14.9 [0.81], 21.4 [2.7], and 7.9 [1.7] µg/dL, respectively (p < 0.01) (Shah et al., 2010). Additionally, Hct, RBC count, and MCV were all decreased in anemic children versus non-anemic children. Although statistical analyses were not reported, the levels of Hb, Hct, RBC count, and MCV in anemic children all fell outside of the reported normal range for these parameters, whereas the reported values in non-anemic children did not. Blood Pb was negatively correlated with Hb level in all groups, with the magnitude of negative correlation increasing with increasing severity of anemia: r = -0.315 (non-anemic children), -0.514 (mild anemia), and -0.685 (severe anemia). In iron-deficient anemic children (n = 23) from Denizli, Turkey, mean (SD) serum Pb levels were statistically increased compared to healthy children (n = 179): 0.013 (0.004) versus 0.008 (0.001) µg/dL, respectively (Turgut et al., 2007). The iron-deficient children were

observed to have decreased Hb, MCV, and ferritin compared to controls, but increased RBC and RDW. In 140 children from southern Brazil aged 2-11 years, living within 25 km of a Pb smelter, blood Pb levels were not observed to differ between anemic and non-anemic children (mean [SD]: 10.36 [6.8] versus 9.73 [5.8] µg/dL, p = 0.98) (Rondo et al., 2006). However, blood Pb levels were significantly negatively correlated with Hb in anemic children (r = -0.41, p = 0.01); this relationship was not observed in non-anemic children (r = 0.018, p = 0.84).

Contrary to the observations in the above studies, Huo et al. (2007) found that children (less than 6 years of age) living near an area where electronic waste was recycled in China had significantly higher mean blood Pb levels than did children in the neighboring town with no waste recycling (15.3 versus 9.94 µg/dL). No difference was detected in the mean Hb levels of the children in the two towns (127.55 g/L in children from the waste recycling town versus 123.46 g/L in children from the town with no recycling). Equivocal findings in studies investigating associations of blood Pb levels with hematological effects in children may be due to the comparatively shorter time period and magnitude of exposure versus those seen in occupational studies.

A number of animal toxicology studies support associations of blood Pb levels with hematological parameters observed in epidemiologic studies. Baranowska-Bosiacka et al. (2009) examined the effects of Pb on RBC hemolysis both in vitro measuring lysate in human RBCs incubated with Pb at concentrations ranging from 0.1–100 µM for 5–30 minutes, and in vivo using a rat RBC lysate from rats exposed to Pb-acetate (0.1 %) in drinking water for 9 months. Rats exposed to Pb in the in vivo portion of the study achieved a blood Pb concentration of 7.1 µg/dL. The concentration of Hb in the plasma of chronically-exposed rats, a marker of RBC hemolysis, was statistically significantly (p = 0.01) increased compared to that in control rats. The in vitro studies demonstrated a similar concentration-dependent increase in the amount of hemolysis, with a significant (fourfold) increase even at the lowest concentration tested (i.e., 0.1 µM). Pb-induced hemolysis in these experiments may be due to inhibition of RBC phosphoribosyltransferases (Section 5.7.5.1). Lee et al. (2005) observed that rats orally administered Pb (25 mg/kg) via gavage once a week for 4 weeks had an average plasma Pb level of 6.5 µg/dL (9.6-fold higher than that in controls, p < 0.05), and had significant decreases in Hct, Hb, and RBCs (p < 0.05). Male mice orally administered 50 mg/kg Pb nitrate in distilled water via gavage for 40 days had mean [SD] final blood Pb levels of 1.72 [0.02] µg/dL versus 0.09 [0.011] µg/dL in control mice. Pb-exposed mice had significantly reduced total RBC counts, total leukocyte counts, Hb, lymphocytes, and monocytes compared to controls (p < 0.001) (Sharma et al., 2010b). Rats exposed to 2 g/L Pb-acetate in drinking water for 30 days (blood Pb not reported) had significantly decreased RBCs, Hb, PCV, MCH, and MCHC compared to controls (p < 0.05) (Simsek

et al., 2009), and not a disruption of hematopoiesis. Mice exposed to 1 g/L Pb-acetate in drinking water (blood Pb not reported) for 90 days, but not those exposed for 15 or 45 days`, had significantly decreased RBC counts and Hct compared to controls ($p < 0.05$) (Marques et al., 2006). Spleen weights were observed to be increased relative to body weight in animals exposed to Pb for 45 days. Mice injected daily with 50 mg/kg Pb-acetate subcutaneously (blood Pb not reported) had significantly reduced Hb, MCV, MCH, and MCHC compared to controls injected with 5% dextrose (Wang et al.). In weanling rats (age = 25 days, n = 10) whose dams were exposed to 2.84 mg/mL Pb-acetate (approximating mean [SD] daily exposures of 342.57 [28.11] and 744.47 [29.27] mg/kg during gestation and lactation, respectively), blood Pb was significantly elevated compared to controls (mean [SE]: 698.1 [78.2] versus 5.4 [0.8] ng/g). The only hematological parameter affected by Pb exposure was Hct, which was decreased in exposed rats (mean [SE]: 27.3 [0.5] versus 33.4 [0.3] percent) (Molina et al., 2011).

Some toxicological studies found no evidence of hematological effects in animals following exposure to Pb. Male rats administered Pb-acetate in the drinking water for 4 weeks at concentrations ranging from 100–1,000 ppm had a concentration-dependent increase in blood Pb (range: 6.57–22.39 µg/dL) compared to controls (0.36 µg/dL), but there were no significant changes in any of the hematological parameters (complete blood cell count performed) measured at the end of treatment (Lee et al., 2006b). Slight, statistically nonsignificant increases in PS expression on RBC membranes were also observed. Similarly, exposure of male rats to 0.5% Pb nitrate in drinking water (blood Pb not reported) for three weeks had no affect on any measured hematological parameter (Gautam and Flora, 2010). In vitro experiments with rat and human blood did not demonstrate a significant increase in hemolysis after 4 hours of treatment with Pb-acetate at concentrations up to 10 µM.

Khaĭrullina et al. (2008) observed that the surface profiles of RBC membrane shadows incubated with 0.5-10 µM Pb-acetate for three hours were much smoother than were untreated RBC membranes when examined by atomic force microscopy. The authors postulate that the observed smoothing in Pb-treated RBC membranes may be due to clusterization of band 3 protein. Band 3 (anion exchanger 1 [AE1]), is a chloride/bicarbonate (Cl^-/HCO_3^-) exchanger and is the most abundant protein in RBC membranes. AE1 is integral in carbon dioxide (CO_2) transport and linkage of the cellular membrane to the underlying cytoskeleton (Akel et al., 2007; Su et al., 2007). The observed smoothing of the RBC membrane may due to Pb interfering with how the membrane attaches to the cytoskeletal structure of the RBC through perturbation of the normal activity of AE1.

Eryptosis

Eryptosis is the suicidal death of RBCs. It is characterized by cell shrinkage, membrane blebbing, and cell membrane phospholipid scrambling associated with PS exposure on the cell membrane that leads to cell destruction via macrophages (Föller et al., 2008; Lang et al., 2008). As previously reported in the 2006 Pb AQCD, Kempe et al. (2005) found that exposing human RBCs to Pb at concentrations ranging from 0.3–3 µM caused increased activation of K^+ channels that led to cell shrinkage and scramblase activation. The activation of scramblase increased the exposure to PS on the cell membrane, which causes an increase in the destruction of the RBCs by macrophages.

Shin et al. (2007) found that in vitro exposure of human RBCs to 1–5 µM Pb-acetate increased PS expression in a time- and concentration-dependent manner. The maximum mean [SE] increase in expression of PS was 26.8 ± 3.15% (compared to deionized water), observed after incubation with 5 µM Pb for four hours. The expression of PS in RBCs is considered to be regulated through a Ca^{2+} dependent mechanism and, correspondingly, $[Ca^{2+}]_i$ was observed to increase with exposure to Pb (mean [SE]: 0.24 [0.21] µM in controls to 6.88 [1.13] µM in RBCs treated with 5 µM Pb for one hour). Consistent with this finding, Shin et al. (2007) also observed that scramblase activity, which is important for induction of PS exposure and is activated by $[Ca^{2+}]_i$, was increased in Pb-exposed RBCs. Flippase, which translates PS exposure to inner membranes, is inhibited by high levels of $[Ca^{2+}]_i$ and was observed to exhibit reduced activity following Pb exposure. The inhibition of flippase is additionally influenced by the depletion of cellular adenosine triphosphate (ATP). ATP levels were decreased in a concentration-dependent manner following exposure to Pb. To corroborate these findings in vivo, Shin et al. (2007) treated male rats i.p. to 25, 50, or 100 mg/kg Pb-acetate (blood Pb not reported). Expression of PS was observed to increase in a concentration-dependent manner at concentrations ≥ 50 mg/kg, confirming the in vitro results. No hemolysis or microvesicle formation was observed in the in vitro and in vivo experiments. In a follow-up study, the same lab observed that exposure of human RBCs to low concentrations of Pb-acetate (0.1-0.5 µM) induced PS expression. Most notably, exposure to 0.1 µM Pb for 24 hours increased PS expression on RBC membranes by approximately 20% (Jang et al., 2011). Accompanying the expression of PS were abnormal, echinocytic RBCs following incubation with Pb. Unlike the above study, incubation with low concentrations of Pb (0.1 µM) induced the generation of microvesicles, which also expressed PS on their membranes. Flippase was inhibited by 0.1 µM Pb following incubation for one hour, but scramblase activity was not changed at any Pb exposure concentration. The intracellular concentration of ATP was decreased at Pb concentrations 0.25 µM and greater, but $[Ca^{2+}]_i$ did not increase following exposure. This decrease in ATP levels, but lack of affect on $[Ca^{2+}]_i$ may explain why flippase activity, but not scramblase, was altered

following Pb incubation. At 0.5 µM, Pb-exposed RBCs with externalized PS were observed to be targeted and engulfed by differentiated macrophages. Similar in vitro effects were observed in rat erythrocytes, although higher concentrations were generally required. PS expression on rat erythrocytes was observed ex vivo in rats exposed to 10 or 50 mg/kg Pb. To corroborate these in vitro and ex vivo findings, rats were exposed to 0, 50, 250, or 1,000 ppm Pb-acetate in drinking water for 4 weeks. At 100 ppm, Hb and Hct were significantly decreased relative to control, and liver and spleen weights were increased. At doses greater than 50 ppm, iron accumulation was observed in the spleen, a clear sign of increased RBC clearance via phagocytosis.

Ciubar et al. (2007) also found that exposure to Pb nitrate (0.5–2 µM) resulted in an increase in PS exposure to RBCs and cell shrinkage, which authors stated were indicators of cell apoptosis. As reported above, Khaĭrullina et al. (2008) observed Pb-induced RBC membrane smoothing that may be due to alterations in AE1 activity. Disruptions in AE1 activity may also result in enhanced PS exposure and premature cell death. Akel et al. (2007) observed that in $AE1^{-/-}$ knockout mice, Pb-induced PS exposure was much greater than that in wild type mice. Decreased RBCs and increased reticulocytes were also observed, an indication of high cell turnover.

5.7.2.3 Red Blood Cell Hematopoiesis

Erythropoietin is a glycoprotein hormone excreted by the kidney to promote the development of RBCs in the bone marrow. Sakata et al. (2007) examined the relationship between blood Pb level and serum erythropoietin levels in Pb-exposed nonanemic tricycle taxi drivers (n=27) working in Kathmandu, Nepal (mean [SD] age: 5.6 [2.6] years). The average blood Pb level in the taxi drivers was 6.4 µg/dL compared to 2.4 µg/dL in nondrivers. Drivers had a significantly lower mean level of serum erythropoietin (12.7 versus 18.8 mU/mL) compared to the nondrivers and there was an inverse relationship between the level of serum erythropoietin and blood Pb ($r = -0.68$, $p < 0.001$). Blood Pb level was not associated with any other hematological effects. The Sakata et al. (2007) study demonstrated that serum erythropoietin levels are affected by Pb even at levels low enough not to cause anemia. While decreased erythropoietin is generally considered a measure of kidney toxicity, it can also indicate that Pb could possibly affect the level of RBCs through decreasing levels of serum erythropoietin.

Celik et al. (2005) observed that exposure of female rats to 140, 250, or 500 mg/kg Pb-acetate via gavage once per week for 10 weeks (blood Pb not reported) resulted in decreased numbers of polychromatic RBCs (PCE) and increased numbers of micronucleated PCEs, compared to controls ($p < 0.001$). Alghazal et al. (2008b) exposed

male and female rats to 100 mg/L Pb-acetate daily in drinking water for 125 days (blood Pb not reported) and observed increases in micronucleated PCEs in female rats ($p = 0.02$) but no significant reduction in the ratio of PCEs to normochromic RBCs (NCE). In male rats, an increase in micronucleated PCEs was observed ($p < 0.001$) along with a decrease in the PCE/NCE ratio ($p = 0.02$). While the results from Alghazal et al. (2008b) indicate that Pb is cytotoxic in male rats only, but is genotoxic in both sexes, results from Celik et al. (2005) indicate that Pb is cytotoxic in female rats as well. Mice exposed to 1 g/L Pb-acetate in drinking water for 90 days (blood Pb not reported) had statistically significant increases in micronucleated PCEs; a small, but statistically nonsignificant decrease in the PCE/NCE ratio was also observed (Marques et al., 2006). Cyto- and geno-toxicity in RBC precursor cells are strong indications of altered hematopoiesis in bone marrow.

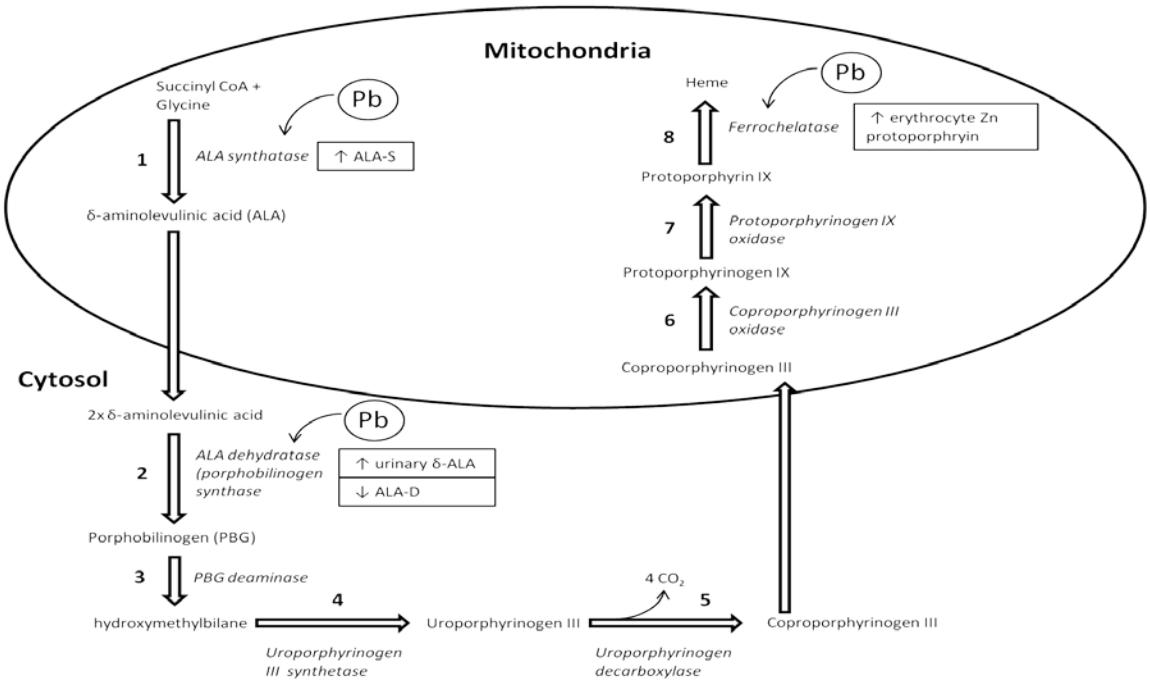
5.7.2.4 Membrane Proteins

There have been few studies examining the effects of Pb on membrane proteins since the 2006 Pb AQCD. According to the 2006 Pb AQCD, Pb has been found to affect RBC membrane polypeptides in exposed workers (Apostoli et al., 1988; Fukumoto et al., 1983). In Pb-exposed workers, Fukumoto et al. (1983) found decreased levels of polypeptides in band 3, which Apostoli et al. (1988) suggested may represent an anion channel protein, and increases in the level of polypeptides in bands 2, 4, 6, and 7. Fukumoto et al. (1983) suggested that the changes in the RBC membrane polypeptides may cause changes in membrane permeability. Apostoli et al. (1988) found that the changes in membrane polypeptides in association with blood Pb levels greater than 50 µg/dL. Exposure to Pb-acetate at concentrations above 0.1 µM for 60 minutes has also been found to increase the phosphorylation of proteins in human RBC membranes in vitro (Belloni-Olivi et al., 1996). Phosphorylation did not occur in cells depleted of protein kinase C (PKC), indicating a PKC-dependent mechanism.

Huel et al. (2008) found that newborn hair and cord blood Pb levels (mean [SD]: 1.22 [1.41] µg/g and 3.54 [1.72] µg/dL) were negatively associated with Ca-ATPase activity in plasma membranes of RBCs isolated from cord blood; newborn hair Pb levels were more strongly associated with cord Ca pump activity than were cord blood Pb ($p < 0.0001$ versus $p < 0.05$). Maternal blood Pb levels were not correlated with Ca pump activity in maternal or cord blood. Pb-induced disruptions in Ca homeostasis in RBCs can lead to cytotoxicity and necrosis, and these effects may be representative of cellular dysfunction in other organ systems.

5.7.3 Red Blood Cell Heme Metabolism

Pb has been found to inhibit several enzymes involved in heme synthesis, namely ALAD (cytoplasmic enzyme catalyzing the second, rate-limiting, step of the heme biosynthesis pathway), coporphyrinogen oxidase (catalyses the sixth step in heme biosynthesis converting coporphyrinogen III into protoporphyrinogen IX), and ferrochelatase (catalyses the terminal step in heme synthesis converting protoporphyrin IX into heme) (Figure 5-45). The observations of decreased Hb (measured as total Hb, MCH, or MCHC) in occupationally-exposed adults (Ukaejiofo et al., 2009; Khan et al., 2008; Patil et al., 2006b; Karita et al., 2005) and Pb-exposed experimental animal models (Sharma et al., 2010b; Simsek et al., 2009; Marques et al., 2006; Lee et al., 2005) and associations with blood Pb levels in children (Riddell et al., 2007), is a direct indicator of decreased heme synthesis due to Pb exposure.



Note: Steps in the pathway potentially affected by Pb are indicated with curved arrows pointing to the affected enzyme, and effects are represented by ↑ and ↓ arrows.

Figure 5-45 Schematic representation of the enzymatic steps involved in the heme synthetic pathway.

5.7.3.1 Red Blood Cell 5-Aminolevulinic Acid Dehydratase

Decreases in RBC 5-aminolevulinic acid dehydratase (ALAD) levels are strongly associated with Pb exposure in humans to such an extent that RBC ALAD activity has been used to assess Pb toxicity. Several epidemiologic studies published since the 2006 Pb AQCD evaluated the relationship between Pb exposure, blood Pb levels and ALAD activity in adults and children (see below). These studies were cross-sectional in nature. This limits their utility in assessing the magnitude, timing, frequency, and duration of Pb exposure necessary to contribute to the observed effects.

As was seen with epidemiologic studies investigating Pb-induced deficits in hematological parameters, most occupationally-exposed cohorts investigated ALAD levels in association with high blood Pb levels, i.e., > 27 µg/dL (range: 27.0-74.4 µg/dL). Although effects observed within these cohorts regarding ALAD levels may not be generalizable to the population as a whole, they are useful in demonstrating consistent and negative effects of Pb on the activity of this enzyme (Quintanar-Escorza et al., 2007; Patil et al., 2006a; Patil et al., 2006b; Ademuyiwa et al., 2005b). Occupationally-exposed adults had levels of inhibition of ALAD that were as great as 90% relative to control (Quintanar-Escorza et al., 2007). There were few studies that investigated Pb-associated decrements in ALAD levels among moderately-exposed workers. Painters in India with a mean blood Pb level of 21.92 µg/dL (mean [SD] duration of exposure: 126.08 [49.53] months) had lower ALAD levels ($p < 0.01$) compared to controls whose mean blood Pb level was 3.06 µg/dL (Mohammad et al., 2008). Stoleski et al. (2008) observed that workers in a Pb smelter in Macedonia (mean [SD]: 16.4 [8.5] µg/dL blood Pb; 18.8 [7.5] years employment) had lower ALAD activity ($p < 0.001$) and higher ALA levels ($p < 0.0005$) compared to workers with no exposure to Pb (mean [SD] blood Pb: 7.0 [5.4] µg/dL). In automotive painters exposed to Pb in Brazil (mean [SD]: 5.4 [0.4] µg/dL blood Pb; 133.9 [14.5] months duration of exposure), the ALAD reactivation index was increased over that in controls; ALAD activity did not differ between groups (Conterato et al., In Press). However, ALAD activity was negatively correlated with blood Pb ($r = -0.59$, $p < 0.05$) but not blood Cd, whereas ALAD reactivation index was positively correlated with blood levels of both metals (Pb: $r = 0.84$, $p < 0.05$; Cd: $r = 0.27$, $p < 0.05$). In a benchmark dose (BMD)-based analysis, Murata et al. (2009) calculated the BMD and 95% lower confidence limit of the BMD (BMDL) for decreased ALAD activity in RBCs of exposed Pb workers. The calculated BMD and BMDL values of 2.7 and 2.3 µg/dL, respectively, were substantially lower than the BMDs (28.7-44.2 µg/dL) and BMDLs (19.4-29.6 µg/dL) for decreased Hb, Hct, and RBC count in similarly exposed workers, indicating decreases in ALAD activity can occur at blood Pb levels that do not decrease RBC survival.

Wang et al. (2010f) found that there was also a concentration-dependent decrease in ALAD activity in both children (4-13 years old) and adults (16-77 years old) (mean blood Pb levels: 7.1 and 6.4 µg/dL, respectively) in rural southwest China. Further, Wang et al. (2010f) observed that the relationship between blood Pb and ALAD activity was nonlinear and exponential, with larger decreases in ALAD activity occurring with blood Pb levels greater than 10 µg/dL. No correlation was observed between urinary ALA levels and blood Pb. Ahamed et al. (2006) studied male urban adolescents in India. The 39 adolescents were separated into groups according to their blood Pb levels (group 1: <10 µg/dL [mean 7.4 µg/dL], group 2: >10 µg/dL [mean 13.27 µg/dL]). Although group 1 and 2 were similar in age (mean [SD]: 16.59 [0.91] versus 16.76 [0.90] years, respectively), height, weight, and body mass index, group 2 had lower ALAD activity than did group 1 ($p < 0.001$). When all 39 adolescents were examined together, an inverse relationship was found between blood Pb and ALAD activity. Similar decreases in ALAD activity were observed in other populations of Indian children (aged 4-12 and 1-7 years) with elevated blood Pb (mean [SD]: 11.39 [1.39] and 21.86 [7.58] µg/dL) compared to children with lower blood Pb levels (mean [SD]: 3.93 [0.61] and 6.89 [2.44] µg/dL) (Ahamed et al., 2007; Ahamed et al., 2005). Decreases were also observed in children 3–6 years of age with > 10 µg/dL, compared to children < 10 µg/dL (mean blood Pb concentration for groups not reported) in northeastern China (Jin et al., 2006).

Decreased ALAD activity in response to Pb exposure is also observed in toxicological studies. Rats administered 500 ppm Pb-acetate in drinking water for 15 or 30 days had decreased blood ALAD activity that was related to duration of exposure and blood Pb (Rendón-Ramirez et al., 2007). Administration of Pb (25 mg/kg) to rats once a week for 4 weeks achieved a blood Pb level of 6.5 µg/dL, which was associated with statistically significant decreases (approximately 50% lower than control levels) in RBC ALAD activity (Lee et al., 2005). Exposure of male Wistar rats to 0.5% Pb-acetate via drinking water for three weeks statistically significantly decreased ALAD activity 72% compared to controls (mean [SD]: 7.35 [0.35] versus 26.14 [2.19] nM/min/mL RBCs) (Gautam and Flora, 2010).

5.7.4 Other Heme Metabolism Enzymes

The 2006 Pb AQCD indicated that Pb affects RBC PBG synthase (Simons, 1995; Farant and Wigfield, 1990, 1987), PBG deaminase (Tomokuni and Ichiba, 1990), and TF endocytosis and iron transport across membranes (Qian and Morgan, 1990), all of which are directly or indirectly involved in heme synthesis. Although there are no new studies that examine the effect Pb has on the activities of other heme metabolism enzymes, a

number of studies investigated associations of blood Pb with concentrations of various intermediate products in the heme biosynthetic pathway.

Pb intoxication is known to inhibit the function of ferrochelatase, the enzyme that catalyzes the last step in the heme biosynthetic pathway. Under normal conditions, ferrochelatase incorporates ferrous iron (Fe^{2+}) into protoporphyrin IX, converting it into a heme molecule (Figure 5-45). However, Pb has been shown to inhibit this insertion of Fe^{2+} into the protoporphyrin ring and instead, Zn is inserted into the ring creating ZPP. A number of recent studies have shown that blood Pb is statistically significantly associated with increased RBC ZPP levels in adults occupationally exposed to high levels of Pb (blood Pb level > 27-54 µg/dL) (Patil et al., 2006b; Ademuyiwa et al., 2005b), workers exposed to moderate levels of Pb (blood Pb level = 21.92 µg/dL) (Mohammad et al., 2008), children aged 1-21 years (blood Pb 18-23 µg/dL) (Counter et al., 2009, 2008; Counter et al., 2007), and animals exposed to 500 ppm Pb via drinking water for 15 or 30 days (Rendón-Ramirez et al., 2007). Interestingly, Wang et al. (2010f) found that in children and adults living in a rural area of Southwest China, ZPP levels were negatively correlated with blood Pb at blood Pb levels < 10 µg/dL and were only positively correlated with blood Pb at higher blood Pb concentrations (i.e., > 10 µg/dL). The authors suggest that this may be representative of ALAD activities at low blood Pb levels, which contributes to lower ZPP levels. Scinicariello et al. (2007) performed a meta-analysis and observed that Pb-exposed individuals who carried the ALAD2 allele had slightly lower concentrations of blood ZPP levels compared to carriers of the ALAD1 allele (overall pooled standardized mean estimate: -0.09 [units not specified]; 95% CI: -0.22, 0.03, p = 0.13).

5.7.5 Other Hematological Parameters

5.7.5.1 Energy Metabolism

RBCs use high energy purine nucleotides (i.e., ATP and guanine triphosphate [GTP]) to support basic metabolic functions. In mature RBCs, these nucleotides are synthesized via salvage reactions via either an adenine pathway, which requires adenine phosphoribosyltransferase (APRT), or an adenosine pathway, which requires adenosine kinase. The 2006 Pb AQCD reported that Pb significantly reduces the nucleotide pool including NAD and NADP, as well as increases purine degradation products resulting in altered RBC energetics. Since the 2006 Pb AQCD, there have been few studies examining Pb effects on energy metabolism. Baranowska-Bosiacka et al. (2009) examined the effects of Pb on RBC APRT and hypoxanthine-guanine

phosphoribosyltransferase (HPRT) due to in vitro and in vivo exposures. For the in vitro exposure, APRT and HPRT were measured in lysate of human RBCs after exposure to Pb at a concentration range from 0.1 to 100 µM for 5–30 minutes. In vivo tests measured APRT and HPRT in rat RBC lysate from rats exposed to Pb-acetate (0.1 %) in drinking water for 9 months. Both the in vivo and vitro studies found a significant decrease in both HPRT and APRT levels. The levels were significantly decreased in vitro after only 5 minutes of exposure to the 0.1 µM concentration, but the decrease was also concentration-dependent. However, the study authors considered the inhibition moderate (30–35%) even with the highest levels used in vitro. Shin et al. (2007) found a concentration-dependent decrease in intracellular ATP in human RBCs in vitro with significant decreases found even with the lowest concentration (i.e., 1 µM).

5.7.5.2 Other Enzymes

The 2006 Pb AQCD reported that K^+ permeability was increased by Pb due to altered sensitivity of the membrane Ca^{2+}-binding site that caused selective efflux of K^+ ions from the RBC membrane. However, inhibition of the RBC Na^+-K^+ ATPase is more sensitive to Pb exposure than is the inhibition of Ca^{2+}-Mg^{2+} ATPase. Few new studies were found that examined the effects of Pb exposure on other enzymes. Ekinci et al. (2007) tested the effects of Pb on two carbonic anhydrase isozymes (I and II) isolated from human RBCs. Carbonic anhydrases are metalloproteins that use Zn to catalyze the equilibrium between carbon dioxide and bicarbonate in the cells of higher invertebrates. Although investigators found that Pb nitrate inhibited both carbonic anhydrase isozymes in a concentration-dependent manner, the concentrations used (i.e., 200-1,000 µM) were above those that would be physiologically relevant. Inhibition of isozyme I was noncompetitive, while the inhibition for isozyme II was uncompetitive. Bitto et al. (2006) examined the mechanisms of action of Pb-induced inhibition of P5N, an enzyme important in the pyrimidine salvage pathway that requires manganese for normal activity. Pb was observed to bind directly to the active site of the enzyme in a different position than the manganese, thus possibly resulting in improper protein folding and inhibition of activity.

5.7.6 Red Blood Cell Oxidative Stress

It has been suggested that the Pb-associated decreases in ALAD activity result in increased oxidative stress, owing to the buildup of ALA. ALA can act as an electron donor in the formation of reactive oxygen species (ROS) (Nemsadze et al., 2009; Ahamed and Siddiqui, 2007). Many epidemiologic and toxicological studies have found

an association between the level of blood Pb and lipid peroxidation, antioxidant levels, or indicators of ROS production.

5.7.6.1 Oxidative Stress, Lipid Peroxidation, and Antioxidant Enzymes

Malondialdehyde (MDA) is an end product of lipid peroxidation and is commonly used as an indicator of lipid peroxidation. Numerous occupational studies demonstrated increased lipid peroxidation in highly-exposed worker populations (blood Pb levels ranging from 29 to 74.4 µg/dL) (Kasperczyk et al., 2009; Khan et al., 2008; Quintanar-Escorza et al., 2007; Patil et al., 2006a; Patil et al., 2006b). There was a correlation between MDA levels and blood Pb even in the unexposed workers who had lower (i.e., <12 µg/dL) blood Pb levels, although the magnitude of correlation in exposed workers was greater. (Quintanar-Escorza et al., 2007). Increases in C-reactive protein and decreases in RBC SOD, catalase, and plasma ceruloplasm were also observed in these workers, further indicating increased RBC oxidative stress due to higher Pb exposure.

Evidence of lipid peroxidation was also observed in occupational cohorts moderately exposed to Pb. These studies were cross-sectional in design; thus, there is uncertainty regarding the magnitude, timing, frequency, and duration of Pb exposure that contributed to the observed associations. In auto repair apprentices in Turkey (mean [SD]: 16.8 [1.2] years of age, 3.8 [1.8] years duration of exposure) with blood Pb levels as low as 7.9 µg/dL (Ergurhan-Ilhan et al., 2008), increases in glutathione peroxidase (GPx) and MDA, as well as decreases in α-tocopherol and β-carotene were observed compared with controls (compared to 2.6 µg/dL in controls; mean [SD] age: 16.3 [1] years). Decreases were observed in SOD and CAT, but the results did not attain statistical significance. In painters in India (mean [SD] duration of exposure: 126.08 [49.53 months]) with a mean blood Pb level of 21.92 µg/dL (compared to 3.06 µg/dL in controls), there was a significant decrease in SOD, glutathione (GSH), and CAT accompanied by a significant increase in oxidized GSH (i.e., GSSG) and thiobarbituric acid reactive species (TBARS, expressed in terms of MDA) measured in plasma and RBC lysate (Mohammad et al., 2008). In automotive painters in Brazil (mean [SE] blood Pb: 5.4 [0.4] µg/dL), glutathione-*S*-transferase, GPx, and SOD were positively correlated with blood Pb ($r = 0.34$, 0.38, and 0.32, respectively; $p < 0.05$) (Conterato et al., In Press). Similar effects on indices of oxidative stress were observed in in vitro studies: increased MDA and decreased SOD and catalase in RBCs exposed to 2 µM Pb (Ciubar et al., 2007), decreased glutathione reductase (GR) activity in human RBCs incubated with 5-18 µM Pb (Coban et al., 2007), and decreased GSH and increased GSSG and lipid peroxidation

in RBCs from healthy volunteers with no Pb exposure incubated with 0.4 µM Pb for 24-120 hours (Quintanar-Escorza et al., 2010).

Evidence of lipid peroxidation was also observed in children moderately exposed to Pb; as with the occupational studies, their cross-sectional design limits their utility in assessing the magnitude, timing, frequency, and duration of Pb exposure necessary to elicit the observed effects. Ahamed et al. (2005) investigated the relationship between blood Pb levels and antioxidant enzyme levels and lipid peroxidation in children aged 4-12 years in Lucknow, India. A total of 62 children, with a mean [SD] blood Pb level of 7.47 [3.06] µg/dL, were included in the study. Children were separated into three groups based on their blood Pb levels. The means (SDs) were: 3.93 (0.61) µg/dL group I; 7.11 (1.25) µg/dL group II; and 11.39 (1.39) µg/dL group III. Lipid peroxidation, measured as blood MDA, was statistically significantly greater in group III, compared to group II and I, whereas GSH was lower in group III relative to groups II and I. Catalase activity was the only measure of oxidative stress that was statistically significantly elevated in group II compared to group I. Additionally, blood Pb levels were found to be statistically significantly positively correlated with MDA and CAT and negatively correlated with GSH. Ahamed et al. (2006) additionally studied male urban adolescents in India. The 39 adolescents were separated into groups according to their blood Pb level (group 1: <10 µg/dL [mean 7.4 µg/dL], group 2: >10 µg/dL [mean 13.27 µg/dL]). Although the groups were similar in age (mean [SD]: 16.59 [0.91] versus 16.76 [0.90] years, respectively), height, weight, and body mass index, group 2 had significantly higher levels of CAT and MDA compared to group 1. There were no significant differences in blood GSH levels. Examining all the study subjects together, investigators found a correlation between blood Pb level and blood MDA and RBC CAT levels, as well as an inverse relationship between ALAD activity and MDA and CAT levels. In a similar study, Ahamed et al. (2008) examined oxidative stress in Indian children (aged 3-12 years) with neurological disorders. There was a significantly higher mean blood Pb level in the study population compared to the control healthy population (18.60 versus 10.37 µg/dL). In addition, the following indicators of oxidative stress were observed in the study population: increased blood MDA, RBC SOD, and CAT levels and decreased blood GSH levels. GPx levels were similar between the two groups. Typical indicators of Pb exposure (active/nonactive ALAD ratio) were found to be correlated with lipid peroxidation and oxidative stress. Children aged 3–6 years old living near a steel refinery in China with blood Pb levels ≥ 10 µg/dL also had a significant increase in plasma MDA compared to the children with blood Pb levels < 10 µg/dL. However, levels of RBC SOD, GSH, and GPx were not different from those in controls (Jin et al., 2006).

Administration of Pb (25 mg/kg) to rats once a week for 4 weeks, which was related to a blood Pb level of about 6.5 µg/dL, caused a significant increase in RBC MDA levels (Lee

et al., 2005). Other indications of Pb-induced oxidative stress included significant increases in RBC SOD and CAT levels accompanied by significant decreases in GSH and GPx. Exposure of rats to 750 mg/kg Pb-acetate in drinking water for 11 weeks resulted in decreased concentrations of plasma vitamin C, vitamin E, nonprotein thiol, and RBC-reduced glutathione, with simultaneous increased activity of SOD and GPx (Kharoubi et al., 2008b). CAT activity was also slightly elevated in Pb-exposed rats, but the increase failed to reach statistical significance. Exposure of male rats to 0.5% Pb nitrate in drinking water (blood Pb not reported) for three weeks decreased GSH levels compared to that in controls (mean [SE]: 1.91 [0.02] versus 2.44 [0.09] mg/mL, respectively) (Gautam and Flora, 2010). SOD activity was significantly decreased in rats injected with 15 mg/kg Pb i.p. for seven days, but not rats treated with 5 mg/kg Pb (Berrahal et al., 2007). GPx activity and MDA concentrations were slightly elevated in the exposed groups, but differences with the control group failed to reach statistical significance.

5.7.6.2 Antioxidant Defense

In addition to the studies listed above that examine lipid peroxidation and oxidative stress, there have been studies that indicate that the use of antioxidants and free radical reactions is protective against Pb-induced RBC oxidative stress. Rats treated with 500 ppm Pb-acetate in drinking water for 15 or 30 days had an increase in free RBC protoporphyrin and TBARS that was related to length of exposure and blood Pb (Rendón-Ramirez et al., 2007). Vitamin E administration after exposure to Pb significantly reduced the TBARS levels and increased ALAD activity, compared to exposure to Pb alone. Co-exposure to vitamin E and Pb simultaneously and exposure to vitamin E before Pb exposure also prevented Pb-induced oxidative stress. In vitro studies by Casado et al. (2007), found that Pb-induced hemolysis and RBC membrane damage was mediated via oxidative stress. The in vitro studies demonstrated a concentration- and time-dependent formation in lipid peroxide that was inhibited with a number of antioxidants, including desferrioxamine (iron chelator), trolox (chain breaking antioxidant), and mannitol and Na formate ($^{\bullet}OH$ scavengers). Results suggested the role of singlet oxygen in Pb-mediated membrane damage and hemolysis of exposed RBCs. In rats exposed to 2,000 ppm Pb in drinking water for 5 weeks, MDA levels were significantly increased, whereas vitamin E concentrations were significantly decreased (Caylak et al., 2008). In the case of MDA, co-exposure to Pb and a number of sulfur-containing antioxidants (e.g., L-methionine, N-acetylcysteine, and L-homocysteine) reduced concentrations to a level not statistically significantly different from that in

controls, but statistically smaller than concentrations observed with Pb alone. Exposure to L-methionine and N-acetylcysteine also reduced Pb-induced depletion of vitamin E.

5.7.7 Summary and Causal Determination

There is consistent toxicological and epidemiologic evidence indicating that exposure to Pb affects hematological endpoints, including decreased RBC survival and function, altered heme synthesis, and increased RBC oxidative stress. Pb has been shown to preferentially partition into RBCs following exposure, with RBC concentrations approximately 100-fold greater than those observed in the plasma (Jin et al., 2008; Timchalk et al., 2006).

Elaborating on the body of evidence presented in the 2006 Pb AQCD, recent epidemiologic and toxicological studies continue to demonstrate that Pb exposure is associated with decreased RBC survival and function, with the largest body of evidence consisting of populations of adults and children in which Pb is associated with effects on several inter-connected and related hematological parameters such as Hb, PCV, MCV, MCH, and MCHC. For adult populations, the largest body of evidence consists of occupationally-exposed workers in which measures of RBC survival are altered when compared with unexposed control populations (Cabaravdic et al., 2010; Ukaejiofo et al., 2009; Khan et al., 2008; Patil et al., 2006a; Patil et al., 2006b; Karita et al., 2005; Conterato et al., In Press). Although the mean blood Pb level in most occupationally exposed populations was in excess of 20 µg/dL, decreases in Hb and PCV were observed in adults with blood Pb levels of 7 µg/dL (compared to controls with blood Pb levels of 3 µg/dL), and significant correlations were observed between RBC distribution width and MCHC and blood Pb levels in adult populations with mean blood Pb levels of 5.4 µg/dL. Only one non-occupational study was found investigating the association of Pb with hematological parameters; in pregnant women, blood Pb levels were found to be negatively correlated with Hb concentrations. Studies in children measuring concurrent blood Pb levels are generally in agreement with those investigating occupationally-exposed adults regarding effects on hematological parameters (i.e., Hb, MCV, (Queirolo et al., 2010; Shah et al., 2010; Ahamed et al., 2007; Huo et al., 2007; Olivero-Verbel et al., 2007; Riddell et al., 2007; Turgut et al., 2007; Ahamed et al., 2006; Rondo et al., 2006). Any differences in the effects on specific hematological parameters observed between study findings for adults and those for children may be due to the comparatively shorter duration and lower magnitude of Pb exposure experienced by children compared to adults, although there is uncertainty regarding the timing and duration of exposure needed to induce effects in adults. In addition, Pb was shown to reduce Ca^{2+}- and Ca^{2+}-Mg^{2+}-ATPase activity in RBC membranes, which leads to an increase in RBC $[Ca^{2+}]_i$,

increased membrane fragility, and abnormal morphological changes in studies of occupationally exposed adults (Quintanar-Escorza et al., 2007) and in in vitro studies (Quintanar-Escorza et al., 2010; Ciubar et al., 2007). Heul et al. (2008) observed a reduction of RBC Ca^{2+}-Mg^{2+}-ATPase activity in children in association with a concurrent group mean cord blood Pb level of 3.54 µg/dL. Toxicological studies have also observed decreases in Hct and Hb and increases in hemolysis and reticulocyte density in rats and mice with blood Pb levels as low as 6.6-7.1 µg/dL (Sharma et al., 2010b; Baranowska-Bosiacka et al., 2009; Simsek et al., 2009; Lee et al., 2005). Pb exposure has also been observed to increase PS expression on RBC membranes, leading to cell shrinkage, erythropoiesis, and destruction of the RBCs by macrophages (Jang et al., 2011; Ciubar et al., 2007; Shin et al., 2007). Suggestive evidence of disrupted hematopoiesis evidenced by decreased serum erythropoietin was observed in occupationally-exposed adults with a mean blood Pb level of 6.4 µg/dL (Sakata et al., 2007); toxicological studies in rats also indicate that Pb is cytotoxic to RBC progenitor cells (Alghazal et al., 2008b; Celik et al., 2005). Taken together, these studies provide consistent evidence that exposure to Pb affects RBC function and survival, and leads to the reduction of RBCs in circulation. Although this decrease in RBCs may be explained by both decreased cell survival and/or disruption of hematopoiesis, the observation of increased reticulocytes seems to represent compensation for decreased RBC survival due to Pb exposure.

Confirming effects observed in the 2006 Pb AQCD, a large body of evidence consisting of cross-sectional epidemiologic studies measuring concurrent blood Pb in adults and children have found that decreases in RBC ALAD levels and activity are strongly associated with higher blood Pb levels (Wang et al., 2010f; Mohammad et al., 2008; Ahamed et al., 2007; Quintanar-Escorza et al., 2007; Ahamed et al., 2006; Patil et al., 2006a; Patil et al., 2006b; Ademuyiwa et al., 2005b; Ahamed et al., 2005; Conterato et al., In Press). Although the body of evidence is smaller than for humans, decreases in blood ALAD activity were also seen in rats with increased blood Pb levels, compared to controls (Lee et al., 2005). In addition to ALAD, recent studies have shown that Pb exposure inhibits the activity of ferrochelatase, leading to increased RBC ZPP in children and occupationally-exposed adults (Counter et al., 2009, 2008; Mohammad et al., 2008; Counter et al., 2007; Patil et al., 2006b; Ademuyiwa et al., 2005b) and animals (Rendón-Ramirez et al., 2007). Pb has also been shown to inhibit the in vitro activities of other enzymes in RBCs, including those involved in nucleotide scavenging, energy metabolism, and acid-base homeostasis (Baranowska-Bosiacka et al., 2009; Ekinci et al., 2007).

Lastly, Pb exposure induces lipid peroxidation and oxidative stress in RBCs. Epidemiologic studies have observed increases in MDA in occupationally-exposed adult populations (Ergurhan-Ilhan et al., 2008; Khan et al., 2008; Mohammad et al., 2008;

Quintanar-Escorza et al., 2007; Patil et al., 2006a; Patil et al., 2006b). Other changes in oxidative stress parameters observed included lowered activities of SOD, GR, and CAT, and increased CRP. Altered indices of RBC oxidative stress were also seen in adolescents and children in association with blood Pb levels (Ahamed et al., 2008; Ahamed et al., 2006; Jin et al., 2006). In vitro and vivo studies have also demonstrated that prior, concurrent, or subsequent treatment with various antioxidants has been shown to ameliorate at least partially Pb-induced oxidative stress in RBCs (Caylak et al., 2008; Casadoa et al., 2007; Rendón-Ramirez et al., 2007).

Similar to the epidemiologic and toxicological studies that demonstrate an association between Pb exposure and hematological effects in humans and laboratory animals, the ecological literature has consistently reported on hematological responses in aquatic and terrestrial invertebrates and vertebrates (Sections 7.4.1.2 and 7.4.2.2). The most consistently observed effect in metal impacted environments is decreased RBC ALAD activity. This effect has been observed across a wide range of taxa, including bivalves, fish, amphibians, birds, and mammals. More limited evidence exists regarding deleterious effects of Pb on serum enzyme levels and white blood cell counts in birds and mammals.

In summary, new epidemiologic and toxicological studies included in the current review provide strong evidence that exposure to Pb is associated with numerous deleterious effects on the hematological system, including effects on RBC survival and function, altered heme synthesis, and increased oxidative stress, and continue to confirm previous conclusions from the 2006 Pb AQCD. The principal finding regarding RBC survival and function are consistent Pb-induced alterations in several inter-connected and related hematological parameters such as Hb, Hct, and MCV across multiple studies, with the weight of evidence provided by epidemiological studies in occupationally-exposed adult populations and children. In occupationally-exposed adults, these findings are most substantiated in populations with current blood Pb levels > 20 µg/dL, although effects on hematological parameters were observed in some occupationally-exposed populations at concurrent blood Pb levels in the range of 5-7 µg/dL. In Pb-exposed children, effects on hematological parameters were most substantiated in populations with blood Pb levels less than 15 µg/dL. The weight of evidence in adult rodents exposed long-term to Pb (i.e, ≥ 4 weeks), although less than the weight of evidence in humans, is coherent with epidemiologic studies regarding decrements in hematological parameters at blood Pb levels as low as 6.6-7.1 µg/dL. Regarding alterations in heme synthesis, the largest body of evidence again is provided by decreased ALAD activity observed in epidemiologic studies in occupationally-exposed adult populations and children. In the occupationally-exposed adult populations, the observation of decreased ALAD activity was most often observed in populations with concurrent blood Pb levels >15 µg/dL. In children, decreases in ALAD activity were observed in populations with concurrent blood Pb

levels in the range of 7-22 µg/dL. Animal toxicological studies also provide to the weight of evidence regarding altered ALAD activity, with effects seen in adult animals exposed for 3-4 weeks with blood Pb levels as low as 6.5 µg/dL. As for the effects listed above, the weight of evidence for oxidative stress (i.e., increased lipid peroxidation or alterations in antioxidant enzyme levels) primarily comes from epidemiological studies in occupationally-exposed adults and children. The majority of evidence for increased oxidative stress in Pb-exposed adults comes from occupational cohorts with concurrent blood Pb levels >15 µg/dL. In children, concurrent blood Pb levels of 7-22 µg/dL were associated with measures of oxidative stress. Due to the cross-sectional nature of the above epidemiologic studies in adults and children, and the measurement of concurrent blood Pb, the timing and duration of exposure necessary to alter RBC survival and function, heme synthesis, or the state of oxidative stress in RBCs is unclear. This uncertainty is greatest in adults as concurrent blood Pb levels reflecting recent exposures is likely to be less than blood Pb levels resulting from past exposures. The consistency of findings in epidemiologic studies investigating effects in adults and children, and the coherence of findings in the toxicological literature and coherence across the disciplines is sufficient to conclude that a causal relationship exists between Pb exposures and effects on heme synthesis and red blood cell function.

5.8 Reproductive and Developmental Effects

The effect of Pb on reproductive outcomes has been of interest for years, starting in cohorts of occupationally-exposed individuals. More recently, researchers have begun to focus on reproductive effects in populations without occupational exposures, with environmentally-relevant levels of Pb exposure. In the toxicological and epidemiologic literature, research on reproductive effects of Pb include female and male reproductive function (hormone levels, fertility, puberty, and effects on reproductive organs and estrus), birth defects, spontaneous abortions, infant mortality, preterm birth, low birth weight/fetal growth, and other developmental effects. In epidemiologic studies, various biological measures of Pb are used including Pb measured in blood and bone; toxicological studies only report exposure using blood Pb. Bone Pb is indicative of cumulative Pb exposure. Blood Pb can represent more recent exposure, although it can also represent remobilized Pb occurring during times of bone remodeling and pregnancy or lactation. More detailed discussion of these measures and Pb transfer via umbilical cord blood Pb across the placenta, and via lactation is given in Section 4.3.5.2 on Pb Toxicokinetics. A few studies of pregnancy-induced hypertension and eclampsia have been conducted and are reported on in the section on hypertension (Section 5.4.2.1).

Briefly, the relatively small number of studies found consistently positive associations between blood Pb levels and pregnancy-induced hypertension.

Overall, the recent reproductive literature continues to support associations reported in earlier Pb AQCDs between Pb exposure and effects on various parameters of sperm (function, motility, count, integrity, histology). The toxicological and epidemiologic literature also indicates that Pb exposure is associated with delayed onset of puberty in both males and females. The new information from epidemiologic and toxicological studies is integrated with conclusions from previous Pb AQCDs below.

5.8.1 Effects on Female Reproductive Function

The epidemiologic studies on Pb and female reproductive function presented in the 2006 Pb AQCD (U.S. EPA, 2006b) provided little evidence for an association between Pb biomarkers and effects on female reproduction and fertility. However, the 1986 and 2006 Pb AQCDs (U.S. EPA, 2006b, 1986a) reported toxicological findings that Pb exposure was associated with effects on female reproductive function that can be classified as alterations in female sexual maturation, effects on fertility and menstrual cycle, endocrine disruption, and changes in morphology or histology of female reproductive organs including the placenta. Since the 2006 Pb AQCD, many epidemiologic studies have been published regarding Pb biomarker levels in women and reproductive effects. For some effects, there are inconsistent findings, but for others, such as delayed puberty, there are clear associations with blood Pb levels. In addition, recent toxicological studies add further knowledge of Pb-related effects on the female reproductive system.

5.8.1.1 Effects on Female Sex Endocrine System and Estrus Cycle

Multiple epidemiologic studies have examined the association between blood Pb levels and hormone levels and the estrus cycle. Epidemiologic studies (characterized in Table 5-30; all studies included in the table used measures of Pb and hormones that were either concurrent or close in time) support the toxicological findings, which are the major body of evidence on endocrine effects of Pb.

Table 5-30 Summary of recent epidemiologic studies of associations between Pb levels and hormones for females

[a]Studies are presented in order of first appearance in the text of this section.

An epidemiologic study using the NHANES III data and including women aged 35-60 years old examined the relationship between blood Pb levels (mean 2.8 µg/dL) and serum follicle stimulating hormone (FSH) and luteinizing hormone (LH) (Krieg, 2007). Deviation from normal FSH and LH levels may indicate endocrine disruption related to ovary functioning. Researchers found that higher blood Pb levels were associated with higher levels of serum FSH and LH among both postmenopausal women and women with both ovaries removed. There was also a trend of increasing serum FSH with blood Pb levels for pre-menopausal women who were not menstruating at the time of the exam or pregnant, although the association was not statistically significant for LH. A limitation of this portion of the study is that FSH and LH were measured without attention to day of a woman's menstrual cycle and LH and FSH are known to vary throughout the cycle of non-menopausal, cycling women who are not taking birth control pills. Higher blood Pb levels were associated with lower levels of serum FSH among women taking birth control pills. The inverse association was also present for LH, but it was not statistically significant. No associations between blood Pb and FSH or LH were apparent for women who were menstruating at the time of the exam or were pregnant. Further analysis indicated that the lowest level of blood Pb for which a statistically significant association between blood Pb and FSH could be observed was 1.7 µg/dL among women with their ovaries removed. For LH, the lowest level of blood Pb for which a statistically significant association between blood Pb and LH could be observed was 2.8 µg/dL among postmenopausal women. Another epidemiologic study was performed in Kaohsiung City, Taiwan among two groups of women aged 23-44 years: those who were seeking help at a fertility clinic after one year of trying to conceive, and those who had previously delivered an infant and were identified from medical records of a postpartum care unit (Chang et al., 2006). The mean (SD) blood Pb in this study was 3.12 (0.19) µg/dL. The study reported a positive association between blood Pb levels and serum estradiol

concentrations during the early follicular phase, which reflects ovary activity. Associations between hormones and blood Pb level were also investigated using the BioCycle study cohort (Jackson et al., 2011; Pollack et al., 2011). These women were premenopausal with normal cycles and not on birth control. Neither study detected an association between unit change in blood Pb and hormone levels. However, when examining tertiles of Pb, women in the highest tertile blood Pb (1.11-6.20 µg/dL) had higher mean progesterone and longer length of a phase shift compared to women in the lowest tertile (0.30-0.72 µg/dL) (Pollack et al., 2011). Other associations were observed but were not statistically significant (Pollack et al., 2011). No associations were detected for anovulation (Pollack et al., 2011) or for cycle length (Jackson et al., 2011).

The effect of Pb exposure on the female endocrine system was demonstrated in toxicological studies reviewed in the 1986 and 2006 Pb AQCD (U.S. EPA, 2006b, 1986a). However, the mechanism by which Pb affects the endocrine system has not been fully elucidated. Several recent articles continue to demonstrate that Pb alters the concentration of circulating hormones in female experimental animals. As mentioned in the previous AQCD, Pine et al. (2006) observed that maternal Pb exposure (during gestation and lactation) caused a decrease in basal LH levels in pre-pubertal female Fisher 344 rat pups as compared to control, non-Pb exposed pups. Dumitrescu et al. (2008a) observed alteration of hormone levels in female Wistar rats after ingesting Pb-acetate (50, 100, 150 ppb) in drinking water for 6 months; measurements were made during the pro-estrous stage of the estrous cycle to allow for consistent timing for comparison of cyclic hormonal variation. The authors reported decreases in FSH, estradiol, and progesterone levels with increases in LH and testosterone levels. Nampoothiri and Gupta (2008) administered Pb-acetate at a concentration that did not affect reproductive performance, implantation or pregnancy outcome (0.05 mg/kg body weight) to Charles Foster female rats 5 days before mating and during the gestational period. They observed a decrease in steroidogenic enzymes, 3β- hydroxysteroid dehydrogenase (HSD) and 17β-HSD, activity in reproductive organs, as well as a decrease in steroid hormones (progesterone and estradiol), suggesting that chronic exposure to low levels of Pb may affect reproductive function of mothers and their offspring. Similarly, Pillai et al. (2010) reported impaired ovarian steroidogenesis in Charles Foster adult female rats (PND56) from dams exposed gestationally and lactationally to Pb-acetate (subcutaneous daily injections of 0.05 µg/kg BW). Pillai observed a decrease in steroidogenic enzymes, 3β-HSD and 17β-HSD, but saw no changes in ovarian steroidogenic acute regulatory protein (StAR) or CYP11 mRNA levels indicating Pb-induced inhibition of ovarian steroidogenesis.

Kolesarova et al. (2010) conducted an in vitro study to examine the secretory activity of porcine ovarian granulose cells after Pb administration. The results of the study showed

that Pb-acetate concentrations of 0.046 mg/mL and 0.063 mg/mL statistically significantly inhibited insulin-like growth factor-1 (IGF-1) release, but concentrations of 0.25 mg/mL and 0.5 mg/mL did not influence IGF-1 release. Progesterone release was not affected by Pb treatment; however, Pb caused a reduction in LH and FSH binding in granulose cells and increased apoptosis as evidenced by increased expression of caspase-3 and cyclin B1, suggesting a Pb-induced alteration in the pathways of proliferation and apoptosis of porcine ovarian granulose cells. Decreased gonadotropin binding was also observed in rats after Pb exposure (Nampoothiri and Gupta, 2006).

No recent toxicological studies were found that examined Pb-induced effects on the estrus cycle.

Overall, toxicological studies report alterations in hormone levels related to blood Pb concentration. Similarly, epidemiologic studies reported associations between blood Pb levels and hormone levels in female adults. Although Pb-associated changes in hormone levels are observed, there are discrepancies about the direction of the hormone changes related to Pb. One explanation is that the direction of change could vary based on current hormonal and reproductive status.

5.8.1.2 Effects on Fertility

Previous studies indicated that Pb exposure does not produce total sterility, but it can disrupt female fertility (U.S. EPA, 2006b). Recent epidemiologic studies and studies in experimental animals support this finding. The epidemiologic studies are summarized in Table 5-31. Most of these studies examined biological measures of Pb collected at or during the period of possible fertilization, although Bloom et al. (2011a) measured blood Pb at baseline and followed women for at least 12 menstrual cycles (or until pregnancy).

Bloom et al. (2011a)	New York 1996-1997	Achieving pregnancy	Women who were aged 18-34 years, were previously part of a study five years prior about fish consumption, and were not currently pregnant	Blood Pb	No positive pregnancy test: 1.55 (0.16) Positive pregnancy test: 1.54 (0.12)	β (95% CI) -0.031 (-1.066, 1.004) per 0.6 µg/dL

[a]Studies are presented in order of first appearance in the text of this section.

Epidemiologic studies examined women having difficulty conceiving by performing studies among patients of fertility clinics or undergoing in vitro fertilization (IVF). Among women aged 23-44 years, a difference in blood Pb was reported between women who were seeking help at a fertility clinic after one year of trying to conceive and women who had previously delivered an infant and were identified from medical records of a postpartum care unit at a medical center (Chang et al., 2006). Higher odds of infertility were observed when comparing women with blood Pb levels >2.5 µg/dL to those with blood Pb levels ≤ 2.5 µg/dL. Another study examining fertility reported on women in Saudi Arabia aged 19-50 years who were undergoing IVF treatment (Al-Saleh et al., 2008a). Women were categorized as having achieved a pregnancy versus not having achieved a pregnancy and achieved fertilization versus not achieving fertilization. The majority of women had follicular Pb levels that were below the limit of detection, whereas less than 2% of women had blood Pb levels below the limit of detection. In addition, less than 2% of women had blood Pb levels that were above 10 µg/dL. Follicular Pb levels were not correlated with the blood Pb. No association was observed between blood or follicular Pb and pregnancy outcomes in either crude or adjusted models. An association was not detected between follicular Pb and fertilization, but higher blood Pb was associated with lower rates of fertilization. Finally, a study that included nine women undergoing IVF treatment in Rhode Island (Silberstein et al., 2006) found that median follicular Pb levels in women who achieved pregnancy were lower than the follicular Pb levels among nonpregnant women. One limitation present in these studies is that the participants, especially in the later two studies, are women who are seeking help for fertility problems. The participants are not samples of the general population and therefore cannot be generalized to all women of childbearing age. The Study of Metals and Assisted Reproductive Technologies (SMART) enrolled women

undergoing their first round of IVF and investigated multiple steps before pregnancy as the outcomes (Bloom et al., 2011b; Bloom et al., 2010). Higher blood Pb levels were associated with lower oocyte maturity although the lack of power made interpretation of models controlling for Cd difficult. No association was observed between blood Pb and oocyte fertilization (Bloom et al., 2010). When examining markers of IVF success, inconsistent results were observed. Embryo cell number was lower in association with higher blood Pb levels but no association was observed for embryo fragmentation score (Bloom et al., 2011b). The study was limited by the small number of participants. Overall, these epidemiologic studies examine a variety of fertility-related endpoints and although some studies demonstrate an association between higher Pb levels and fertility/pregnancy, as a whole the results are inconsistent across studies.

A prospective cohort study enrolled women who previously participated in a study of fish consumption for a length of <1 to >6 menstrual cycles and investigated the relationship between blood Pb levels and having a positive pregnancy test (Bloom et al., 2011a). No association was observed between blood Pb and achieving pregnancy.

Animal toxicology studies following female fertility looked at various outcomes. Several studies observed a decrease in litter size when females were exposed to Pb before mating or during pregnancy (Dumitrescu et al., 2008b; Iavicoli et al., 2006b; Teijon et al., 2006). Pups in a study by Teijon et al. (2006) receiving 400 ppm Pb-acetate in drinking water had blood Pb of 97 µg Pb/dL blood at 1 week post-weaning and 18.2 µg Pb/dL blood at 2 week post-weaning. Dumitrescu et al. observed a modification in sex ratio of pups born to dams exposed to Pb before mating and during pregnancy. As the dose of Pb increased, the number of females per litter also increased (i.e., 1 male to 0.8 female in non-Pb exposed group; 1 male to 0.66 female in 50 ppb Pb-acetate group; 1 male to 2.25 females in 100 ppb group; and 1 male to 2.5 females in 150 ppb group). These results are not consistent with earlier results of Ronis et al. (1998b), who did not observe differences in sex ratio dams and offspring were exposed only during pregnancy. Thus, Pb exposure in animal studies during or before pregnancy have shown effects on litter size and mixed effects on sex ratio.

Nandi et al. (2010) demonstrated a concentration-dependent decline in viability rate, maturation, fertilization, and cleavage rates of buffalo oocytes cultured in medium containing 1-10 µg/mL Pb-acetate. Karaca and Şimşek (2007) observed an increase in the number of mast cells in ovary tissue after Pb exposure (2,000 µg/mL in drinking water) suggesting that Pb may stimulate an inflammatory response in the ovaries which may contribute to Pb-induced female infertility.

In contrast, Nampoothiri and Gupta (2008) did not observe any statistically significant change in fertility rate or litter size in female rats subcutaneously administered Pb

(0.05 mg/kg body weight daily before mating and during pregnancy) with a resulting blood Pb of 2.49 µg/mL. Although reproductive performance was not affected in this study, the authors did report an alteration in implantation enzymes. Cathepsin-D activity decreased and alkaline phosphatase activity increased after Pb exposure.

Recent epidemiologic and toxicological studies on the effect of Pb on fertility outcomes have generated inconsistent results. However, the bulk of the evidence including the current and historical Pb literature (U.S. EPA, 2006b) indicate that increased Pb exposure may decrease fertility.

5.8.1.3 Effects on Puberty

Recent toxicological studies of rodents have examined the effects of Pb on pubertal and reproductive organ development and on biomarkers of pubertal development. There have also been recent epidemiologic studies examining associations between blood Pb levels and onset of puberty, which are summarized in Table 5-32 and in the text below. All of the epidemiologic studies examined concurrently measured blood Pb and puberty and are reported below. Additionally, Naicker et al. (2010) followed girls to determine their age of menarche; however, blood Pb levels were measured once at 13 years of age.

Table 5-32 Summary of recent epidemiologic studies of associations between Pb levels and puberty for females

Reference[a]	Study Location and Years	Outcome	Study Population	Pb Biomarker	Mean Pb (SD) in µg/dL	Adjusted Effect Estimates
Tomoum et al. (2010)	Cairo, Egypt 2007	Hormones and pubertal development	Healthy children aged 10-13 yr; seeking treatment for minor health problems and living in one of two designated areas (one with high-risk for Pb contamination and one with no Pb source)	Blood Pb	NS for girls only (combined with boys in the study the mean was 9.46 [3.08])	Breast Development <10 µg/dL: Stage 2: 36.4% Stage 3: 63.6% ≥ 10 µg/dL: Stage 2: 100% Stage 3: 0% Chi-square p-value<0.01 Pubic Hair Development <10 µg/dL: Stage 2: 36.4% Stage 3: 63.6% ≥ 10 µg/dL: Stage 2: 77.8% Stage 3: 22.2% Chi-square p-value>0.05 *Quantitative results for hormones not provided
Denham et al. (2005)	Akwesasne Mohawk Nation (boundaries of New York, Ontario, and Quebec NS	Age at menarche	10- to 16.9-yr-old girls in the Akwesasne community	Blood Pb	0.49 (0.905) Median: 1.2	Coefficients for binary logistic regression predicting menarche with Pb centered at the mean: log blood Pb -1.29 (p-value 0.01) log blood Pb -squared: -1.01 (p-value 0.08) Non-linear relationship observed and Pb below the mean did not appear to affect the odds of menarche. Increasing blood Pb from 0.49 to 0.98 µg/dL decreased the odds of menarche attainment by 72%

[a]Studies are presented in order of first appearance in the text of this section.

Several epidemiologic studies investigated the association between blood Pb and indicators of puberty onset. A study among girls aged 10-13 years (median: 12 years)

reported lower levels of FSH and LH levels in the group with blood Pb of at least 10 µg/dL compared to the group with blood Pb less than 10 µg/dL (Tomoum et al., 2010). In addition, there were some indications of lower Tanner stages of breast development associated with Pb levels of at least 10 µg/dL, but this relationship was not present for stages of pubic hair development. A study of girls aged 10-16.9 years of age in the Akwesasne Mohawk Nation reported a nonlinear positive association between blood Pb and age at menarche (Denham et al., 2005). No association was observed below blood Pb of 0.49 µg/dL in a nonlinear model of the Pb-menarche relationship. A study conducted in South Africa reported a positive association between blood Pb levels and age at first menarche and pubertal development (Naicker et al., 2010). Another study reporting on girls with low blood Pb concentrations observed an association between blood Pb and pubic hair but not breast development (Den Hond et al., 2011). The association was no longer statistically significant when a marker for polychlorinated biphenyl exposure was included in the model. A study performed in NYC among 9 year old girls reported no association between Pb levels and pubertal development (Wolff et al., 2008), but this age group may be too young to study when investigating delayed puberty as the outcome.

Multiple studies have been performed examining blood Pb levels and puberty using NHANES III data (Gollenberg et al., 2010; Selevan et al., 2003; Wu et al., 2003b). A study that included girls aged 8-16 years and reported an association for delayed attainment of menarche and pubic hair development, but not for breast development (Wu et al., 2003b). The associations were observed even at blood Pb levels of 2.1-4.9 µg/dL compared to girls with blood Pb levels <2.1 µg/dL. Another NHANES III study included girls 8-18 years of age and reported the results stratified by race (Selevan et al., 2003). Higher blood Pb levels were associated with lower Tanner stage of breast and pubic hair development and later age at menarche among African Americans and with lower stage of breast and pubic hair development among Mexican Americans. For whites, the associations were in the same directions, but none reached statistical significance. In a study of girls ages 6-11 years old from NHANES III data, higher blood Pb levels were associated with lower inhibin B, a protein that inhibits FSH production, but no association was observed for LH. (Gollenberg et al., 2010). The inverse association between blood Pb and inhibin B was greater among girls with iron deficiency compared to those with high Pb but sufficient iron levels. Inhibin B and LH were chosen for this study because, as the authors indicated, these hormones are, “believed to be relevant for younger girls… near the onset of puberty and…serve as markers for hypothalamic-pituitary-gonadal functioning.”

Earlier studies showed that prenatal and lactational exposures to Pb can cause a delay in the onset of female puberty in rodents. Recent studies corroborate these findings and show that puberty onset is one of the more sensitive markers of effects of Pb exposure as is demonstrated in the exposure response array (Figure 5-46 and Table 5-33 Figure 5-45; including outcomes described in sections that follow). Dumitrescu et al. (2008b) exposed adult Wistar female rats to varying doses of Pb-acetate (50-150 ppb) in drinking water for 3 months before mating and during pregnancy. Vaginal opening, an indicator of sexual maturation, was statistically significantly delayed in pups from all Pb treated groups when compared to pups from non-treated dams. The age at vaginal opening in female pups from the Pb treated groups increased, in a concentration-dependent manner, from 39 days to 43-47 days. The authors also observed a correlation between body weight and age at vaginal opening meaning that as body weight decreased the age at vaginal opening increased. This effect also exhibited a concentration-dependent relationship.

In another recent study, Iavicoli et al. (2006b) reported a statistically significant delay in several indicators of sexual maturity in offspring (Swiss mice, F_1 generation) born to dams that ingested 3.5-40 ppm Pb in their daily diet; offspring had continuous dietary exposure until the termination of the experiment. Maternal ingestion of Pb at the various

doses resulted in female pup blood Pb levels of 3.5-13 µg/dL. For all diet groups in this range (3.5-13 µg/dL), there was a delay in age at vaginal opening, age of first estrus, age of vaginal plug formation, and age of first parturition when compared to the group at background Pb concentration (2 µg/dL). A novel finding in the Iavicoli study was that very low dose Pb (blood Pb of 0.7 µg/dL, food concentration of 0.02 ppm continuous through gestation, lactation and until the termination of the experiment) induced statistically significant acceleration of markers of sexual maturation in female offspring versus background Pb level animals (blood Pb of 2 µg/dL). There were statistically significant increases in time of vaginal opening (30% earlier), first estrous, first vaginal plug formation, and first parturition at the very low Pb exposure versus 2 µg/dL animals. Thus, the timing of puberty is delayed in a concentration-dependent fashion with very low dose Pb having a statistically significant earlier onset of puberty than the background Pb animals (2 µg/dL). Also, the animals exposed to the higher dose of Pb (blood Pb up to 13 µg/dL) had statistically significant delays in onset of puberty when compared to the other dose groups.

In addition, Pb-induced shifts in sexual maturity were observed in the subsequent generation (F_2 generation) across that dose range. These F_2 animals continued to be exposed to same concentrations of Pb over multiple generations through the diet. Results in the F_2 generation closely resembled those of the F_1 generation, as both generations received Pb exposure. The authors concluded that a modest elevation in blood Pb level (13 µg/dL) over background (2-3 µg/dL) can result in a profound delay in the onset of puberty (15-20%). In the F_2 generation, reduction in blood Pb (0.7 µg/dL) below background (2-3 µg/dL) was associated with an earlier onset of sexual maturity (30% increase) above background.

In the 2006 Pb AQCD (U.S. EPA, 2006b), it was reported that a statistically significant reduction in the circulating levels of insulin-like growth factor 1 (IGF-1), LH, and estradiol (E2) was associated with Pb-induced delayed puberty in Fisher 344 pups. Subsequently, Pine et al. (2006) evaluated whether IGF-1 replacement could reverse the effects of Pb on delayed female puberty onset. The authors reported that offspring from dams exposed to Pb during gestation and lactation (daily oral gavage of dam with 1.0 mL solution of Pb-acetate 12 mg/mL; mean maternal blood Pb level 40 µg/dL) exhibited a marked increase in LH and luteinizing hormone releasing hormone (LHRH) secretion after IGF-1 administration (200 ng^3/µL i.p. injection twice daily from PND23 until the appearance of vaginal opening which appears in control animals at ~ PND 40) resulting in restored timing of vaginal to that of control animals. It should be noted that, IGF-1 replacement in Pb-exposed animals did not cause advanced puberty over non-Pb-exposed controls. The results of this study provide support to the theory that Pb-induced delayed onset of puberty may be due to disruption of pulsatile release of sex hormones (U.S.

EPA, 2006b) and not necessarily due to a direct toxic effect on the hypothalamic-pituitary-gonadal axis (Salawu et al., 2009), and IGF-1 may play a prominent role in the process.

In sum, epidemiologic studies consistently show an association between higher concurrent blood Pb and delayed pubertal development in girls. This association is apparent even at low blood Pb levels. New evidence from the toxicology literature continues to support Pb-induced delays in the onset of puberty. Further, the biological plausibility of delayed puberty is expanded with the toxicological literature that shows this pathway is mediated by IGF-1.

5.8.1.4 Effects on Lactation

Experiments in laboratory animals have shown that dietary manipulation of maternal fatty acid (FA) levels in diet can worsen Pb-related behavioral effects of offspring after lactational Pb exposure (Lim et al., 2005). To determine if components of dam milk contributed to this change, dam dietary fatty acids were altered via diet. Diets deficient in n-3 fatty acids can lead to a deficiency of DHA, which is essential for proper nervous system development. Lim et al. (2005) found that dam Pb exposure (Long-Evans rats, 0.2% Pb-acetate trihydrate/BW) during lactation (PND 0-21) led to a decrement in non-essential fatty acids in the maternal organs at PND25 (mean [SD] blood Pb levels in dams: 308 [56] µg/dL). In animals with a diet deficient in n-3 FAs, there was a Pb-diet interaction on the 20-carbon n-6 PUFAs. In general, Pb exposure caused a decrement in shorter chain monounsaturated and saturated FAs in maternal organs.

Dietary supplementation with calcium can be an especially important contributor to Pb mobilization during periods of high calcium demand including pregnancy/lactation. For example, mothers with elevated blood Pb levels given calcium phosphate and ascorbic acid supplementation during lactation had a 90% decrease in placental Pb content and a 15% decrease in the concentration of Pb in breast milk (Altmann et al., 1981) versus the control group that did not receive dietary treatment. Another study (Gulson et al., 2004a) has shown that calcium supplementation during the lactation is less beneficial in modulating maternal blood Pb levels (mean blood Pb at first sampling was 2.4 µg/dL); the Gulson cohort was limited by power (n=10 women). In a cohort of women from Mexico City, daily calcium supplementation during lactation reduced maternal blood lead by 15–20% and lead in breast milk by 5–10% (Ettinger et al., 2004a). Another study by the same investigators showed that using calcium supplements daily during pregnancy also reduced blood lead levels during pregnancy (Ettinger et al., 2009) with the effect strongest in women with higher biomarkers of Pb exposure (elevated baseline bone Pb or

>5 µg/dL blood Pb) or in women with higher Pb exposure (self-reported use of lead-glazed ceramics). Thus, dietary modulation with calcium supplementation during pregnancy and lactation may decrease the amount of Pb to which the developing fetus of infant is exposed. The evidence for this seems especially strong for protection during pregnancy and more mixed for protective effects of calcium during lactation.

5.8.1.5 Summary of Effects on Female Reproductive Function

In summary, Pb exposure was found to affect female reproductive function as demonstrated by both epidemiologic and toxicological studies. At low concurrent blood Pb levels, associations are observed with delayed puberty. These associations are noted among girls with mean blood Pb levels of 10 µg/dL and lower. Some evidence is also available regarding blood Pb levels and altered hormone levels in adults, although the direction of the change varied among studies. Although studies reported inconsistent findings for the association between Pb and fertility, there is some evidence of a potential relationship. Most of the epidemiologic studies are cross-sectional, thus there is uncertainty regarding the lifestages of Pb exposure associated with the greatest risk. Toxicological studies are often dealing with prenatal or early postnatal exposures, except for puberty studies which use concurrent exposure. Although epidemiologic and toxicological studies provide information on different exposure periods, both types of studies support the conclusion that Pb affects at least some aspects of female reproductive function.

5.8.2 Effects on Male Reproductive Function

The 2006 Pb AQCD (U.S. EPA, 2006b) reported on male Pb exposure or biomarker levels and reproductive functions as measured by sperm count/motility/morphology, time to pregnancy, reproductive history, and chromosomal aberrations. Despite limitations, most of the studies found slight associations between high blood Pb levels (i.e., ≥ 45 µg/dL) and reduced male fecundity or fertility (U.S. EPA, 2006b). Evidence reviewed in the 1986 Pb AQCD (U.S. EPA, 1986a) also demonstrated that Pb exposure affects male reproductive function in humans and experimental animals. Recently published research has continued to support an association between Pb and reproductive function in males. These studies are described in the sections below.

5.8.2.1 Effects on Sperm/Semen Production, Quality, and Function

Multiple epidemiologic and toxicological studies have examined the relationship between Pb and sperm and semen production, quality, and function. These studies are summarized in the text below. In addition, recent epidemiologic studies are included in Table 5-34. The biological samples in these studies are from concurrent measures. The biological samples measuring Pb levels and outcomes were collected concurrently in the epidemiologic studies.

Table 5-34 Summary of recent epidemiologic studies of associations between Pb levels and effects on sperm and semen

Reference[a]	Study Location and Years	Study Population	Pb Biomarker or Exposure Measurement	Mean Pb (SD) in µg/dL	Adjusted Effect Estimates
Naha and Manna (2007)	Bangalore, India NS	Non-occupationally exposed controls and occupationally exposed workers	Categorized by work history as controls, low exposure (7-10 yr of exposure for 8 h/day) and high exposure (>10 yr of exposure for 8 h/day)	Blood Pb measurement Controls 10.25 (2.26) Low exposure 50.29 (3.45) High exposure 68.26 (2.49) Semen Pb measurement Controls 2.99 (0.76) Low exposure 15.85 (1.95) High exposure 25.30 (2.28)	p-values for difference across the three groups for mean values of semen profiles were <0.01 for: liquefaction time, seminal volume, sperm count, sperm DNA hyploidy, sperm morphological abnormality, sperm motility, sperm ATPase activity, seminal plasma fructose, seminal plasma total protein, seminal plasma free amino acid, seminal plasma cholesterol

[a]Studies are presented in order of first appearance in the text of this section.

International epidemiologic studies of men occupationally exposed to Pb have reported on associations between Pb exposure or biomarker levels and sperm count and quality and semen quality. In most of these occupational studies, blood Pb levels over 40 µg/dL have been reported for individuals occupationally exposed to Pb. For example, studies performed in India (Naha and Manna, 2007; Naha and Chowdhury, 2006) reported that men in the highest exposure group (men working in battery or paint manufacturing plants for 10-15 years for 8 hours/day) had mean blood Pb levels of 77.22 µg/dL (Naha and Chowdhury, 2006) and 68.26 µg/dL (Naha and Manna, 2007). Control groups in these studies (those without occupational Pb exposure) had mean blood Pb levels below 15 µg/dL. Increases in levels of Pb in semen were also noted across exposure groups. Both studies report decreases in sperm count and in sperm velocity and motility with increasing Pb exposure. Higher Pb exposure was also associated with greater hyploidy of sperm DNA and morphologic abnormalities (Naha and Manna, 2007; Naha and Chowdhury, 2006). Decreased viability and increased lipid peroxidation were detected (Naha and Chowdhury, 2006). A study performed in Taiwan among men with high levels of blood Pb reported that men with higher blood Pb levels had increased sperm head abnormalities, increased sperm DNA denaturation, and increased sensitivity to denaturation compared to men with lower blood Pb levels (Hsu et al., 2009b). No difference was detected between three Pb exposure groups and semen volume, sperm count, motility, velocity, and reactive oxygen species production. A similar study in

Poland included employees exposed to Pb and compared them with a group of male office workers (Kasperczyk et al., 2008). Pb levels measured in seminal fluid were slightly higher among those in the exposed groups although they were not statistically different from the levels in the control group. No difference was observed for semen volume, sperm count, or sperm morphology among the groups. Sperm motility was lower in the highest exposure group compared to both the control and moderate exposure groups. Lipid peroxidation, which can induce tissue damage in sperm via reactive oxygen species, was greater in the highest exposure group compared to the controls.

A study performed in Croatia recruited men who had never been occupationally exposed to metals and therefore had lower blood Pb levels than the occupational studies (Telisman et al., 2007). Increased blood Pb was associated with increased percentages of pathologic sperm, wide sperm, and round sperm. There was also a slight increase in immature sperm although it was not statistically significant. Similar results were seen when other biomarkers for Pb (erythrocyte protoporphyrin and δ-aminolevulinic acid dehydratase [ALAD]) were used instead.

A few studies examined blood or seminal plasma Pb levels and semen quality of men at infertility clinics (Mendiola et al., 2011; Slivkova et al., 2009; Meeker et al., 2008). In general, these men had lower levels of Pb biomarkers than men that were occupationally exposed. Meeker et al. (2008) detected no associations between higher blood Pb and semen concentration, morphology, or motility (although a slight positive trend was observed between higher Pb levels and motility in unadjusted models). In models that include multiple metals, blood Pb was associated with being below the WHO limit of sperm concentration levels (less than 20 million sperm/mL), although the 95% CI was wide for the 4th quartile of Pb levels and included the null. Slivkova et al. (2009) reported a negative correlation between semen Pb and pathological changes in sperm (specifically, flagellum ball), but no correlations were observed for other alterations in the sperm. Another study reported a positive association between seminal plasma Pb concentration and percentage of immotile sperm, but this analysis did not adjust for exposure to other metals reported to be correlated with Pb concentration in the seminal plasma (Mendiola et al., 2011). No association was observed for seminal plasma Pb concentration and sperm concentration or percentage of morphologically normal sperm. Additionally, neither Pb levels in whole blood or plasma were associated with sperm concentration, percentage of immotile sperm, or percentage of morphologically normal sperm.

An abundance of evidence in the toxicological literature demonstrates that Pb exposure is detrimental to the quality and overall health of testicular germ cells. Earlier studies showed that chronic Pb exposure (15 weeks) in adult male rabbits, resulting in blood Pb

of 16-24 µg/dL, induced statistically significant decrements in semen quality and greater testicular pathology (Moorman et al., 1998). Recent studies corroborate earlier findings that Pb alters sperm parameters such as sperm count, viability, motility, and morphology. Anjum et al. (2010) exposed 50 day old male albino Wistar/NIN rats to Pb-acetate (273 or 819 mg/L in drinking water, 0.05% or 0.15%, respectively) for 45 days. Affected endpoints included reduced epididymal sperm count, motile sperm, and viable sperm, indicating decreased sperm production and quality. Anjum did not report blood Pb values. Wistar/NIN rats (0.15% Pb-acetate in drinking water for 70 days) supplemented with the herb Centella asiatica had significant attenuation of the Pb-induced changes observed by Anjum et al. (2010). Pillai et al. (In Press) found gestational and lactational treatment with Pb-acetate in Charles Foster rats (subcutaneous injection of 0.05 mg/kg BW/day) induced effects on sperm in adults (PND65) including significant decreases in testicular sperm count, epididymal sperm count, and sperm motility. Oliveira et al. (2009) observed a negative correlation between Pb dose and intact acrosomes. Rubio et al. (2006), Biswas and Ghosh (2006), and Salawu et al. (2009) observed a decrease in absolute testicular weight after Pb exposure. Rubio et al. (2006) and Biswas and Ghosh (2006) also observed a Pb-induced decrease in seminal vesicle and ventral prostate weights and Rubio et al. (2006) reported that Pb-acetate, in a exposure concentration-dependent manner (8-24 mg/kg body weight), reduced the length of certain stages of the spermatogenic cycle of rat seminiferous tubules and thus affected spermatogenesis. Oral Pb-acetate exposure (25 mg/kg bw in drinking water for 3 months, resulting in blood Pb level of 5.3 µg/dL) to adult male albino rats produced significant histological seminiferous tubule damage (epithelium, spermatocytes, acrosomes) that was attenuated with ascorbic acid treatment (Pb exposure + 100 mg/kg bw/day ascorbic acid, resulting in blood Pb level of 4.7 µg/dL) (El Shafai et al., 2011). Reshma Anjum et al. (2010) reported decreased testicular and epididymal weights, sperm count, and viable sperm of male rats exposed to Pb-acetate (273 mg/L or 819 mg/L in drinking water) which were significantly attenuated with Pb co-exposure to the herb Centella asiatica (Sainath et al., 2011). Pb induced morphological abnormalities in sperm in a concentration-dependent manner (Allouche et al., 2009; Oliveira et al., 2009; Salawu et al., 2009; Shan et al., 2009; Tapisso et al., 2009; Massanyi et al., 2007; Wang et al., 2006a). Sperm abnormalities reported after Pb exposures were amorphous sperm head, abnormal tail, and abnormal neck. Dong et al. (2009) reported decreased epididymis and body weights in mice after exposure to 0.6% Pb-acetate in drinking water. However, the majority of studies did not observe a statistically significant difference in body weight or reproductive organ weights after Pb exposure at the doses used in the studies. Not all of the aforementioned studies observed changes in every parameter. This may be due to the use of different strains or species, chemical form of the Pb compound administered,

dosage schedule, duration of exposure, and age of animals at the time of the study (Oliveira et al., 2009).

Data from recent studies suggest that a component of Pb-induced toxicity is the generation of reactive oxygen species (ROS) which can then affect antioxidant defense systems of cells (Pandya et al., 2010). Salawu et al. (2009) observed a statistically significant increase in malondialdehyde (MDA, oxidative stress marker) and a significant decrease in the activity of antioxidant enzymes superoxide dismutase (SOD) and catalase (CAT) in plasma and testes of adult male Sprague Dawley rats after administration of 1% Pb-acetate in drinking water for 8 weeks. Supplementation with tomato paste (used as a source of antioxidants) reduced Pb-induced ROS production and prevented the Pb-induced increase in MDA formation and decrease in SOD and CAT activity. Furthermore, co-treatment of Pb with substances that are known to have antioxidant properties [i.e., tomato paste, Maca (*Lepidium meyenii*), and ascorbic acid] prevented the Pb-induced reduction in sperm count, sperm motility, and sperm viability (Salawu et al., 2009; Shan et al., 2009; Madhavi et al., 2007; Rubio et al., 2006; Wang et al., 2006a).

Recent studies also demonstrate that Pb may be directly toxic to mature spermatozoa (Tapisso et al., 2009; Hernandez-Ochoa et al., 2006) as well as primary spermatocytes (Nava-Hernandez et al., 2009; Rafique et al., 2009). Nava-Hernandez et al. (2009) exposed two groups of rodent to Pb via drinking water (L1 and L2). In their study, all Pb-treated animals had blood Pb levels statistically significantly higher than controls (L1:19.54 µg/dL and L2:21.90 µg/dL); no statistically significant difference in blood Pb levels existed between the two Pb exposure groups likely because the L2 group drank less water than did the L1 group. Piao et al. (2007) reported that Pb exposure caused DNA damage to sperm; the Pb exposed group had a blood Pb of 67 µg/l. Piao et al. (2007) also examined the effect of Zn supplementation on Pb-induced sperm aberrations and found that the proportion of abnormal sperm was statistically significantly higher in the Pb group and the Pb+Zn group than in controls. However, the proportion of abnormal sperm in Pb+Zn group was statistically significantly lower than in Pb alone group. Hernandez-Ochoa et al. (2006) reported that Pb reaches the sperm nucleus in the epididymis of mice chronically exposed (16 weeks in adult animals) to Pb (resulting in mean blood Pb of 75.6 µg/dL) by binding to nuclear sulfhydryl groups from the DNA-protamine complex, increasing sperm chromatin condensation, and thereby interfering with the sperm maturation process without altering sperm quality parameters. Tapisso et al. (2009) observed a statistically significant increase in the number of micronuclei and frequency of sister chromatid exchange with increasing treatment duration in adult male mice administered 21.5 mg/kg body weight Pb-acetate by i.p. injection. Nava-Hernandez (2009) reported a concentration-dependent increase in DNA damage in rat primary spermatocytes after a 13-week exposure period to Pb-acetate in

drinking water (resulting in mean blood Pb levels between 19.5 and 21.9 µg/dL). Rafique et al. (2009) reported degenerative changes from pyknosis to apoptosis in primary spermatocytes. Hepatic expression of spermatogenic genes was transiently down-regulated in 8 week old male Wistar-Kyoto (WKY) rats in response to Pb nitrate (100 µmol single i.v. injection) 3 hours after injection and recovered to baseline by 12 hours (Nemoto et al., 2011); this effect was not seen in the stroke-prone spontaneously hypertensive rats, which are from a WKY background, or in Sprague-Dawley rats, demonstrating strain specificity.

Pb-induced apoptosis in germ cells within the seminiferous tubules is another suggested mechanism by which Pb exerts its toxic effects on sperm production and function (Wang et al., 2006a). Dong et al. (2009) reported a exposure concentration-related increase in apoptosis in spermatogonia and spermatocytes of Kunming mice after exposure to 0.15-0.6% Pb-acetate in drinking water. Pb-induced testicular germ cell apoptosis was associated with up-regulation of genes involved in the signal pathway of MAPK and death receptor signaling pathway of FAS. For instance, up-regulation of K-ras and Fas expressions was concomitant with activation of c-fos and active caspase-3 proteins. Wang et al. (2006a) observed a exposure concentration-dependent increase in the expression of apoptotic markers TGFβ1 and caspase-3 in spermatogenic cells, Sertoli cells, and Leydig cells. Shan et al. (2009) also reported a statistically significant increase in mRNA expression and protein levels of Fas, Fas-L and caspase-3 after Pb exposure. Supplementation with ascorbic acid inhibited or reduced the Pb-induced apoptosis in germ cells and protected testicular structure and function (El Shafai et al., 2011; Shan et al., 2009; Wang et al., 2006a) suggesting ROS generation is a major contributing factor in decreased male fertility observed after chronic Pb exposure.

Similar to the results summarized in previous Pb AQCDs, recent epidemiologic and toxicological studies indicate that high levels of Pb exposure have effects on sperm and semen. In studies of men exposed to Pb in occupational settings, associations were observed between blood Pb levels as low as 20-45 µg/dL and sperm count and quality. Multiple epidemiologic studies of occupational cohorts included control populations with high blood Pb levels (close to or greater than 10 µg/dL), which makes identification of effects at lower levels difficult. Future studies are warranted to determine whether this association is observed at lower Pb levels.

5.8.2.2 Effects on Hormone Levels

The 2006 Pb AQCD (U.S. EPA, 2006b) provided evidence that Pb acts as an endocrine disruptor in males at various points along the hypothalamic-pituitary-gonadal axis. The

2006 Pb AQCD also reported inconsistencies in the effects of Pb exposure on circulating testosterone levels. Recent epidemiologic and toxicological studies are reported below. Epidemiologic studies are summarized in Table 5-35 (biological samples used for the measurement of Pb in these studies were measured concurrently with hormone levels).

Table 5-35 Summary of recent epidemiologic studies of associations between Pb levels and hormones for males

[a]Studies are presented in order of first appearance in the text of this section.

Hormone levels were measured in a few recent epidemiologic studies. In a study of men non-occupationally exposed to Pb in Croatia, increased blood Pb level was associated with increasing serum testosterone and estradiol but decreasing serum prolactin (Telisman et al., 2007). In addition, the analysis of an interaction term for blood Pb and blood cadmium levels demonstrated a synergistic effect on increasing serum testosterone levels. No association was observed between blood Pb and FSH or LH. Another study of men with high blood Pb levels reported no difference in serum FSH, LH, and testosterone among the three groups (controls: mean blood Pb 10.25 µg/dL, low exposure: mean blood Pb 50.29 µg/dL, high exposure: mean blood Pb 68.26 µg/dL) (Naha and Manna, 2007). A study of occupationally-exposed men in Taiwan reported an association between measures of cumulative blood Pb levels and inhibin B levels, but no association was detected when using current blood Pb levels (Hsieh et al., 2009a). A correlation between cumulative blood Pb measures and LH levels was detected but correlations were not present when examining FSH or testosterone levels. No correlations were apparent between FSH, LH, or testosterone and current blood Pb levels.

Among men recruited from infertility clinics in Michigan, median blood Pb levels were much lower than those observed in the other studies of Pb and hormone levels among

men (Meeker et al., 2010). No association was detected between blood Pb and levels of FSH, LH, inhibin B, sex hormone-binding globulin (SHBG), free androgen index (FAI) or a measure of Leydig cell function (T/LH). A positive association between the highest quartile of blood Pb and testosterone was present, but this association did not persist when other metals were included in the model. Similarly, another study of men recruited from infertility clinics observed no association between Pb concentrations from seminal plasma, whole blood, or blood plasma and FSH, LH, or testosterone (Mendiola et al., 2011).

In a recent toxicological study, Rubio et al. (2006) observed a decrease in testosterone levels in Pb-acetate-treated rats in a exposure concentration-related fashion (8-24 mg/kg body weight), and this decrease correlated with reduced lengths of spermatogenic cycle stages VII-VIII (spermiation) and IX-XI (onset of spermatogenesis). Anjum et al. (2010), who dosed 50 day old male rats with 273 or 819 mg/L Pb-acetate in drinking water (0.05% or 0.15%, respectively; blood Pb not reported), found significant decreases in serum testosterone and testicular 3β-HSD and 17β-HSD levels in Pb-exposed animals versus controls. Pandya et al. (2010) reported altered hepatic steroidogenic enzyme activity. Pillai et al. (In Press) found gestational and lactational exposure to Pb-acetate in Charles Foster rats (subcutaneous injection of 0.05 mg/kg BW/day, blood Pb not reported) induced significant decreases in testicular 17β-HSD and serum testosterone. Biswas and Ghosh (2006) reported a Pb-induced decrease in serum testosterone and gonadotropins (FSH, LH) with inhibition of spermatogenesis, however, there was a statistically significant increase in adrenal steroidogenic enzyme, Δ5-3β-HSD activity and serum corticosterone levels indicating disruption of the adrenocortical process. Exposure concentration-dependent decreases in serum testosterone were reported in Pb-exposed male rats (Reshma Anjum et al., 2010). In contrast, Salawu et al. (2009) did not observe a decrease in serum testosterone between control animals and animals administered 1% Pb-acetate in drinking water for 8 weeks. Allouche et al. (2009) not only did not observe any statistically significant changes in serum FSH or LH, but reported an increase in serum testosterone levels after 0.05-0.3% Pb-acetate treatment in drinking water (only statistically significant in animals administered 0.05% Pb-acetate). The results of these recent studies further support the theory that compensatory mechanisms in the hypothalamic-pituitary-gonadal axis may allow for the adaptation of exposed animals to the toxic endocrine effects of Pb (Rubio et al., 2006; U.S. EPA, 2006b).

Overall, recent epidemiologic and toxicological studies report mixed findings regarding hormone aberrations in males associated with Pb exposure or Pb biomarker levels. These results are similar to those from the 2006 Pb AQCD on the effects of Pb exposure on circulating testosterone levels.

5.8.2.3 Fertility

Epidemiologic studies have been performed comparing Pb and infertility in men. A study conducted in Turkey reported that blood and seminal plasma Pb levels were different in fertile (mean [SD] blood Pb: 23.16 [5.59] µg/dL) and infertile men (mean [SD] blood Pb: 36.82 [12.30] µg/dL)($p < 0.001$, ANOVA) (Kiziler et al., 2007). The SMART study examined the success of IVF treatment for women and their partners starting their first round of treatment (Bloom et al., 2011b; Bloom et al., 2010). A small number of the male partners participated. Their mean (SD) blood Pb level was 1.50 (0.80) µg/dL. Higher blood Pb concentration was associated with greater oocyte fertilization (OR 1.08 [95% CI: 0.97, 1.21] per 1 µg/dL increase in blood Pb when adjusted for Cd), which is not the expected direction (Bloom et al., 2010). However, higher blood Pb was associated with lower embryo cell number (a predictor of IVF success) and associated with higher embryo fragmentation score (an inverse predictor of IVF success) (OR for embryo cell number: 0.58 [95% CI: 0.37, 0.91]; OR for embryo fragmentation score: 1.47 [95% CI 1.11, 1.94] per 1 µg/dL, controlled for Cd and Hg) (Bloom et al., 2011b). Another study examined occupational Pb exposure (determined by self-report of occupational exposure) and detected no difference in reported exposure for infertile versus fertile men (OR 0.95 [95% CI: 0.6, 1.6]) (Gracia et al., 2005). Blood Pb was not measured but approximately 5.0% of infertile men and 5.3% fertile men reported occupational exposure to Pb. As with the fertility studies among women, a limitation present in these studies is that the cases included are men who are seeking help at fertility clinics; the study populations are not a sample of the general population regarding fertility.

A couple of recent animal toxicology studies assessed paternal-mediated reproductive fitness by examining the reproductive success of Pb-exposed males with non-exposed control females. Anjum et al. (2010) found that adult male rats who were exposed to 273 or 819 mg/L Pb-acetate in drinking water (0.05%or 0.15%, respectively; blood Pb not reported) spent a significantly longer time copulating than did their control littermates. The Pb-exposed males were less successful copulators with only 73% of the 0.05% Pb-acetate exposed males, and 53% of the 0.15% exposed males generating copulatory plugs in the unexposed female mates. While the number of pregnant females did not significantly differ from controls, Pb exposed males contributed to the formation of significantly fewer implantations/dam, and significantly fewer fetuses/dam. Pb-exposed males were able to sire offspring, but produced fewer offspring per litter. In a group of males rats with co-exposure to Pb and the herb Centella asiatica, these reproductive decrements were attenuated relative to rats exposed to Pb alone (Sainath et al., 2011).

5.8.2.4 Puberty

Research has also been published examining the association between blood Pb and onset of puberty in males. These epidemiological studies are summarized in Table 5-36. The majority of studies used concurrent measures of blood Pb and puberty (Den Hond et al., 2011; Tomoum et al., 2010; Hauser et al., 2008), but Williams et al. (2010) performed a longitudinal analysis of blood Pb levels measured at ages 8-9 years and pubertal onset.

Table 5-36 Summary of recent epidemiologic studies of associations between Pb levels and puberty for males

(2011)	Flanders 2003-2004	Tanner staging and gynecomastia	Boys ages 14 and 15, in their 3rd year of secondary education and living in the same study areas for at least 5 years	Blood Pb	Median: 2.50 10th percentile: 1.20 90th percentile: 5.12	OR (95% CI) for gynecomastia with doubling of exposure 1.84 (1.11, 3.05) No association between Pb and pubic hair or genital development (results not given)

[a]Studies are presented in order of first appearance in the text of this section.

Studies were performed among a cohort of Russian boys enrolled between ages 8-9 years (Williams et al., 2010; Hauser et al., 2008). The area where these studies were performed had various environmental contaminants such as dioxin, polychlorinated biphenyls, and other metals, present. Both the cross-sectional study (Hauser et al., 2008) and the

prospective study with annual follow-ups (Williams et al., 2010) demonstrated an association; higher blood Pb levels at 8-9 years of age was associated with later onset of puberty. In a study of boys in Egypt, boys with higher blood Pb had delayed pubertal development compared to those with lower levels (median age in the high blood Pb group was 12.5 years compared to 13.0 years in the low blood Pb group) (Tomoum et al., 2010). In addition, compared to the low blood Pb group, those boys with higher blood Pb had lower testosterone, FSH, and LH levels. A study in Flanders reported no associations between blood Pb concentration and pubertal development among 14 and 15 year old boys (Den Hond et al., 2011). However, higher blood Pb levels were associated with an increased odds of gynecomastia.

No recent toxicological studies address Pb-induced male sexual maturation and development, but older studies do provide support to findings in epidemiologic cohorts. Pb exposure resulted in delayed sexual maturity as measured by prostate weight in male Sprague-Dawley pups at PND 35. These pups were exposed chronically to 0.15 or 0.45% Pb-acetate in dam or their own drinking water from GD5 until PND85 and had blood Pb ranges from low to high of 88-196 and 120-379 μg/dL, respectively (Ronis et al., 1998b). Cynomolgus monkeys exposed to Pb over a lifetime (10 years, blood Pb levels ranging from 30–60 μg/dL) had altered pituitary and Sertoli cell function along with decreases in inhibin/FSH ratio and reduced gonadotropin-releasing hormone (GnRH) stimulation of LH release in adulthood (Foster et al., 1993; Foster, 1992), all indicators that are important in proper sexual maturation. Further mechanistic understanding of the effect of Pb can be gleaned from studies in adult male Wistar rats exposed to Pb for 1 month (starting at PND56, 0.1 or 0.3% Pb-acetate in drinking water, respective blood Pb levels of 34 or 60 μg/dL) that showed significant decreases in FSH, ventral prostate weight and serum testosterone but no change in serum LH (Sokol et al., 1985). These Pb-exposed adult male rats (0.3% Pb-acetate in drinking water starting at PND56 for 30 days) demonstrated an impaired pituitary release of LH in response to challenge of the hypothalamic–pituitary–adrenal (HPA) axis with the opiate antagonist naloxone, an enhanced release of LH from the pituitary in response to direct stimulation of the pituitary with luteinizing hormone-releasing hormone (LHRH), an enhanced response to human chorionic gonadotropin (hCG) by the testes, increased pituitary LH stores, and increased GnRH mRNA levels in the hypothalamus (Klein et al., 1994; Sokol, 1987). Thus, Pb likely interferes with the male HPA axis, contributing to its reproductive toxicity.

In summary, recent epidemiologic studies have demonstrated an inverse effect of Pb on pubertal development among boys at low concurrent blood Pb levels. No recent toxicological studies were found that addressed the effect of Pb on male sexual development and maturation; however, the 2006 Pb AQCD (U.S. EPA, 2006b) supported

earlier findings that Pb exposure may result in delayed onset of male puberty and altered reproductive function later in life in experimental animals.

5.8.2.5 Effects on Morphology and Histology of Male Sex Organs

Recent toxicological studies further support historical findings that showed an association between Pb exposure and changes in the sex organs as well as germ cells. Histological changes of testes in Pb nitrate-treated animals (a single i.p. dose of 12.5, 25, or 50 mg/kg of BW and were sacrificed 48 hours later) included seminiferous tubule atrophy, Sertoli cell and Leydig cell shrinkage with pyknotic nuclei (Shan et al., 2009; Wang et al., 2006a), dilatation of blood capillaries in the interstitium, undulation of basal membrane, and occurrence of empty spaces in seminiferous epithelium (Massanyi et al., 2007). Pillai et al. (In Press) found gestational and lactational exposure to Pb-acetate in Charles Foster rats (subcutaneous injection of 0.05 mg/kg BW/day) induced significant decreases in absolute organ weight (testes and epididymis) and significant decreases in relative epididymal weight. Anjum et al. (2010), who exposed 50 day old male albino Wistar/NIN rats to Pb-acetate (273 or 819 mg/L in drinking water, 0.05% or 0.15%, respectively, blood Pb levels not reported) for 45 days, reported significant decreases in relative reproductive organ weight (epididymis, testis, vas deferens, and seminal vesicle) in Pb-exposed animals. .

5.8.2.6 Summary of Effects on Male Reproductive Function

Evidence of associations between Pb exposure and male reproductive function vary by outcome. The strongest evidence of an association is the relationship observed between Pb and negative effects on sperm and semen in both recent epidemiologic and toxicological studies and studies reviewed in previous Pb AQCDs. Many of the epidemiologic studies included occupational cohorts, which had high blood Pb levels. Recent toxicological studies also reported an association between Pb exposure and decreases in reproductive organ weight, organ histological changes in the testes and germ cells. Male rats exposed to Pb also showed subfecundity in that they produced smaller litters when mated with unexposed females. In addition, recent epidemiologic studies found blood Pb levels to be associated with delayed pubertal development in boys with low concurrent blood Pb levels (mean/median blood Pb levels <10 µg/dL). This is supported by earlier toxicological studies. Similar to the 2006 Pb AQCD (U.S. EPA, 2006b), recent epidemiologic and toxicological studies reported inconsistent results regarding hormone aberrations associated with Pb exposure. Mixed findings were also apparent among epidemiologic studies of fertility among men.

5.8.3 Effects on Ovaries, Embryo Development, Placental function, and Spontaneous Abortions

The 2006 Pb AQCD (U.S. EPA, 2006b) included studies of Pb exposure among men and women and their associations with spontaneous abortions. The 2006 Pb AQCD concluded that overall there was little evidence to support an association between Pb exposure among women and spontaneous abortion (U.S. EPA, 2006b). Most of the studies examined in the 2006 Pb AQCD assigned exposure based on living near a smelter or working in occupations that often result in Pb exposure and the results of these studies were inconsistent. Little evidence was available in the 2006 Pb AQCD to suggest an association with paternal Pb levels (U.S. EPA, 2006b), and no recent studies have been performed to examine paternal Pb levels and spontaneous abortion. Since the 2006 Pb AQCD, multiple epidemiologic studies have been published that examine Pb levels in women and their possible association with spontaneous abortion. Additionally, toxicological studies have studied the effects of Pb on fetal loss and the contribution of the ovaries and placenta to fetal loss.

Table 5-37 Summary of recent epidemiologic studies of associations between Pb levels and spontaneous abortions

Reference[a]	Study Location	Outcome	Study population	Pb Biomarker	Mean Pb (SD) in µg/dL	Adjusted Effect Estimates
Yin et al. (2008)	Shanxi Province, China 2004-2006	Anembryonic pregnancy	Women age 25-35 yr old and at 8-12 weeks of gestation at study entry; cases were anembryonic pregnancies and controls were normal pregnancies that ended in a live birth between 37-42 weeks	Maternal blood Pb after miscarriage for cases and at study enrollment for controls	Cases: 5.3 (95% CI: 5.2, 5.9) Controls: 4.5 (95% CI: 3.7, 5.0)	Comparisons between log-transformed blood Pb levels of cases and controls performed via Student's t-test had a p-value of 0.03

(2010)	Tehran, Iran 2006-2008	Pregnancy ended before 20 weeks of gestation	Women who were non-smokers, non-obese, had no chronic health conditions, had their last menstrual period less than 12 weeks prior, and were pregnant with a singleton infant	Maternal blood Pb during weeks 8-12 of pregnancy	3.8 (2.0) Spontaneous abortion: 3.51 (1.42) Non-spontaneous abortion: 3.83 (1.99)	T-test for difference in mean values: 0.41 OR: 0.331 (95% CI: 0.011, 10.096) for an increase in log-transformed blood Pb (units not given, assume 1 µg/dL)
Lamadrid-Figueroa et al. (2007)	Mexico City, Mexico 1997-1999, 2001-2004	Previous miscarriage	Women who had a previous pregnancy and were currently pregnant with gestational age of ≤ 14 wks	Maternal and umbilical cord blood Pb, maternal bone Pb	Overall: Blood Pb: 6.2 (4.5) Plasma Pb: 0.014 (0.013) Cases: Blood Pb: 5.8 (3.4) Plasma Pb: 0.014 (0.013) Controls: Blood Pb: 6.5 (4.9) Plasma Pb: 0.013 (0.013)	Categorized Plasma Blood Pb ratio: 1st tertile: 1.00 (Ref) 2nd tertile: 1.16 (p-value 0.61) 3rd tertile: 1.90 (p-value 0.015) IRR (95%CI) Per 1 SD increase: Plasma Pb 1.12 (p-value 0.22) Blood Pb 0.93 (p-value 0.56) Plasma/Blood Pb ratio 1.18 (p-value 0.02) Patella Pb 1.15 (p-value 0.39) Tibia Pb 1.07 (p-value 0.56)
Gundacker et al. (2010)	Vienna, Austria 2005	Previous miscarriage	Women recruited during the second trimester of pregnancy	Whole placentas shortly after birth	Median (IQR): 25.8 (21.0, 36.8)	Median Placenta Pb: Women who had not previously miscarried: 27 µg/kg Women who had previously miscarried: 39 µg/kg (p-value for difference: 0.039)

[a]Studies are presented in order of first appearance in the text of this section.

Table 5-37, above, provides a summary of the recent epidemiologic studies examining the association between Pb biomarker levels and past and current spontaneous abortion. Yin et al. (2008) performed a study in the Shanxi Province of China to examine if plasma Pb levels were associated with anembryonic pregnancies (spontaneous abortions during the first trimester, which account for 15% of all spontaneous abortions). Women were enrolled at 8-12 weeks of gestation. Women who delivered a term pregnancy had mean plasma Pb levels that were lower than those of women who had an anembryonic pregnancy. Of note, among cases plasma Pb level was inversely correlated with folate and vitamin B12, but this correlation was not observed among those who delivered at term; no models examining plasma Pb levels adjusted for nutrient status. Another study

examining spontaneous abortions occurring early in the pregnancy was conducted in Iran (Vigeh et al., 2010). Mean blood Pb concentrations were similar in women who did and did not have spontaneous abortions. Higher blood Pb levels were not associated with greater odds of spontaneous abortions before 20 weeks of pregnancy. A study in Turkey reported on groups of women who either had a spontaneous abortion before the 20th week of gestation or who had a viable pregnancy (Faikoglu et al., 2006). No difference was detected between the blood Pb levels of the two groups (Pb levels not reported here due to calculation errors discovered in the paper; errors do not appear to affect conclusions). A study in Mexico City examined a group of pregnant women (maximum gestational period at enrollment was 14 weeks) who had previously been pregnant and either given birth or had a spontaneous abortion (Lamadrid-Figueroa et al., 2007). Women in the highest tertile of plasma/blood Pb ratio had higher rates of previous spontaneous abortions than did women in the lowest tertile. The authors state that the plasma/whole blood ratio represents the bioavailability of Pb, which is capable of crossing the placental barrier for a given blood concentration. No association was observed when examining the relationship between Pb and spontaneous abortions using whole blood, plasma, or bone Pb alone. Similarly, a study of placental Pb levels among pregnant women in Austria observed higher placenta Pb levels among women who had miscarried a previous pregnancy compared to women who had not miscarried a previous pregnancy (Gundacker et al., 2010). It is important to note that the number of women included in the study was small (only 8 women reported previously having a miscarriage)

In toxicological studies, isolated embryo cultures are often used to understand the mechanisms responsible for aberrant embryo development as it may contribute to teratogenesis, fetal loss or negative postnatal pup outcomes. Nandi et al. (2010) demonstrated an exposure concentration-dependent decline in embryo development of fertilized buffalo oocytes cultured in medium containing 0.05-10 µg/mL Pb-acetate as evidenced by reduced morula/blastocyst yield and increased four-to eight-cell arrest, embryo degeneration, and asynchronous division. This study provides evidence of the negative effect of Pb on embryo development and contributes mechanistic understand to Pb-dependent pregnancy loss.

A possible explanation for reduced fertility and impaired female reproductive success as a result of Pb exposure is changes in morphology or histology in female sex organs and the placenta (Dumitrescu et al., 2007; U.S. EPA, 2006b). Wang et al. (2009e) observed that elevated maternal blood Pb (0.6-1.74 µM, ~12.4-36.0 µg/dL) compared to control (0.04 µM, ~0.83 µg/dL) were associated with decreased fetal body weight, pup body length, and placental weight in Wistar rats. The authors reported that placentae from Pb-exposed groups showed concentration-dependent increasing pathology of cytoarchitecture and cytoplasmic organelles. The authors also reported a positive

expression of NF-κB, a transcription factor that controls the expression of genes involved in immune responses, apoptosis, and cell cycle, in the cytotrophoblasts, decidual cells, and small vascular endothelial cells in rat placenta under a low-level Pb exposure condition which correlated with low blood Pb levels.

Pb-exposed (273 mg/L or 819 mg/L in drinking water, 0.05 or 0.15% Pb Acetate, respectively) male rats from Reshma Anjum et al. (2010) that had an exposure concentration-dependent decreases in serum testosterone, decreased male reproductive organ weight and decreased sperm were mated to untreated females. These untreated dams had male related exposure concentration-dependent decreased implantation rate and higher pre- and post-implantation loss, indicating paternally mediated fetal loss. The magnitude of these effects in dams was dependent on the concentration of Pb exposure in their male mating partners.

As observed in sperm cells, Pb stimulates changes in antioxidant enzyme activity in rat ovaries indicating that oxidative stress may be a contributing factor in Pb-induced ovarian. Nampoothiri et al. (2007) observed a reduction in SOD activity and an increase in CAT activity along with a decrease in glutathione content and an increase in lipid peroxidation in rat granulosa cells after 15 days of Pb treatment (0.05 mg/kg body weight).

Previous studies demonstrated that Pb accumulates in the ovaries and causes histological changes, thus contributing to Pb-induced effects on female fertility (U.S. EPA, 2006b). In support of historical studies, recent studies demonstrate Pb-induced histological changes in ovarian cells of pigs (Kolesarova et al., 2010) and rats (Nampoothiri et al., 2007; Nampoothiri and Gupta, 2006). Kolesarova et al. (2010) observed a reduction of the monolayer of granulosa cells after Pb addition (0.5 mg/mL). Nampoothiri and Gupta (2006) reported that Pb exposure caused a decrease in cholesterol and total phospholipid content in the membranes of granulosa cells which resulted in increased membrane fluidity. A possible explanation for reduced fertility and impaired female reproductive success as a result of Pb exposure is changes in morphology or histology in female sex organs and the placenta (Dumitrescu et al., 2007; U.S. EPA, 2006b).

Overall, the recent studies support the conclusions of the 2006 Pb AQCD that there is insufficient evidence among epidemiologic studies to suggest an association between Pb and spontaneous abortions. It is important to note that studies of spontaneous abortions are difficult to conduct. The majority of spontaneous abortions are during the first trimester, which makes them difficult to capture. Women may miscarry before being enrolled in a study and many women may not have known they were pregnant when they miscarried. This limits the ability to detect subtle effects, especially if higher Pb levels do lead to increased risk of early spontaneous abortions. Toxicological data provide

mechanistic understanding of the contribution of Pb exposure to spontaneous abortions. These laboratory data show that Pb exposure impaired placental function, induced oxidative stress and histological changes in the ovaries, and affected embryo development. The toxicological and epidemiologic data provide mixed evidence on the role of Pb in spontaneous abortions.

5.8.4 Infant Mortality and Embryogenesis

The 2006 Pb AQCD (U.S. EPA, 2006b) concluded that Pb exposure can increase fetal mortality and produce sublethal effects (disrupt growth and development) in offspring of Pb exposed dams at concentrations that do not result in clinical toxicity to the dams by disrupting implantation and pregnancy, particularly at the blastocyst stage of development. In rodent studies gestational exposure to Pb (blood Pb 32 to >70 μg/dL) resulted in smaller litters and fewer implantation sites and in non-human primates pre- and perinatal mortality was reported in squirrel monkeys exposed to Pb (mean dam blood Pb of 54 μg/dL) in the last two-thirds of gestation (U.S. EPA, 2006b). There is substantial evidence to show that there is no apparent maternal-fetal barrier to Pb and it can easily cross the placenta and accumulate in fetal tissue during gestation (Pillai et al., 2009; Wang et al., 2009e; Uzbekov et al., 2007). No recent studies have reported on the relationship between Pb levels and infant mortality.

5.8.5 Birth Defects

The 2006 Pb AQCD (U.S. EPA, 2006b) reported the possibility of small associations between high Pb exposure and birth defects, but many of the epidemiologic studies used occupational histories instead of actual measures of blood Pb levels. Among the studies included in the 2006 Pb AQCD, a couple studies reported possible associations between parental exposure to Pb and neural tube defects (Irgens et al., 1998; Bound et al., 1997). Recent studies also examined indicators of Pb exposure and neural tube defects (Table 5-38). No other recent epidemiologic studies of Pb exposure and birth defects were identified in the literature. No recent toxicological studies were found that investigated Pb-induced changes in morphology, teratology effects, or skeletal malformations of developing fetuses as a result of maternal Pb exposure; however, in the 2006 Pb AQCD toxicological studies demonstrated associations between exposure to high doses of Pb and increased incidences of teratogenic effect in experimental animals.

Table 5-38 Summary of recent epidemiologic studies of associations between Pb levels and neural tube defects

Reference[a]	Study Location	Study Population	Pb Biomarkers and Exposure Measurement	Mean Pb (SD) in µg/dL	Adjusted Effect Estimates
Zeyrek et al. (2009)	Turkey NS	Infants with gestational age of at least 20 wks	Maternal and umbilical cord blood Pb taken 0.5h after birth	Cases: Maternal: 15.5 (15.0) Umbilical cord: 18.2 (17.8) Controls: Maternal: 12.5 (12.7) Umbilical cord: 16.5 (16.1)	P-values for differences of Student's t-test or Mann-Whitney U test (dependent on distribution) were 0.35 for maternal blood Pb and 0.63 for umbilical cord blood Pb

[a]Studies are presented in order of first appearance in the text of this section.

Among the recent epidemiologic studies (described in Table 5-38), a study of women in Turkey detected no difference between the blood Pb of mothers or the umbilical cord blood Pb of the newborns for healthy infants compared with infants with neural tube defects (cases of spina bifida occulta were excluded, but other forms of spina bifida were included) (Zeyrek et al., 2009). Brender et al. (2006) performed a study of Mexican-American women living in Texas. Measurements were taken 5-6 weeks postpartum, which is a limitation of this study because the blood Pb levels may be different from those during the developmental period of gestation. The OR comparing women with at least 6 µg/dL blood Pb to those with less than 6 µg/dL blood Pb was 1.5 (95% CI: 0.6, 4.3). This increased after adjusting for breast feeding, although this variable was not a confounder because it cannot be associated with neural tube defects. For these women, neither occupational exposure to Pb nor proximity of residence to a facility with Pb air emissions at the time of conception was associated with increased odds of neural tube defects. A study with an ecologic design was performed in China and did not use individual-level biomarkers to determine Pb levels (Huang et al., 2011b). A positive association between Pb levels in soil samples and neural tube defects was reported Exposure to multiple other trace elements also demonstrated a positive association but no control for co-exposures was included in the models for Pb.

Previous studies included in the 2006 Pb AQCD observed associations between Pb and neural tube defects but were limited due to the lack of biologically measured Pb [Pb was measured in drinking water (Bound et al., 1997) and estimated from occupational reports (Irgens et al., 1998)]. A recent ecologic study reported an association between Pb in the soil and neural tube defects but was also limited by its lack of biological samples, as well as a lack of individual-level data and the prevalence of several other metals (Huang et al.,

2011b). Other recent epidemiologic studies of maternal blood Pb levels and neural tube defects observed no associations (Zeyrek et al., 2009; Brender et al., 2006).

5.8.6 Preterm Birth

Epidemiologic studies on preterm birth included in the 2006 Pb AQCD (U.S. EPA, 2006b) reported inconsistent findings regarding the relationship between Pb and gestational age. Recent studies have examined this potential association and again mixed results were reported (Table 5-39). Of these studies, the ones that categorized births as preterm or term all defined preterm birth as less than 37 weeks of gestation. One limitation to note for these studies is that if Pb affects spontaneous abortion and length of gestation via a similar pathway, then the studies that only collect data at delivery and not at earlier stages of pregnancy would be biased toward the null.

Table 5-39 Summary of recent epidemiologic studies of associations between Pb levels and preterm birth

Reference[a]	Study Location	Outcome	Study Population	Pb Biomarkers or Exposure Measurement	Mean Pb (SD) in µg/dL	Adjusted Effect estimates
Berkowitz et al. (2006)	Idaho 1970-1981	Preterm birth (<37wk)	Singleton births with 28-45 wk gestation	Three time periods of two locations (unexposed and exposed/near smelter): pre-fire, "high-exposure period" (when a fire happened at the smelter and resulted in damages leading to high air Pb concentrations for 6 mo), and "post-fire"	NS	OR (90% CI) (unexposed location is referent group): Pre-fire 0.93 (0.67, 1.28) High exposure 0.68 (0.34, 1.35) Post-fire 1.17 (0.95, 1.45)

[a]Studies are presented in order of first appearance in the text of this section.

A study of preterm birth included women living in two different residential areas over three different time periods (Berkowitz et al., 2006). One residential area had consistently lower exposures but the other had a period of high Pb emissions due to damage at a local

factory. Preterm birth rates were examined during three time periods: before, during, and after the time of higher Pb exposure. No association was observed between women living in the high exposure area compared to those in the low exposure area during any of the exposure time periods, but the number of preterm infants born during the period of higher exposure was small.

In another study, measurements of umbilical cord blood were taken after birth at a hospital in Nagpur, India (Patel and Prabhu, 2009). A sample of women had their blood Pb measured and among this sample, maternal blood Pb was correlated with the umbilical cord Pb levels. Mean gestational age differed between infants with >5 µg/dL cord blood Pb and infants with ≤ 5 µg/dL cord blood Pb. In a linear regression model, gestational age was found to decrease with increasing umbilical cord Pb levels. A study of women in Tennessee consisted primarily of African American women living in an urban setting (Jones et al., 2010). The mean level of umbilical cord blood Pb was slightly higher among infants born preterm but the difference was not statistically significant. Using umbilical cord blood Pb measures, a study reported no association between cord blood Pb levels and gestational age. The concentrations of cord blood Pb among study participants were overall low (99.3% had umbilical cord blood Pb ≤ 5 µg/dL) (Wells et al., 2011a).

In a study taking place in California, women with information on blood Pb levels during pregnancy based on their participation in a surveillance program (reason for participation in the surveillance program was unknown but the authors speculate it was likely because of potential Pb exposure) were matched with the birth certificates of their infants (Jelliffe-Pawlowski et al., 2006). Almost 70% of women had maximum blood Pb measurements <10 µg/dL with the majority being <5 µg/dL. Preterm birth was associated with higher blood Pb when comparing women with maximum blood Pb levels ≥ 10 µg/dL to women with blood Pb levels <10 µg/dL in adjusted analyses. In analyses of maximum Pb levels further refined into additional categories, the odds of preterm birth were elevated among women with maximum blood Pb measurement ≥ 20 µg/dL compared with women with maximum blood Pb levels ≤ 5 µg/dL. A study in Iran also reported higher maternal blood Pb for preterm births than for term births (Vigeh et al., 2011). The women in this study had lower blood Pb levels than did those observed in the Jelliffe-Pawlowski et al. study (Jelliffe-Pawlowski et al., 2006). Higher maternal blood Pb level was associated with higher odds of preterm birth. Another study examining blood Pb and gestational age among women with lower blood Pb levels reported an inverse association between maternal blood Pb concentration and gestational age, especially for blood Pb levels early in pregnancy (Cantonwine et al., 2010a). However, a study conducted in New York among women with lower blood Pb levels (inclusion criteria mandated that blood Pb concentration be less than 10 µg/dL), no association was observed between blood Pb levels and preterm birth (Zhu et al., 2010). Similarly, a study

of maternal and paternal blood Pb concentrations reported no association between maternal or paternal blood Pb levels and preterm birth (Chen et al., 2006a).

A study of breast milk in the second month postpartum reported no difference in breast milk Pb levels for those infants born preterm or term; however, a limitation of this study is that Pb levels were not measured until two months after the birth (Örün et al., 2011).

In sum, as in the 2006 Pb AQCD, recent epidemiologic studies report inconsistent findings for a relationship between indicators of Pb exposure and preterm birth. No patterns were apparent within type of exposure measurement or Pb level.

5.8.7 Low Birth Weight/Fetal Growth

The 2006 Pb AQCD reported inconsistent epidemiologic study results for the associations between Pb and birth weight/fetal growth and concluded that there could be a small effect of Pb exposure on birth weight and fetal growth (U.S. EPA, 2006b). Since then, multiple epidemiologic studies on the relationship between Pb exposure and birth weight and fetal growth have been published using various measures of exposure, such as air levels, umbilical cord blood, and maternal blood and bone. These studies are summarized in Table 5-40 below. Additionally, there have been a few recent toxicological studies evaluating the effect of Pb exposure during gestation on birth weight.

Table 5-40 Summary of recent epidemiologic studies of associations between Pb levels and low birth weight and fetal growth

[a]Studies are presented in order of first appearance in the text of this section.

Women residing in two different towns in Yugoslavia (one with a Pb smelter and one without a Pb smelter) were recruited during their first prenatal visit (Lamb et al., 2008) (study based on previous work by Factor-Litvak et al. (1991). The mid-pregnancy blood Pb levels were greater in women from the town with a Pb smelter. No association was reported between maternal blood Pb and height or BMI at birth for the infants of these women despite the differences in maternal blood Pb between the two towns. Multiple studies were conducted that examined the association between maternal blood Pb and birth weight/fetal growth. In California, blood Pb measurements of women during pregnancy were matched with the corresponding birth certificates (Jelliffe-Pawlowski et

al., 2006). The adjusted OR for low birth weight that compared women with blood Pb levels ≥ 10 µg/dL to women with levels <10 µg/dL was elevated. However, it was difficult to draw conclusions about the relationship between blood Pb and birth weight due to small numbers (n = 9 for low birth weight) and the subsequently wide 95% CI. An association was detected for high blood Pb and having an infant who was small of his/her gestational age (SGA). A study of term births in Iran reported no difference in blood Pb of women giving birth to a normal weight infant and women giving birth to an infant with low birth weight (Iranpour et al., 2007). A study in Vienna, Austria reported an inverse association between maternal blood Pb levels and birth weight but no associations for birth length or head circumference (Gundacker et al., 2010). Similarly, increased maternal blood Pb was associated with decreased birth weight, with the strongest associations observed at the lowest blood Pb level (Zhu et al., 2010). No association was observed between maternal blood Pb and SGA. A study in Taiwan examined both maternal and paternal blood Pb levels among those occupationally exposed to Pb and their associations with birth weight and SGA (Chen et al., 2006a). Paternal blood Pb levels were not associated with increased risk of low birth weight or SGA. Higher maternal blood Pb concentration was associated with higher risk of low birth weight and SGA, although not all of the associations were statistically significant. There were small numbers of infants with low birth weight or SGA, especially at the highest blood Pb levels (≥ 20 µg/dL).

A study examining the association between Pb biomarker levels and birth weight used tibia bone measurements from mothers living in Mexico City (Kordas et al., 2009). Tibia Pb levels were inversely associated with birth weight but not with birth length. This association between Pb and birth weight was not modified by maternal folate consumption or maternal or infant MTHFR genotype, although the association between tibia Pb levels and birth weight was greater in magnitude among women with certain genotypes (statistical tests not reported). Another study in Mexico City reported no association between maternal tibia Pb levels and birth weight among girls but reported a positive association for boys (Afeiche et al., 2011). No associations were observed with maternal patella Pb concentration, although among boys, the relationship was positive but not statistically significant. One of the cohorts used by Afeiche et al. (2011) was also evaluated in another study (Cantonwine et al., 2010b). An inverse association was observed between tibia Pb and birth weight, especially at higher levels. This association was stronger among those mothers with variants of the hemochromatosis iron gene (HFE).

Multiple studies examined the relationship between Pb level and birth weight using Pb measured from the placenta or umbilical cord. Researchers in Chile collected the placentas from term births and compared the Pb levels for those born with normal birth

weights to those with low birth weights (Llanos and Ronco, 2009). Pb levels were greater in the placentas of infants with low birth weights. In addition, the authors note that 3 low birth weight infants had extremely high Pb levels in the placentas (>1.5 µg/g) and were excluded from these analyses. A study in Brazil examined Pb levels in umbilical cord blood from term births of women residing within 5 km of a Pb smelter (Zentner et al., 2006). The cord blood Pb level was found to be inversely correlated with length and weight of the infants. A study with high Pb concentrations in umbilical cord blood reported an inverse association between Pb levels and birth weight (Atabek et al., 2007). However, no correlation was detected in an analysis restricted to umbilical cord Pb less than 10 µg/dL. No association with other measures of growth, such as birth length and mid-arm circumference, were detected. In Saudi Arabia, a study was conducted among non-occupationally exposed women (Al-Saleh et al., 2008b). Umbilical cord blood Pb concentrations were low and an association was observed between umbilical cord Pb and head circumference. Another study recruited women in Pakistan (Janjua et al., 2009). Umbilical cord blood Pb levels were not associated with low birth weight. The study by Iranpour et al. (2007) discussed above investigated the association with umbilical cord blood Pb levels in addition to their examination of maternal whole blood Pb. They again report no difference in levels between term infants of normal and low birth weight. A study comparing geometric mean umbilical cord blood Pb levels reported no difference in the levels for normal and low birth weight infants born to women living primarily in urban areas of Memphis, TN (Jones et al., 2010). A study performed in Baltimore, MD also reported no association between umbilical cord blood Pb concentration and birth weight (Wells et al., 2011a). This study had low blood Pb levels, with only 0.7% of participants having umbilical cord blood Pb measuring > 5 µg/dL. A study previously mentioned that observed an inverse association between maternal tibia Pb and birth weight in Mexico City reported no association between umbilical cord blood Pb concentration and birth weight (Cantonwine et al., 2010b). Finally, a study in Vienna measured Pb in the placenta (Gundacker et al., 2010). A positive correlation was observed between placenta Pb and birth length and weight; however, in the same study, maternal blood Pb was inversely related to birth weight.

A study performed in Turkey examined the relationship between Pb levels in breast milk two months postpartum and size at birth (Örün et al., 2011). No association was observed between breast milk Pb concentration and birth weight or head circumference.

A few studies examined air exposures and reported inverse associations between air Pb concentrations and birth weight. Williams et al. (2007) examined Pb concentrations in the air during the first trimester. The purpose of their study was to demonstrate the use of hierarchical linear models and they used the example of air pollution and birth weight in Tennessee. The model results showed an association between ambient Pb concentration

and birth weight, with an estimated decrease in birth weight of 38 grams for every 0.04 µg/m^3 (i.e., one standard deviation) increase in Pb concentration. Another study of air Pb levels was conducted in Idaho and included two areas over three time periods. One study area was affected by damage to a local factory that lead to high Pb emissions during one of the time periods under study (Berkowitz et al., 2006). No levels of Pb are provided. Mean birth weight for term births was decreased among infants born to women living in the high exposure area during the period of high exposure compared to those living in the lower exposure area. The difference in birth weight of term births remained, but was reduced, between the two areas during the time period after the exposure ended. During the period of higher exposure, the odds of low birth weight among term births was increased among those living in the higher exposed area compared to those in the lower exposed area, but the odds were not different between the two study areas during the time periods before or after the high level of exposure. An increase in SGA infants (defined as infants with weights less than or equal to the lowest 5th percentile of birth weight for their sex and age) was also associated with living in the higher exposed area during the time period of higher exposure. The odds of SGA infants decreased during the time period after the exposure but the odds were still elevated compared to those residing in the lower exposed area.

Evidence from previous toxicological studies has shown an association between gestational Pb exposure and reduced birth weight and impaired postnatal growth (U.S. EPA, 2006b). More recent studies have reported conflicting results. Wang et al. (2009e) demonstrated a statistically significant decrease in fetal body weight and body length of Wistar rats after maternal exposure to 0.025% Pb-acetate during gestation days 1-10, 11-20, or 1-20. The greatest decrease in fetal body weight and length was observed in the group exposed to Pb during gestation days 1-20 followed by the group exposed to Pb during gestation days 11-20. Teijón et al. (2006) observed that when pregnant dams were administered 200 ppm or 400 ppm Pb-acetate in drinking water, litter weight was significantly decreased (400 ppm Pb only) versus controls due to significant decrements in female pup birth weight; male birth weight was unaffected. This effect did not persist in the postnatal growth of the rats. The results of these studies indicate that as Pb exposure increases, the body weight of exposed offspring decreases. Massó-González and Antonia-García (2009) also observed an 8-20% decrease in body weight of pups from rat dams given 300 mg/L Pb-acetate in drinking water (exposure during gestation and lactation resulting in mean blood Pb level of 22.8 µg/dL), but no changes in body length were reported. In contrast, Leasure et al. (2008) reported a statistically significant inverse relationship between Pb exposure and body weight for male mice exposed to low (27 ppm)-and high (55 ppm)-levels of Pb during gestation. Male mice exposed to the low and high Pb concentrations during gestation were 26% and 13% heavier than controls at 1 year of age, respectively. In this study, dams were administered 27 ppm (low), 55 ppm

(moderate), and 109 ppm (high) Pb in drinking water beginning 2 weeks before mating and continuing until PND10. Resulting blood Pb levels ranged from 10 µg/dL or less in the low-exposure offspring to 42 µg/dL in the high-exposure offspring at PND10. The authors also reported that when dams received low or moderate levels of Pb in drinking water from birth to weaning neither male nor female offspring exposed to Pb postnatally exhibited a difference in body weight when compared to control offspring.

In summary, associations were observed between Pb and low birth weight in a study of maternal bone Pb and studies of Pb air exposures and birth weight. However, the associations were less consistent when using maternal blood Pb or umbilical cord and placenta Pb as the exposure measurement. Previous toxicological studies observed an association between gestational Pb exposure and reduced birth weight with moderate to high dose Pb. More recent findings using low dose Pb exposure reported increased offspring body weight after developmental Pb exposure.

5.8.8 Effects on Postnatal Stature and Body Weight

Findings from previous toxicological studies of rodents and primates have demonstrated Pb induced impairment of postnatal growth (U.S. EPA, 2006b). Several recent epidemiologic studies examining the association of various biomarkers of Pb exposure with stature and body weight have been conducted and the evidence reported is mixed.

Table 5-41 Summary of recent epidemiologic studies of associations between Pb levels and postnatal growth

[a]Studies are presented in order of first appearance in the text of this section.

Results from recent epidemiologic studies of postnatal growth are summarized in Table 5-41. Afeiche et al. (2011) conducted a longitudinal study of children in Mexico City, born between 1994 and 2005. Maternal bone Pb during pregnancy was associated with a significant decrease in BW at age 5 years in girls but not in boys. The findings were robust to additional adjustment for child's blood Pb level. In a study of children in Sardinia Italy, Sanna et al. (2011) measured Pb in hair at three points in time (1997, 2002, and 2007) and reported cross-sectional results from regression analyses for each of these time periods. Pb in hair decreased over time and significant associations of Pb in hair

with height were observed only in earlier time periods when hair Pb levels were relatively high.

Ignasiak et al. (2006) studied school children aged 7-15 years living close to copper smelters and refineries in Poland to assess the impact of Pb exposure on their growth status. There was a statistically significant linear relationship between concurrent blood Pb and reduced weight, height, trunk, leg and arm lengths. This decrease in height was more influenced by decreases in leg length than trunk length. These results also indicated that there was attenuation in osteoblast activity associated with higher blood Pb levels, consistent with animal toxicological studies (Long et al., 1990). Hauser et al. (2008) investigated the relationship between blood Pb and height in boys living in Chapaevsk, Russia. In a multivariate adjusted regression analysis, height significantly decreased with increasing blood Pb. Statistically nonsignificant decreases in weight and BMI were also observed. The association of blood Pb with height, weight and BMI was examined among two cohorts of children living near Pb smelters in Texas (Little et al., 2009). The first cohort included children 2-12 years old in 1980 and the second cohort included children of the same age in 2002 when blood Pb levels were substantially lower. Decreases in height, weight and BMI with increasing blood Pb levels were observed among children in both cohorts and increases in height and weight were observed comparing children from the 2002 cohort to those from the 1980 cohort. In a study with Korean children, Min et al. (2008b) observed that height and total arm length decreased significantly with increasing blood Pb in multivariate adjusted regression models. A statistically nonsignificant decrease in body weight was observed with increasing blood Pb while no effect on BMI reported. A study in New York reported an association between maternal blood Pb during the second trimester of pregnancy and various measures of growth, especially among those mothers with blood Pb levels of at least 3 µg/dL (Schell et al., 2009). These associations did not persist for those with maternal blood Pb levels less than 3 µg/dL. Among infants, 6 month blood Pb levels were not associated with 12 month measures of growth. In comparisons of changes in blood Pb levels over time, high maternal blood Pb combined with low 12 month blood Pb among infants (indicating a decrease in blood Pb over time) resulted in the greatest growth, even compared to those with both low maternal and infant blood Pb measures.

Contrary to the results summarized above, several studies do not observe associations between blood Pb levels and impaired growth. In a prospective study of 309 mother-child pairs from Yugoslavia, the relationship between maternal blood Pb and attained height in children was investigated in those living in an highly exposed town with a smelter and battery plant and those living in a relatively lower exposed town (Lamb et al., 2008). In multivariate adjusted regression models, neither attained height (at birth, 1, 4, 6.6, or 10 years age) nor rate of height change per month (at birth-1 year, 1-4 years, 4-6.5 years,

6.5-10 years age) was associated with maternal pregnancy blood Pb levels in either the industrial or less exposed town. Weight was also not associated with maternal blood Pb in this study. In a study with a similar design, Zailina et al. (2008) studied the relationship of blood Pb and height in 7 year-old Malaysian school children comparing those attending two schools in an urban setting to those attending a school near an industrial area. After adjustment for age no statistically significant associations between concurrent blood Pb and physical development were observed. Tomoum et al. (2010) investigated the association between blood Pb and height in pubertal children in Cairo, Egypt. Neither boys nor girls with concurrent blood Pb levels > 10 µg/dL differed significantly in height or weight when compared to those with blood Pb < 10 µg/dL. In a simple correlation analysis of children aged 5-9 years in Colombia, Olivero-Verbel et al. (2007) reported that concurrent blood Pb levels were negatively associated with body size ($r = -0.224$, $p < 0.002$). However, when a partial correlation analysis was performed controlling for age, the association between blood Pb and body size was no longer statistically significant. In a study of school children in China chest and head circumference were found to differ between high (>10µg/dL) and low concurrent blood Pb level groups; however, the direction of the difference was not consistent (Liu et al., 2011a). Among girls, comparing those with high and low blood Pb levels, a reduction in head circumference was observed. Among children greater than 6 years of age, those with higher blood Pb levels were reported to have greater head and chest circumferences. In a study of children aged 7-11 years and living in an area of Iran with or without Pb smelters, age-standardized weight and height did not vary by study area (Mahram et al., 2007).

Recent toxicological studies report significant changes in postnatal or adult body weight after Pb exposure during different developmental windows. Masso-Gonzalez and Antonio-Garcia (2009) found Pb-induced decreased body weights at weaning (PND21) in rat pups from dams exposed to Pb during pregnancy and lactation. Blood Pb level in the control group was 1.43 µg/dL, in the Pb group it was 22.8 µg/dL. Dong et al. (2009) reported decreased body weight in adult Kunming mice after exposure to 0.6% Pb-acetate in drinking water for 8 weeks. In contrast, Leasure et al. (2008) reported a statistically significant inverse relationship between Pb exposure and body weight for male mice exposed to lower (27 ppm), moderate (55 ppm) and higher levels (109 ppm) levels of Pb during gestation and lactation (2 weeks before mating, through gestation and to PND10) with those exposed to the lowest dose having the highest adult body weight among the overweight Pb-exposed animals. Male mice exposed to the lower and higher Pb concentrations during gestation were 26% and 13% heavier than were controls at 1 year of age, respectively. In this study, dams were administered 27 ppm (low), 55 ppm (moderate), and 109 ppm (high) Pb in drinking water beginning which resulted in respective blood Pb levels from 10 µg/dL or less in the low-exposure offspring to 42 µg/dL in the high-exposure offspring at PND10. Leasure et al. (2008) also exposed a

separate group of mice to Pb only during the postnatal period (PND0-PND21, lactation only exposure) and mice exposed to the same aforementioned low or high dose of Pb did not exhibit a difference in body weight when compared to control offspring. Wang et al. (2009e) observed a statistically significant decrease in fetal body weight and body length of Wistar rats at GD20 after maternal exposure to 0.025% Pb-acetate during gestation days 1-10, 11-20, or 1-20. Also, associations were reported between elevated maternal blood Pb levels (0.6, 1.3, or 1.74 µM, respectively or ~12.4, 26.9, or 36.0 µg/dL, respectively) compared to control (0.04 µM or ~ 0.83 µg/dL) and decreased pup body length, and placental weight in Wistar rats at GD20. The greatest decrease in fetal body weight and length was observed in the group exposed to Pb during gestation days 1-20 followed by the group exposed to Pb during gestation days 11-20. Teijón et al. (2006) observed reductions in birthweight of litters administered 200 ppm or 400 ppm Pb-acetate in drinking water, but found that this effect did not persist in the postnatal growth of the rats.

Notably, previous toxicological studies observed reductions in postnatal weight as well as birth weight after exposure to Pb, albeit often at higher concentrations of Pb exposure. Ronis et al. (2001; 1998a; 1998b; 1996) have published a series of papers exposing rats to Pb over different developmental windows, showing associations between Pb exposure and deficits in growth. Sprague-Dawley rats with lifetime Pb exposure to 0.6% Pb-acetate in drinking water (gestational-termination of experiment Pb exposure, maximum blood Pb of 316 µg/dL in males and 264 µg/dL in females) had sex-independent pre-pubertal growth suppression, male-specific suppression of pubertal growth and loss of growth effects postnatally but still maintained an overall decreased body size out to PND60 due to earlier deficits. In a follow up study using the same exposure duration with a dose of 0.45% Pb-acetate (resulting in blood Pb of 263 µg/dL at PND85) yielded the same results (Ronis et al., 1996) with mechanistic insight showing decrements in insulin-like growth factor 1 (IGF1) accompanying the decreases in growth rates.

The body of toxicological literature on postnatal growth with Pb exposure indicates that Pb exposure can induce decrements in both height/body length and BW that may be persistent and differ by sex. However, findings from epidemiologic studies of postnatal growth are not consistent. Animal toxicology studies give insight to mechanistic changes that may contribute to this Pb-induced decrement and to the windows of exposure that may contribute greatest to these decrements.

5.8.9 Toxicological Studies of Developmental Effects

5.8.9.1 Developmental Effects on Blood and Liver

The 1986 and 2006 Pb AQCDs reported studies that suggest Pb may alter hematopoietic and hepatic function during development. Some recent studies provide evidence that support these findings; however recent results are not consistent among the studies.

Massó et al. (2007) reported a decrease in liver weights of pups born to dams that consumed 300 mg/L Pb in drinking water during gestation and lactation. They also reported an increase in the number of erythrocytes; however the erythrocyte size was diminished by 62%. Pb produced microcytic anemia as evidenced by decreased hemoglobin content and hematocrit values without changes in mean corpuscular hemoglobin (MCH) concentration. Alkaline phosphatase (ALP) activity, CAT activity, or thiobarbituric acid reactive substances (TBARS) production did not change in pups at postnatal 0, but increased statistically significantly by PND21 indicating reactive oxygen generation. No change in acid phosphatase (ACP) activity was observed in the livers of pups at PND0 or 21.

Massó-González and Antonia-García (2009) reported normochromic and microcytic anemia and a significant decrease in hematocrit values and blood δ-aminolevulinic acid dehydratase (ALAD) activity (90% reduction) in pups from dams administered 300 mg/L Pb-acetate in drinking water during gestation. The authors also reported that erythrocyte osmotic fragility was four times greater in Pb-exposed pups than in control pups. Massó-González and Antonia-García (2009) reported increases in TBARS and CAT activity in the liver after Pb exposure. Intoxication with Pb also resulted in decreased liver protein concentrations and manganese-dependent SOD activity. Abnormalities in liver function were further exemplified by increases in liver concentrations of ALP and ACP.

Teijón et al. (2006) observed that gestational exposure to Pb caused a decrease in erythrocytes, hemoglobin, and MCH at weaning; however, by 1 and 3 months postweaning, these parameters had returned to normal values. The authors observed a slight increase in serum ALP, alanine aminotransferase (ALT), and aspartate aminotransferase (AST) levels after Pb exposure in the absence of liver histological changes.

Pb-induced effects on SOD activity in the liver of fetuses after Pb intoxication was supported by a study by Uzbekov et al. (2007). The authors reported an initial increase in SOD activity in livers of pups exposed to 0.3 mg/L and 3.0 mg/L Pb nitrate during gestation for 1 month (mean daily consumption 27 µg/kg). In contrast, long-term

exposure (5 months) to the same concentrations of Pb nitrate concentration during gestation resulted in decreased hepatic SOD activity.

Effects on hepatic Phase I and Phase II enzymes after early developmental exposure of offspring to Pb during gestation and lactation was evaluated by Pillai et al. (2009). In the study, pregnant Charles Foster rats were administered 0.05 mg/kg body weight Pb subcutaneously throughout gestation until PND21. Pups were evaluated on PND56. Results of the study show that Phase I xenobiotic-metabolizing enzymes (NADPH- and NADH cytochrome c reductase) and Phase II xenobiotic- and steroid-metabolizing enzymes (δ-glutamyl transpeptidase, UDPGT, glutathione-s-transferase, and 17β-hydroxysteroid oxidoreductase) were reduced in both male and female pups by PND56. Only inhibition in glutathione-s-transferase and 17β-hydroxysteroid oxidoreductase activities demonstrated a sex-specific pattern (glutathione-s-transferase inhibition in males; 17β-hydroxysteroid oxidoreductase inhibition greater in females). Observed Pb-induced histological changes included massive fatty degeneration in hepatocytes, large vacuoles in cytoplasm, appearance of pyknotic nuclei, and infiltration of lymphocytes in the liver. Antioxidant enzymes (SOD, CAT, glutathione peroxidase, and glutathione reductase) were also reduced after Pb intoxication. Alterations in biochemical parameters included decreased DNA, RNA, and cholesterol content.

5.8.9.2 Developmental Effects on Skin

The 2006 Pb AQCD (U.S. EPA, 2006b) reported a study that demonstrated Pb-induced abnormalities in skin development. No current studies were identified that addressed Pb-induced skin alterations.

5.8.9.3 Developmental Effects on the Retina

The 2006 Pb AQCD concluded that Pb exposure during early postnatal development (resulting in blood Pb levels ~20 µg/dL) impaired retinal development in female Long-Evans hooded rats. A more recent study (Fox et al., 2008) exposed female Long-Evans hooded rats to low (27 ppm), moderate (55 ppm), and high (109 ppm) levels of Pb-acetate in drinking water beginning 2 weeks before mating, throughout gestation, and until PND10. Blood Pb levels measured in these pups on postnatal days 0-10 were 10-12 µg/dL (low), 21-24 µg/dL (moderate), and 40-46 µg/dL (high). Results of the study demonstrated supernormal persistent rod photoreceptor-mediated (scotopic) electroretinograms (ERGs) (Figure 5-46, Table 5-33) in adult rats similar to ERG findings in male and female children after gestational exposure to low- and moderate-

levels of Pb. Low- and moderate-levels of Pb increased neurogenesis of rod photoreceptors and rod bipolar cells without affecting Müller glial cells and statistically significantly increased the number of rods in central and peripheral retina (Figure 5-46, and Table 5-33). High-level Pb exposure (109 ppm) statistically significantly decreased the number of rods in central and peripheral retina. Pb-exposure induced concentration-dependent decreases in adult rat retinal dopamine synthesis and utilization/release.

5.8.9.4 Developmental Effects on Teeth

Pb has been associated with multiple health effects including dental caries, however, there is very limited information available on the temporal and spatial incorporation of Pb in dental tissue (Arora et al., 2005). Arora et al. (2005) demonstrated that Wistar rat pups exposed to Pb during gestation and lactation (40 mg/L of Pb nitrate in drinking water of pregnant dams) had higher concentrations of Pb on the surface of enamel and in the dentine immediately adjacent to the pulp. The authors concluded that additional research is needed on the intracellular uptake of Pb during tooth development to fully understand the spatial distribution of Pb in teeth.

5.8.10 Summary and Causal Determination

Many epidemiologic and toxicological studies of the effects of Pb on reproductive outcomes have been conducted since the 2006 Pb AQCD. These studies covered outcomes such as female and male reproductive function, birth defects, spontaneous abortions, infant mortality, preterm birth, low birth weight, and developmental effects. There is an abundance of evidence in the literature demonstrating that Pb induces reproductive and developmental effects in laboratory animals exposed to Pb during gestation and/or lactation. Many of the Pb-induced effects occur in a concentration-dependent manner and have been observed at maternal blood Pb levels that do not result in clinical toxicity in the dams. Additionally, epidemiologic studies have demonstrated strong evidence of an association between Pb and delayed puberty as well as decrements to sperm/semen quality and function.

Many of the animal toxicology studies included in the 2006 Pb AQCD examined the effect of Pb on reproduction and development at blood Pb levels greater than 40 µg/dL, a dose where maternal toxicity can develop during pregnancy. Data from the 2006 Pb AQCD on male fertility showed Pb exposure or biomarkers of Pb-exposure were associated with decrements in semen quality. Recent studies have shown the effects of Pb exposure during early development to include disruption of endocrine function; delay in

the onset of puberty and alteration in reproductive function later in life; and changes in morphology or histology in sex organs and placenta. Additionally, recent epidemiologic studies of reproductive factors among males and females investigated whether Pb biomarker levels were associated with hormone levels, fertility, and onset of puberty. Epidemiologic studies showed associations between blood Pb and hormone levels for females. Studies of Pb and fertility are limited and inconsistent for females and males. Strong and consistent associations were observed between Pb levels in males in occupational settings with blood Pb levels as low as 20-45 µg/dL and sperm count and quality.

Delayed puberty has been linked to decreased peak bone mass and increased risk of osteoporotic fractures (Gilsanz et al., 2011; Naves et al., 2005). Multiple epidemiologic studies of Pb and puberty have shown associations between concurrent blood Pb levels and delayed pubertal development for girls and boys (evidence is stronger among girls). These associations are consistently observed in multiple epidemiologic studies in populations with blood Pb levels <10µg/dL. Confounders considered in the epidemiologic studies that performed regression analyses varied. Most studies controlled for age and BMI. Other variables, such as measures of diet and SES and race/ethnicity, were included in some of the studies. Many of the studies demonstrating positive associations adjusted for many of the potential confounders. No patterns were detected in the associations between Pb and puberty based on inclusion of specific confounders.

Pb-mediated changes in levels or function of reproductive and growth hormones have been demonstrated in past and more recent toxicological studies; however the findings are inconsistent. More data are needed to determine whether Pb exerts its toxic effects on the reproductive system by affecting the responsiveness of the hypothalamic-pituitary-gonad axis or by suppressing circulating hormone levels. More recent toxicological studies suggest that oxidative stress is a major contributor to the toxic effects of Pb on male and female reproductive systems. The effects of ROS may involve interference with cellular defense systems leading to increased lipid peroxidation and free radical attack on lipids, proteins, and DNA. Several recent studies showed an association between increased generation of ROS and germ cell injury as evidenced by destruction of germ cell structure and function. Co-administration of Pb with various antioxidant compounds either eliminated Pb-induced injury or greatly attenuated its effects. In addition, many studies that observed increased oxidative stress also observed increased apoptosis which is likely a critical underlying mechanism in Pb-induced germ cell DNA damage and dysfunction.

Overall, results of pregnancy outcomes were similar to those of the 2006 Pb AQCD; inconsistent evidence of a relationship with Pb was available for preterm birth and little

evidence was available to study the associations with spontaneous abortions. The 2006 Pb AQCD included a few studies that reported potential associations between Pb and neural tube defects, but the recent epidemiologic studies found no association. Some associations were observed between Pb and low birth weight when epidemiologic studies used measures of maternal bone Pb or air exposures, but the associations were less consistent when using maternal blood Pb or umbilical cord and placenta Pb (maternal blood Pb or umbilical cord and placenta Pb were the biomarkers most commonly used in studies of low birth weight). Effects of Pb exposure during early development on toxicological studies included reduction in litter size, implantation, birth weight and postnatal growth. Findings from epidemiologic studies of postnatal growth are inconsistent.

Toxicological studies demonstrated that the effects of Pb exposure during early development include impairment of retinal development and alterations in the developing hematopoietic and hepatic systems. Negative developmental outcomes were also noted including effects on the eyes and teeth.

Similar to toxicological and epidemiologic studies that observed Pb to be associated with delayed puberty, delays of dynamic changes in the HPT axis are seen in the ecological literature, i.e., delayed metamorphosis in Pb exposed frogs. Additionally, Pb exposure has been shown to have detrimental effects on sperm, albeit often at higher blood Pb levels in epidemiology studies but in lower doses in the toxicology literature. Again, these findings agree with the ecological literature where Pb-dependent sperm effects are seen in rotifers, earthworms, and trout (Sections 7.3.5.2, 7.2.4.2, and 7.3.5.3).

In conclusion, the recent toxicological and epidemiologic literature provides strong evidence that Pb exposure is associated with effects on reproduction and development. The weight of the evidence supports the association of Pb exposure with delayed onset of puberty in both males and females and detrimental effects on sperm and semen quality in occupationally-exposed males and in laboratory animals. In cross-sectional epidemiologic studies of girls (ages 6-18 years) with mean and/or median concurrent blood Pb levels less than 5 µg/dL consistent associations with delayed pubertal development (measured by age at menarche, pubic hair development, and breast development) were observed. Toxicological studies indicate that prenatal and lactational exposures to Pb can cause a delay in the onset of female puberty at blood Pb levels as low as 8 µg/dL (Iavicoli et al., 2006b; Iavicoli et al., 2004). Recent studies show that pubertal onset is one of the more sensitive markers of Pb exposure with effects observed after maternal exposures leading to blood Pb levels in the pup of 3.5-13 µg/dL (Iavicoli and Carelli, 2007). In boys (ages 8-15 years), fewer studies were conducted but associations were observed in most. Male animal toxicology studies have reported delayed sexual

maturity as measured with prostate weight, among other outcomes, seeing significant decrements at blood Pb levels of 34 µg/dL (Sokol et al., 1985). Additionally, Pb exposure has been shown to have detrimental effects on sperm. These were observed in epidemiologic studies at population mean blood Pb levels of 30 µg/dL and greater among men occupationally exposed (mean blood Pb levels in study controls around 10 µg/dL) and in animal toxicological studies with rabbits exposed to subcutaneous Pb 3 times per week for 15 weeks with blood Pb levels of 20 µg/dL (Moorman et al., 1998). The data on preterm birth, low birth weight, spontaneous abortions, birth defects, hormonal influences, and fecundity are less consistent between the toxicological and epidemiologic literature. The collective body of evidence integrated across epidemiologic and toxicological studies with a focus on the strong relationship observed with detrimental effects on sperm and delayed pubertal onset is sufficient to conclude that there is a causal relationship between Pb exposures and reproductive and developmental effects.

5.9 Effects on Other Organ Systems

5.9.1 Effects on the Hepatic System

Hepatotoxic effects of Pb indicated in various animal models and human populations include alterations in hepatic metabolism, hepatic cell proliferation, changes in cholesterol metabolism, as well as oxidative stress-related injury. Animal studies have also shown that exposure to Pb causes a decrease in Phase I along with a simultaneous increase in Phase II enzymes following exposure to Pb. Induction of oxidative stress by Pb exposure is well supported by an increase in lipid peroxidation along with a decrease in glutathione (GSH) levels and catalase (CAT), superoxide dismutase (SOD) and glutathione peroxidase (GPx) activities.

5.9.1.1 Summary of Key Findings of the Effects on the Hepatic System from the 2006 Lead AQCD

The 2006 Pb AQCD stated that the large experimental animal database indicated hepatotoxic effects, including liver hyperplasia, at very high dose Pb exposures. Other effects noted in the liver following exposure to Pb included altered cholesterol synthesis, DNA synthesis and glucose-6-phosphotase dehydrogenase (G6DP) activity . The 2006 Pb AQCD reported that cytochrome (CYP) P450 levels decreased following single doses of Pb nitrate. Inhibition of induced and constitutive expression of microsomal CYP 1A1 and 1A2 was observed among various P450 isozymes. Inhibition of Phase I enzymes was

accompanied by an increase in Phase II enzymes following exposure to Pb nitrate and other Pb compounds, suggesting that Pb is capable of causing a biochemical phenotype similar to hepatic nodules. Studies relating to Pb-induced hepatic hyperplasia suggested alterations in the gluconeogenic mechanism, DNA hypomethylation along with changes in proto-oncogene expression as well as cholesterol synthesis. Cholesterol metabolism changes following exposure to Pb were reportedly mediated as a result of induction of several enzymes related to cholesterol metabolism as well as a decrease in the cholesterol catabolizing enzyme, 7 α-hydroxylase. Tumor necrosis factor α*lpha* (TNF-*α*) was reported to be one of the major mitogenic signals that mediated Pb nitrate-induced hepatic hyperplasia in studies using inhibitors to block TNF-α activity. Other Pb-related effects presented in the 2006 Pb AQCD include liver cell apoptosis mediated by Kupffer cell derived signals and Pb-induced oxidative stress in vitro cell cultures. The 2006 Pb AQCD further suggested that alterations in liver heme metabolism may involve changes in 5-aminolevulinic acid dehydrogenase (ALAD) activity, porphyrin metabolism, transferrin (TF) gene expression and changes in iron metabolism.

With regard to human studies, the 2006 Pb AQCD stated that nonspecific liver injury generally observed as increases in liver enzymes in the serum was reported in adults with occupational Pb exposure, although associations specifically with Pb exposures have not been well established. In addition, similar to effects noted in animal studies, cytochrome P450 activity was also suppressed in children and adults (drawn from the general population) following exposure to Pb. The 2006 Pb AQCD reported that hepatic effects occurred only at high Pb exposure levels (blood Pb levels > 30 µg/dL).

5.9.1.2 New Epidemiologic Studies

A few occupational epidemiologic studies examined liver biochemical parameters effects on antioxidant status and oxidative stress resulting from exposure to Pb. However all of these occupationally-exposed cohorts represented populations highly exposed to Pb, with blood Pb levels ranging from 29 to 53 µg/dL. Although the hepatotoxicity observed within these cohorts may not be generalizable to the general population as a whole, they are useful in demonstrating consistent effects on a number of liver outcomes, including altered liver function (i.e., changes in the level of liver function enzymes), oxidative stress, and antioxidant status (Can et al., 2008; Khan et al., 2008; Patil et al., 2007). Additionally, these studies were cross-sectional in design; thus, there is uncertainty regarding the magnitude, timing, frequency, and duration of Pb exposure that contributed to the observed associations.

In one of the occupational cohorts (spray painters in western Maharashtra, India, exposed to Pb for > 6 hours/day for 2 to 20 years) examined by Patil et al. (2007), mean (SD) blood Pb levels in workers were 22.32 (8.87) µg/dL. The blood Pb levels in workers were statistically significantly higher compared to those in the concurrent control group (mean [SD]: 12.52 [4.08] µg/dL), who had no history of Pb exposure. Liver function enzymes, including serum glutamic oxaloacetic transaminase (SGOT)/AST, and serum glutamic pyruvic transaminase (SGPT)/ALT levels were statistically significantly increased in spray painters compared to those in controls, whereas total serum protein levels were decreased. In another occupational epidemiolgic study, Conterato et al. (In Press) investigated liver function parameters in automotive painters exposed to Pb in Brazil. Exposed painters had a mean (SD) blood Pb concentration of 5.4 (0.4) µg/dL compared to 1.5 (0.1) µg/dL in controls. The mean (SD) duration of exposure to Pb in painters was 133.9 (14.5) months, whereas the controls were not occupationally exposed to Pb. In exposed workers, the levels of aspartate aminotransferase (AST), but not γ-glutamyltranseferase, were increased approximately 2-fold compared to levels in controls ($p < 0.05$). The activity of AST was positively correlated with blood Pb levels ($r = 0.26$, $p < 0.05$). The authors suggested that confounding exposures to toxic constituents of the paints regularly used by painters, and not Pb, may be the etiological cause of decrements in AST function as these effects were not also seen in battery workers with much higher blood Pb levels (49.8 µg/dL). Co-exposure to other environmental contaminants may also explain the effects seen in occupationally-exposed spray-painters in Patil et al. (2007).

5.9.1.3 New Toxicological Studies

Hepatic Metabolism

As stated in the 2006 Pb AQCD, acute exposures of rodents to Pb nitrate and other Pb compounds cause a decrease in Phase I enzymes accompanied by a simultaneous increase in Phase II enzymes. The conclusions presented in the 2006 Pb AQCD were also reviewed by Mudipalli (2007).

Changes in biochemical parameters, suggestive of liver damage, in undernourished male Wistar rats (fed low-protein diet without mineral supplements) treated with 500 ppm Pb-acetate in drinking water over a 10 month period, included decreases in serum protein and albumin levels as well as increases in aspartate aminotransferase (AST), alanine aminotransferase (ALT), serum alkaline phosphatase (ALP), and gamma glutamyl transpeptidase (GGT) levels (DS et al., 2009). In Pb-treated animals, the blood Pb levels steadily increased throughout the initial portion of the study period, reaching a maximum of approximately 30 µg/dL after 2 months. After this time, blood Pb levels rapidly

increased to approximately 110 µg/dL (greatly in excess of blood levels in the general human population) by six months time and remained at this level until the termination of exposure at 10 months. The study authors reported that similar biochemical changes were not observed in animals treated with Pb-acetate maintained on protein-adequate, mineral rich diet and concluded that nutritional management is important in managing Pb-related poisoning. Mice gavaged with 50 mg/kg Pb nitrate for 40 days demonstrated similarly increased activities of AST, ALT, ALP, and acid phosphatase (ACP) compared to controls (Sharma et al., 2010a). Upadhyay et al. (2009) reported that treatment of Sprague-Dawley rats with 35 mg/kg Pb via i.p. injection for 3 days (blood Pb not reported) significantly increased the activities of ALT, AST, serum ALP, and acid phosphatase over those in controls, whereas alkaline phosphatase activity was decreased in Pb-treated animals. Concomitant treatment with zinc and varying levels of ascorbic acid were observed to ameliorate the toxic effects of Pb. The serum activities of glutamic pyruvic transaminase (GPT) and lactate dehydrogenase (LDH) were similarly significantly increased over those in controls in mice subcutaneously injected with 50 mg/kg Pb-acetate daily for 15 days (blood Pb not reported) (Wang et al.). Swarup et al. (2007) investigated serum biochemical changes in cows living in Pb-contaminated environments. Serum levels of ALT, AST, alkaline phosphatase, total protein, albumin, globulin, and A/G ratio were statistically significantly altered in cows living near Pb-Zn smelters (mean [SD] blood Pb: 86 [6] µg/dL, greatly in excess of blood levels in general human populations) compared to control cows (mean [SD] blood Pb: 7 [1] µg/dL). Significant positive correlations were found between blood Pb and ALT and AST, whereas a negative correlation was observed between blood Pb and total lipids, protein, and albumin.

Pillai et al. (2009) investigated effects on hepatic phase I and II enzymes in male and female rats born to dams that were treated with 50 µg/kg Pb-acetate via subcutaneous injection daily throughout gestation and continuing until PND21. Thus, the offspring of treated dams were exposed to Pb via placental and lactational transfer. The female and male pups were then allowed to reach sexual maturity (PND55-56) to assess continuing exposure to bioaccumulated Pb. The activities of hepatic phase I enzymes NADPH- and NADH-cytochrome c reductase were statistically significantly reduced in Pb-exposed male and female rats on PND56 (blood Pb not reported), compared to controls. In rats treated with 25 µg/kg Pb and Cd, the effect on phase I enzymes was increased. Pb treatment additionally decreased the activities of phase II enzymes uridine diphosphate-glucoronyl transferase and GST in males and females, but no effect was observed on GGT or 17β-hydroxysteroid oxidoreductase. Additionally, no effect was observed in Pb-treated rats on serum glutamate pyruvate dehydrogenase or ALP activities in males or females. Histological observations in both male and female rats demonstrated fatty degeneration, vacuolization, and pycnotic nuclei, indicating general hepatotoxicity

following Pb treatment. In a similar study, Teijon et al. (2006) exposed Wistar rats to 200 or 400 ppm throughout gestation, lactation, and 3 months postweaning, or only 1 month postweaning. In the animals exposed continuously throughout gestation and lactation, the concentrations of Pb in the liver were elevated in the 200- and 400-ppm groups 1 and 3 months postweaning. Liver concentrations of Pb were greater in the 200 ppm animals compared to the 400 ppm animals at one month postweaning (mean [SE]: 1.19 µg Pb/g tissue [0.30] versus 0.76 [0.06], respectively), but were similar between the 2 dosing regimens at 3 months postweaning (mean [SE]: 0.054 [0.06] versus 0.55 [0.07], respectively). ALP activity was increased at 2 weeks postweaning in animals continuously exposed to Pb throughout gestation and lactation, whereas ALT activity was decreased only at 2 and 3 months postweaning. In animals exposed only for 1 month postweaning, serum ALP activity was significantly increased, although not in a concentration-dependent manner. ALT and AST activities were not affected.

Cheng et al. (2006) studied the mechanism of Pb effects on bacterial lipopolysaccharide (LPS)-induced TNF-α expression. A/J mice were injected via i.p with 100 µmol/kg Pb, with or without 5 mg/kg LPS. Pb alone did not affect liver function (measured as AST or ALT activity) or the level of TNF-α in the serum. In comparison, treatment of mice with low doses of Pb and LPS together caused a statistically significant increase in TNF-α induction as well as enhanced liver injury, suggesting that Pb potentiated LPS-induced inflammation. In an in vitro study, the authors reported that co-exposure of Pb and LPS stimulated the phosphorylation of p42/44 mitogen-activated protein kinase (MAPK) and increased TNF-α expression in mouse whole blood cells, peritoneal macrophages, and RAW264.7 cells (a macrophage cell line) and concluded that monocytes/macrophages (rather than hepatocytes) were primarily responsible for Pb increasing LPS- induced TNF-α levels via the protein kinase C (PKC)/MAPK pathway. Similarly, Pb chloride potentiated bovine serum albumin (BSA)-induced inflammation in the livers of mice subcutaneously injected with Pb (Sá et al., In Press).

Lipid Metabolism

In a lipid metabolism study, Ademuyiwa et al. (2009) reported that male albino Sprague Dawley rats exposed to 200, 300 and 400 ppm Pb in drinking water had mean (SD) blood Pb levels of 40.63 (9.21), 61.44 (4.63), and 39.00 (7.90) µg/dL, respectively. Animals exposed to 200 ppm Pb had mean (SD) liver Pb concentrations of 10.04 (1.14) µg/g, compared to 3.24 (1.19) and 2.41 (0.31) in animals exposed to 300 or 400 ppm Pb, respectively. Animals exposed to Pb exhibited increased hepatic cholesterogenesis at all doses tested compared to controls. Additionally, a decrease in triglyceride was observed at 300 and 400 ppm Pb; a decrease in phospholipid levels was observed at 400 ppm Pb. The authors also reported positive correlations between tissue cholesterol and

phospholipids and Pb accumulation in liver across all doses. In contrast, the association between tissue triglyceride levels and Pb accumulation was negative. In related studies, Khotimchenko and Kolenchenko (2007) reported that adult male albino rats treated with 100 mg/kg Pb-acetate for as little as 14 days (blood Pb not reported) exhibited disorders in lipid metabolism that were supported by increased levels of total cholesterol and triglyceride levels in the liver tissue, whereas Sharma et al. (2010a) reported increased liver cholesterol in mice gavaged with 50 mg/kg Pb nitrate for 40 days. Pillai et al. (2009) observed decreases in total liver cholesterol in PND56 male and female rats that had been exposed to 50 µg/kg Pb-acetate continuously throughout gestation and lactation. These results suggest that induction of cholesterogenesis and phospholipidosis in the liver by Pb may cause subtle effects at the cellular level that may lead to hepatotoxicity. Kojima and Degawa (2006) examined the sex-related differences in the hepatic sterol regulatory element binding protein-2 (SREBP-2) and 3-hydroxy-3-methylglutaryl-CoA reductase (HMGR) gene expressions in male and female Sprague Dawley rats injected with 100 µmol/kg body weight of Pb nitrate intravenously (blood Pb not reported). The SREBP-2 expression, which is a transcription factor for the HMGR gene, was significantly increased in males and females with the increase occurring earlier in male rats (6-12 hours, compared to 24-36 hours in females). In contrast, expression of the HMGR gene, a rate limiting enzyme in cholesterol biosynthesis, was significantly increased in both Pb-exposed males and females at earlier time frames (3-48 hours in males; 12-48 hours in females) compared to the SREBP-2 gene expression. Significant increases in total liver cholesterol were also observed in Pb-exposed males and females at 3-48 and 24-48 hours, respectively. These results suggest that the SREBP-2 and HMGR gene expressions and increase in total cholesterol levels in the liver in response to Pb occur earlier in males compared to females and also suggest that the HMGR gene expression and increase in total cholesterol levels in the liver occur before an increase in the SREBP-2 gene expression in either sex.

Hepatic Oxidative Stress

A number of studies pertaining to hepatic oxidative stress as a result of exposure to various Pb compounds were identified. Adegbesan and Adenuga (2007) reported that protein undernourished male Wistar rats injected with 100 µmol/kg Pb nitrate (blood Pb not reported) exhibited increased lipid peroxidation, increased CAT activity, decreased SOD activity, and increased GSH levels, compared to undernourished rats not exposed to Pb. Increased lipid peroxidation and decreased CAT and SOD activity were also observed when comparing undernourished Pb-exposed rats to well-nourished control rats. Study authors concluded that malnutrition exacerbated Pb exposure effects on liver lipid peroxidation and the involvement of free radicals in Pb toxicity. Male Foster rats treated

with 0.025 mg/kg Pb via i.p. injection (blood Pb not reported) also exhibited statistically significant increases in lipid peroxidation levels and decreases in SOD, CAT, and glucose-6-phosphatase dehydrogenase (G6PD) levels in liver mitochondrial and postmitochondrial fractions (Pandya et al., 2010). Statistically nonsignificant decreases were also observed in GSH levels and GPx and GR activities in Pb-treated animals. In mice gavaged with 50 mg/kg Pb nitrate for 40 days, lipid peroxidation was increased and SOD, CAT, and GSH were decreased compared to controls (Sharma et al., 2010a). Additionally, exposure to Pb nitrate resulted in histopathological changes in the structure of the liver: hepatocytes were damaged and were marked by cytoplasmic vacuolization and pycnotic nuclei. Yu et al. (2008) reported similar concentration-dependent increases in lipid peroxide levels and decreases in GSH levels and CAT, SOD and GPx activities in castrated boars that received a supplemental diet with 0, 5, 10, or 20 mg/kg Pb. The level of hepatic CuZnSOD mRNA was also reduced in Pb-treated animals. The study authors suggested that this decrease in SOD mRNA expression and activity of antioxidant enzymes may lead to a reduction free radical scavenging capability, along with increased lipid peroxidation, potentially causing serious damage to hepatic function and structure. Khotimchenko and Kolinchenko (2007) also reported an increase in lipid peroxidation and development of hepatitis in male albino rat liver parenchyma following treatment with 100 mg/kg Pb-acetate for as little as 14 days. Lipid peroxidation was demonstrated by increases in malondialdehyde (MDA) levels along with decreases in GSH and thiol groups indicating injury in the liver antioxidant system. In another experiment, Jurczuk et al. (2007) reported that male Wistar rats treated with 500 mg/L Pb in drinking water (blood Pb not reported) exhibited decreases in liver vitamin E and GSH levels along with an increase in lipid peroxidation. The study authors hypothesized that vitamin E is involved in the mechanism of peroxidative action of Pb in the liver, and concluded that the suggested protective role of vitamin E in the potential toxicity by Pb may be related to scavenging of free radicals that are generated either directly or indirectly by Pb. In a study examining the role of low molecular weight thiols on peroxidative mechanisms, Jurczuk et al. (2006) stated that male Wistar rats treated with 500 mg/L Pb-acetate in drinking water exhibited a decrease in blood ALAD as well as decreases in GSH and nonprotein sulfhydryl (NPSH) levels in the liver. Metallthionein levels were also reported to be higher in the liver following exposure to Pb. Levels of hepatic lipid peroxidation were observed to be significantly increased in rats treated with 35 mg/kg Pb via i.p. injection (blood Pb not reported), whereas hepatic GSH was significantly decreased (Upadhyay et al., 2009). In vitro exposure of human embryonic hepatocytes (WRL-68) to 5 µM Pb-acetate for 30 days resulted in increase production of reactive oxygen species (ROS) throughout the incubation period (Hernández-Franco et al., 2011). Concurrent with this increase in ROS generation, the activities of SOD and the levels of membrane

lipid peroxidative damage also increased throughout the first 24 days of exposure, but returned to normal levels by the end of the incubation period.

In a study examining the effects of Pb exposure to fetuses, Massó et al. (2007) exposed pregnant Wistar rats with 300 mg/L Pb in drinking water starting at day 1 of pregnancy to parturition or until weaning to determine the effects of Pb exposure in the fetal liver. Blood Pb levels were higher at parturition (mean [SD]: 31.5 [0.80] µg/dL) than at weaning (mean [SD]: 22.8 [0.50] µg/dL). Pups exhibited liver damage that was accompanied by an increase in thiobarbituric acid-reactive species (TBARS) production and increased CAT activity compared to controls. In addition, increased ALP and acid phosphatase activity was also observed. Uzbekov et al. (2007) exposed female Wistar rats to 0.3 and 3.0 mg/L Pb nitrate for 1 and 5 months prior to, and continuing during pregnancy, and measured fetal hepatic SOD activity on GD20. Control rats had a mean (SD) blood Pb level of 16.1 (0.63) µg/dL, whereas rats exposed to 0.3 and 3.0 mg/L Pb had mean blood Pb levels that were 26.5% (20.4 µg/dL) and 51.8% (24.4 µg/dL) higher, respectively. In the fetuses from dams exposed for 1 month prior to pregnancy, a concentration-dependent increase in liver SOD activity was observed, whereas SOD activity was decreased in the fetuses from dams exposed for 5 months prior to pregnancy. The increase in SOD activity in the livers of fetuses from dams exposed to 0.3 or 3.0 mg/L Pb nitrate for one month suggests that activation of SOD in response to increased free radical production, while the decrease in SOD production in fetal livers from dams exposed to the same concentrations for 5 months suggests that longer durations of Pb exposure impairs the antioxidant defense mechanism. No effects on GSH or MDA levels were observed in PND56 male and female rats following continuous exposure to 50 µg/kg Pb-acetate throughout gestation and lactation (blood Pb not reported) (Pillai et al., 2009).

The studies presented above all support the possible oxidative stress impacts following exposure to various doses of Pb administered in various forms and the potential for hepatotoxicity as a result of oxidative stress.

Hepatic Apoptosis

Fan et al. (2009b) reported that a single i.v. injection (tail vein) of 200 µmol/kg Pb nitrate resulted in an increase in the expression of ferritin light-chain (FLT) in rats (mean [SD]: 3.5 [1.0]-fold increase) over that in controls. Immunohistochemical analysis revealed that hepatocytes around the central vein were heavily stained by anti-FTL antibodies, as were nonparenchymal cells identified as Kupffer cells. The authors hypothesized that the expression of FTL in Kupffer cells may be the result of phagocytosis of apoptotic cells: in Pb-treated rats, apoptotic hepatocytes represented a mean (SD) 2.5 (1.4)% of total cells

whereas only a mean (SD) 0.31 (0.31)% of hepatocytes were apoptotic in control animals. FTL expression in Kupffer cells was not increased in rats treated with clofibrate, which induced hepatocellular proliferation, but not apoptosis.

5.9.2 Effects on the Gastrointestinal System

Gastrointestinal effects of Pb exposure resulting in blood Pb levels ranging from 30 up to 80 µg/dL in humans primarily include abdominal pain, constipation, and internal paralysis. In animals, degeneration of the intestinal epithelial mucosa and a decrease in duodenal motility has been reported following Pb exposure.

5.9.2.1 Summary of Key Findings on the Effects on the Gastrointestinal System from the 2006 Lead AQCD

The 2006 Pb AQCD stated that a number of factors influence the gastrointestinal absorption of Pb including the chemical and physical form of Pb, the age at Pb intake, as well as various nutritional factors. Potential malabsorption of Pb as a result of degeneration of the intestinal epithelial mucosa has been observed in rats exposed to Pb. In suckling rat pups, casein micelles incidences were reported as a result of Pb present in bovine and rat milk and in infant milk formula. Pb ingestion through water was more toxic compared to Pb ingestion via milk. Pb ingested in milk was reported to be taken up by the ileal tissue, whereas Pb administered intragastrically as a soluble salt was primarily accumulated in the duodenum irrespective of vehicle used for administration. Decreases in duodenal motility and the amplitude of contractility in the intestinal tract were observed in rats following Pb exposure. Nutritional studies examining different dietary levels of Pb in rats, calcium, and vitamin D indicated competition in absorption between Pb and calcium. Dietary supplement with vitamin D led to an increase in intestinal absorption of Pb and calcium. In instances where severe calcium deficiency was noted, ingestion of Pb caused a clear decrease in 1,25-dihydroxy vitamin D (1,25-(OH)2D3) levels. Overall, the 2006 Pb AQCD stated that studies in rat intestine have shown that the largest amount of Pb absorption occurs in the duodenum with the mechanisms of absorption involving active transport and diffusion via the intestinal epithelial cells. Absorption has been reported to occur, through both saturable and nonsaturable pathways based on results from various animal studies. The 2006 Pb AQCD reported evidence that symptoms associated with gastrointestinal colic (abdominal pain, constipation, intestinal paralysis) were prevalent in occupationally exposed adults with blood Pb levels $\geq$ 50 µg/dL.

5.9.2.2 New Epidemiologic Studies

The 2006 Pb AQCD reported that in humans, gastrointestinal effects generally include abdominal pain, constipation, and internal paralysis. Kuruvilla et al. (2006) reported gastrointestinal effects including stomach pain and gastritis along with other Pb-related clinical manifestations in painters (mean [SD] blood Pb: 8.04 [5.04] µg/dL) occupationally exposed to Pb in India. Case reports involving children and individuals occupationally exposed to Pb with very high blood Pb levels (> 15 µg/dL) were consistent with these observations of GI pain and gastritis (Fonte et al., 2007).

5.9.2.3 New Toxicological Studies

A few new studies pertaining to gastrointestinal effects of Pb exposure were identified. Santos et al. (2006b) examined the impact of Pb exposure on nonadrenergic noncholinergic (NANC) relaxations in rat gastric fundus. Male Wistar rats treated with 0.008% Pb-acetate (80 ppm) via drinking water for 15, 30, and 120 days (blood Pb not reported) exhibited a significant difference in NANC relaxations in the gastric fundus following electrical field stimulus (EFS). While frequency-dependent relaxations were observed in all groups, including the control group, the relaxations were significantly inhibited in rats treated with Pb-acetate for all three durations. When gastric fundus strips from rats were incubated with L-nitroarginine (L-NOARG), a nitric oxide synthase (NOS) inhibiter, no additional inhibition in relaxations was observed. In contrast, incubation with sodium nitroprusside and 8-Br-GMPc (a Cyclic guanosine monophosphate [cGMP] analog), resulted in a concentration-dependent relaxation in strips in the control group and group exposed to Pb-acetate for 120 days. Study authors concluded that chronic exposure to Pb causes inhibition in NANC relaxation probably due to the modulated release of NO from the NANC nerves or due to interaction with the intracellular transducer mechanism in the rat gastric fundus.

In another study examining Pb-induced oxidative stress in the gastric mucosa, Olaleye et al. (2007) treated Albino Wistar rats with 100 or 5,000 mg/L of Pb-acetate for 15 weeks (blood Pb not reported). Exposure to Pb-acetate caused a significant increase in gastric mucosal damage caused by pretreatment with acidified ethanol. Study authors reported that though the basal gastric acid secretory rate was not altered, stomach response to histamine was significantly higher in animals treated with Pb-acetate compared to that in the controls. Additionally, there was a significant increase in gastric lipid peroxidation at both the 100 and 5,000 mg/L dose levels. In contrast, CAT, and SOD activities and nitrite levels were significantly decreased in the gastric mucosa. Study authors concluded that

exposure to Pb may increase the formation of gastric ulcers as a result of changes in the oxidative metabolism in the stomach.

5.9.3 Effects on the Endocrine System

Endocrine processes that are most commonly found to be impacted by Pb exposure include changes in the thyroid, such as changes in the thyroid stimulating hormone (TSH), triiodothyronine (T3), and thyroxine (T4).

5.9.3.1 Summary of Key Findings of the Effects on the Endocrine System from the 2006 Lead AQCD

The 2006 Pb AQCD reported that endocrine processes impacted by occupational Pb exposure include thyroid hormone levels, changes in male sex hormone levels, as well as changes in the production of 1,25-(OH)2D3 levels. However, these effects were reported to be observed only with blood Pb levels exceeding 30–40 µg/dL. In addition, alterations in calcitropic hormones were affected in children with blood Pb levels ranging from 10-120 µg/dL. A summary of key findings pertaining to reproductive hormones in males and females in the current document is presented in the section on reproductive and developmental effects (Sections 5.8.1 and 5.8.2).

5.9.3.2 New Epidemiologic Studies

Recent epidemiologic studies have reported associations between indicators of exposure to Pb and thyroid hormone levels. In workers highly exposed to Pb (blood Pb = 71.1 µg/dL) thyroid stimulating hormone (TSH) and free T4, but not free T3, were increased over levels in controls (mean blood Pb level of 0.2 µg/dL), although these results are most likely not generalizable to the general public due to the high blood Pb levels of exposed workers (Pekcici et al., 2010). Abdelouahab et al. (2008) performed a cross-sectional study in a Canadian population characterized by high consumption of freshwater fish. The median concurrent blood Pb level was 3.1 µg/dL for men and 1.7 µg/dL for women. It is important to note that the median blood Pb level for women was lower than the limit of detection for Pb in the blood (2.1 µg/dL), effectively meaning that greater than 50% of women in the study had nondetectable levels of Pb in their blood. The study authors conducted a stratified analysis and concluded that TSH levels were negatively correlated with blood Pb in women who consumed fish contaminated with Pb and other environmental pollutants. No associations T3 and T4 levels were

reported in women. TSH, T3 and T4 levels were not observed to be correlated with blood Pb in males. However, study authors stated that occupational exposure to Pb in men can affect pituitary thyroid axis homeostasis and the relation between low-level Pb exposure thyroid hormone homeostasis in men and women needs to be investigated further. The authors also concluded that environmental contaminants not investigated (e.g., As) may be influencing TSH levels. Dundar et al. (2006) examined associations of blood Pb with thyroid function in 42 male adolescent auto repair workers exposed long term to Pb. A control group comprising 55 healthy subjects was also used for comparison purposes. Mean blood Pb levels were reported to be higher in the auto repair workers compared to the control subjects (mean [SD]: 7.3 [2.92] versus 2.08 [1.24] µg/dL). Free T4 (FT4) levels were significantly lower in the study group compared to the control group, which had no abnormal FT4 levels reported. In contrast, free T3 (FT3) and TSH levels were comparable between the study and control group. Blood Pb level was reported to be negatively correlated with FT4 levels. Based on the study outcome, the study authors reported that long-term Pb exposures that result in the studied blood Pb levels may lead to lower FT4 levels without impact on T3 and TSH levels in adolescents. The study authors stated that this effect is likely secondary to the toxic effects of Pb on the pituitary-thyroid axis and to the earlier findings of primary hypothyroidism as a result of impaired production of peripheral thyroid hormones. Similar findings were reported by Croes et al. (2009) in a study conducted in Belgium. Croes et al. (2009) examined the hormone levels in 1,679 adolescents residing in nine study areas with varying exposures to multiple industrial pollutants including Pb. The median concurrent blood Pb of the participants from the nine different regions ranged from 1.6 to 2.8 µg/dL. The study authors reported that, after adjustment for potential confounding, significant interregional differences were observed FT3 hormone levels. When individual neighborhoods were analyzed within the larger study areas, altered levels of FT3 levels were also observed. Though varying levels of FT3 levels were observed, the study authors reported that these changes were not wholly due to exposure to various pollutants, including Pb that were measured in the study and stated that other pollutants and environmental factors may also have contributed to the effects noted. In a prospective study of 309 mother-child pairs from Yugoslavia, the relationship between maternal TSH and T4 and blood Pb was investigated in those living in a highly exposed town with a smelter and battery plant (n = 156 mother-child pairs) and those living in a relatively unexposed town (n = 153 mother-child pairs) (Lamb et al., 2008). The mid-pregnancy blood Pb levels were highly elevated in the industrial town compared to the unexposed town (mean [SD]: 20.56 [7.38] versus 5.60 [1.99] µg/dL). Mid-pregnancy maternal free T4 levels were observed to be inversely related with maternal blood Pb levels, but this association was not observed in the unexposed town. In 24 newborns delivered in Tokyo, Japan, neither TSH nor free T4

(sampled 4-6 days postpartum) was associated with cord blood Pb sampled at delivery (mean: 0.67 µg/dL) (Iijima et al., 2007).

Gump et al. (2008) examined cortisol response to acute stress in children (aged 9.5 years) whose prenatal and postnatal blood Pb levels had been determined prior to the study at birth (from cord blood) and at a mean (SD) age of 2.62 (1.2) years, respectively. For prenatal blood Pb, the children were divided into the following quartiles: ≤ 1, 1.1-1.4, 1.5-1.9, and 2.0-6.3 µg/dL. For postnatal blood Pb, the quartiles were 1.5-2.8, 2.9-4.1, 4.2-5.4, and 5.5-13.1 µg/dL. The study authors reported that blood Pb was not associated with initial salivary cortisol levels. However following an acute stressor, which comprised submerging the dominant arm for a minute in a gallon of one part ice to one part water, increasing prenatal and postnatal blood Pb levels were statistically significantly associated with increases in salivary cortisol responses. Children in the 2nd, 3rd and 4th prenatal blood Pb quartiles and in the 4th postnatal quartile had increased salivary cortisol responses compared to children in the 1st quartile. When blood Pb was treated as a continuous variable, regression analysis showed that both prenatal and postnatal blood Pb levels were significantly correlated to salivary cortisol reactivity. Based on these results, the study authors reported that relatively low prenatal and postnatal blood Pb levels, notably those well below 10 µg/dL, can alter adrenocortical responses of children following acute stress and the health impact and behavioral aspects of this Pb-induced HPA deregulation in children needs to be further examined.

In another study on the impact of Pb in children, Kemp et al. (2007) examined the blood Pb levels in 142 young, U.S. urban African-American and Hispanic children in winter and summer to determine the seasonal increase in blood Pb and its association with vitamin D (1,25-(OH)2D3), age and race. There was a winter/summer (W/S) increase in blood Pb levels in children aged between 1 and 3 years (mean [SE]: 4.94 [0.45] µg/dL in winter, 6.54 [0.82] µg/dL in summer), with a smaller W/S increase observed in children aged between 4 and 8 years (mean [SE]: 3.68 [0.31] µg/dL in winter, 4.16 [0.36] µg/dL in summer). Additionally, the winter and summer blood Pb levels were highly correlated with one another. The percentage of African-American children with blood Pb levels ≥ 10 µg/dL increased from 12.2% in winter to 22.5% in summer. In children aged 4-8 years, the concentrations of 1,25-(OH)2D3 were greater in the summer compared to the winter (mean [SE]: 33.8 [1.1] µg/L in summer versus 25.3 [1.2] µg/L in winter). No difference in seasonal 1,25-(OH)2D3 was observed in children 1-3 years old. Additionally, winter and summer concentrations of 1,25-(OH)2D3 were highly correlated ($r = 0.635$, $p < 0.0001$). There was a significant correlation between seasonal differences in blood Pb and serum 1,25-(OH)2D3 in all children and African-American children between 4 and 8 years. Based on these results, the study authors concluded that higher summertime increase in serum 1,25-(OH)2D3 levels in children between 4 and 8 years is

most likely due to increased sunlight-induced vitamin D synthesis and may be a contributing factor to seasonal changes in blood Pb levels.

5.9.3.3 New Toxicological Studies

. In a study examining the effects of Pb and cadmium in adult cows reared in a polluted environment in India, Swarup et al. (2007) stated that the mean plasma T3 and T4 levels were significantly higher in cows near Pb and zinc smelters (mean [SD] blood Pb: 86 [6] µg/dL) and near closed Pb and operational zinc smelters (mean [SD] blood Pb: 51 [9] µg/dL) when compared to cows in unpolluted areas (mean [SD] blood Pb: 7 [1] µg/dL). Regression analyses from 269 cows examined in the study showed a significant positive correlation between blood Pb and plasma T3 and T4 levels, whereas the correlation between blood Pb and plasma cortisol was nonsignificant. Mean plasma estradiol level was significantly higher in cows near closed Pb and operational zinc smelter industries compared to the control group. Based on these results, the study authors concluded that endocrine profile in animals can be impacted following exposure to Pb in polluted environments.

Biswas and Ghosh (2006) investigated the effect of Pb treatment on adrenal and male gonadal functions in Wistar rats treated with 8.0 mg/kg Pb-acetate via i.p. injection for 21 days (blood Pb not reported). Pb treatment was observed to significantly increase adrenal steroidogenic enzyme activity and serum corticosterone levels. Accessory sex organ (prostate and seminal vesicle) weights were decreased in Pb-treated animals, whereas adrenal weights were increased. Spermatogenesis was decreased and the percent of spermatid degeneration was increased in animals treated with Pb. Lastly, serum concentrations of testosterone, FSH, and LH, were decreased in Pb-treated animals. Supplementation with testosterone during the last 14 days of Pb treatment was observed to ameliorate these effects.

5.9.4 Effects on Bone and Teeth

Primary effects on bone as a result of Pb exposure have included an increase in osteoporosis, increased frequencies of falls and fractures, changes in bone cell function as a result of replacement of bone calcium with Pb and depression in early bone growth. Similar to bone, calcium in the teeth can be easily substituted by Pb following Pb exposure. Exposure of animals to high levels of Pb (30 mg/kg body weight) may result in the formation of “Pb line” and Pb can also cause a decrease in cell proliferation, procollagen type I production, intracellular protein, and osteocalcin in human dental pulp

cell cultures. Accumulation of Pb was also associated with tooth loss and higher incidence of periodontitis.

5.9.4.1 Summary of Key Findings of the Effects on Bone and Teeth from the 2006 Lead AQCD

The 2006 Pb AQCD reported many effects on bone and some in teeth in animals and following exposure to Pb. Pb easily substituted for calcium in bone and was taken up by the bone causing changes in bone cell function. Exposure of animals to Pb during gestation and immediate postnatal period was reported to significantly depress early bone growth with the effects showing a concentration-dependent trends,. In mature animals, long-term exposure (up to one year) to Pb, along with poor nutrition (low calcium) affected bone growth as well bone density. Systemic effects of Pb exposure included disruption in bone mineralization during growth, alteration in bone cell differentiation and function due to alterations in plasma levels of growth hormones and calcitropic hormones such as 1,2-[OH]2D3 and impact on calcium binding proteins and increases in calcium and phosphorus concentrations in the bloodstream. Bone cell cultures exposed to Pb had altered vitamin D-stimulated production of osteocalcin accompanied by inhibited secretion of bone-related proteins such as osteonectin and collagen. In addition, Pb exposure caused suppression in bone cell proliferation most likely due to interference from factors such as growth hormone (GH), epidermal growth factor (EGF), transforming growth factor-beta 1 (TGF-β1), and parathyroid hormone-related protein (PTHrP).

As in bone, Pb can easily substitute for calcium in the teeth and is taken and incorporated into developing teeth in experimental animals. Since teeth do not undergo remodeling like the bone does during growth, most of the Pb in the teeth remains in a state of permanent storage. High dose exposure of Pb to animals (30 mg/kg body weight) has lead to the formation of a “Pb line” that is visible in both the enamel and dentin and is localized in areas of recently formed tooth structure. Areas of mineralization are easily evident in the enamel and the dentin within these “Pb lines.” Pb has also been shown to decrease cell proliferation, procollagen type I production, intracellular protein, and osteocalcin in human dental pulp cell cultures. Adult rats exposed to Pb have exhibited an inhibition of the posteruptive enamel proteinases, delayed teeth eruption times, as well as decrease in microhardness of surface enamel. Pb was reported to be widely dispersed and incorporated into developing apatite crystal during enamel formation process; however, post formation, Pb was reported to be capable of entering and concentrating in enamel areas that were calcium deficient. The 2006 Pb AQCD also reported that a number of epidemiologic and animal studies have both separately suggested that Pb is a caries-promoting element.

5.9.4.2 New Toxicological and Epidemiologic Studies

As reported in the 2006 Pb AQCD, Pb appears to be capable of causing effects in bones of humans and animals following exposure. The association between blood Pb levels and osteoporosis was examined in several epidemiologic studies. Most studies were cross-sectional in design; thus, there is uncertainty regarding the magnitude, timing, frequency, and duration of Pb exposure that contributed to the observed associations. Campbell and Auigner (2007) examined subjects ≥ 50 years of age using NHANES III for association between concurrent blood Pb level and osteoporosis. The study authors used the bone mineral density in the hip as the primary outcome in groups comprising non-Hispanic white men (mean blood Pb: 4.9, range: 0.7 to 48.1 µg/dL), non-Hispanic white women (mean blood Pb: 3.6, range: 0.7 to 28.7 µg/dL), African-American men (mean blood Pb: 7.7, range: 0.7 to 52.9 µg/dL), and African-American women (mean blood Pb: 4.5, range: 0.7 to 23.3 µg/dL). The results indicated that the adjusted mean total hip bone mineral density in the non-Hispanic white males who had the lowest blood Pb levels (actual concentration not reported) was statistically significantly higher than that in the males with higher blood Pb levels. Similar associations, although not statistically significant, were reported among white females. Likely due to the small sample size, similar results were not observed among African-American men and women. No association was observed between blood Pb and osteoporotic fractures in any sex/race group. Since the NHANES study comprised a cross-sectional design, no inferences could be made regarding the temporal sequence of the observed association. The study authors concluded that further inquiry was needed to study the possible causal association between Pb exposure and osteoporosis. In a similar study, Sun et al. (2008b) examined the association between concurrent blood Pb levels and osteoporosis in 155 males and 37 females in China occupationally-exposed to Pb (mean blood Pb: 20.22 and 15.5 µg/dL, respectively). Bone mineral density was reported to be statistically significantly lower in exposed females compared to exposed males. When all participants (including 36 male and 21 female unexposed controls) were divided into groups according to blood Pb and urinary Pb levels, the study authors reported that there were significant decreases in bone mineral density in groups that had high urinary Pb levels (≥ 5 µg/g creatinine) compared to groups with low urinary Pb in both sexes. In contrast, a significant difference was observed between blood Pb and bone mineral density only in males with blood Pb >30 µg/dL. Prevalence of osteoporosis was reported to increase significantly with increasing blood Pb in a linear manner. Khalil et al. (2008) reported similar associations between blood Pb level and osteoporosis in older women. The study authors conducted a prospective study using 533 women aged 65-87 years with a mean (SD) blood Pb of 5.3 (2.3) µg/dL to determine the association between blood Pb and recurring fractures. Analysis of bone mineral density was conducted in 1986-1990 and 1993-1994, while

blood Pb was measured from 1990-1991. The bone mineral density was 7% lower in the total hip ($p < 0.02$) and 5% lower in the femoral neck ($p < 0.03$) in the highest blood Pb group (≥ 8 µg/dL) compared to the lowest blood Pb group (≤ 3 µg/dL). The trend across all dose groups was also observed to be statistically significant for hip and femoral neck bone mineral density. In addition, hip, femoral neck, and calcaneus bone loss was observed to be greater in the medium (blood Pb: 4-7 µg/dL) and high Pb groups compared to the low Pb group, but the observed trend was only significant for calcaneus bone loss. Multivariate analysis indicated that women with high blood Pb levels had an increased risk of non-spine fracture and women with medium or high blood Pb levels had a higher risk of falls compared to the low blood Pb level group. Based on these results, the study authors concluded that blood Pb is associated with an increased risk of falls and fractures leading to osteoporosis-related fractures.

To examine the association between biomarkers of joint tissue metabolism and blood Pb levels, Nelson et al. (In Press) performed a cross-sectional analysis of 329 male and 342 female participants in the Johnson County Osteoarthritis Project Metals Exposure Sub-study. In women (mean age = 62 years), the median concurrent blood Pb level was 1.9 µg/dL (range: 0.5-25.4 µg/dL). Blood Pb levels were higher in African-American compared to Caucasian women. Unadjusted correlation analyses demonstrated significant positive correlations between blood Pb and uNTX-I (a marker of bone resorption/turnover), uCTX-II (a marker associated with the progression of radiographic knee and hip osteoarthritis), and COMP (a cartilage biomarker related to osteoarthritis); however, significant associations only remained for uNTX-I and uCTX-II after adjusting for age, BMI, race, and smoking status. In men (median age = 65), the median blood Pb level was 2.2 µg/dL (range: 0.5-25.1 µg/dL). As with women, African-American men had higher blood Pb levels than did Caucasian men. In unadjusted correlation analyses, blood Pb levels in men were positively associated with uCTX-II, COMP, and C2C:CPII ratio (an indication of the balance between cartilage collagen degradation and synthesis), and negatively associated with CPII (a marker of collagen synthesis). After controlling for age, BMI, race, and smoking, only the positive association between blood Pb and COMP remained borderline statistically significant in men. The authors concluded that blood Pb is associated with bone turnover and mineralized cartilage turnover in women and non-mineralized cartilage turnover in men; however, as this study was cross-sectional in nature, it is impossible to conclude whether increased cartilage turnover is a product of increased blood Pb, or whether cartilage turnover itself results in increased Pb. Similarly, Machida et al. (2009) investigated bone matrix turnover rates in Japanese women related to menopause status and blood Pb. Perimenopausal women (n = 319) were observed to have significantly higher geometric mean blood Pb (2.0 µg/dL), than did premenopausal women (n = 261, blood Pb = 1.6 µg/dL), younger postmenopausal women (n = 397, blood Pb = 1.8 µg/dL), or older postmenopausal women (n = 248, blood Pb = 1.7 µg/dL).

In all subjects and perimenopausal women, markers of bone matrix turnover (osteocalcin [OC], bone-specific alkaline phosphatase [BALP], and N-telopeptide cross-linked collagen type I [NTx]) were significantly positively associated with blood Pb in unadjusted correlation analyses. In multivariate regression models controlling for bone-mineral density, NTx, and age, OC was additionally statistically positively associated with blood Pb in all subjects and perimenopausal women. Bone mineral density and NTx were also positively associated with blood Pb in these models for all subjects. As with Nelson et al. (In Press), the cross-sectional nature of this study precludes a determination whether higher blood Pb is cause of increased bone matrix turnover biomarkers, or a consequence of increased bone turn over.

To understand the importance of bone as a target tissue of Pb toxicity, Jang et al. (2008) studied the effect of Pb on calcium release activated calcium influx (CRACI) using primary cultures of human osteoblast-like cells (OLC). When cells were incubated with 1,000 or 3,000 µM Pb, a concentration-dependent impact on the CRACI was observed, as was a concentration-dependent increase in the influx of Pb into human OLC. These results suggest that Pb interferes with CRACI in human OLCs by initiating the CRACI (i.e., the measurable influx of calcium upon re-addition of calcium is partially inhibited by Pb) and the influx of Pb is enhanced after CRACI is induced. Since studies have found associations between higher blood Pb level and reduced skeletal growth in children, Zuscik et al. (2007) conducted a study using murine limb bud mesenchymal cells (MSCs) to test the hypothesis that Pb alters chondrogenic commitment of mesenchymal cells and also to assess the effects of Pb on various signaling pathways. Exposure to 1 µM Pb caused increased basal and TGF-β/BMP induction of chondrogenesis in MSCs which was supported by nodule formation and upregulation of Sox-9, type 2 collagen, and aggrecan which are all key markers of chondrogenesis. The study authors also observed enhanced chondrogenesis during ectopic bone formation in mice that had been pre-exposed to Pb in drinking water (55 or 233 ppm, corresponding to 14 or 40 µg/dL blood Pb). MSCs exposed to Pb exhibited an increase in TGF-β, but BMP-2 signaling was inhibited. Pb was also reported to induce NF-κB and inhibit AP-1 signaling. Based on these results, the study authors concluded that chondrogenesis following exposure to Pb most likely involved modulation and integration of multiple signaling pathways including TGF-β, BMP, AP-1, and NF-κB.

Effects of Pb exposure on teeth were examined in a few epidemiologic studies. Since individuals may be impacted by the release of Pb stored in their skeletal compartments, Arora et al. (2009) examined the association between bone Pb concentrations and loss of natural teeth in 333 male participants of the NAS. Tooth loss in men was categorized as 0, 1-8 or ≥ 9. Individuals with ≥ 9 teeth missing had significantly higher tibia and patella Pb concentrations (measured within 3 years of dental assessment) compared to those with

no tooth loss; no significant difference in blood Pb levels (measured within 3 years of dental assessment [(Hu et al., 1996a)]) was observed between the categories of teeth loss. Following adjustment for age, education, smoking status, pack-years of smoking, and diabetes, men with the highest tibia Pb concentrations (>23 µg/g) had higher odds of tooth loss (OR: 3.03 [95% CI: 1.60, 5.75]) compared to men with tibia Pb ≤ 15 µg/g. Men with the highest patellar Pb (>36 µg/g) also had higher odds of tooth loss (OR: 2.41 [95% CI: 1.30, 4.49]) compared to men with patellar Pb ≤ 22.0 µg/g. Tooth loss was not statistically associated with blood Pb levels. Based on these results, the study authors concluded that long-term cumulative exposure to Pb is associated with increased odds of tooth loss. In a study examining the effects of Pb exposure on periodontitis in the U.S, Saraiva et al. (2007) analyzed data for 2,500 men and 2,399 women aged between 30 and 56 years from NHANES III. The analysis took into account various covariates including age, NHANESIII phase, cotinine levels, poverty ration, race/ethnicity, education, bone mineral density, diabetes, calcium intake, dental visits, and menopause in women. After adjusting for these covariates and comparing individuals with a concurrent blood Pb level of >7 µg/dL to those with a blood Pb level of <3 µg/dL, the prevalence ratios of periodontitis was 1.70 (95% CI: 1.02, 2.85) for men and 3.80 (95% CI: 1.66, 8.73) for women. Based on these results, the study authors concluded that there was a positive association between periodontitis and blood Pb levels for both men and women. In a similar study, Yetkin et al. (2007) recruited 60 male subjects (30 apprentices with Pb exposure, 30 controls), to examine the impact of occupational exposure to Pb on periodontal status and association between periodontitis and blood Pb or oxidative stress. The results of their analysis indicated that blood Pb was significantly higher in apprentices exposed to Pb compared to controls (mean [SD]: 7.38 [4.41] versus 2.27 [1.49] µg/dL, respectively). No clinical periodontal or oxidative stress parameters were significantly different between apprentices and controls. While the correlation between blood Pb and periodontal parameters was not reported, significant correlations between plaque index and CAT, probing depth and SOD, clinical attachment level and SOD, and clinical attachment level and malondialdehyde in Pb-exposed apprentices were observed. These results demonstrate that there is significant association between clinical periodontal parameters and oxidative stress/damage indices in Pb-exposed apprentices. In a multiple regression analysis, a statistically significant association between gingival index and working status, family income and either probing depth or clinical attachment level was noted.

5.9.5 Effects on Ocular Health

Ocular effects most commonly indicated to be associated with exposure to Pb include formation of cataract, impaired vision, edema and retinal stippling.

5.9.5.1 Summary of Key Findings of the Effects on Ocular Health from the 2006 Lead AQCD

The 2006 Pb AQCD stated that various changes in the visual system were observed with Pb poisoning including retinal stippling and edema, cataract, ocular muscle paralysis and impaired vision. The 2006 Pb AQCD reported that retinal responses were observed in children of mothers with a blood Pb range of 10.5 to 32.5 μg/dL during pregnancy, while cataracts were noted in middle-aged male with tibia bone Pb levels of 31-126 μg/g.

5.9.5.2 New Toxicological and Epidemiologic Studies

A small number of human studies pertaining to ocular effects of Pb were identified. Mosad et al. (2010) studied the association between subcapsular cataract and Pb, cadmium, vitamin C, vitamin E, and beta carotene blood levels in middle-aged male smokers compared to nonsmokers. Blood Pb was statistically significantly elevated in light (mean [SD]: 14.5 [0.41] μg/dL), moderate (14.5 [0.41] μg/dL), and heavy smokers (18.7 [1.24] μg/dL) compared to nonsmokers (12.2 [0.21] μg/dL). Blood Pb concentrations were also observed to be statistically higher in the cataracts of smokers versus nonsmokers. Similar associations were also observed for cadmium blood and lens levels, while vitamins C, E, and beta carotene levels were significantly decreased in smokers. Based on these results, the study authors concluded that the Pb and cadmium present in high concentration in smokers were associated with cataracts due to oxidative stress which was indicated by reduced levels of antioxidants such as vitamins C, and E and beta carotene. Erie et al. (2009) investigated the association between age-related macular degeneration and Pb and Cd in retinal tissue of human eye donors. The authors observed that Pb, but not Cd, was significantly elevated in the neural retina tissue of donors with age-related macular degeneration (n = 36 donors, 72 eyes; median [IQR]: 12.0 [8-18] ng/g Pb) versus normal control donors (n = 25 donors, 50 eyes; median [IQR]: 8.0 [0-11] ng/g Pb). Neither heavy metal was significantly elevated in the retinal pigment epithelium-choroid complex in donors with age-related macular degeneration and normal controls.

New animal studies pertaining to the ocular effects of Pb have investigated endpoints such as retinal progenitor cell proliferation and neurogenesis,(Section 5.3.4.3). An in vitro study was found that investigated whether exposure of cultured lenses from rats (4-6 weeks age) to 1 µM Pb nitrate increased opacity with or without secondary oxidative challenge (Neal et al., 2010b). Lenses incubated for 3 days in the presence of 1 µM Pb were transparent, with no difference in amino acid incorporation compared to control lenses. The authors concluded this indicated that short-term Pb exposure does not induce osmotic swelling or lens shrinkage. However, exposure to lenses to Pb for 5 days dramatically decreased the percentage of transparent lenses (30%) compared to controls (80%). In Pb-exposed lenses, 30% displayed "definite cataracts" compared to only 2.5% in control lenses. By culture day 8, all exposed lenses were described either as clearly opaque or definite cataracts, while only 7% of control lenses displayed these characteristics, indicating that prolonged exposure of lenses to Pb induced an accelerated formation of opacity/cataract compared to unexposed lenses. Pb-exposed lenses cleared the media of hydrogen peroxide more rapidly than did control lenses, potentially due to increased CAT activity. Exposure to hydrogen peroxide resulted in total opacity in Pb-exposed lenses at culture day 7, compared to less than 20% in control cells. Exposure to Pb additionally altered epithelial nutrient transport and lens histology relative to that in controls.

5.9.6 Effects on the Respiratory System

The collective body of toxicological and epidemiologic studies demonstrates Pb-associated effects on multiple immunological pathways, including a shift from a Th1 to a Th2 phenotype, increased IgE antibody production, and increased inflammatory responses (Sections 5.2.5.1. and 5.6). These are well recognized pathways that contribute to increased susceptibility to infections and also to the development of respiratory diseases such as asthma. Recent investigation of the respiratory effects of Pb exposure has been limited; however, cross-sectional studies have indicated an association of increasing blood Pb level with increased prevalence of asthma in children (Section 5.6.4.2). As described in Section 5.2.4, Pb has been shown to induce the generation of ROS. ROS are implicated in mediating increases in bronchial responsiveness and activating neural reflexes leading to decrements in lung function. Studies investigating these airway responses also are limited in number and collectively do not provide strong evidence of an association with blood Pb (Section 5.6.6). Collectively, panel and time-series epidemiologic studies demonstrate associations between Pb measured in $PM_{2.5}$ or PM_{10} air samples and decreases in lung function and increases in respiratory symptoms, and asthma hospitalizations in children but not adults

(Section 5.6.4.3). Toxicological studies have found pulmonary inflammation induced by CAPs in which Pb was one of numerous components (Wei et al., 2011; Duvall et al., 2008; Godleski et al., 2002; Saldiva et al., 2002). Despite this evidence for respiratory effects related to air-Pb concentrations, it is important to note the limitations of air-Pb studies, including the limited data on the size distribution of Pb-PM (Section 3.5.3), the uncertain relationships of Pb-PM_{10} and Pb-$PM_{2.5}$ with blood Pb levels, and the lack of adjustment for other correlated PM chemical components.

5.9.7 Summary

There is evidence from epidemiologic and toxicological studies that substantial exposure to Pb can result in altered liver function and hepatic toxicity. Biochemical changes indicative of liver injury, including decreases in serum protein and albumin levels and increased AST, ALT, ALP, and GGT activities, have been observed in occupationally-exposed humans (blood Pb > 22 µg/dL) (Can et al., 2008; Khan et al., 2008; Patil et al., 2007) mature animals exposed to high levels of Pb during adulthood (Sharma et al., 2010a; Wang et al.; DS et al., 2009; Cheng et al., 2006), and animals exposed during gestation and lactation (Pillai et al., 2009; Teijon et al., 2006). In humans with mean blood Pb levels 5.4 µg/dL, altered AST levels were observed, but increases may be related to exposure to contaminants other than Pb (Conterato et al., In Press). Increased hepatic cholesterogenesis, altered triglyceride and phospholipid levels, and disorders in lipid metabolism accompanied by increased levels of total cholesterol and triglycerides have been reported in the animal literature (Ademuyiwa et al., 2009; Khotimchenko and Kolenchenko, 2007). These results suggest that induction of cholesterogenesis and phospholipids in the liver may cause subtle effects at the cellular level, leading to hepatic injury. Multiple studies in humans and animals have observed hepatic oxidative stress, generally indicated by an increase in lipid peroxidation along with a decrease in GSH levels and CAT, SOD, and GPx activities following exposure to Pb (Pandya et al., 2010; Sharma et al., 2010a; Khan et al., 2008; Yu et al., 2008; Adegbesan and Adenuga, 2007; Jurczuk et al., 2007; Khotimchenko and Kolenchenko, 2007; Jurczuk et al., 2006). Indices of increased oxidative stress were additionally observed in the livers of fetuses exposed to Pb throughout gestation (Massó et al., 2007).

Relatively few human studies have been conducted on the gastrointestinal toxicity of Pb since the completion of the 2006 Pb AQCD. A case study reporting on GI symptoms in a child reported that elevated blood Pb was associated with nonlocalized abdominal pain, vomiting, nausea, constipation, lack of appetite, fatigue, and headaches (Cabb et al., 2008). Symptoms were reported to diminish following cessation of exposure. Similar GI symptoms (stomach pain and gastritis) were observed in battery works and painters

exposed to Pb in India with blood Pb levels ranging from 0.4-116.6 µg/dL (Kuruvilla et al., 2006). Toxicological evidence for Pb-induced GI effects in rats includes inhibition of NANC relaxations in the gastric fundus and the observation of oxidative stress (lipid peroxidation, decreased SOD and CAT) in the gastric mucosa (Olaleye et al., 2007; Santos et al., 2006b). The observation of oxidative stress was accompanied gastric mucosal damage.

The endocrine processes most impacted by exposure to Pb include changes in thyroid function. FT4, but not FT3, was decreased in adolescent male auto repair workers (Dundar et al., 2006) and mid-pregnancy T4 levels were negatively associated in women living in a highly contaminated town in Yugoslavia, whereas this association was not observed in a non-contaminated town (Lamb et al., 2008). Toxicological evidence for similar effects was found in adult cows reared in an environment contaminated with Pb. A positive correlation was reported between blood Pb and plasma T3 and T4 levels (Swarup et al., 2007). In children challenged with an acute stressor, increasing prenatal maternal and age 2-year blood Pb levels were associated with significant increases in salivary cortisol responses at age 9 years, even with blood Pb levels less than 10 µg/dL (Gump et al., 2008). A summary of key findings pertaining to reproductive hormones in males and females in the current document is presented in the section on reproductive and developmental effects (Sections 5.8.1 and 5.8.2).

Numerous epidemiologic studies investigated the association between Pb biomarkers and osteoporosis in adults. Higher blood Pb was observed to be associated with decreased bone mineral density in non-Hispanic white males (Campbell and Auinger, 2007), whereas urinary Pb, but not blood Pb, was associated with decreased bone mineral density in Chinese individuals occupationally exposed to Pb (Sun et al., 2008b). In elderly women, blood Pb levels were positively associated with risk of falls and osteoporosis-related fractures (Khalil et al., 2008). Linear skeletal growth was reduced in children living near copper smelters and refiners (concurrent mean blood Pb level = 7.7 µg/dL) (Ignasiak et al., 2006). In vitro studies indicate that Pb interferes with CARCI in human OLCs and that Pb perturbs multiple signaling pathways during murine limb bud growth, potentially resulting in altered skeletal development (Jang et al., 2008; Zuscik et al., 2007). Blood Pb levels have also been shown to be related to biomarkers of joint tissue metabolism in elderly populations, but the cross-sectional nature of these analyses prevents conclusions being drawn on whether Pb increases bone and joint turnover biomarkers, or whether increased turnover releases Pb into the bloodstream (Machida et al., 2009; Nelson et al., In Press). Epidemiologic studies investigating Pb exposure and tooth loss indicate that long-term, cumulative exposure to Pb is associated with increased odds of tooth loss, periodontitis in men and women, and that periodontitis is associated

with oxidative stress/damage in individuals exposed in an occupational setting (Arora et al., 2009; Saraiva et al., 2007; Yetkin-Ay et al., 2007).

New toxicology studies have reported ocular effects (i.e., retinal progenitor cell proliferation) due to Pb exposure (Section 5.3.4.3). and studies in humans report associations between heavy smoking, increased blood Pb levels, and cataracts (Mosad et al., 2010) and retinal Pb concentrations and age-related macular degeneration (Erie et al., 2009). Investigation of the respiratory effects of Pb exposure has been limited; however, cross-sectional studies have indicated an association of higher blood Pb levels with increased prevalence asthma in children (Section 5.6.4.2).

In summary, recent toxicological and epidemiologic evidence regarding the effects of Pb exposure on the liver, GI tract, endocrine system, bone and teeth, eyes, and respiratory tract largely are supportive of those effects noted in the 2006 Pb AQCD. However, recent evidence of these effects is relatively limited, and therefore no causal determinations are made regarding Pb-induced effects in these organ systems.

5.10 Cancer

The previous epidemiologic studies included in the 2006 Pb AQCD (U.S. EPA, 2006b) "provide[d] only very limited evidence suggestive of Pb exposure associations with carcinogenic or genotoxic effects in humans" and the studies were summarized as follows:

> "The epidemiologic data …suggest a relationship between Pb exposure and cancers of the lung and the stomach… Studies of genotoxicity consistently link Pb-exposed populations with DNA damage and micronuclei formation, although less consistently with chromosomal aberrations."

The International Agency for Research on Cancer (IARC) recently classified inorganic Pb compounds as probable human carcinogens (Group 2A of IARC classifications) based on stronger evidence in animal studies than human studies, and organic Pb compounds as not classifiable (Group 3 of IARC classifications) (IARC, 2006a; Rousseau et al., 2005). Additionally, the National Toxicology Program has listed Pb and Pb compounds as "reasonably anticipated to be human carcinogens" (NTP, 2004). The typical cancer bioassays used by IARC or NTP as evidence of Pb-induced carcinogenicity used rodents that were continuously exposed to Pb-acetate in chow or drinking water for 18 months to two years in duration. These two year cancer bioassays and the doses administered are typical of cancer bioassays used with other chemicals.

In the following sections, recent epidemiologic and toxicological studies published since the 2006 Pb AQCD regarding Pb and cancer mortality and incidence are examined. In

addition, recent studies of Pb and DNA and cellular damage, as well as epigenetics studies, are summarized. When the information is available, the form of the Pb compound under study (e.g., inorganic, organic) is indicated. In epidemiologic studies, various biological measures of Pb are used including Pb measured in blood and bone. Bone Pb is indicative of cumulative Pb exposure. Blood Pb can represent more recent exposure, although it can also represent remobilized Pb occurring during times of bone remodeling. Toxicological studies only report exposure by blood Pb or exposure dose. More detailed discussion of these measures is given in Section 4.3.5.

5.10.1 Cancer Incidence and Mortality

Recent studies have included epidemiologic evaluations of the associations between Pb and both specific cancers, such as lung cancer and brain cancer, and overall cancer. Table 5-42 provides an overview of the study characteristics and results for the epidemiologic studies that reported effect estimates. This section also evaluates toxicological evidence on the potential carcinogenicity of Pb.

Table 5-42 Summary of recent epidemiologic studies[a] of cancer incidence and mortality

Reference[a]	Study Location	Cancer Outcome	Study Population	Measure of Pb Exposure	Mean Pb (SD)	Adjusted Effect Estimates
Cancer Mortality:						
Menke et al. (2006)	Multiple U.S. locations	Overall cancer mortality	NHANES III cohort with Blood Pb measures in 1988-1994 At least 12 years of follow-up Blood Pb <10 µg/dL	Blood Pb at baseline	2.58 µg/dL (geometric mean) Tertile 1: <1.93 µg/dL Tertile 2: 1.94-3.62 µg/dL Tertile 3: ≥ 3.63 µg/dL	Tertile 1: 1.00 Tertile 2: 0.72 (95% CI: 0.46, 1.12) Tertile 3: 1.10 (95% CI: 0.82, 1.47)
Schober et al. (2006)	Multiple U.S. locations	Overall cancer mortality	NHANES III cohort At least 40 years of age	Blood Pb at baseline	Blood Pb<5 µg/dL: 67.7% Blood Pb 5-9 µg/dL: 26.0% Blood Pb>=10 µg/dL: 6.3%	Blood Pb<5 µg/dL: 1.00 Blood Pb 5-9 µg/dL: 1.44 (95% CI: 1.12, 1.86) Blood Pb≥ 10 µg/dL: 1.69 (95% CI: 1.14, 2.52) Note: Modification by age assessed and associations varied slightly
Weisskopf et al. (2009)	Boston, MA	Overall cancer mortality	NAS Included men only Mean follow-up period for this study: 8.9 yr	Blood Pb at baseline, Patella Pb at baseline	Blood Pb: 5.6 µg/dL (3.4) Tertile 1 of Blood Pb: <4 µg/dL Tertile 2 of Blood Pb: 4-6 µg/dL Tertile 3 of Blood Pb: >6 µg/dL Tertile 1 of patella Pb: <22µg/g Tertile 2 of patella Pb: 22-35µg/g Tertile 3 of patella Pb: >35 µg/g	Blood Pb Tertile 1: 1.00 Blood Pb Tertile 2: 1.03 (95% CI: 0.42, 2.55) Blood Pb Tertile 3: 0.53 (95% CI: 0.20, 1.39) Patella Pb Tertile 1: 1.00 Patella Pb Tertile 2: 0.82 (95% CI: 0.26, 2.59) Patella Pb Tertile 3: 0.32 (95% CI: 0.08, 1.35)
Khalil et al. (2009a)	Baltimore, MD, and Monongahela Valley, PA	Overall cancer mortality	Subgroup of the Study of Osteoporotic Fractures cohort Included white women aged 65-87; 12 yr (+/- 3 yr) follow-up	Blood Pb at baseline	Blood Pb Level 5.3 (2.3)µg/dL	Blood Pb<8 µg/dL: 1.00 Blood Pb≥ 8 µg/dL: 1.64 (95% CI: 0.73, 3.71)
Lung Cancer:						
Lundstrom et al. (2006)	Sweden	Lung cancer (incidence and mortality)	Male Pb smelter workers first employed for ≥ 3 months between 1928 and 1979 Followed up for mortality from 1955 - 1987	Median peak blood Pb level Median number of yr with at least one blood sample obtained Median cumulative blood Pb index (sum of annual blood Pb Level)	Median peak blood Pb Level: cases 2.4 µmol/L, controls 2.7 µmol/L Median number of yr with at least one blood sample obtained: cases 4.5 yr, controls 6.0 yr Median cumulative blood Pb index: cases 9.0 µmol/Pb, controls 11.9 µmol/Pb	Median peak blood Pb Level: 1.00 (95% CI: 0.71, 1.42) Median number of yr with at least one blood sample obtained: 0.96 (95% CI: 0.91, 1.02) per µmol/L Median cumulative Blood Pb index: 0.99 (95% CI: 0.96, 1.02) per µmol/L Note: similar results were observed when restricted to smokers only

Reference[a]	Study Location	Cancer Outcome	Study Population	Measure of Pb Exposure	Mean Pb (SD)	Adjusted Effect Estimates
Jones et al. (2007)	Humberside, UK	Lung cancer mortality	Male tin smelter employees	Personnel record cards and air sampling conducted from 1972-1991 Three exposure scenarios determined for working lifetime cumulative exposure – all have similar medians of approximately 2 mg yr/m^3	NA	RR for Pb exposure weighted age and time since exposure: 1.54 (90% CI: 1.14, 2.08) Note: Similar results for other exposure determination scenarios.
Rousseau et al. (2007)	Montreal, Canada	Lung cancer and other cancer incidence	Men aged 35-79	Interview of job history and exposure matrix	Ever exposed to: Organic Pb 3.0% Inorganic Pb 17.0% Pb in gasoline emissions 38.6%	Organic Pb exposure compared to no exposure: Lung 1.3 (95% CI: 0.5, 3.1) Inorganic Pb exposure compared to no exposure: Lung 1.1 (95% CI: 0.7, 1.7) Pb in gasoline emissions exposure compared to no exposure: Lung 0.8 (95% CI: 0.6, 1.1) Note: results are for comparisons using population-based controls; results for controls with other types of cancers were similar
Brain Cancer:						
van Wijngaarden and Dosemeci (2006)	Multiple U.S locations	Brain cancer mortality	National Longitudinal Mortality Study – included individuals with occupational information -included follow-up from 1970-1989	Interview about current or most recent job within the past 5 years and a job exposure matrix	NA	Any Pb exposure compared to no exposure 1.56 (95% CI: 1.00, 2.43) Note: HRs were greatest among those with high probabilities of exposure and medium/high exposure intensity
Rajaraman et al. (2006)	Phoenix, AZ, Boston, MA, and Pittsburgh, PA	Brain cancer incidence	NCI Brain Tumor Study – included individuals >=18 yr diagnosed with brain cancer less than 8 wk before hospitalization; frequency-matched controls were individuals admitted to the same hospitals for non-neoplastic conditions	Interviews of lifetime work history and exposure databases	NA	Meningioma: Ever exposure to Pb 0.8 (95% CI: 0.5, 1.3) Glioma: Ever exposure to Pb 0.8 (95% CI: 0.6, 1.1) Note: positive associations between Pb exposure and meningioma incidence was observed among individuals with ALAD2 genotypes, but not individuals with ALAD1 genotypes; these associations were not observed for glioma incidence

Reference[a]	Study Location	Cancer Outcome	Study Population	Measure of Pb Exposure	Mean Pb (SD)	Adjusted Effect Estimates
Bhatti et al. (2009)	Phoenix, AZ, Boston, MA, and Pittsburgh, PA	Brain cancer incidence	NCI Brain Tumor Study – included non-Hispanic whites ≥ 18 yr diagnosed with brain cancer less than 8 wk before hospitalization; frequency-matched controls were individuals admitted to the same hospitals for non-neoplastic conditions	Interviews of lifetime work history and exposure databases	Glioma: 70.5 µg/m^{3}y (193.8 µg/m^{3}y) Glioblastoma multiform: 97.5 µg/m3y (233.9 µg/m^{3}y) Meningioma: 101.1 µg/m^{3}y (408.7 µg/m^{3}y) Controls: 69.7 µg/m^{3}y (248.8 µg/m^{3}y)	Per 100 µg/m^{3}y increase in cumulative Pb exposure Glioma: 1.0 (95% CI: 0.9, 1.1) Glioblastoma multiform: 1.0 (95% CI 0.9, 1.1) Meningioma: 1.1 (95% CI: 1.0, 1.2) Note: modification by SNPs was conducted and associations varied by SNP
Breast Cancer:						
Pan et al. (2011)	Canada	Breast cancer incidence	National Enhanced Cancer Surveillance System (NECSS) – population-based sample of cancer cases and controls with information collected from 1994-1997	Self-reported previous addresses and their proximity to Pb smelters (determined using Environmental Quality Database [EQDB])	NA	Residing >3.2 km from Pb smelter or no nearby smelter: 1.00 Residing 0.8-3.2 km from Pb smelter: 0.41 (95% CI: 0.11, 1.51) Residing <0.8 km from Pb smelter: 0.61 (95% CI: 0.11, 3.42)
Multiple and Other Cancers:						
Absalon and Slesak (2010)	Silesia province, Poland	Overall cancer incidence	Children living in this province at least five years	Pb-related air pollution measures	NA	Reported correlations between changes in Pb and cancer incidence – no/low correlations observed (correlation coefficients between -0.3 and 0.2)
Obhodas et al. (2007)	Island of Krk, Croatia	Incidence rates for neoplasms	Individuals living in the Island of Krk from 1997-2001	Soil and vegetation samples, household potable water samples, children's hair samples	NA	No association observed between Pb in the samples and incidence of neoplasm (numerical results not provided)
Mendey et al. (In Press)	Multiple U.S. locations	Incidence of cancer or "malignancy of any kind"	2007-2008 NHANES cohort – at least 20 years of age	Concurrently measured creatinine-adjusted urinary Pb	Geometric mean for creatinine-adjusted urinary Pb marker: 0.59 µg/g (95% CI: 0.57, 0.61)	Greater than log-transformed mean creatinine-adjusted urinary Pb level compared to less than log-transformed mean creatinine-adjusted urinary Pb level: 0.76 (95% CI: 0.44, 1.33)

5.10.1.1 Overall Cancer Mortality

Several recent epidemiologic studies examined the association between Pb levels and cancer mortality, including multiple analyses of the NHANES III population. In one NHANES III analysis, the cohort was followed for 12 years and individuals with blood Pb levels greater than 10 µg/dL were excluded from the study (mean baseline blood Pb level was 2.58 µg/dL). No association was observed between blood Pb and cancer mortality (HR of highest tertile [≥ 3.63 µg/dL]compared to lowest tertile [<1.93 µg/dL]: 1.10 [95% CI: 0.82, 1.47]) (Menke et al., 2006). Another analysis of the NHANES III population, which was restricted to individuals 40 years and older at the time of blood Pb collection and included individuals with all blood Pb levels (including those greater than 10 µg/dL), reported associations between blood Pb and cancer mortality (Schober et al., 2006). In this study, median follow-up time was 8.6 years. The RRs were 1.69 (95% CI: 1.14, 2.52) for individuals with blood Pb levels of at least 10 µg/dL and 1.44 (95% CI: 1.12, 1.86) for blood Pb levels of 5-9 µg/dL compared to individuals with blood Pb levels less than 5 µg/dL. When stratified by age, point estimates comparing blood Pb levels of 5-9 versus less than 5 µg/dL were similar across all age groups but only statistically significant among 75-84 year olds. The odds of mortality associated with blood Pb levels ≥ 10 µg/dL in the groups aged 40-74 years and 85 years and older were elevated. A study of men from the greater Boston area enrolled in the NAS found no association between

blood or bone Pb and cancer mortality in adjusted analyses. The mean (SD) blood Pb level for this population was 5.6 (3.4) µg/dL and blood Pb was poorly correlated with measured bone Pb (Weisskopf et al., 2009). As part of the Study of Osteoporotic Fractures , white women aged 65-87 were included in a sub-study of blood Pb level and cancer mortality and were followed for approximately 12 years (Khalil et al., 2009a). The mean (SD) blood Pb levels were 5.3 (2.3) µg/dL and no association was detected between blood Pb and cancer mortality in the study population.

Overall, epidemiologic studies of blood Pb levels and cancer mortality reported inconsistent results. One epidemiologic study using NHANES III data demonstrated an association between blood Pb and increased cancer mortality; however, other studies reported weak or no associations.

5.10.1.2 Lung Cancer

Most of the evidence regarding lung cancer incidence is provided by studies of occupationally-exposed adults. In a study of smelter workers, no association was observed between several metrics of Pb exposure (peak blood Pb values, number of years Pb samples were obtained, and cumulative blood Pb index) and lung cancer incidence and mortality combined (Lundstrom et al., 2006). The median follow-up in the study was about 30 years and the median peak blood Pb values during employment were 49.7 µg/dL for lung cancer cases and 55.9 µg/dL for controls. In a study of tin smelters workers, no association was observed between Pb exposure and lung cancer mortality in unweighted analyses, but when the analyses were weighted by age and time since exposure, positive associations were apparent (Jones et al., 2007). In this study, Pb exposure was calculated by combining historical air sampling data and personnel record cards, which specified work histories. The median Pb exposure was estimated to be approximately 2 mg-year/m^3. It is important to note that the smelter workers were exposed to other metals as well, such as arsenic and antimony. A population-based case-control study performed among men in Montreal, Canada assessed Pb exposure via interviews regarding job histories and calculated the likely Pb exposures associated with the job activities (Rousseau et al., 2007). No association was apparent between organic Pb, inorganic Pb, or Pb from gasoline emissions and lung cancer.

Studies of Pb and lung cancer that compared the lung tissue of individuals with lung cancer to those without lung cancer were also conducted. The controls for these studies were individuals with metastases in the lung from other primary cancers (De Palma et al., 2008) and individuals with non-cancerous lung diseases (De Palma et al., 2008; Kuo et al., 2006). Findings are mixed among the studies. De Palma et al. (De Palma et al., 2008)

reported higher Pb concentrations in the cancerous and non-cancerous lung tissue of individuals with non-small cell lung cancer compared to control groups (although the authors report these results may be confounded by smoking). Kuo et al. (Kuo et al., 2006) found no statistical difference in Pb levels for lung tissue of individuals with lung cancer compared to controls .

Some studies in the 2006 Pb AQCD reported associations between Pb exposure and lung cancer; however, more recent epidemiologic studies of lung cancer reported no associations. Overall, these recent epidemiologic studies included only men, limiting the generalizability. The studies by Jones et al. (2007) and Rousseau et al. (2007) also have the disadvantage of not obtaining actual measures of Pb levels. In addition, studies limited to occupational exposures may be confounded by other workplace exposures.

5.10.1.3 Brain Cancer

A few studies of brain cancer examined the association between cancer and Pb using exposures determined via exposure databases and patient interviews about past jobs and known exposures. Interpretation of these results is limited due to the lack of biological Pb measures and the potential confounding by other occupational exposures. The National Longitudinal Mortality Study, a study that included a national sample of the U.S. population, estimated Pb exposure based on current/most recent employment among individuals (Van Wijngaarden and Dosemeci, 2006). Although not all estimates are statistically significant, a pattern of increased associations between Pb exposure and brain cancer mortality was observed in the study population. In a case-control study of brain tumors, glioma was reported to have no association with any Pb exposure metric; however, positive associations were observed between high cumulative Pb exposure and meningioma among individuals with *ALAD2* genotypes (OR 2.4 [95% CI 0.7, 8.8] comparing individuals ever exposed to Pb with those not exposed to Pb; OR 12.8 [95% CI 1.4, 120.8] comparing individuals with cumulative Pb exposure $\geq$ 100 $\mu g/m^3y$ to those not exposed to Pb) (Rajaraman et al., 2006). This association was not present among individuals with the *ALAD1* genotypes (OR 0.5 [95% CI 0.3, 1.0] comparing individuals ever exposed to Pb with those not exposed to Pb; OR 0.7 [95% CI 0.2, 1.8] comparing individuals with cumulative Pb exposure $\geq$ 100 $\mu g/m^3y$ to those not exposed to Pb). Another study of the association between Pb exposure (measured using self-reported occupational exposure history) and brain tumors reported none or slight overall associations with types of brain tumors; however, positive associations were observed among individuals with certain genetic single nucleotide polymorphisms (SNPs) (Bhatti et al., 2009). After control for multiple comparisons, individuals with *GPX1* variants (rs1050450) had positive associations between cumulative Pb exposure and glioblastoma

multiforme and meningioma. Individuals without *RAC2* variants (rs2239774) showed a positive association between Pb and glioblastoma multiforme. Also, individuals without *XDH* variants (rs7574920) displayed a positive association between Pb and meningioma.

Overall, associations between Pb exposure and brain cancer incidence and mortality were found to vary according to several genetic variants. These studies were limited in their methods because they do not have individual level biological measures and the potential for confounding by other workplace exposures exist. Future research will be important in confirming these associations and the modification by various genetic variants.

5.10.1.4 Breast Cancer

A population-based case-control study in Canada examined the proximity to a Pb smelter based on residential addresses (Pan et al., 2011). No association was reported between proximity of a Pb smelter and breast cancer incidence, but the study was limited by the small number of women who resided near a Pb smelter (n=13 lived ≤ 3.2 km from Pb smelter).

A few studies examined Pb levels and breast tumors among individuals with and without breast tumor and/or cancer present. A study of newly diagnosed breast cancer patients and controls examined Pb levels in blood and hair samples and reported higher levels of both for cancer cases, although the difference in the Pb content in hair samples was not statistically significant (Alatise and Schrauzer, 2010). Siddiqui et al. (2006) observed higher blood Pb levels in women with benign and malignant tumors compared to controls. Additionally, although blood Pb levels were higher among those with malignant breast tumors compared to those with benign tumors, both had similar levels of Pb detected in breast tissues. Another study of Pb levels present in breast tissue also reported no statistical difference in Pb levels (Pasha et al., 2008b). However, one study of breast tissue did observe a statistically significant difference between Pb levels in the breast tissue of cancer cases and controls (Ionescu et al., 2007). Finally, a study of Pb levels in urine reported a positive association between urine Pb and breast cancer, but this association became null when women taking nonsteroidal aromatase inhibitors but not taking bisphostphonates (a combination responsible for bone loss) were excluded from the analysis (McElroy et al., 2008).

Overall, these studies demonstrate the possibility that women with breast cancer may have higher Pb levels in blood measurement, whereas the results for actual breast tissue are mixed. However, these studies are limited by their study design. The samples are taken after cancer is already present in the cases, leading to issues of temporality for the

Pb levels. Additionally, the sample sizes are often small and the studies may be underpowered.

5.10.1.5 Other Cancers

Studies of all cancers combined, multiple different cancers, or cancers not listed above have also been performed. An ecologic analysis compared levels of Pb in the air from 1990 to 2005 with incidence rates of cancer (cancer sites not specified) among children during this time period (Absalon and Slesak, 2010). The highest Pb levels were measured in 1990 when over 50% of the study area exceeded the limit of 1 $\mu g/m^2 \cdot$year. No correlation was observed both overall and in sex-specific analyses. A similar study examined correlations between Pb concentrations in soil, water, vegetation, and hair samples with incidence of neoplasms (Obhodas, 2007). The Pb concentrations were not correlated with incidence of neoplasms. A recent study using the 2007-2008 NHANES cohort reported no association between higher creatinine-adjusted urine Pb levels and having ever had cancer or a malignancy (Mendy et al., In Press). The timing of cancer diagnosis in relation to the urine sample collection was not identified.

A study performed among men evaluated multiple cancer outcomes and determined exposures to organic Pb, inorganic Pb, and Pb from gasoline emissions via interviews regarding job histories and then subsequent exposure approximations by chemists and hygienists (Rousseau et al., 2007). Adults exposed to organic Pb exposure had greater odds of stomach cancer compared to adults never exposed to organic Pb. A positive association was also observed for rectal cancer when population-based controls were used but was null when the control population was limited to individuals with other types of cancers. No association was detected for cancers of the esophagus, colon, pancreas, prostate, bladder, kidney, melanoma, or non-Hodgkin's lymphoma. None of the cancers were associated with exposure to inorganic Pb. When occupational exposure to Pb in gasoline was categorized as unexposed, nonsubstantial level, and substantial level, a positive association with stomach cancer was observed when cancer controls were used as the comparison group; however the association was not present when population controls were utilized as the control group). Another case-control study using participant interviews and a job exposure matrix, including only men, reported no association between Pb exposure and esophageal squamous cell carcinomas, but an association was present between high Pb exposure and adenocarcinoma of the esophagus (Santibanez et al., 2008). However, neither of these studies was able to quantify Pb levels using biological measurements.

Several studies compared Pb levels in blood, tissue, and urine of individuals who have cancer with individuals who are cancer-free. Compared to control groups, higher Pb levels were observed in the blood and bladder tissue of individuals with bladder cancer (Golabek et al., 2009), the kidney tissue of individuals with renal cell carcinoma (with highest levels among those with the highest stage tumors) (Calvo et al., 2009), the tissue (but not serum) of individuals with laryngeal cancer (Olszewski et al., 2006), the blood of individuals with gastric cancer (Khorasani et al., 2008), the plasma and hair of individuals with gastrointestinal cancer (Pasha et al., 2010), the blood and hair of individuals with non-specified types of cancer (Pasha et al., 2008c; Pasha et al., 2007), and the hair of individuals with benign tumors (Pasha et al., 2008a). No statistical difference in Pb levels was reported for colon tissue of individuals with colorectal polyps (Alimonti et al., 2008) or urine of individuals with bladder cancer (Lin et al., 2009) compared to control groups. A study examining Pb levels in kidney tissue reported the highest levels of Pb in normal kidney tissue samples that were adjacent to neoplastic tumors. The Pb levels reported in the kidney tissue of neoplastic tumors were elevated compared to those detected in corpses without neoplastic tumors of the kidney (Cerulli et al., 2006). All of these comparison studies are limited by the inability to examine temporality as Pb biomarkers were measured after the cancer diagnosis; the level of Pb may be due to changes that result from having cancer, not changes that result in cancer. Many of these studies attempted to control for this by including only cases who have not undergone certain treatments. Additionally, studies are limited by their small sample size and the selection of the control populations. Control populations are supposed to represent the general population from which the cases are drawn; some of the control subjects in these studies are individuals with diseases/conditions warranting tissue resections, which are not prevalent in the general population.

In sum, epidemiologic studies reported no associations between various measures of Pb exposure and overall cancer incidence. Studies examining specific cancers reported varying associations. Associations were null for Pb and most cancer sites examined; however a positive association was observed between Pb exposure and adenocarcinoma of the esophagus as well as exposure to organic Pb and stomach cancer. Associations between organic Pb exposure and rectal cancer and exposure to Pb in gasoline and stomach cancer were inconsistent. These conclusions are limited by the small number of studies and a lack of biological measurements of Pb.

5.10.1.6 Toxicological Models of Carcinogenicity

Carcinogenicity in Animal Models

Previous AQCDs have established that Pb has been shown to act as a carcinogen in animal toxicology models, albeit at relatively high concentrations. The 2006 Pb AQCD pointed out that because Pb is a "well-established animal carcinogen…., focus has been more on the mechanism of neoplasia and possible immunomodulatory effects of Pb in the promotion of cancer." This focus continues to date. The kidneys are the most common target of Pb-dependent carcinogenicity (Kasprzak et al., 1985; Koller et al., 1985; Azar et al., 1973; Van Esch and Kroes, 1969) but the testes, brain, adrenals, prostate, pituitary, and mammary gland have also been affected (IARC, 2006a). The typical cancer bioassays used by IARC or NTP as evidence of Pb-induced carcinogenicity were designed using rodents, typically males but sometimes animals of both sexes, that were continuously exposed to Pb-acetate in chow (i.e., 0.1 or 1% Pb-acetate) or drinking water (i.e., 26 or 2,600 ppm Pb-acetate) for 18 months to two years in duration (Kasprzak et al., 1985; Koller et al., 1985; Azar et al., 1973; Van Esch and Kroes, 1969). These two year cancer bioassays and the doses employed are typical of cancer bioassays employed by other chemicals. Recognition of the importance of windows of exposure in Pb-induced cancer bioassays is a focus of more recent studies. In one study, early life gestational and lactational exposure of laboratory rodents to inorganic Pb induced carcinogenicity in adult offspring (Waalkes et al., 1995). Another recent study considered Pb-dependent carcinogenesis in laboratory animals with early life Pb exposure. Tokar et al. (2010) considered tumorigenesis in homozygous metallothionein I/II knockout mice and their corresponding wild type controls (groups of ten mice each) that were exposed by drinking water to 2,000 or 4,000 ppm Pb-acetate and compared to untreated controls. Study animals were exposed in utero, through birth and lactation, and then postnatally to drinking water until 8 weeks old. The Pb-exposed metallothionein I/II knockout mice had increased testicular teratomas and renal and urinary bladder preneoplasia. Pb exposed wild-type mice were not statistically significantly different than controls. The data suggest that metallothionein can protect against Pb-induced tumorigenesis. Concerns with the study are that the doses are at levels of Pb to which humans would not likely be exposed and there is no metallothionein null condition in humans, though there is variability in the expression of metallothionein. The data do not address whether this variability would have any impact on Pb-dependent carcinogenesis in humans. Thus, the animal toxicology data demonstrate that Pb is a well-established animal carcinogen in studies employing high dose Pb exposure over a continuous extended duration of exposure (i.e., 2 years), which is typical of cancer bioassays. Newer studies are showing

early life maternal Pb exposure can contribute to carcinogenicity in offspring and have shown that metallothionein is protective against cancer in this pathway.

Neoplastic Transformation Studies, Human Cell Cultures

Carcinogenesis can be measured in cell culture systems through neoplastic transformation models that monitor change by following morphological transformation of cells, i.e., formation of a focus (or foci) of cell growth.. Xie et al. (2007) treated BEP2D cells (human papilloma virus- immortalized human bronchial cells) with 0, 1, 5, or 10 µg/cm2 $PbCrO_4$ for 120 h. $PbCrO_4$ induced foci formation in a concentration-dependent manner. Xie et al. (2008) treated BJhTERT cells (hTERT-immortalized human skin fibroblasts) and ATLD-2 cells (hTERT-immortalized human skin fibroblasts deficient in Mre11) with 0, 0.1, 0.5, and 1 µg/cm^2 $PbCrO_4$ for 120 h. $PbCrO_4$ induced foci formation in a concentration-dependent manner in the Mre11 deficient cells. Mre11 was required to prevent $PbCrO_4$-induced neoplastic transformation.

Immune Modulation of Tumorigenesis by Pb

As described in the 2006 Pb AQCD (U.S. EPA, 2006b), Pb-induced immunotoxicity can contribute to increased risk of cancer, primarily due to the intersection of suppressed Th1 responses and misregulated inflammation. First, Pb-induced misregulation of inflammation involving innate immune cells has been shown to result in chronic insult to tissues. These insults, excessive lipid and DNA oxidation production by overproduction of ROS and weakened anti-oxidant defenses, can increase the likelihood of mutagenesis, cellular instability, and tumor cell formation. For example, Xu et al. (2008) found toxicological evidence that supports the association with Pb exposure and DNA damage and concluded that it is a possible route to increased Pb-induced tumorigenesis. The second component of increased risk of cancer involves Pb-induced suppression of Th1-dependent anti-tumor immunity as acquired immunity shifts statistically significantly toward Th2 responses. With cytotoxic T lymphocytes and other cell-mediated defenses dramatically lessened, the capacity to resist cancer may be compromised.

5.10.2 Cancer Biomarkers

A study of men aged 21-40 years without occupational history of metals exposure examined prostate specific antigen (PSA), a biomarker for prostate cancer. This study reported a positive association between Pb levels and PSA levels (measured in the same blood samples) in regression models adjusted for confounders, including other metals

(Cd, Zn, Se, and Cu) (Pizent et al., 2009). The median blood Pb level was 2.6 µg/dL (range 1.0-10.8 µg/dL). The authors note that the study population was young and at lower risk of prostate cancer than are older men.

5.10.3 DNA and Cellular Damage

Multiple studies have been performed examining the relationship between Pb and DNA and cellular damage. Details of the recent epidemiologic and toxicological studies follow.

5.10.3.1 Epidemiologic Evidence for DNA and Cellular Damage

Multiple studies examined the relationship between Pb and sister chromatid exchange (SCE). SCEs are exchanges of homologous DNA material between chromatids on a chromosome and is a test for mutagenicity or DNA damage. A study of male policemen reported mean blood Pb levels for the study population of 43.5 µg/dL (Wiwanitkit et al., 2008). When dichotomized as having high or low blood Pb levels (cut-off at 49.7 µg/dL), the higher blood Pb group was observed to have higher mean SCE. Another study of adult males compared the SCE of storage battery manufacturing workers (mean blood Pb levels of 40.14 µg/dL) and office workers (mean blood Pb levels of 9.77 µg/dL) (Duydu et al., 2005). The exposed workers had higher SCE levels and also a greater number of cells in which the SCEs per cell were higher than the 95th percentile of the population. Finally, a study of children aged 5-14 years old (mean [SD] blood Pb levels of 7.69 [4.29] µg/dL) reported no correlation between blood Pb levels and SCE (Mielzyńska et al., 2006). However, the study did report a positive association between blood Pb and micronuclei (MN) levels.

Other studies of DNA damage have reported mixed results. A study of children ages 6-11 years old and environmentally-exposed to Pb (children attending a school far from a Pb smelter: median blood Pb levels 4.6 µg/dL; children attending a school near a Pb smelter: median blood Pb levels 28.6 µg/dL for) reported no association between blood Pb and baseline DNA damage or repair ability after a peroxide challenge (Méndez-Gómez et al., 2008). Another study included adult participants aged 50-65 years and reported an association between blood Pb and carcinoembryonic antigen (CEA) but not with DNA-strand breaks, MN frequency, or oxidative DNA damage (median blood Pb level of the study population: 3.92 µg/dL) (De Coster et al., 2008). A study conducted among workers exposed to Pb (mean blood Pb level: 30.3 µg/dL) and unexposed controls (mean blood Pb level: 3.2 µg/dL) reported greater cytogenetic damage (measured by MN frequency), chromosomal aberrations, and DNA damage in the Pb-exposed group

(although this was not statistically significant in linear regression models controlling for age) (Grover et al., 2010). A study of painters in India, where Pb concentrations in paint are high, reported a mean (SD) blood Pb level of 21.56 (6.43) µg/dL among painters who reported painting houses for 8-9 hours/day for 5-10 years (Khan et al., 2010b); the mean (SD) blood Pb level was 2.84 (0.96) µg/dL for healthy workers who had not been occupationally exposed to Pb. Cytogenetic damage was higher among the painters compared to the healthy controls. Another study compared the blood Pb of metal workers and office workers and reported higher blood Pb levels (both current and 2 year average) among the metal workers (blood Pb level ≥ 20 µg/dL) compared to the office workers (blood Pb level < 10 µg/dL for) (Olewińska et al., 2010). Overall, the workers had increased DNA strand breaks versus the office workers (this held true at various blood Pb levels). Finally, a study of Pb battery workers with symptoms of Pb toxicity and a group of controls were examined (Shaik and Jamil, 2009). Higher chromosomal aberrations, MN frequency, and DNA damage were reported for the battery workers as compared to the controls.

5.10.3.2 Toxicological Evidence for DNA and Cellular Damage

Sister Chromatid Exchanges

Tapisso et al. (2009), considered sister chromatid exchanges (SCE) in Algerian mice (groups of six mice each) that were exposed by i.p. injection to 5 or 10 doses of 0.46 mg/kg Pb-acetate. The SCE in bone marrow were elevated after Pb exposure alone, which increased with time. Co-exposure with cadmium or zinc further increased SCE levels.

SCE was also followed in cultured human cells. Ustundag and Duydu (2007), considered the ability of N-acetylcysteine and melatonin to reduce Pb nitrate-induced SCE in a single human donor. Cells were treated with 0, 1, 5, 10, or 50 µM Pb nitrate. SCE statistically significantly increased at every Pb concentration in a concentration dependent manner. Both 1 and 2 mM N-acetylcysteine and melatonin were able to statistically significantly reduce SCE levels in Pb-exposed animals. In another study, Turkez et al. (In Press) considered the ability of boron compounds to prevent Pb chloride-induced SCE in human lymphocytes. Cells were obtained from 4 non-smoking donors. Both 3 and 5 ppm Pb chloride induced a statistically significant increase in SCE levels over controls. Boron was able to statistically significantly diminish these levels. For both studies, exposure times were not provided and the full interpretation of these data is limited by the limited number of donors and the absence of an exposure time for the SCE assay.

Micronuclei Formation

The 2006 Pb AQCD stated "studies of genotoxicity consistently find associations of Pb exposure with DNA damage and MN formation" and the current document continues to report these associations. Alghazal et al. (2008b), considered the ability of Pb-acetate trihydrate to induce MN in bone marrow of Wistar rats. Animals were given a daily dose of 100 mg/l in their drinking water for 125 days. The mean number of MN in male and female rats was statistically significantly higher in Pb-exposed animals than in unexposed controls. Tapisso et al., (2009), considered Pb alone, Pb plus zinc and Pb plus cadmium-induced MN in rodents. Algerian mice were exposed by i.p. injection to 5 or 10 doses of 0.46 mg/kg Pb-acetate and compared to untreated controls. The MN in bone marrow were elevated after Pb exposure and increased with time. Co-exposure with cadmium or zinc did not further increase MN levels.

MN formation has also been followed in cultured human cells. Ustundag and Duydu (2007) considered the ability of N-acetylcysteine and melatonin to reduce Pb nitrate-induced MN in a single human donor. Cells were treated with 0, 1, 5, 10, or 50 µM Pb nitrate. MN formation statistically significantly increased at the two highest Pb concentrations in a concentration dependent manner. Both 1 and 2 mM N-acetylcysteine and melatonin were not able to statistically significantly reduce MN levels. In another study, Turkez et al. (In Press) considered the ability of boron compounds to prevent Pb chloride-induced MN in human lymphocytes. Cells were obtained from 4 non-smoking donors. Both 3 and 5 ppm Pb chloride induced a statistically significant increase in MN levels over controls. Boron induced a statistically significant attenuation of these Pb-induced levels. For both studies, exposure times were not provided, and the full interpretation of these data is limited by the limited number of donors and the absence of an exposure time for the MN assay. Gastaldo et al. (2007) evaluated the ability of Pb to induce MN. Human endothelial HMEC cell line was treated with 1–1,000 µM Pb nitrate for 24 hours. MN increased in a statistically significant, concentration-dependent manner.

Hypoxanthine-guanine phosphoribosyltransferase Mutations

The potential mutagenicity of Pb in human or animal cells was evaluated by monitoring mutations at the hypoxanthine-guanine phosphoribosytransferase (HPRT) locus. Li et al. (2008a) evaluated Pb-acetate-induced HPRT in the non-small-cell lung carcinoma tumor cell line, CL3 and in normal human diploid fibroblasts (specific tissue source not reported). All cells were exposed to 0, 100, 300 or 500 µM Pb-acetate for 24 hours in serum-free medium ± a 1-hour pretreatment with a MKK1/2 inhibitor or a PKC-alpha inhibitor. Pb alone did not induce HPRT mutations. Inhibiting the ERK pathway via either inhibitor statistically significantly increased Pb-induced mutagenesis. Wang et al.

(2008c), investigated Pb-acetate -induced HPRT mutations in CL3 cells. All cells were exposed to 0, 100, 300 or 500 µM Pb-acetate for 24 hours in serum-free medium ± a 1-hour pretreatment with a PKC-alpha inhibitor or siRNA for PKC-alpha. Pb alone did not induce HPRT mutations. Inhibiting PKC-alpha via either inhibitor statistically significantly increased Pb-induced mutagenesis. McNeill et al. (2007) considered Pb-acetate induced HPRT mutations in Chinese hamster ovary AA8 cells and AA8 cells overexpressing human Ape1. Cells were treated with 5 µM Pb-acetate for 6 hours. No increases in HPRT mutations were observed after Pb exposure in either cell line but with specific pathway perturbations (PKC-alpha or ERK) Pb was able to induce HPRT mutations.

Chromosomal Aberrations

Chromosomal aberrations, an indicator of cancer risk, were followed in Pb-exposed rodents (El-Ashmawy et al., 2006). Dietary exposure to Pb-acetate administered as a single dose of 0.5% w/w to male Swiss albino mice caused statistically significant increased levels of chromosomal aberrations in the Pb treatment alone group, particularly with respect to fragments, deletions, ring chromosomes, gaps, and end-to-end associations. In addition, the authors found turmeric and myrrh powders were protective. Concerns with the study include the use of only a single dose of Pb-acetate along with the high levels of unusual aberrations such as ring chromosomes and end-to-end associations. Typically, these aberrations are rare after metal exposure, but were the most commonly observed aberration in this study raising questions about the quality of the metaphase preparations. An additional concern was that only 50 metaphases per dose were analyzed instead of the more common 100 metaphases per dose. The authors did not explain why their spectrum of aberrations was so different, why they only used one dose, or analyzed fewer metaphases per dose.

Multiple studies considered the ability of Pb to induce chromosomal aberrations in cultured human cells. The ability of Pb nitrate to induce chromosomal aberrations was examined in primary human peripheral blood lymphocytes obtained from healthy, nonsmoking donors (Pasha Shaik et al., 2006). Cells were treated with 0, 1.2 or 2 mM Pb-nitrate for 2 hours. No increase in chromosomal aberrations was reported. Some aneuploidy was observed. Concerns with the study are that only a 2 hour exposure was used, which may not be long enough for DNA damage to be expressed as a chromosomal aberration. It also appears from the data presentation that only three subjects were used; one for a control, one for the low dose and one for the high dose. Experiments were not repeated, thus given the small number of subjects, this study may not have had sufficient power to detect any effects. Holmes et al. (2006a), treated WHTBF-6 cells (hTERT-immortalized human lung cells) with 0, 0.1, 0.5, or 1 µg/cm^2 Pb chromate for 24-120

hours or with 0, 0.1, 0.5, 1, 5 or 10 µg/cm^2 Pb oxide for 24 or 120 hours. Pb chromate induced statistically significant, concentration-dependent increases in centrosome abnormalities and aneuploidy. Wise et al. (2006b) treated BEP2D cells with 0, 0.5, 1, 5, or 10 µg/cm^2 Pb chromate for 24 hours. Pb chromate induced statistically significant concentration-dependent increases in chromosomal aberrations. Holmes et al. (2006b), treated WHTBF-6 cells with 0, 0.1, 0.5, or 1 µg/cm^2 Pb chromate for 24-72 hours. Pb chromate induced statistically significant, concentration-dependent increases in chromosomal aberrations. The effects of the chromate anion cannot be ruled out as causative in inducing these chromosomal aberrations. Wise et al. (2006a), treated WHTBF-6 cells with 0, 0.1, 0.5, or 1 µg/cm^2 Pb chromate for 24-120 hours. Pb chromate induced statistically significant, concentration-dependent increases in spindle assembly checkpoint disruption, effects of mitosis and aneuploidy. By contrast, chromate-free Pb oxide did not induce centrosome amplification. The effects were likely attributable to the chromate anion. Xie et al. (2007) treated BEP2D cells with 0, 1, 5, or 10 µg/cm^2 Pb chromate for 24 hours. Pb chromate induced statistically significant, concentration-dependent increases in chromosomal aberrations and aneuploidy. Wise et al. (2010) treated WHTBF-6 cells with 0, 0.1, 0.5, or 1 µg/cm^2 Pb chromate for 24 hours in a study comparing 4 chromate compounds. Pb chromate induced statistically significant, concentration-dependent increases in chromosomal aberrations

Multiple investigators considered the ability of Pb chromate to induce chromosome aberrations in rodent cell cultures. Grlickova Duzevik et al. (2006) treated Chinese hamster ovary (CHO) cells with 0, 0.1, 0.5, or 1 µg/cm^2 Pb chromate for 24 h. Specific CHO lines used included AA8 (wildtype) EM9 (XRCC1-deficient), and H9T3 (EM9 complemented with human XRCC1 gene). Pb chromate induced statistically significant, concentration-dependent increases in chromosomal aberrations that were statistically significantly increased by XRCC1 deficiency. Nestmann and Zhang (2007) treated Chinese hamster ovary cells (clone WB(L)) with 0, 0.1, 0.5, 1, 5, or 10 µg/cm^2 Pb chromate (as pigment yellow) for 18 h. No increases in chromosomal aberrations were observed. Savery et al. (2007) treated CHO cells with 0, 0.1, 0.5, 1, or 5 µg/cm^2 Pb chromate for 24 h. Specific CHO lines used included AA8 (wildtype), KO40 (*Fancg*-deficient), and 40BP6 (*Fancg*-complemented). Pb chromate induced statistically significant, concentration-dependent increases in chromosomal aberrations that were increased by *Fancg*-deficiency. The *Fancg* gene plays an important role in cellular resistance to DNA interstrand crosslinks, protecting against genetic instability. Camrye et al., (2007) treated CHO cells with 0, 0.1, 0.5, 1, 5, or 10 µg/cm^2 Pb chromate for 24 hours. Specific CHO lines used included CHO-K1 (parental), xrs-6 (Ku80 deficient), and 2E (xrs-6 complemented with Ku80 gene). Pb chromate induced statistically significant, concentration-dependent increases in chromosomal aberrations that were not affected by Ku80 deficiency. Ku80 is a gene a gene involved in nonhomologous end-joining repair

and its absence can contribute to genetic instability. Stackpole et al. (2007) treated CHO and Chinese hamster lung (CHL) cells with 0, 0.1, 0.5, or 1 µg/cm^2 Pb chromate for 24 hours. Specific CHO lines used included AA8 (wildtype), irs1SF (XRCC3-deficient), and 1SFwt8 (XRCC3 complemented). XRCC3 is DNA repair enzyme involved in homologous recombination. CHL lines used included V79 (wildtype), irs3 (Rad51C deficient) and irs3#6 (Rad51C complemented). Rad51C is a gene which encodes strand-transfer proteins that are thought to be involved in recombinational repair of damaged DNA and in meiotic recombination. Pb chromate induced statistically significant, concentration-dependent increases in chromosomal aberrations that were statistically significantly increased by both XRCC3 and Rad51C deficiency.

Multiple studies considered the ability of Pb chromate to induce chromosome aberrations in marine mammal cell cultures. Li Chen et al. (2009) treated primary North Atlantic right whale lung and skin fibroblasts with 0, 0.5, 1.0, 2.0, and 4.0 µg/cm^2 Pb chromate for 24 hours. Wise et al. (2009) treated primary Steller sea lion lung fibroblasts with 0, 0.1, 0.5, 1 and 5 µg/cm^2 Pb chromate for 24 hours. Wise et al. (2011) treated primary sperm whale skin fibroblasts with 0, 0.5, 1, 3, 5, and 10 µg/cm^2 Pb chromate for 24 hours. In all three studies, Pb chromate induced statistically significant, concentration-dependent increases in chromosomal aberrations.

In summary, exposure of various cell models and an in vivo model to Pb (acetate, chromate, or nitrate) induced significant increases in chromosomal aberration that often responded in a concentration dependent manner. The use of various cell lines deficient in specific DNA repair enzymes helped to elucidate which pathways may be most sensitive to Pb-dependent chromosomal aberration.

COMET Assay

Multiple studies considered the ability of Pb to induce DNA single strand breaks in laboratory animals using the comet assays. The COMET assay measures DNA damage assessed by single cell electrophoresis of a lysed cell and measurement of the fragmented DNA or tail length. Xu et al. (2008) considered the ability of Pb-acetate to induce DNA damage measured by the comet assay in lymphocytes of male ICR mice. Animals (5 per group) were given Pb-acetate by gavage at doses of 0, 10, 50, or 100 mg/kg body weight every other day for 4 weeks. Pb exposure statistically significantly increased both tail length and tail moment in a dose-dependent manner. Nava-Hernandez et al. (2009) considered the ability of Pb-acetate to induce DNA damage in primary spermatocyte DNA of male Wistar rats. Animals (3 per group) were treated for 13 weeks with 0, 250 or 500 mg/L Pb in their drinking water. There was statistically significantly less DNA damage in the controls compared to the two treatment groups. Narayana and Al-Bader

(2011) considered the ability of Pb nitrate to induce DNA damage in liver tissue of adult male Wistar rats. Animals (8 per group) were treated for 60 days with doses of 0, 0.5 or 1% $Pb(NO_3)2$ in their drinking water. There were no statistical differences between treated groups and controls. Drosophila melanogaster larvae (72 hours old) exposed to Pb nitrate (2,000, 4,000, and 8,000 µM in culture media for 24 hours) yielded haemocytes that tested positive in the comet assay; Pb chloride (8,000 µM) did not cause DNA damage with the comet assay (Carmona et al.).

Other studies used the COMET assay in cultured human cells. Pasha Shaik et al. (2006) treated primary human peripheral blood lymphocytes obtained from healthy, nonsmoking donors with 0, 2.1, 2.4, 2.7, 3.0, 3.3 Pb nitrate for 2 hours and found dose-dependent increases in Comet tail length. Concerns with the study are that apparently no untreated control was used. It also appears from the data presentation that only five subjects were used; one for each dose. Experiments were not repeated. Thus, given the small number of subjects and the absence of a negative control, this study may only be detecting background levels. Xie et al. (2008) treated BJhTERT cells (hTERT-immortalized human skin fibroblasts) and ATLD-2 cells (hTERT-immortalized human skin fibroblasts deficient in Mre11) with 0, 0.1, 0.5, and 1 $\mu g/cm^2$ Pb chromate for 24 hours. Mre11 is a component of the MRN complex and plays a role in telomere maintenance and double-strand break repair. Pb chromate induced a concentration-dependent increase in DNA double strand breaks measured by the comet assay. In another study, Pb nitrate exposure (30 µg/mL) induced statistically significant increased DNA damage in human liver HepG2 cells that was statistically significantly attenuated with co-exposure with the antioxidant NAC (500 µM) (Yedjou et al., 2010).

Other studies used the comet assay to examine Pb-induced DNA single strand breaks in rodent cell cultures. Xu et al. (2006), treated PC12 cells with 0, 0.1, 1 or 10 µM Pb-acetate. Both tail length and tail moment statistically significantly increased in a concentration-dependent manner. Kermani et al. (2008) exposed mouse bone marrow-mesenchymal stem cells to 60 µM Pb-acetate for 48 hours. There was an increase in several comet assay measurements including tail length.

Other Assays

Other studies considered the ability of Pb to induce DNA double strand breaks by measuring gamma-H2A.X foci formation in cultured human cells. Xie et al. (2008) treated BJhTERT cells (hTERT-immortalized human skin fibroblasts) and ATLD-2 cells (hTERT-immortalized human skin fibroblasts deficient in Mre11) with 0, 0.1, 0.5, and 1 $\mu g/cm^2$ Pb chromate for 24 hours. Pb chromate induced a concentration-dependent increase in DNA double strand breaks measured by gamma-H2A.X foci formation.

Gastaldo et al. (2007) evaluated the ability of Pb to induce DNA double strand breaks with both gamma-H2A.X foci formation and pulse-field gel electrophoresis in cultured human cells. The human endothelial HMEC cell line was treated with 1 to 1,000 µM Pb nitrate for 24 hours. DNA double strand breaks increased in a concentration-dependent manner. Wise et al. (2010) treated WHTBF-6 cells with 0, 0.1, 0.5, or 1 µg/cm^2 Pb chromate for 24 hours in a study comparing four chromate compounds. Pb chromate induced statistically significant, concentration-dependent increases in DNA double strand breaks measured by gamma-H2A.X foci formation, at a similar level to the other three compounds. Two studies demonstrated the ability of Pb to destabilize DNA by forming DNA-histone cross links, which can lead to histone aggregation. Extracts of rat liver co-incubated with Pb nitrate (<300 µM) were shown to react with chromatin components and induce chromatin aggregation via histone-DNA cross links (Rabbani-Chadegani et al., 2011; Rabbani-Chadegani et al., 2009).

Genotoxicity testing of Drosophila melanogaster larvae (72 hours old) using the Wing Spot test showed that neither Pb chloride nor Pb nitrate (at concentrations of 2,000, 4,000 and 8,000 µM in culture media with exposure until pupation) was able to induce significant increases in the frequency of wing spots (Carmona et al.). Further, wing spot assays employing Pb co-exposure with gamma radiation showed no effect of Pb on gamma radiation induced spotting frequency. The wing spot test can detect mitotic recombination and multiple mutational events such as point mutations, deletions, and certain types of chromosome aberrations (Graf and Würgler, 1986).

Multiple studies considered Pb and DNA repair. Most were conducted in cultured cells, and one was done in an animal model. El-Ghor et al. (In Press) followed microsatellite instability (MSI) in Pb-acetate trihydrate exposed adult male rats; MSI reflects impaired DNA mismatch repair, and contributes to an increased risk of cancer. DNA from leukocytes of male albino rats exposed to Pb-acetate (acute: single oral dose of 467 mg/kg BW or sub-chronic: 47 mg/kg BW six d/wk for 4 wk) showed increased MSI at three microsatellite loci (D6mit3, D9mit2, and D15Mgh1). This study is limited by its small sample size (n=2 to 3 rodents per treatment group). Li et al., (2008a), evaluated Pb-acetate-induced effects on nucleotide excision repair efficiency in CL3 cells. All cells were exposed to 0, 100, 300 or 500 µM Pb-acetate for 24 hours in serum-free medium. Pb increased nucleotide excision repair efficiency. Gastaldo et al. (2007) evaluated the ability of Pb to affect DNA repair in cultured human cells. The human endothelial HMEC cell line was treated with 100 µM Pb nitrate for 24 hours. Pb inhibited non-homologous end joining (NHEJ) repair, over activated MRE11-dependent repair and increased Rad51-related repair. Xie et al. (2008) treated BJhTERT cells (hTERT-immortalized human skin fibroblasts) and ATLD-2 cells (hTERT-immortalized human skin fibroblasts deficient in Mre11) with 0, 0.1, 0.5, and 1 µg/cm^2 Pb chromate for 24 or 120 hours. Mre11 was

required to prevent Pb chromate-induced DNA double strand breaks. McNeill et al, (2007) considered Pb-acetate effects on Ape1. Chinese hamster ovary cells (AA8) were treated with 0, 0.5, 5, 50, or 500 µM Pb-acetate and then whole cell extracts were used to determine AP site incision activity. The data show that Pb reduced AP endonuclease function. Finally, studies considered Pb-induced cellular proliferation in laboratory animals. An earlier study in rats showed Pb nitrate-induced increased proliferation of liver cells after a partial hepatectomy, effects that were more prominent in males than females (sexual dimorphism) (Tessitore et al., 1995). The newer studies showed similar trends in males. Fortoul et al. (2005) exposed adult male CD1 mice (24 animals per group) to 0.01 M Pb-acetate, 0.006 M cadmium chloride or a mixture of the two chemicals for 1 h twice a week for 4 weeks by inhalation. The lungs were then examined by electron microscopy for changes. Pb induced cellular proliferation in the lungs. Kermani et al. (2008) exposed mouse bone marrow-mesenchymal stem cells to 0-100 µM Pb-acetate for 48 hours. As measured by the MTT assay, Pb decreased cell proliferation at all concentrations tested.

5.10.4 Effects of Lead within Mixtures

Several studies considered the impact of mixtures with Pb. All considered genotoxicity. Mendez-Gomez et al., (2008), evaluated 65 children from Mexico exposed to both arsenic and Pb. DNA damage and decreased DNA repair were seen using the comet assay and other assays, but did not correlate with urinary arsenic or blood Pb levels. Tapisso et al., (2009), considered Pb alone, Pb plus zinc and Pb plus cadmium-induced MN in rodents. Algerian mice (groups of six mice each) were exposed (i.p.) to 5 or 10 doses of 0.46 mg/kg Pb-acetate and compared to untreated controls. The MN in bone marrow were elevated after Pb treatment alone and increased with time. Co-exposure with cadmium or zinc did not further increase MN levels but did increase SCE levels. Glahn et al., (2008) performed a gene array study in primary normal human bronchial epithelial cells from four donors treated with 550 µg/L Pb chloride, 15 µg/L cadmium sulfate, 25 µg/L cobalt chloride or all three combined for 72 hours. There was a clear interaction of all three metals impacting RNA expression.

No recent studies of the protective role of calcium in Pb-dependent carcinogenesis or genotoxicity were found. There were some data suggesting that boron, melatonin, N-acetylcysteine, turmeric and myrrh protect cells against Pb-induced genotoxicity (Sections 5.10.3.2 and 5.10.6).

A new study details Pb and selenium interactions in virus-dependent carcinogenesis in laboratory animals. Schrauzer (2008) considered the impact of selenium on

carcinogenesis by studying 4 groups of weanling virgin female C3H/St mice infected with murine mammary tumor virus (groups of 20-30 mice), which induces mammary tumor formation. One set of two groups were fed a diet containing 0.15 ppm selenium and then were exposed via drinking water to acetic acid (control group) or 0.5 ppm Pb-acetate (treated group). The second set of two groups were fed a diet containing 0.65 ppm selenium and then similarly exposed to acetic acid or 0.5 ppm Pb-acetate. The study was primarily focused on the general effects of a low selenium diet. The data suggest that selenium is anticarcinogenic as in the groups without Pb exposure, the animals exposed to the higher selenium levels had fewer mammary tumors and these tumors had a delayed onset of appearance. Pb exposure with low selenium caused the same delayed onset as did the higher dose of selenium and also caused some reduction in the tumor frequency. Pb exposure with higher selenium increased the tumor frequency and the onset of the tumors. Pb also induced weight loss at 14 months in both exposed groups. The data suggest that there may be interactions of Pb and selenium, but they suggest that Pb mimics or antagonizes selenium. They do not suggest that selenium is protective of Pb-induced toxicity or carcinogenesis.

5.10.5 Modes of Action

The carcinogenic mechanism of action of Pb is poorly understood. It is unclear whether the mechanism of action of Pb is best understood within the framework of multistage carcinogenesis, genomic instability or epigenetic modification. For example, multistage carcinogenesis involves a series of cellular and molecular changes that result from the progressive accumulation of mutations that induce alterations in cancer-related genes. Pb does not appear to follow this paradigm and the literature suggests it is weakly mutagenic. Pb does appear to have some ability to induce chromosomal mutation and DNA damage, i.e., clastogenicity. However, the ability of Pb to alter gene expression (epigenetic effects) and to interact with proteins may be a means by which Pb induces its carcinogenicity. It is known that Pb can replace zinc in zinc-binding (zinc-finger) proteins, which include hormone receptors, cell-cycle regulatory proteins, the Ah receptor, estrogen receptor, p53, DNA repair proteins, protamines, and histones. These zinc-finger proteins all bind to specific recognition elements in DNA. Thus, Pb may act at a post-translational stage to alter protein structure of Zn-finger proteins, which can in turn alter gene expression, DNA repair and other cellular functions. To recapitulate, cancer develops from one or a combination of multiple mechanisms including modification of DNA via epigenetics or enzyme dysfunction and genetic instability or mutation(s). These modifications then provide the cancer cells with a selective growth advantage. In this schematic, Pb appears to contribute to epigenetic changes, and chromosomal aberrations.

The genomic instability paradigm requires a cascade of genome-wide changes caused by interfering with DNA repair, kinetochore assembly, cellular checkpoints, centrosome duplication, microtubule dynamics or a number of cell maintenance processes. These processes have been rarely studied for Pb, thus there are few data that suggest Pb may interfere with some of these processes. Furthermore, the bulk of the literature in this area involves Pb chromate and it is unclear if the effects are due to Pb or chromate. Epigenetic modifications can lead to cancer by altering cellular functions without altering the genetic material. The most commonly studied epigenetic change is methylation alterations. A small number of studies show that Pb can induce epigenetic changes, but studies are still missing to clearly tie these effects to Pb-induced carcinogenesis and genotoxicity. Thus, the mechanism is difficult to define but, if Pb is a human carcinogen, the mechanism likely involves either genomic instability or epigenetic modification paradigms or some combination of the two. However, Pb-dependent carcinogenicity is it not likely to occur by a multistage paradigm. More work is needed to determine the mechanism.

Exposure to mixtures can also contribute to understanding of modes of action. No recent studies of the protective role of calcium or zinc in Pb-dependent carcinogenesis or genotoxicity were found. There were some data suggesting that metallothionein protects rodents from Pb-induced cancers. There were some data suggesting that boron, melatonin, N-acetylcysteine, turmeric and myrrh protected cells against Pb-induced genotoxicity. There were some data suggesting that Pb mimics or antagonizes selenium in rodents. These data are discussed in more detail elsewhere in the cancer section and point to the relevance of mixtures in assessing toxicity.

5.10.5.1 Epigenetics

Air pollution exposure is being linked increasingly with epigenetic changes (Pavanello et al., 2010; Baccarelli and Bollati, 2009; Tarantini et al., 2009; Bollati et al., 2007). Epigenetic changes involve changes in DNA expression without actual changes in the DNA sequence and these changes may be heritable. Epigenetic changes are mediated by histone modification, DNA methylation, miRNA changes, or pathways that affect these three mediators. Differential epigenetic modification has the possibility to contribute to disease. Epigenetic studies have been conducted to examine the associations between Pb biomarker levels and global DNA methylation markers [Alu and long interspersed nuclear element-1 (LINE-1)] in humans (Wright et al., 2010; Pilsner et al., 2009). Wright et al. (2010) utilized a sample of participants from the NAS with mean (SD) Pb levels of 20.5(14.8)g/g for tibia measures, 27.4 (19.7)g/g for patella measures, and 4.1 (2.4) µg/dL for blood measures. In both crude and adjusted analyses, patella Pb levels were inversely associated with LINE-1 methylation but not with Alu, both of which are indicators of

global methylation. When examining the relationship between patella Pb and LINE-1 more closely, a non-linear trend was observed with a smaller magnitude of effect estimated for higher patella Pb (≥ 40 µg/g). No associations were observed for tibia or blood Pb and either LINE-1 or Alu. Another study included maternal-infant pairs from the Early Life Exposures in Mexico to Environmental Toxicants study and measured LINE-1 and Alu methylation in umbilical cord blood samples (Pilsner et al., 2009). In unadjusted models, maternal pregnancy tibia Pb levels [mean (SD) 10.5 (8.4) µg/g] were inversely associated with Alu methylation; maternal patella Pb levels [mean (SD) 12.9 (14.3) µg/g] were inversely associated with LINE-1 methylation. The associations persisted in adjusted models although the association between patella Pb and LINE-1 was only apparent when the adjusted models also included umbilical cord blood Pb levels. No association was detected between umbilical cord Pb levels and the DNA methylation markers. Overall, the studies consistently demonstrate an association between patella Pb levels and LINE-1 methylation.

Toxicological studies have been performed examining Pb-dependent epigenetic changes and gene expression, DNA repair, and mitogenesis. Glahn et al., (2008) performed a gene array study in primary normal human bronchial epithelial cells from four donors after in vitro treatment of the cells with 550 µg/L Pb chloride, 15 µg/L cadmium sulfate, 25 µg/L cobalt chloride or all three combined for 72 hours. The authors describe a pattern of RNA expression changes indicating " ...coordinated stress-response and cell-survival signaling, deregulation of cell proliferation, increased steroid metabolism, and increased expression of xenobiotic metabolizing enzymes." These are all known targets of possible epigenetic changes, but full interpretations of the data as epigenetic changes are complicated by the absence of a measure to determine if these changes were a result of genotoxic effects. A recent publication using HepG2 cells in tissue culture showed that cells exposed to a high dose of Pb (100 µM Pb-acetate) experienced ALAD gene promoter hypermethylation and decreased ALAD transcription. This was in agreement with findings in battery plant workers who showed ALAD hypermethylation (versus non-occupationally exposed controls) and an association of this hypermethylation with elevated risk of Pb poisoning (Li et al., 2011).

5.10.6 Summary and Causal Determination

In summary, the toxicological literature on the genotoxic, mutagenic, and carcinogenic potential of Pb provide strong evidence of effects in laboratory animals. In laboratory studies, high-dose Pb has been demonstrated to be an animal carcinogen. There are data

to suggest Pb is a human carcinogen among toxicological studies, but they are not definitive. Multiple toxicological studies showed neoplastic transformation in cultured cells, but all focused on Pb chromate and the positive response to the chromate ion and not the Pb likely contributed to these findings. Multiple epidemiologic studies have been performed examining the association between cancer incidence and mortality and Pb exposures, estimated with biological measures and exposure databases. Mixed results have been reported for cancer mortality studies; a large NHANES epidemiologic study demonstrated a positive association between blood Pb and cancer mortality, but the other studies reported null results. Although the 2006 Pb AQCD reported some studies that found an association between Pb exposure indicators and lung cancer, current studies mostly included occupationally-exposed adults and observed no associations. Most studies of Pb and brain cancer were null among the overall study population, but positive associations were observed among individuals with certain genetic variants. However the studies of Pb and brain cancer were all performed among occupational cohorts using interviews instead of biological measurements to represent Pb exposure. A limited amount of research has been performed on other types of cancer. The 2006 Pb AQCD reported evidence that suggested an association between Pb exposure and stomach cancer, but recent studies of stomach cancer are lacking. One study examining Pb and stomach cancer has been performed since the last AQCD and the results of the study are mixed

Among epidemiologic studies, high Pb levels were associated with SCEs among adults but not children. Other epidemiologic studies of DNA damage reported inconsistent results. Consistent with previous toxicological findings, Pb does appear to have genotoxic activity in animal and in vitro models, inducing SCE, MN and DNA strand breaks, but continues to not produce chromosomal aberrations except for Pb chromate; this again is likely due to the chromate. Pb does not appear to be very mutagenic as the HPRT assays were typically negative unless a cell signaling pathway was disturbed.

Mechanistic understanding of the carcinogenicity of Pb is expanding with work on the antioxidant selenium and metallothionein, a protein that binds Pb and reduces its bioavailability. Metallothionein has been shown to be protective against the effect of Pb on carcinogenicity. Pb is clastogenic and mutagenic in some but not all models. Clastogenicity and mutagenicity may be possible mechanisms contributing to cancer but are not absolutely associated with the induction of cancer. Because Pb has a higher atomic weight than does zinc, Pb replaces zinc at many zinc binding sites or zinc finger proteins. This substitution has the potential to induce indirect effects that can contribute to carcinogenicity via interactions at hormone receptors, at cell-cycle regulatory proteins, with tumor suppressor genes like p53, with DNA repair enzymes, with histones, etc.

These indirect effects may act at a post-translational level to negatively alter protein structure and DNA repair.

Epigenetic changes associated with Pb exposure, particularly with respect to methylation and effects on DNA repair, are beginning to appear in the literature. These modifications may further alter DNA repair or change the expression of a tumor suppressor gene or oncogene. A small number of epidemiologic studies examining Pb and global epigenetic changes including LINE-1 and Alu demonstrated an inverse association between patella Pb and LINE-1 methylation, an emerging area of research. Toxicological studies show that Pb can activate or interfere with a number of signaling and repair pathways, though it is unclear whether these are due to epigenetic responses or genotoxicity. Thus, an underlying mechanism is still uncertain, but likely involves either genomic instability, epigenetic modifications, or both.

In conclusion, the toxicological literature provides the strongest evidence for Pb exposure and cancer with supporting evidence provided by the epidemiologic literature. This is substantiated by the findings of other agencies including IARC, which has classified inorganic Pb compounds as a probable human carcinogen and the National Toxicology Program, which has listed Pb and Pb compounds as "reasonably anticipated to be human carcinogens." Strong evidence from toxicological studies demonstrates an association between Pb and cancer, genotoxicity/clastogenicity or epigenetic modification. Carcinogenicity in historical animal toxicology studies with Pb exposure has been reported in the kidneys, testes, brain, adrenals, prostate, pituitary, and mammary gland, albeit at high doses of Pb. Epidemiologic studies of cancer incidence and mortality reported inconsistent results; one strong epidemiologic study demonstrated an association between blood Pb and increased cancer mortality, but the other studies reported weak or no associations. In the 2006 Pb AQCD, Pb exposure was found to be associated with stomach cancer, but there was only one recent study on stomach cancer and Pb exposure, which reported mixed findings. Similarly, some studies in the 2006 Pb AQCD reported associations between Pb exposure and lung cancer. More recent epidemiologic studies of lung cancer focused on occupational exposures and reported no associations. The majority of epidemiologic studies of brain cancer had null results overall, but positive associations between Pb exposure and brain cancer were observed among individuals with certain genotypes. In toxicological studies, chromosomal aberrations after Pb exposure are most often reported with Pb chromate exposure, which is likely due to toxicity of the chromate moiety. Mechanistic understanding of Pb and its effect on cancer and genotoxicity is expanding through toxicological work focusing on antioxidants and other proteins that sequester Pb or reduce its bioavailability. The collective body of evidence integrated across toxicological and epidemiologic studies is sufficient to conclude that there is a likely causal relationship between Pb exposure and cancer.

CHAPTER 6 POTENTIALLY AT-RISK POPULATIONS

The NAAQS are intended to provide an adequate margin of safety for both the population as a whole and those groups with unique factors that make them potentially at increased risk for health effects in response to ambient air pollutants (Preface to this ISA). Interindividual variation in human responses to air pollution exposure suggests that some populations are at increased risk for detrimental effects of ambient exposure to an air pollutant. To facilitate the identification of populations at greater risk for Pb-related health effects, studies have evaluated various factors that may contribute to susceptibility and/or vulnerability to Pb. The definitions of susceptibility and vulnerability vary across studies, but in most instances "susceptibility" refers to biological or intrinsic factors (e.g., age, sex) while "vulnerability" refers to nonbiological or extrinsic factors (e.g., socioeconomic status [SES]) (U.S. EPA, 2010a, 2009). Additionally, in some cases, the terms "at-risk" and "sensitive" populations have been used to encompass these concepts more generally. In this ISA, "at-risk" groups are defined as those with characteristics that increase the risk of Pb-related health effects in a population. These characteristics include various factors, such as genetic background, race and ethnicity, sex, age, diet, pre-existing disease, SES, and characteristics that may modify exposure or the response to Pb.

To examine whether Pb differentially affects certain populations, epidemiologic studies conduct stratified analyses to identify the presence or absence of effect measure modification. A thorough evaluation of potential effect measure modifiers may help identify populations that are at greater risk for Pb-related health effects. Toxicological studies, using animal disease models, also provide support and biological plausibility for factors that may lead to increased risk for Pb-related health effects. These epidemiologic and toxicological studies provide the scientific basis for an overall weight of the evidence evaluation for the increased risk of specific populations to Pb-related health effects.

The first section of this chapter summarizes physiological factors that possibly influence Pb levels in the body. The second section of this chapter summarizes information on factors potentially related to differential Pb exposure. The studies presented in this section supplement the material provided in Chapters 3 and 4 by examining how factors such as age, sex, race and ethnicity, SES, proximity to Pb sources, and residential factors may affect Pb exposure. The third section of this chapter discusses the epidemiologic and toxicological studies evaluated in Chapter 5 that provide information on potential factors related to increased risk of Pb-induced health effects. Highlighted studies include only those where the population was stratified into subgroups (e.g., males versus females or

smokers versus nonsmokers) for comparative analysis. In the case of many biomarker studies and the epidemiologic studies considered, this approach allowed for a comparison between populations exposed to similar Pb concentrations and within the same study design. Numerous studies that focused on only one potentially at-risk population were described in previous chapters (Chapter 5) but are not discussed in detail in this chapter because they lacked stratified analysis with adequate comparison groups. For example, pregnancy is a lifestage with potentially increased risk for mothers and fetuses, but because there are no comparison groups for stratified analyses, these studies were presented in Chapter 5 but are not included here. Included toxicological studies may have categorized the study populations by age, sex, diet/nutrition status, genetics, etc. or are those that examined animal models of disease.

Additionally, it is understood that some of the stratified variables/factors discussed in this third section may not be effect measure modifiers but instead may be mediators of Pb-related health effects. Mediators are factors that fall on the causal pathway between Pb and health outcomes, whereas effect measure modifiers are factors that result in changes in the measured associations between Pb and health effects. Because mediators are caused by Pb exposure and are also intermediates in the disease pathway that is studied, mediators are not correctly termed “at-risk” factors. Some of the factors discussed in this third section could be mediators and/or modifiers. These are noted in Table 6-4.

6.1 Physiological Factors that Influence the Internal Distribution of Lead

Blood and bone Pb measures are influenced to varying degrees by biokinetic processes (absorption, distribution, metabolism, etc.), which are discussed in detail in 0. These processes can be affected by multiple factors, such as age, genetics, diet, and co-exposure with other metals and non-metals.

Age influences the biokinetic response to Pb within the body. Infants may be an at-risk population because Pb easily crosses the placental barrier and accumulates in fetal tissue during gestation (Pillai et al., 2009; Wang et al., 2009e; Uzbekov et al., 2007). This transfer of Pb from mother to fetus is partly due to the remobilization of the mother’s bone stores (O'Flaherty, 1998; Franklin et al., 1997). This also results in increased maternal blood Pb levels (Lamadrid-Figueroa et al., 2006; Gulson et al., 2004a; Hertz-Picciotto et al., 2000; Gulson et al., 1997; Lagerkvist et al., 1996; Schuhmacher et al., 1996; Rothenberg et al., 1994a). Bone growth rate is high during childhood. The majority of a child’s Pb body burden is not permanently incorporated in the bone, but some Pb does remain in the bone until older age (McNeill et al., 2000; O'Flaherty, 1995; Leggett,

1993). Older adults are more likely to have age-related degeneration of bones and organ systems and a possible redistribution of Pb stored in the bones into the blood stream (Popovic et al., 2005; Garrido Latorre et al., 2003; Gulson et al., 2002).

Various genes can also affect Pb biomarker concentrations. Genetic variants of the vitamin D receptor (VDR) in humans have been associated with varied bone and plasma Pb levels (Rezende et al., 2008; Theppeang et al., 2004; Schwartz et al., 2000a). Multiple studies have also examined the association between the aminolevulinate dehydratase (ALAD) polymorphism and blood Pb levels and found that the ALAD-2 polymorphism may be biologically related to varying Pb levels, although some studies report no difference for ALAD alleles (Miyaki et al., 2009; Shaik and Jamil, 2009; Sobin et al., 2009; Chen et al., 2008c; Rabstein et al., 2008; Scinicariello et al., 2007; Zhao et al., 2007; Montenegro et al., 2006; Wananukul et al., 2006).

It is well established that diets sufficient in minerals such as calcium, iron, and zinc offer some protection from Pb exposure by preventing or competing with Pb for absorption in the GI tract. A study in China reported that children who regularly consumed breakfast had lower blood Pb levels than those children that did not eat breakfast (Liu et al., 2011b). Diets designed to limit or reduce caloric intake and induce weight loss have been associated with increased blood Pb levels in adult animals (Han et al., 1999). A toxicological study reported negative effects of Pb on osmotic fragility, TBARS production, catalase activity, and other oxidative parameters, but most of these effects were reduced to the levels observed in the control group when the rats were given supplementation of zinc and vitamins (Massó-González and Antonio-García, 2009). Toxicological studies by Jamieson et al. (2008; 2006) also reported that a zinc-deficient diet increases bone and renal Pb content and impairs skeletal growth and mineralization. A zinc-supplemented diet attenuated bone and renal Pb content. Toxicological studies have shown that dietary deficiency of calcium induces increased Pb absorption and retention (Fullmer, 1992; Mykkanen and Wasserman, 1981; Six and Goyer, 1970). Increased calcium intake reduces accumulation of Pb in bone and mobilization of Pb during pregnancy and lactation (Bogden et al., 1995). Additionally, studies have reported that iron deficiencies may result in higher Pb absorption or altered biokinetics (Schell et al., 2004; Marcus and Schwartz, 1987; Mahaffey and Annest, 1986).

Finally, co-exposures with other metals and non-metals have also been studied to assess how they affected the uptake and absorption of Pb. Recent toxicological studies examined the addition of arsenic (As) to Pb and cadmium (Cd) mixtures, and reported increased bioavailability of Pb (Wang and Fowler, 2008). A toxicological study by Sawan et al. (2010) reported co-exposure with fluoride increased Pb deposition in calcified tissues.

In summary, age, genetics, diet, and other exposures affect the biokinetics of Pb, which in turn affects the internal distribution of Pb. These factors were discussed in greater detail in 0 where more information on overall biokinetics and physiological factors affecting Pb distribution was provided.

6.2 Population Characteristics Potentially Related to Differential Lead Exposure

Elevated or differential Pb exposure and related biomarker levels (such as blood Pb), have been shown to be statistically related to several population characteristics, including age, sex, race and ethnicity, SES, proximity to Pb sources, and residential factors (U.S. EPA, 2006b). In most cases, exposure, absorption, and biokinetics of Pb are all influenced to varying degrees by such characteristics. Additionally, the relative importance of population characteristics on exposure, absorption, and biokinetics varies on an individual basis and is difficult to quantify. This section presents recent studies demonstrating a relationship between each population characteristic and exposure status. The studies presented in this section build upon the current body of literature suggesting that population characteristics differentially influence Pb exposure; the new literature does not alter our previous understanding of the differential influence of population characteristics on Pb exposure. Differential response to given Pb exposures is discussed in Section 6.3.

6.2.1 Age

6.2.1.1 Early Childhood

Typically, children have increased exposure to Pb compared with adults because children's behaviors and activities include increased hand-to-mouth contact, crawling, and poor hand-washing that typically result in increased ingestion compared with adults (U.S. EPA, 2006b). Children can also be susceptible to Pb exposure because outdoor play can lead to hand-to-mouth contact with contaminated soil. For example, Zahran et al. (2010) observed that a 1% reduction in soil Pb concentration led to a 1.55 µg/dL reduction in median blood Pb levels ($p < 0.05$) among New Orleans children.

Age of the children may influence blood Pb levels through a combination of behavioral and biokinetic factors. The 2007-2008 NHANES data are presented in Table 6-1 by age and sex. Among children, highest blood Pb levels occurred in the 1-5 year age group

(children under age 1 were not included), and within this subgroup (not shown on the table), 1 year old children had the highest blood Pb levels (99th percentile: 16.9 µg/dL). It is possible that high blood Pb levels among these young children may also be related to in utero exposures resulting from maternal Pb remobilization from bone stores from historic exposures (Miranda et al., 2010) or from contemporaneous Pb exposures if the mothers were located near sources. Jones et al. (2009a) analyzed the NHANES datasets for the years 1999-2004 to study trends in blood Pb among two different age groups of children over time (see Table 6-2). They observed greater percentages of children aged 1-2 years having blood Pb levels of 2.5 to <5 µg/dL, 5 to <7.5 µg/dL, and ≥ 10 µg/dL, compared with 3-5 year-old children, but no age difference was noted for the 7.5 to <10 µg/dL bracket. These distribution differences may be attributable to differences in exposure, age-dependent variability in biokinetics or diet (e.g., milk versus solid diets). Yapici et al. (2006) studied the relationship between blood Pb level and age among a cohort of children younger than 73 months living in proximity to a Turkish coal mine. They observed a low but statistically significant negative correlation between blood Pb and age ($r = -0.38$, $p < 0.001$).

Fetal and child Pb biomarkers have been demonstrated to relate to maternal Pb biomarkers; several older studies in the literature were presented in the 2006 Pb AQCD (U.S. EPA, 2006b). Kordas et al. (2010) observed that maternal hair Pb concentration was a statistically significant predictor of child hair Pb concentration ($\beta = 0.37 \pm 0.07$, $p < 0.01$). Miranda et al. (2010) observed that pregnant women (ages 30-34 years and 35-39 years) had statistically significant higher odds of having greater blood Pb levels than younger pregnant women in the (25- to 29-year-olds) reference age category. These results could be related to a historical component to Pb exposure among mothers. These findings were also consistent with observations that Pb storage in bones increased with age before subsequent release with bone loss occurring during pregnancy, as described in Section 4.2 and summarized in Section 6.1. Elevated blood Pb levels among mothers

present a potential exposure route to their children in utero or through breast milk. Additionally, maternal pica presents a potential Pb source to a developing fetus (Hamilton et al., 2001).

6.2.1.2 Adulthood

Blood Pb levels tend to be higher in older adults compared with the general adult population (U.S. EPA, 2006b). Table 6-1 presents 2007-2008 NHANES data broken down by age group and shows that blood Pb levels were highest in the 65+years age group in comparison with adults aged 20-64 years. In a study of blood Pb and saliva Pb in a mostly female population in Detroit, Nriagu et al. (2006) found that age was a statistically significant positive predictor of blood Pb ($p < 0.001$). Average blood Pb levels among 14- to 24-year-old subjects was 2.60 ± 0.16 µg/dL compared with 4.29 ± 0.56 µg/dL among subjects aged 55 years or older. Higher average and median levels among older adults could potentially be due to a shared experience of higher historical Pb exposures stored in bone in conjunction with remobilization of stored Pb during bone loss (Section 4.2).

Theppeang et al. (2008b) studied Pb concentrations in the blood, tibia, and patella of subjects age 50-70 as part of the Baltimore Memory Study. They found a statistically significant relationship between age and tibia Pb ($\beta = 0.37$, $p < 0.01$ in a model including age, race/ethnicity, Yale energy index, and 2 diet variables; $\beta = 0.57$, $p < 0.01$ in a model including age, sex, and an interaction term for sex and age, which was also statistically significant at $p = 0.03$). Theppeang et al. (2008b) also noted that patella Pb concentrations increased with age, although the data quality for patella Pb was not as high, so the authors did not present the data or significance levels. A statistically significant relationship was not observed between the log-transform of blood Pb and age ($\beta = 0.007$, $p = 0.11$), although the age range of subjects may not have been sufficient to discern a difference in blood Pb level.

6.2.2 Sex

Several studies have suggested that sex influences levels of Pb biomarkers because differences in behavior between sexes may cause a differential increase in exposure. The 2007-2008 NHANES showed that overall, males have significantly higher blood Pb levels (average: 1.94 µg/dL) than females (average: 1.45 µg/dL) ($p < 0.0001$). Among adults aged 20-64 years, average blood Pb levels were 51% higher for males compared with females ($p < 0.0001$). Among adults 65 years or older, average blood Pb levels were

33% higher for males compared with females ($p < 0.0001$). In their study of Pb burden among Baltimore adults aged 50-70 years, Theppeang et al. (2008b) observed that average blood Pb levels were statistically significantly higher ($p < 0.01$) among men (4.4 µg/dL) than women (3.1 µg/dL). For average tibia Pb levels, Theppeang et al. (2008b) noted no difference ($p = 0.12$) between men (18.0 µg/g) and women (19.4 µg/g).

Among U.S. children, the 2007-2008 NHANES data showed that blood Pb levels were higher among girls than boys for the 1- to 5-years age group (Table 6-1). Blood Pb levels became slightly higher among boys for the 6- to 11-years age group, and levels were substantially higher among adolescent males than females in the 12- to 19-years age group. At the same time, blood Pb levels among both adolescent males and females were lower than blood Pb levels for the other age groups. The 2007-2008 NHANES data suggest that sex-based differences in blood Pb levels are not substantial until adolescence.

6.2.3 Race and Ethnicity

Higher blood Pb and bone Pb levels among African Americans has been well documented (U.S. EPA, 2006b). Recent studies are consistent with those previous findings. For instance, Levin et al. (2008) and Jones et al. (2009a) both analyzed NHANES survey data to examine trends in childhood blood Pb levels. Data from the Jones et al. (2009a) study, using NHANES data (NCHS, 2010) from 1988-1991 and 1999-2004 are shown in Figure 6-1. The authors found that differences among children from different racial/ethnic groups with regard to the percentage with blood Pb levels ≥ 2.5 µg/dL over the period 1999-2004 have decreased since the period of 1988-1991 . The non-Hispanic black group still had higher percentages with blood Pb levels ≥ 2.5 µg/dL compared with non-Hispanic whites and Mexican Americans, with large observable differences for blood Pb levels between 2.5 and <10 µg/dL. It is notable that the distributions of blood Pb levels among Mexican American and non-Hispanic white children were nearly identical in the 1999-2004 dataset. Theppeang et al. (2008b) also explored the effect of race and ethnicity on several Pb biomarkers in a study of older adults living in Baltimore, MD. They observed a statistically significant difference between African American (AA) and Caucasian (C) subjects with respect to tibia Pb (AA: 21.8 µg/g, C: 16.7 µg/g, $p < 0.01$) but not patella Pb (AA: 7.1 µg/g, C: 7.1 µg/g, $p = 0.46$) or blood Pb levels (AA: 3.6 µg/dL, C: 3.6 µg/dL, $p = 0.69$). Greater tibia (but lower patella) Pb levels may indicate greater historical exposure among African Americans compared to Caucasians in the Baltimore population studied by Theppeang et al. (2008b).

Note: from the NHANES survey, 1988-1991 (top) and 1999-2004 (bottom).

Figure 6-1 Percent distribution of blood Pb levels by race/ethnicity among U.S. children (1-5 years).

Differences in exposure among ethnic and racial groups have also been noted. In a study of three parishes in the greater metropolitan New Orleans area, Campanella and Mielke (2008) found that, where soil Pb levels were less than 20 mg/kg, the population was 36% black, 55% white, 3.0% Asian, and 6.0% Hispanic, based on the 2000 Census, with the percentage based on the total number living in Census blocks with the same soil Pb levels. In contrast, they found that for Census blocks in which soil Pb levels were between 1,000 and 5,000 mg/kg, the population was 62% black, 34% white, 1% Asian,

and 4% Hispanic (Figure 6-2). As described in Section 6.2.4, the differences observed by Campanella and Mielke (2008) may also be attributable to SES factors, or SES may be a confounding factor in the relationship between Pb soil levels and race/ethnicity of nearby residents.

Note: By Census 2000 race/ethnicity demographic groups.

Figure 6-2 Soil Pb concentration exposure among the population of three parishes within greater metropolitan New Orleans.

6.2.4 Socioeconomic Status (SES)

Socioeconomic factors have sometimes been associated with Pb exposure biomarkers, although these relationships have not always been consistent (U.S. EPA, 2006b). Nriagu et al. (2006) performed a multiple regression analysis of blood Pb and saliva Pb levels on various socioeconomic, demographic, and exposure variables among an adult population

in Detroit, Michigan. Blood and saliva Pb were both used as indicators of Pb in unbound plasma that is available to organs. Nriagu et al. (2006) found that education ($p < 0.001$), income ($p < 0.001$), and employment status ($p = 0.04$) were all statistically significant predictors of blood Pb levels, with blood Pb decreasing with some scatter as education and income level increased. Statistically significant relationships were also reported by Nriagu et al. (2006) for saliva Pb level with respect to education ($p < 0.001$), income ($p < 0.001$), and employment ($p = 0.06$). However, the highest educational attainment and income categories had higher saliva Pb levels compared with other groups; Nriagu et al. (2006) attributed these inconsistencies to small sample sizes among the high educational attainment and income categories.

On a national level, the gap between income levels with respect to blood Pb has been decreasing. For example, Levin et al. (2008) cited 1991-1994 NHANES data [analyzed in Pirkle et al. (1994)] that the percentage of children aged 1-5 years with blood Pb levels ≥ 10 µg/dL was 4.5% for the lowest income group compared with 0.7% for the highest income group. Levin et al. (2008) also analyzed data from the 1999-2002 NHANES and found no statistically significant difference between the percent of children with blood Pb levels above 10 µg/dL for Medicaid-enrolled children (1.7%) compared with non-enrolled children (1.3%). However, Medicaid-enrolled children did have higher median blood Pb levels (2.6 µg/dL) compared to children not enrolled in Medicaid (1.7 µg/dL). When adding data for 2003-2004 to the analysis (i.e., for 1999-2004), the gap between Medicaid enrolled and non-enrolled children widened for blood Pb levels ≥ 10 µg/dL (1.9% versus 1.1%), but the difference was still not statistically significant ($p > 0.05$). Median blood Pb levels with respect to Medicaid status did not change when adding the 2003-2004 data (Levin et al., 2008). Likewise, Jones et al. (2009a) analyzed blood Pb levels with respect to poverty-income ratio (PIR), which is the ratio of family income to the poverty threshold appropriate for a given family size. They found statistically significant differences in median blood Pb for PIR ≤ 1.3 compared with PIR >1.3. The percentage of 1- to 5-year-old children having blood Pb ≥ 10 µg/dL was higher for PIR ≤ 1.3 (1.8 versus 0.8); however, this difference was not statistically significant. Additionally, Campanella and Mielke (2008) observed a linear increase in soil Pb content outside a home with respect to decreasing average household income, with soil Pb between 2.5 and 20 mg/kg associated with a Census block-averaged median household income of $40,000 per year, while soil Pb between 5,000 and 20,000 mg/kg was associated with a Census block-averaged median household income of $24,000 per year.

6.2.5 Proximity to Lead Sources

Airborne and soil Pb concentrations are higher in some industrialized and urbanized areas, as described in Sections 3.2, 3.3, 3.5 and 4.1, as a result of historical and contemporaneous Pb sources. The highest air Pb concentrations measured using the Pb-TSP monitoring network have been measured at monitors located near sources emitting Pb. Elevated soil Pb concentrations have also been measured in urbanized areas compared with less urbanized or rural locations (Mielke et al., 2010a; Laidlaw and Filippelli, 2008; Weiss et al., 2006). Several studies describe mechanisms by which larger particles present in soil can become resuspended to the air by perturbation from traffic- and wind-generated turbulence (Harris and Davidson, 2008; Lough et al., 2005; Zereini et al., 2005; Nicholson, 1988; Gillette et al., 1974). However, there are no recent monitoring studies of this process, and the current routine monitoring network is not designed for the assessment of the specific contribution of resuspension to ambient air concentrations. Air Pb concentrations exhibit high spatial variability even at low concentrations (~0.01 $\mu g/m^3$) (Martuzevicius et al., 2004). Proximity to an industrial source likely contributes to higher Pb exposures, as described in the 2006 Pb AQCD (U.S. EPA, 2006b) for several studies of Superfund and other industrial sites. This is consistent with the observation of higher air concentrations at source oriented Pb monitoring sites compared with non-source oriented sites in the 2007-2009 data presented in Section 3.5.

Jones et al. (2010) found that neonates born near a Pb-contaminated hazardous waste site had significantly higher umbilical cord blood Pb levels (median: 2.2 µg/dL [95% CI: 1.5, 3.3 µg/dL]) compared with a reference group of neonates not living near a potentially contaminated site (median: 1.1 µg/dL [95% CI: 0.8, 1.3 µg/dL]), suggesting that Pb-contaminated hazardous waste sites contribute to neonatal Pb levels. The population studied in Jones et al. (2010) was 88% African American; 75% had a high school degree or equivalent, while 20% had a college degree and 5% attended but did not graduate from high school. However, the Jones et al. (2010) study did not analyze covariation between exposure and maternal characteristics, so it cannot be determined if differences in characteristics among the maternal groups (which did and did not report nearby hazardous waste sites) confounded these results.

Studies have suggested that soil Pb exposure is related to land use type and historical exposures of the soil, as described in Section 3.6.1. For instance, Wu et al., (2010) observed that bioavailable Pb concentrations in Los Angeles soils were significantly associated with traffic-related variables and parcel age (i.e., length of time since the parcel was first developed), with parcel age being a highly significant predictor of bioavailable soil Pb in most models ($p < 0.0001$). Zahran et al. (2011) observed that soil Pb levels dropped following Hurricanes Katrina and Rita, from 329 mg/kg to 203 mg/kg

when comparing samples from 2000 with those from 2006. The reduction in soil Pb was thought to occur because sediments with lower Pb concentrations were distributed by the storms and coated existing soils having higher Pb concentrations. At the same time, blood Pb levels obtained from children ages 0-6 years at the same time periods declined by 1.55 µg/dL for each 1% reduction in soil Pb ($p \leq 0.05$). Following this observation, that lower Pb concentration material can be used to contain older soils with higher concentrations of Pb, Mielke et al. (2011b) initiated an experiment where a playground was covered with geotextile material topped with 15 cm of river alluvium. Median soil Pb concentrations decreased from 558 mg/kg to 4.1 mg/kg after the mitigation.

6.2.6 Residential Factors

A recent study of the association between blood Pb and housing factors by Dixon et al. (2009), which drew inference from the NHANES national survey for 1999-2004, is consistent with previous studies presented in the 2006 Pb AQCD that drew associations between blood Pb and house dust (U.S. EPA, 2006b; Lanphear et al., 1998; Laxen et al., 1987). Dixon et al. (2009) used NHANES data from 1999-2004 to perform a linear regression of blood Pb among children 12-60 months old on several factors including year of construction, floor surface condition, floor dust Pb level, windowsill dust Pb level, and renovation in homes built before 1978. They found that blood Pb (log transformed) was significantly associated with homes built after 1950 ($p = 0.014$), windowsill Pb level ($p = 0.002$), dust Pb level ($p < 0.001$), and renovation in pre-1978 homes ($p = 0.045$). Detailed results of this regression are shown in Table 6-3. As part of the same study, Gaitens et al. (2009) performed a regression analysis of floor dust Pb (PbD) and windowsill dusts Pb on several factors. Floor dust Pb (log transformed) was significantly associated with the following housing-related factors: floor surface condition ($p < 0.001$), windowsill dust Pb (log transformed) ($p < 0.001$), year of construction ($p < 0.001$), and renovation in a pre-1950 home ($p < 0.001$). Windowsill dust Pb (log transformed) was significantly associated with the following housing-related factors: year of construction ($p < 0.001$), window surface condition (0.001), and deteriorated indoor paint ($p = 0.028$).

Renovation activities on older homes have been shown to produce excess Pb dust concentrations. Gaitens et al. (2009) performed a regression analysis on dust Pb concentrations from 1994-2004 NHANES on demographic and housing variables and found that renovation of windows, cabinets, or walls in a pre-1950 home was

significantly associated with floor dust Pb concentration ($p < 0.001$). Paint scraping within the last twelve months was nearly significantly associated with windowsill dust Pb concentration ($p = 0.053$). Dixon et al. (2009) performed a regression analysis on log-transformed blood Pb levels from NHANES (1999-2004) on several demographic and housing variables and found that renovation of windows, cabinets, or walls in pre-1978 homes was significantly associated with blood Pb concentration ($p = 0.045$). Mielke et al. (2001) tested dust produced roughly six months after a home (having paint containing ~130,000 mg Pb/kg) was power sanded. Dust concentrations in various locations around the house ranged from 390-27,600 mg/kg after the first sampling. Following several rounds of cleaning, Pb concentrations dropped. Eight months later, most interior Pb concentrations were < 3 mg/kg, but five sites ranged from 17-1,340 mg/kg. Two children had blood Pb tested as part of this study. A 33 month-old child exhibited no change in blood Pb before or after renovation (blood Pb = 4 µg/dL), while a twelve-month old child had an increase from 4 µg/dL to 12 µg/dL. Note that blood was acquired in different manners from the children because the younger child had smaller veins; the older child had a venous sample while the younger child had a finger-stick. It is unclear if either of these methods is more prone to contamination than the other. In an occupational study of men performing home renovations in the U.K., window renovation and wood-stripping workers specializing in renovation of old houses had significantly higher median blood Pb levels compared with all workers in similar occupations (wood strippers: 37 µg/dL; window renovators: 32 µg/dL; all workers: 13.7 µg/dL; $p < 0.001$) (Mason et al., 2005).

6.3 Factors Potentially Related to Increased Risk of Lead Induced Health Effects

This section evaluates factors examined in recent studies as effect measure modifiers that potentially increase the risk of various Pb-related health effects. Table 6-4 provides an overview of the factors examined and populations identified as “at-risk” of Pb-related health effects based on the recent evidence integrated across disciplines. Each characteristic is described in greater detail in the following subsections.

Table 6-4 Summary of evidence for factors that potentially increase the risk of lead-related health effects

Factor Evaluated	Potentially Related to Increased Risk
Age (Section 6.3.1)	Children
Sex (Section 6.3.2)	Males,[a] Females[a]
Genetics (Section 6.3.3)	ALAD[a], VDR[a]*, DRD4[a]*, GSTM1[a], TNF-α[a], eNOS[a], APOE[a], HFE[a]
Pre-existing Disease (Section 6.3.4)	Autism[a], Atopy[a,b], Hypertension[b]
Smoking (Section 6.3.5)	Smokers[a]
Race/Ethnicity (Section 6.3.6)	Non-Hispanic Blacks[a], Hispanics[a]
Socioeconomic Status (SES) (Section 6.3.7)	Low SES[a]
Nutrition (Section 6.3.10)	Iron deficiency[a]
Stress (Section 6.3.11)	High stress[a]
Cognitive Reserve (Section 6.3.12)	Low cognitive reserve[a,b]
Other Metals (Section 6.3.13)	High/co-exposure to Cd[a], As[a], Mn[a]

[a]Evidence for this factor was limited.
[b]Possible mediator

6.3.1 Age

Below is information from epidemiologic and toxicological studies regarding studies of increased risk for Pb-related health effects among children and older adults. Other age groups, such as adolescents, have not been evaluated here, if they were not part of stratified studies of lifestage.

6.3.1.1 Children

According to the 2000 Census, 28.6% of individuals living in the U.S. were under the age of 20, with 6.8% aged 0-4 years, 7.3% aged 5-9 years, 7.3% aged 10-14 years, and 7.2% aged 15-19 years (SSDAN CensusScope, 2010a). It is recognized that Pb can cross the placenta and affect the developing nervous system of the fetus (Sections 4.2.2.4 and 5.3.9) and there is strong evidence of increased risk to the neurocognitive effects of Pb exposure during several lifestages throughout gestation, childhood, and into adolescence (for more detail, Section 5.3.2.1). However, most recent studies among children do not have adequate comparison groups between children of various age groups or between children and adults, and were therefore only presented in Chapter 5.

A study including multiple U.S. locations examined associations of blood Pb levels with various immune parameters among individuals living near Pb industrial sites and matched controls (Sarasua et al., 2000). For several of these endpoints, the association in the youngest group (ages 6-35 months) and the oldest group (ages 16-75 years) were in opposite directions. For example, among children ages 6-35 months, the associations between blood Pb levels and Immunoglobulin A (IgA), Immunoglobulin M (IgM), and B-cell abundance were positive, whereas the associations among 16-75 year olds were negative. The opposite associations were also present for T cell abundance. Ig antibodies, which are produced by activated B cells, are important mediators of the humoral immune response to antigens. T cells are important mediators of cell-mediated immune responses that involve activation of other immune cells and cytokines. These findings by Sarasua et al. (2000) indicate that very young children may be at increased risk for Pb-associated activation of humoral immune responses and perturbations in cell-to-cell interactions that underlie allergic, asthma, and inflammatory responses (for more information, see Sections 5.6.2.1 and 5.6.3).

A study among Lebanese children examined the association between blood Pb levels and transferrin saturation (TS) less than 12% and iron-deficiency anemia (IDA) (Muwakkit et al., 2008). A positive association was detected for blood Pb levels ≥ 10 µg/dL and both TS less than 12% and IDA among children aged 11-23 months old; however, null associations were observed among children 24-35 months old. Calculations were not performed for children aged 36-75 months because there were no children in the highest Pb group (≥ 10 µg/dL) with either TS <12% or IDA. The authors noted that it is difficult to know whether the Pb levels were "a cause or a result of" IDA levels since previous studies linked iron deficiency with Pb toxicity.

Overall evidence indicates early childhood as a lifestage of increased risk for Pb-related health effects. Both recent epidemiologic studies summarized above reported associations among the youngest age groups, although different age cut-points were used with one study including only infants 35 months of age and younger. Toxicological studies provide support for increased health effects of Pb among younger age groups. Toxicological studies have reported that younger animals, whose nervous systems are developing (i.e., laying down and pruning neuronal circuits) and whose junctional barrier systems in the brain (i.e., the blood brain barrier) and GI system (i.e., gut closure) are immature, are more at risk from the effects Pb exposure (Fullmer et al., 1985).

6.3.1.2 Older Adults

The number of Americans over the age of 65 will be increasing in upcoming years (estimated to increase from 12.4% of the U.S. population to 19.7% between 2000 to 2030, which is approximately 35 million and 71.5 million individuals, respectively) (SSDAN CensusScope, 2010a; U.S. Census Bureau, 2010). As of the 2000 Census, 7.2% of the U.S. population were ages 60-69, 5.8% were 70-79, and 3.3% were age 80 and older (SSDAN CensusScope, 2010a).

A study using the NHANES III cohort examined blood Pb levels and mortality among individuals less than 60 years old and individuals 60 years and older (Menke et al., 2006). Positive hazard ratios were observed in both age groups but the hazard ratios were greater in those less than 60 years old. The interactions terms were not statistically significant. A similar study using the NHANES III cohort examined the relationship between blood Pb levels and mortality from all-cause, cardiovascular disease, and cancer broken down into more specific age groups (Schober et al., 2006). Point estimates were elevated for the association comparing blood Pb levels ≥ 10 µg/dL to blood Pb levels <5 µg/dL and all-cause mortality for all age groups (40-74, 75-84, and 85+ year olds), although the association for 75-84 year olds did not reach statistical significance. The association was also present when comparing blood Pb levels of 5-9 µg/dL to blood Pb levels <5 µg/dL among 40-74 year olds and 75-84 year olds, but not among those 85 years and older. None of the associations between blood Pb and cardiovascular disease-related mortality reached statistical significance but the point estimates for cardiovascular disease-related mortality comparing blood Pb levels ≥ 10 µg/dL to blood Pb levels <5 µg/dL were elevated among all age groups. Finally, the association between blood Pb levels ≥ 10 µg/dL and cancer mortality was positive among those 40-74 years old and 85 years and older but the association was null for those 75-84 years old. Among 75-84 year olds the association was positive comparing blood Pb levels of 5-9 µg/dL to <5 µg/dL. The other age groups had similar point estimates but the associations were not statistically significant.

A study using the Normative Aging Study cohort reported an interaction between Pb and age (Wright et al., 2003b). The inverse association between age and cognitive function was greater among those with high blood or patella Pb levels. Effect estimates were in the same direction for tibia Pb but the interaction was not statistically significant.

Finally, a study of current and former Pb workers reported that an interaction term of Pb and age (dichotomous cutpoint at 67th percentile but exact age not given) examined in models of Pb (measured from blood and patella) and blood pressure was not statistically significant (Weaver et al., 2008). Thus, no modification by age was observed in this study of Pb and blood pressure.

Toxicological studies have demonstrated Pb-related health effects among older populations. The kidneys of older animals appear to be more at-risk for Pb-related health effects from the same dose of Pb (i.e., continuous 50 mg/L Pb-acetate drinking water) than younger animals (Berrahal et al., 2011). Increased risk related to older age is also observed for effects on the brain. Recent studies have demonstrated the importance of Pb exposure during early development in promoting the emergence of Alzheimer's like pathologies in aged animals. Development of pathologies of old age in brains of aged animals that were exposed to Pb earlier in life has been documented in multiple species (mice and monkeys, for more details see Section 5.3.6). These pathologies include the development of neurofibrillary tangles and increased amyloid precursor protein and its product beta-amyloid (Basha et al., 2005; Zawia and Basha, 2005). Some of these findings were seen in animals that no longer had elevated blood Pb levels.

In summary, results for age-related modification of the association between Pb and mortality had mixed results. Limited evidence was available for the associations between Pb and cognitive function or other health effects among older adults. Toxicological studies have shown increases in Pb-related health effects by age that may be relevant in humans. Future studies will be instrumental in understanding older age as a factor that potentially affects the risk of Pb-related outcomes.

6.3.2 Sex

The distribution of males and females in the U.S. is similar. In 2000, 49.1% of the U.S. population was male and 50.9% was female. The distribution of sex varied by age with a greater prevalence of females ≥ 65 years old compared to males (SSDAN CensusScope, 2010a). The 2006 Pb AQCD reported that boys are often found to have higher blood Pb levels than girls, but findings were "less clear" regarding differences in Pb-related health effects between males and females (U.S. EPA, 2006b).

Multiple epidemiologic studies have examined Pb-related effects on cognition stratified by sex. In previous studies using the Cincinnati Lead Study cohort, Dietrich et al. (1987b) and Ris et al. (2004) observed interactions between blood Pb (prenatal and postnatal) and sex ; associations of prenatal and postnatal blood Pb and subsequent decrements in memory, attention, and visuoconstruction were observed only among male adolescents. More recently, Wright et al. (2008) examined early life blood Pb levels and criminal arrests in adulthood. The attributable risks were greater among males than females. Additionally, the association between childhood blood Pb levels and adult gray matter volume loss was greater among males than females (Cecil et al., 2008). In an expanded analysis of the developmental trajectory of childhood blood Pb levels on adult gray

matter, researchers found that associations between yearly mean blood Pb levels and volume of gray matter loss were more pronounced in the frontal lobes of males than females (Brubaker et al., 2010). Multiple studies were also conducted in Port Pirie, Australia that examined blood Pb levels at various ages throughout childhood and adolescence (Tong et al., 2000; Baghurst et al., 1992; McMichael et al., 1992). These studies observed Pb effects on cognition deficits were stronger in girls throughout childhood and into early adolescence. A study in Poland also investigated the association between umbilical cord blood Pb levels and cognitive deficits and reported a positive association for boys at 36 months but not for girls (Jedrychowski et al., 2009a). No association was detected for boys or girls at 24 months.

An epidemiologic study examined the association between concurrent blood Pb levels and kidney function among 12-20 year olds using the NHANES III study cohort (Fadrowski et al., 2010). The results were stratified by sex and no effect measure modification was apparent.

Similarly, a study of current and former Pb workers examined an interaction term between sex and Pb for the study of blood Pb and blood pressure (Weaver et al., 2008). No modification by sex was present.

Epidemiologic studies have also been performed to assess differences between males and females for Pb-related effects on various biomarkers. A study comprised mostly of females reported positive associations between blood Pb and total immunoglobulin E (IgE) for women not taking hormone replacement therapy or oral contraceptives (Pizent et al., 2008). No association was reported in males, but other associations, such as bronchial reactivity and reactive skin prick tests were observed in the opposite of the expected direction, which questions the validity of the results among the male study participants. Analysis of an NHANES dataset detected no association between blood Pb levels and inflammatory markers (Songdej et al., 2010). Although there was no clear pattern, a few of the associations were positive between blood Pb and C-reactive protein for males but not females. A study of children living at varying distances from a Pb smelter in Mexico reported that blood Pb was associated with increased release of superoxide anion from macrophages, which was greater among males than females (Pineda-Zavaleta et al., 2004).

Epidemiologic investigations of cancer have also examined the associations by sex. A study of the association between occupational exposure to Pb and brain tumors reported no sex-specific associations for gliomas, but a positive association for cumulative Pb exposure and meningiomas for males but not females (Rajaraman et al., 2006). An ecologic analysis of Pb pollution levels and cancer incidence among children reported

weak correlations overall and the weak correlations were more apparent among males, whereas no correlation was observed among females (Absalon and Slesak, 2010).

A study of all-cause and cardiovascular mortality using the NHANES III cohort reported no modification of the association between blood Pb and all-cause or cardiovascular mortality by sex (Menke et al., 2006). This did not differ among women when classified as pre- or post-menopausal.

Toxicological studies have also reported sex differences in Pb-related effects to various organ systems. Donald et al. (1986) reported a different time course of enhanced social investigatory behavior between male and female mice exposed to Pb. In a subsequent publication, Donald et al. (1987) showed that non-social behavior in mice decreased in females and increased in males exposed to Pb. Males also had a shorter latency to aggression with Pb treatment versus controls. Pb affected mood disorders differently for males and females. Behavioral testing in rats showed males experienced emotional changes and females depression-like changes with Pb exposure (de Souza Lisboa et al., 2005). In another study, gestational exposure to Pb impaired memory retrieval in male rats at all 3 doses of Pb exposure; memory retrieval was only impaired in low-dose female rats (Yang et al., 2003). Sex-specific differences in mice were also observed for gross motor skills; at the lowest Pb dose, balance and coordination were most affected among males (Leasure et al., 2008).

Pb and stress are co-occurring factors that act in a sex-divergent manner to affect behavior, neurochemistry, and corticosterone levels. Pb and stress act synergistically to affect fixed interval operant behavior and corticosterone in female rat offspring. Virgolini et al. (2008a) found that effects on the offspring's central nervous system by developmental Pb exposure (maternal exposure and transferred to the offspring through lactation) were enhanced by combined maternal and offspring stress and females were most at risk. Behavioral related outcomes after gestational and lactational Pb exposure (with and without stress) exhibited sex-differences in exposed offspring (Virgolini et al., 2008b). Pb-induced changes in brain neurochemistry, with or without concomitant stress exposure, are complex with differences varying by brain region, neurotransmitter type, and sex of the animal.

The brain is known to have a sexually dimorphic area in the hypothalamus, termed the sexually dimorphic nucleus (SDN). Lesions in this area affect sex-specific phenotypes including behavior. Across species the SDN has a greater cell number and larger size in males versus females. This sexually dichotomous area is especially vulnerable to perturbation during fetal life and the early postnatal period. This may be one area of the brain that could explain some of the sexually dichotomous effects that are seen with Pb exposure. One study supporting this line of thought showed that high-dose in utero Pb

exposure (pup blood Pb level 64 µg/dL at birth) induced reductions in SDN volume in 35% of Pb-exposed male rats (McGivern et al., 1991). Interestingly, another chemical that is known to cause a hypothalamic lesion in this area, monosodium glutamate, is associated with adult onset obesity (Olney, 1969); adult onset obesity is seen in the Pb literature.

Obesity in adult offspring exposed to low-dose Pb in utero was reported for male but not female mice (Leasure et al., 2008). Obesity was also found in male rat offspring exposed in utero to high doses of Pb that persisted to 5 weeks of age/end of the study, but among female rats, body weight remained elevated over controls only to 3 weeks of age (Yang et al., 2003). Additionally, low-dose Pb exposure induced retinal decrements in exposed male mice offspring (Leasure et al., 2008).

A toxicological study of Pb and antioxidant enzymes in heart and kidney tissue reported that male and female rats had differing enzymatic responses, although the amount of Pb in the heart tissue or the disposition of Pb also varied between males and females (Sobekova et al., 2009; Alghazal et al., 2008a). The authors reported these results could be due to greater deposition of Pb in female rats or greater clearance of Pb by males (Sobekova et al., 2009).

Multiple associations between Pb and various health endpoints have been examined for effect measure modification by sex. Although not observed in all endpoints, some studies reported differences between the associations for males and females, especially in neurological studies. However, studies on cognition from the Cincinnati Lead Study cohort and a study in Poland reported males to be an at-risk population, whereas studies from Australia pointed to females as an at-risk population. A difference in sex is supported by toxicological studies. Further research is needed to confirm the presence or absence of sex-specific associations between Pb and various health outcomes and in which sex the associations are greater.

6.3.3 Genetics

The 2006 Pb AQCD stated that, "genetic polymorphisms in certain genes have been implicated as influencing the absorption, retention, and toxicokinetics of Pb in humans" (U.S. EPA, 2006b). The majority of discussion there focused on the aminolevulinate dehydratase (ALAD) and vitamin D receptor (VDR) polymorphisms. These two genes, as well as additional genes examined in recent studies, are discussed below.

6.3.3.1 Aminolevulinate Dehydratase

The aminolevulinate dehydratase (ALAD) gene encodes for an enzyme that catalyzes the second step in the production of heme and is also the principal Pb-binding protein (U.S. EPA, 2006b). Studies have examined whether ALAD variants altered associations between Pb and various health effects.

Associations between Pb and brain tumors observed in an epidemiologic study varied by ALAD genotype status (Rajaraman et al., 2006). Positive associations between Pb exposure (determined via interview about occupational exposures) and meningioma were reported among ALAD2 individuals, but this association was not found among individuals who had the ALAD1 allele. No associations were observed between Pb and glioma regardless of ALAD genotype.

Studies investigating the association between Pb levels and cognitive function have also examined modification by ALAD polymorphisms. The evidence is provided by an NHANES analysis (Krieg et al., 2009) as well as multiple analyses from the NAS cohort examining different tests of cognitive function (Rajan et al., 2008; Weuve et al., 2006). In the study using a cohort from NHANES III, for several indices of cognitive function, associations with concurrent blood Pb levels were more pronounced in groups with CC and CG ALAD genotypes (i.e., ALAD2 carriers) (Krieg et al., 2009). In the NAS cohort of men, Weuve et al. (2006) found that concurrent blood Pb level but not bone Pb level was associated with a larger decrease in a test of general cognitive function among ALAD2 carriers. Another NAS study examined functioning of specific cognitive domains (e.g., vocabulary, memory, visuospatial skills) and found variable evidence for effect modification by ALAD genotype across tests (Rajan et al., 2008). For example, among ALAD2 carriers, concurrent blood Pb level was associated with a more pronounced decrease in vocabulary score but less pronounced decrease in a memory index and no difference in the associations with other cognitive tests. For tibia and patella Pb levels, ALAD genotype was found to modify associations with different tests, for example, executive function and perceptual speed. It is not clear why the direction of effect modification would vary among different cognitive domains. The limited number of populations examined, and the different cognitive tests performed in each study, make it difficult to conclusively summarize findings for effect modification by ALAD variants. However, in the limited available body of evidence, blood and bone Pb levels were generally associated with lower cognitive function in ALAD2 carriers.

A study of current and former workers exposed to Pb examined the association between blood Pb and blood pressure and reported no modification by ALAD genotype (Weaver et al., 2008). However, another study of blood Pb and blood pressure reported

interactions between blood Pb and ALAD, but this varied by race/ethnicity (non-Hispanic white, non-Hispanic black, and Mexican American) (Scinicariello et al., 2010).

Individuals with ALAD2 variants had greater associations between Pb and kidney effects; among those with the variant, higher Pb was associated with higher glomerular filtration measures (Weaver et al., 2006; Weaver et al., 2005b; Weaver et al., 2003b). A study of workers at a battery plant storage facility in China reported workers with the ALAD2 allele demonstrated greater associations between blood Pb levels and renal injury (Gao et al., 2010a). Another study of renal function among Pb workers in Asia also reported greater associations between blood Pb concentrations and renal function by ALAD, especially at high blood Pb levels (Chia et al., 2006).

6.3.3.2 Vitamin D Receptor

The vitamin D receptor (VDR) is a regulator of calcium absorption and metabolism. A recent study of the NHANES III population examined the association between blood Pb levels and various neurocognitive tests with assessment of effect measure modification by SNPs and haplotypes of VDR (Krieg et al., 2010). The results were varied, even among specific SNPs and haplotypes, with some variants being associated with greater modification of the relationship between Pb and one type of neurocognitive test compared to the modification of the relationship between Pb and other neurocognitive tests. In an epidemiologic study of blood Pb levels and blood pressure among a group of current and former Pb-exposed workers, no modification was reported by VDR (Weaver et al., 2008).

6.3.3.3 Methylenetetrahydrofolate reductase

Methylenetetrahydrofolate reductase (MTHFR) catalyzes the conversion of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate, which in turn, is involved in homocysteine remethylation to the amino acid methionine. A study in Mexico of the association between Pb and Bayley's Mental Development Index (MDI) score at 24 months reported no effect measure modification by MTHFR 677T allele (Pilsner et al., 2010). Another study in Mexico examined the association between maternal Pb and birth weight (Kordas et al., 2009). No modification of the Pb-birth weight association by MTHFR was observed.

6.3.3.4 Apolipoprotein E

Apolipoprotein E (APOE) is a transport protein for cholesterol and lipoproteins. The gene appears to regulate synapse formation (connections between neurons), which may be particularly critical in early childhood. A genetic variant, called the APOE4 allele is a haplotype between two exonic SNPs and is perhaps the most widely studied genetic variant with respect to increasing risk of neurologic disease. A study of occupationally-exposed adults observed tibia Pb levels to be associated with greater cognitive decrements in some, but not all, neurobehavioral tests (such as digit symbol, pegboard assembly, and complex reaction time) among adults with at least one APOE-ε4 allele (Stewart et al., 2002). Conversely, in a study of children in Mexico, children without the APOE-ε4 allele had a greater inverse association between umbilical cord blood Pb and Bayley's MDI than children with this allele, although the interaction term was not statistically significant (Wright et al., 2003a).

6.3.3.5 Hemochromatosis

The hemochromatosis (HFE) gene encodes a protein believed to be involved in iron absorption. A difference was observed between the association of tibia Pb levels and cognitive function for men with and without HFE allele variants (Wang et al., 2007a). No association between tibia Pb and cognitive function was present for men with HFE wildtype, but a decline in function was associated with tibia Pb levels among men with any HFE allele variant. A study of bone Pb levels and HFE reported no difference in effect estimates for bone Pb and pulse pressure between different HFE variants and HFE wild-type (Zhang et al., 2010a). An interaction was observed between an HFE variant in mothers and maternal tibia Pb in a study of maternal Pb and birth weight (Cantonwine et al., 2010b). The inverse association between maternal tibia Pb levels and birth weight was stronger for those infants whose mothers had the HFE variant. The interaction was not present between the HFE variants and maternal blood Pb or cord blood Pb concentrations.

6.3.3.6 Other Genetic Polymorphisms

Some other genetic polymorphisms were also examined as to whether they modify Pb-related health effects, but only limited data were available for these polymorphisms. These include dopamine receptor D4 (DRD4), dopamine receptor D2 (DRD2), dopamine transporter (DAT1), glutathione S-transferase Mu 1 (GSTM1), tumor necrosis factor-*alpha* (TNF-α), endothelial nitric oxide synthase (eNOS), and various SNPS.

A prospective birth cohort reported that increasing blood Pb levels were associated with poorer rule learning and reversal, spatial span, and planning in their study population (Froehlich et al., 2007). These inverse associations were exacerbated among those lacking DRD4-7. A study of prenatal and postnatal Pb levels in Mexico City reported no modification of the associations between Pb levels and neurocognitive development by DRD2 or DAT1 (Kordas et al., 2011).

A study of university students in South Korea reported blood Pb levels to be associated with biomarkers of inflammation among individuals with GSTM1 null genotype and not among individuals with GSTM1 present (Kim et al., 2007). This study of blood Pb levels and inflammation also examined individuals with TNF-α GG, GA, or AA alleles. An association was present for those with TNF-α GG but not for those with TNF-α GA or AA.

A study of blood Pb and plasma NO_X reported no overall association but did report an inverse correlation among subjects with the eNOS TC+CC genotype (Barbosa et al., 2006a). No correlation was observed for subjects with the eNOS TT genotype; however the number of subjects in this group was small, especially for those with high blood Pb levels.

One study examined how the association between occupational Pb exposure and brain tumors varied among multiple single nucleotide polymorphisms (SNPs) (Bhatti et al., 2009). No effect measure modification of the association between Pb and glioma was observed for any of the SNPs. GPX1 (the gene encoding for glutathione peroxidase 1) modified the association for glioblastoma multiforme and meningioma. The association between Pb and glioblastoma multiforme was also modified by a RAC2 (the gene encoding for Rac2) variant, and the association between Pb and meningioma was also modified by XDH (the gene encoding for xanthine dehydrogenase) variant.

Overall, studies of ALAD observed increased Pb-related health effects associated with certain gene variants. Other genes, such as VDR, APOE, HFE, DRD4, GSTM1, TNF-α, and eNOS, may also affect the risk of Pb-related health effects but conclusions are limited due to the small number of studies.

6.3.4 Pre-existing Diseases/Conditions

Studies have also been performed to examine whether certain morbidities increase an individual's risk of Pb-related effects on health. Recent studies have explored relationships for autism, atopy, diabetes, and hypertension.

6.3.4.1 Autism

Rates of individuals with autism have increased in recent years. A study reported a prevalence rate in 2006 of 9.0 per 1,000 individuals (95% CI: 8.6, 9.3) determined from a monitoring network (Autism and Developmental Disabilities Monitoring Network) with 11 sites across the U.S. (CDC, 2009).

A cross-sectional study of children with and without autism examined the association between blood Pb levels and various immune function and inflammation genes (Tian et al., 2011). Blood Pb levels of children with and without autism were associated with expression of the genes under study; however, the associations observed were in opposite directions (for children with autism, increased blood Pb levels were associated with increased expression, whereas for children without autism, increased blood Pb levels were associated with decreased expression).

6.3.4.2 Atopy

Atopy, a type of allergic hypersensitivity, was evaluated as a factor affecting risk in a study of Pb and IgE (Annesi-Maesano et al., 2003). The study examined hair Pb levels in infants and IgE and reported a positive correlation overall. However, in stratified analyses, this association remained only among infants of mothers without atopy. Among mothers with atopy, the correlation was positive, although smaller, and was not statistically significant.

6.3.4.3 Diabetes

Approximately 8% of U.S. adults have diabetes (Pleis et al., 2009). A few studies have been conducted to investigate the possibility of diabetes as a modifying factor for Pb and various health outcomes.

Differences in the association between bone and blood Pb levels and renal function for individuals with and without diabetes at baseline was examined using the Normative Aging Study cohort (Tsaih et al., 2004). Tibia and blood Pb levels were positively associated with measures of poor renal function among individuals with diabetes but not among individuals without diabetes. However, this association was no longer statistically significant after the exclusion of individuals who were hypertensive or who used diuretic medications. Another study with this cohort reported no associations between bone Pb and heart rate variability, which did not differ among those with and without diabetes (Park et al., 2006).

The NHANES III data were used to evaluate whether the association between blood Pb and both all-cause and cardiovascular mortality varied among individuals with and without diabetes (Menke et al., 2006). The 95% CIs among those with diabetes were large and no difference was apparent among those with and without diabetes.

Overall, recent epidemiologic studies found that associations between Pb concentrations and health outcomes did not differ for individuals with and without diabetes. However, results from the 2006 Pb AQCD found that individuals with diabetes are at "increased risk of Pb-associated declines in renal function" (U.S. EPA, 2006b). Future research examining associations between Pb and renal function, as well as other health outcomes, among individuals with and without diabetes will inform further on the potential for increased risk among individuals with diabetes.

6.3.4.4 Hypertension

Hypertension affects approximately 24% of adults in the U.S. and the prevalence of hypertension increases with age (61% of individuals ≥ 75 years old have hypertension) (Pleis et al., 2009).

The Normative Aging Study mentioned above evaluating modification of the association between Pb levels and renal function by diabetes also examined modification by hypertensive status (Tsaih et al., 2004). The association between tibia Pb and renal function, measured by change in serum creatinine, was present among individuals with hypertension but not among individuals that were normotensive. Models of the follow-up serum creatinine levels demonstrated an association with blood Pb for individuals with hypertension but not individuals without hypertension (this association was not present when using tibia or patella Pb). Another study using this population examined modification of the association between bone Pb and heart rate variability, measured by low frequency power, high frequency power, and their ratio (Park et al., 2006). Although a statistically significant association between bone Pb and heart rate variability was not observed among individuals with or without hypertension, the estimates were different, with greater odds for individuals with hypertension (bone Pb levels were positively related to low frequency power and the ratio of low frequency to high frequency power and were inversely related to high frequency power).

A study using the NHANES III cohort reported a positive association between blood Pb levels and both all-cause and cardiovascular mortality for individuals with and without hypertension but the associations did not differ based on hypertensive status (Menke et al., 2006).

The 2006 Pb AQCD reported that individuals with hypertension had increased risk of Pb-related effects on renal function (U.S. EPA, 2006b). This is supported by recent epidemiologic studies. As described above, studies of Pb-related effects on renal function and heart rate variability have observed some differences among individuals with hypertension, but the difference between adults with and without hypertension was not observed for Pb-related mortality.

6.3.5 Smoking

The rate of smoking among adults 18 years and older in the U.S. is approximately 20% and about 21% of individuals identify as former smokers (Pleis et al., 2009). Studies of Pb and various health effects have examined smoking as an effect measure modifier.

A study of blood Pb levels and all-cause and cardiovascular mortality reported no modification of this association by smoking status, measured as current, former, or never smokers (Menke et al., 2006). The Normative Aging Study also examined the association between blood and bone Pb levels and renal function and also reported no interaction with smoking status (Tsaih et al., 2004).

A study of Pb-exposed workers and controls reported similar levels of absolute neutrophil counts (ANC) across Pb exposure categories among non-smokers (Di Lorenzo et al., 2006). However, among current smokers, higher Pb exposure was associated with higher ANC. Additionally, a positive relationship was observed between higher blood Pb levels and TNF-α and granulocyte colony-stimulating factor (G-CSF) among both smokers and nonsmokers, but this association was greater among smokers (Di Lorenzo et al., 2007). A recent study of fertile and infertile men examined blood and seminal plasma Pb levels for smokers and non-smokers (Kiziler et al., 2007). The blood and seminal plasma Pb levels were higher for smokers of both fertile and infertile groups. Additionally, the Pb levels were lowest among non-smoking fertile men and highest among smoking infertile men.

Prenatal smoking exposure was examined in a study of children's concurrent blood Pb levels and prevalence of attention-deficit/hyperactivity disorder (ADHD) among children aged 8-15 years. An interaction was observed between children's current blood Pb levels and prenatal tobacco smoke exposure; those children with high Pb levels and prenatal tobacco smoke exposure had the highest odds of ADHD (Froehlich et al., 2009).

Overall, the studies have mixed findings on whether smoking modifies the relationship between Pb levels and health effects. Future studies of Pb-related health effects and current, former, and prenatal smoking exposures among various health endpoints will aid in determining changes in risk by this factor.

6.3.6 Race/Ethnicity

Based on the 2000 Census, 69.1% of the U.S. population is comprised of non-Hispanic whites. Approximately 12.1% of people reported their race/ethnicity as non-Hispanic black and 12.6% reported being Hispanic (SSDAN CensusScope, 2010b). Studies of multiple Pb-related health outcomes examined effect measure modification by race/ethnicity.

A study of adults from the NHANES III cohort examined the association between blood Pb levels and all-cause and cardiovascular mortality (Menke et al., 2006). Stratified analyses were conducted for non-Hispanic whites, non-Hispanic blacks, and Mexican Americans and no interaction for race/ethnicity was reported. Other studies have also used NHANES cohorts to study blood Pb levels and hypertension (Scinicariello et al., 2010; Muntner et al., 2005). While no association was observed between blood Pb and hypertension for non-Hispanic whites or Hispanics, a positive association was reported for non-Hispanic blacks in a study using the NHANES III cohort (Scinicariello et al., 2010). In another study, although none of the associations between blood Pb levels and hypertension were statistically significant, increased odds were observed among non-Hispanic blacks and Mexican Americans but not for non-Hispanic whites (Muntner et al., 2005).

A study of girls aged 8-18 years from the NHANES III cohort reported an inverse association between blood Pb levels and pubertal development among blacks and Mexican Americans (Selevan et al., 2003). For non-Hispanic whites, the associations were in the same direction but did not reach statistical significance. Of note, less than 3% of non-Hispanic whites had blood Pb levels over 5 µg/dL, whereas 11.6% and 12.8% of blacks and Mexican Americans, respectively, had blood Pb levels greater than 5 µg/dL.

A study linking educational testing data for 4th grade students in North Carolina reported declines in reading and mathematics scores with increasing levels of blood Pb (Miranda et al., 2007b). Although not quantitatively reported, a figure in the study depicted the association stratified by race, and the slopes appeared to be similar for white and black children.

Blood Pb and asthma incidence was examined for white and black children living in Michigan (Joseph et al., 2005). When utilizing separate referent groups for the two races, the only association is an increase among whites (although not statistically significant), but when restricting to the highest blood Pb levels, the association was no longer apparent. Whites with low blood Pb levels were used as the referent group for both races in additional analysis. Although the estimates were elevated for black children compared

to white children (including at the lowest blood Pb levels), the confidence intervals for the associations overlapped indicating a lack of a difference by race.

The results of these recent epidemiologic studies suggest that there may be race/ethnicity-related increased risk for some outcomes, although the overall understanding of potential effect measure modification by race/ethnicity is limited by the small number of studies. Additionally, these results may be confounded by other factors, such as socioeconomic status.

6.3.7 Socioeconomic Status

Based on the 2000 Census data, 12.4% of Americans live in poverty (poverty threshold for family of 4 was $17,463) (SSDAN CensusScope, 2010c). Ris et al. (2004) examined modification of the associations between early-life Pb levels and Learning/IQ among adolescents in the Cincinnati Lead Study. In models examining the association between Pb and Learning/IQ, the prenatal and 78-month blood Pb levels were associated with larger decrements in Learning/IQ in the lower two quintiles of socioeconomic status (SES) (measured based on family SES levels).

6.3.8 Body Mass Index

In the U.S. self-reported rates of obesity were 26.7% in 2009, up from 19.8% in 2000 (Sherry et al., 2010). The NHANES III cohort was utilized in a study of blood Pb levels and all-cause and cardiovascular mortality, which included assessment of the associations by obesity (Menke et al., 2006). Positive associations were observed among individuals within both categories of body mass index (BMI; normal [<25 kg/m^2] and overweight/obese [≥ 25 kg/m^2], determined using measured values of height and weight) but there was no difference in the association between the two categories. Using the Normative Aging Study data, an investigation of bone Pb levels and heart rate variability was performed and reported slight changes in the association based on the presence of metabolic syndrome; however, none of the changes resulted in associations that were statistically significant (Park et al., 2006). Overall, no modification by BMI or obesity was observed among recent epidemiologic studies.

6.3.9 Alcohol Consumption

There are a limited number of studies examining alcohol as a factor affecting Pb-related risk. A study using the Normative Aging Study cohort investigated whether the association between blood and bone Pb levels and renal function would be modified by an individual's alcohol consumption (Tsaih et al., 2004). No interaction with alcohol consumption was observed. However, a toxicological study reported that ethanol potentiated the effect of Pb exposure by decreasing renal total protein sulfhydryls (endogenous antioxidants) in rats. Pb and ethanol also decreased other endogenous renal antioxidants (glutathione and non-protein sulfhydryls) (Jurczuk et al., 2006).

6.3.10 Nutritional Factors

Different components of diet may affect the association between Pb concentrations and health outcomes. Recent epidemiologic and toxicological studies of specific mineral intakes/dietary components are detailed below.

6.3.10.1 Calcium

Using the Normative Aging Study cohort, researchers examined the association between Pb levels and hypertension, modified by calcium intake (Elmarsafawy et al., 2006). The associations between Pb levels (measured and modeled separately for blood, patella, and tibia) and hypertension did not differ based on dichotomized calcium intake (800 mg/day).

6.3.10.2 Iron

The 2006 Pb AQCD included studies that indicated individuals with iron-deficiency and malnourishment had greater inverse associations between Pb and cognition (U.S. EPA, 2006b). A recent epidemiologic study of pubertal development among girls observed inverse associations between blood Pb and inhibin B, but this association was modified by iron deficiency; girls with iron deficiency had a stronger inverse association between Pb and inhibin B than those who were iron sufficient (Gollenberg et al., 2010). Toxicological studies also reported that iron-deficient diets exacerbate or potentiate the effect of Pb. A study of pregnant rats given an iron-deficient diet and exposed to Pb through drinking water over GD6-GD14, had decreased litter size, more pups with reduced fetal weight and reduced crown-rump length, increased litter resorption, and a

higher damblood Pb level in the highest exposure groups (Singh et al., 1993; Saxena et al., 1991). Thus, in this model, iron deficiency makes rat dams more at risk for Pb-dependent embryo and fetotoxicity (Singh et al., 1993).

6.3.10.3 Folate

A study by Kordas et al. (2009) examined Pb levels and birth size among term births in Mexico City. The authors reported no interaction between maternal tibia Pb and folate levels.

6.3.10.4 Protein

No recent epidemiologic studies have evaluated protein intake as a factor affecting Pb-related health effects. However, a toxicological study demonstrated that differences in maternal protein intake levels could affect the extent of Pb-induced immunotoxicity among offspring (Chen et al., 2004).

6.3.11 Stress

A study of bone (tibia and patella) Pb levels and hypertension reported modification of the association by perceived stress levels (Peters et al., 2007). Among individuals with greater perceived stress levels, stronger associations between blood Pb levels and hypertension were present. Among the same study population, higher perceived stress was also reported to affect the association between blood Pb levels and cognitive function; the higher stress group showed a greater inverse association between Pb and cognitive function than those in the low stress group (Peters et al., 2008). In another study, the inverse association between tibia Pb levels and some measures of cognitive function were similarly strengthened by neighborhood psychosocial hazards (Glass et al., 2009).

Toxicological studies have demonstrated that early life exposure to Pb and maternal stress can result in toxicity related to multiple systems (Rossi-George et al., 2009; Cory-Slechta et al., 2008; Virgolini et al., 2008a; Virgolini et al., 2008b), including dysfunctional corticosterone responses (Rossi-George et al., 2009; Virgolini et al., 2008b). Additionally, toxicological studies have demonstrated that stressors to the immune system can also affect associations with Pb exposure. Chickens with low Pb exposure in ovo, with additional viral stressors, had increased immune cell mobilization

and trafficking dysfunction (Lee et al., 2002). Similarly, mice with neonatal Pb exposure, and an additional immune challenge, had a sickness behavior phenotype, likely driven by IL-6 production (Dyatlov and Lawrence, 2002).

Similar to studies of stress in animals, maternal self-esteem has also been shown to modify associations between blood Pb levels and health effects in children. Surkan et al. (2008) studied the association between children's blood Pb levels and Bayley's MDI and Psychomotor Development Index (PDI) among mother-child pairs. High maternal self-esteem was independently associated with higher MDI score and also appeared to attenuate the negative effects of the child's increased blood Pb levels on MDI and PDI scores. Greater decreases in MDI and PDI were associated with increased blood Pb levels among children whose mothers were in the lower quartiles of self-esteem. The investigators indicated that high maternal self-esteem may serve as a buffer against stress by improving mother-child interactions and care giving practices, and maternal self esteem may also be a surrogate of biological stress responses in the child.

Although examined in a limited number of studies, recent epidemiologic studies observed modification of the association between Pb and various nervous system health effects by stress-level. Increased risk of Pb-related health effects by stress is further supported by toxicological studies.

6.3.12 Cognitive Reserve

Cognitive reserve has been defined as "the maintenance of cognitive performance in spite of ongoing underlying brain pathology" (Bleecker et al., 2007b). A study of Pb smelter workers reported that an inverse association between lifetime weighted blood Pb levels and cognitive function was present among workers with low cognitive reserve (measured using a reading achievement test) but no association was present in workers with high cognitive reserve (Bleecker et al., 2007b). Inverse associations between lifetime-weighted blood Pb levels and motor functions existed among all workers regardless of cognitive reserve. No other recent epidemiologic studies were performed examining cognitive reserve as a factor affecting risk of Pb-related health outcomes.

6.3.13 Other Metal Exposure

The 2006 Pb AQCD reported that the majority of studies that examined other toxicants did so as confounders and not as effect measure modifiers (U.S. EPA, 2006b). Recent epidemiologic studies have begun to explore the possible interaction between Pb

exposure and co-exposures with other metals. These studies, as well as toxicological studies of these metals, are described below.

6.3.13.1 Cadmium

In a study of girls in the NHANES III cohort, inverse associations were observed between blood Pb and inhibin B concentrations (Gollenberg et al., 2010). These inverse associations were stronger among girls with high cadmium (Cd) and high Pb compared to those with high Pb and low Cd. Additionally, higher blood Pb and Cd levels together were positively associated with albuminuria and reduced estimated glomerular filtration rate, compared to those with the lowest levels of Pb and Cd (Navas-Acien et al., 2009).

Toxicological studies reported that in rats, the addition of Cd to Pb exposure reduced the histological signs of renal toxicity from each element alone; however, urinary excretion of porphyrins were increased, indicating that although measured tissue burdens of Pb were reduced, the biologically available fraction of Pb was actually increased (Wang and Fowler, 2008). In other studies, Cd synergistically exacerbated Pb-dependent renal mitochondrial dysfunction (Wang et al., 2009c).

Overall, epidemiologic and toxicological studies have reported increased risk of Pb-related health effects among those with high Cd levels as well; however, the number of studies examining both metals is small.

6.3.13.2 Arsenic

In a study of immune function among children living at varying distances from a Pb smelter in Mexico, higher levels of both Pb and arsenic (As) were associated with greater decreases in NO and greater increases in superoxide anion (Pineda-Zavaleta et al., 2004).

6.3.13.3 Manganese

Among children in South Korea taking part in a study of IQ, an interaction was reported between Pb and manganese (Mn) blood levels (Kim et al., 2009b). Compared to children with low blood Mn levels, those with high blood Mn levels had greater reductions in full scale IQ and verbal IQ associated with increased blood Pb levels. No effect measure modification by Mn was observed for the association between blood Pb levels and performance IQ. A study performed among children in Mexico City observed greater decreases in neurodevelopment with increases in blood levels of Pb and Mn at 12

months, compared to decreases in neurodevelopment observed for increased Pb levels with low levels of Mn (Claus Henn et al.). No interaction was observed between the two metals and neurodevelopment at 24 months.

6.4 Summary

Among children, the youngest age groups were observed to be most at risk of elevated blood Pb levels, with levels decreasing with increasing age of the children. Recent epidemiologic studies of infants/children detected increased risk of Pb-related health effects, and this was supported by toxicological studies. However, this is based on a limited number of epidemiologic studies, and more studies are needed for comparing various age groups and examining adolescents.

For adults, elevated Pb biomarkers were associated with increasing age. It is generally thought that these elevated levels are related to remobilization of stored Pb during bone loss. Studies of older adults had inconsistent findings for effect measure modification of Pb-related mortality but no difference was observed for other health effects. However, toxicological studies support the possibility of age-related differences in Pb-related health effects.

Some studies suggest that males at some ages have higher blood Pb levels than comparably aged females; this was supported by stratifying the total sample of NHANES subjects. Sex-based differences appeared to be prominent among the adolescent and adult age groups but were not observed among the youngest age groups (1-5 years and 6-11 years). Studies of effect measure modification of Pb and various health endpoints by sex were inconsistent, although it appears that there are some differences in associations for males and females. This is also observed in toxicological studies.

Regarding race and ethnicity, recent data suggest that the difference in blood Pb levels between black and white subjects is decreasing over time, but black subjects still tend to have higher Pb body burden and Pb exposures than white subjects. Similarly, the gap between SES groups with respect to Pb body burden appears to be diminishing, with Pb body burden being higher, but not appreciably higher, among lower income subjects. Studies of race/ethnicity as a factor affecting risk indicate that some modification of associations between Pb levels and health effects may be present. Compared to whites, non-white populations were observed to be more at risk of Pb-related health effects; however, this could be related to confounding by factors such as SES or differential exposure levels, which was noted in some of the epidemiologic studies. Although limited by the number of studies, individuals with lower SES appear to represent an at-risk population. A study of Pb and IQ reported greater inverse associations among those in the

lowest SES groups. Additionally, there is evidence associating proximity to areas with Pb sources, including urban areas with large industrial sources, with increased Pb body burden and risk of Pb exposure.

Various genes were examined as potentially modifying the associations between Pb and health effects. Epidemiologic and toxicological studies reported that ALAD variants may increase the risk of Pb-related health effects. Other genes examined that may also affect risk of Pb-related health effects were VDR, DRD4, GSTM1, TNF-α, eNOS, APOE, and HFE, although the number of studies examining effect measure modification by these genes was small.

Evidence for other factors (pre-existing diseases/conditions, smoking, BMI and/or obesity, alcohol consumption, nutritional factors, stress, cognitive reserve, and co-exposure with other metals) was limited regarding their effect on Pb-related health outcomes. Pre-existing diseases/conditions have the potential to affect the risk of Pb-related health effects. Recent epidemiologic studies did not support modification of associations between Pb and health endpoints by the prevalence of diabetes; however, past studies have found individuals with diabetes to be an at-risk population with regard to renal function. Hypertension was observed to be a factor affecting risk in both past and recent epidemiologic studies. Studies of Pb levels and both renal effects and heart rate variability demonstrated greater odds of the associations among hypertensive individuals compared to those that are normotensive. Epidemiologic studies also examined autism and atopy as potential factors affecting Pb-related health effects; differences were observed but few studies were available to examine these factors. Recent epidemiologic studies examining smoking as a factor potentially affecting risk reported mixed findings. It is possible that smoking modifies the effects of only some Pb-related health outcomes. BMI, alcohol consumption, and nutritional factors were also examined in recent epidemiologic and toxicological studies. Modification of associations between Pb and various health effects (mortality and heart rate variability) was not observed for BMI/obesity. Also, no modification was observed in an epidemiologic study of renal function examining alcohol consumption as a modifier, but a toxicological study supported the potential of alcohol to affect risk. Among nutritional factors, those with iron deficiencies were observed to be an at-risk population for Pb-related health effects in both epidemiologic and toxicological studies. Other nutritional factors, such as calcium, zinc, and protein intake, demonstrated the potential to modify associations between Pb and health effects in toxicological studies. Recent epidemiologic studies of these factors were either not performed or observed no effect modification. Folate was also examined in an epidemiologic study of birth size but no interaction was reported between Pb and folate. Stress was evaluated as a factor that potentially increases the risk of Pb-related health outcomes and although there were a small number of recent epidemiologic studies,

increased stress was observed to negatively impact the association between Pb and health endpoints. Toxicological studies supported this finding. An epidemiologic study evaluated cognitive reserve as a modifier of the associations between Pb and cognitive and motor functions. Cognitive reserve was an effect measure modifier for the association between Pb and cognitive function but not motor function. Finally, interactions between Pb and co-exposure with other metals were evaluated in recent epidemiologic and toxicological studies of health effects. High levels of other metals, such as Cd, As, and Mn, were observed to result in greater effects for the associations between Pb and various health endpoints.

CHAPTER 7 ECOLOGICAL EFFECTS OF LEAD

This chapter synthesizes and evaluates the most policy-relevant science to help form the foundation for the review of the secondary (welfare-based) NAAQS for Pb. The Clean Air Act definition of welfare effects includes, but is not limited to, effects on soils, water, wildlife, vegetation, visibility, weather, and climate, as well as effects on materials, economic values, and personal comfort and well-being. This chapter discusses the effects of Pb on ecosystem components and processes and is organized into four sections. The introduction (Section 7.1) presents the organizing principles of this chapter and several important general ecology concepts. Section 7.2 reviews the effects of Pb on terrestrial ecosystems; how soil biogeochemistry affects Pb bioavailability, biological effects of Pb exposure and subsequent vulnerability of particular ecosystems. A similar discussion of the effects of Pb on freshwater and saltwater ecosystems is presented in Section 7.3, including water-only exposures and sediment related effects. Both the terrestrial and aquatic sections conclude with a discussion of alterations in ecosystem service functions as a consequence of Pb deposition. Finally, an integrative synthesis of effects of Pb across biota and causal determinations for effects of Pb in both terrestrial and aquatic systems are presented in Section 7.4. Although terrestrial and aquatic ecosystems are considered separately in this chapter, the deposition of Pb to land and water and the subsequent flux of Pb through watersheds are interconnected by fate and transport processes discussed in Section 3.3. Areas not addressed here include literature related to ingestion of Pb shot or pellets and studies that examine human health-related endpoints which are described in other chapters of this document.

7.1 Introduction to Ecological Concepts

Metals, including Pb, occur naturally in the environment at measurable concentrations in soils, sediments, and water. Organisms have developed adaptive mechanisms for living with metals, some of which are required micronutrients (but not Pb). However, anthropogenic enrichment can result in concentrations that exceed the capacity of organisms to regulate internal concentrations, causing a toxic response and potentially death. Differences in environmental chemistry may enhance or inhibit uptake of metal from the environment, thus creating a spatial patchwork of environments that are at greater risk than other environments. Similarly, organisms vary in their degree of adaptation to, or tolerance of, the presence of metals. These fundamental principles of how metals interact with organisms and ecosystems are described in detail in EPA's Framework for Metals Risk Assessment (Fairbrother et al., 2007). This section introduces

critical concepts for understanding how Pb from atmospheric deposition may affect organisms, communities, and ecosystems. The sections that follow provide more detail for how aquatic and terrestrial ecosystems respond to Pb and how environmental chemistry interacts with organisms to affect exposure and uptake.

7.1.1 Ecosystem Scale, Function, and Structure

For this assessment, an ecosystem is defined as the interactive system formed from all living organisms (biota) and their abiotic (chemical and physical) environment within a given area (IPCC, 2007).The boundaries of what could be called an ecosystem are somewhat arbitrary, depending on the focus of interest or study. Thus, the extent of an ecosystem may range from very small spatial scales to, ultimately, the entire Earth (IPCC, 2007). Ecosystems cover a hierarchy of spatial scales and can comprise the entire globe, biomes at the continental scale, or small, well-circumscribed systems such as a small pond (U.S. EPA, 2008e). A pond may be a small but complex system with multiple trophic levels ranging from phytoplankton to several feeding guilds of fish plus fish-eating birds or mammals. A large lake, on the other hand, may be a very simple ecosystem, such as the Great Salt Lake in Utah that covers approximately 1,700 square miles but contains only bacteria, algae, diatoms, and two invertebrate species. All ecosystems, regardless of size or complexity, share the commonality of multiple interactions between biota and abiotic factors, and a reduction in entropy through energy flow from photosynthetic organisms to top predators. This includes both structural (e.g., soil type and food web trophic levels) and functional (e.g., energy flow, decomposition, nitrification) attributes. Changes are often considered undesirable if important structural or functional components of ecosystems are altered following pollutant exposure (U.S. EPA, 1998).

Ecosystems are most often defined by their structure, and are based on the number and type of species present. Structure may refer to a variety of measurements including the species richness, abundance, community composition and biodiversity as well as landscape attributes. Individual organisms of the same species are similar in appearance and genetics, and can interbreed and produce fertile offspring. Interbreeding groups of individual organisms within the same species form populations, and populations of different species form communities. The community composition may also define an ecosystem type, such as a pine forest or a tall grass prairie. Pollutants can affect the ecosystem structure at any of these levels of biological organization (Suter et al., 2005). Individual plants or animals may exhibit changes in metabolism, enzyme activities, hormone function, or overall growth rates or may suffer gross lesions, tumors, deformities, or other pathologies. Effects on the nervous system of animals may cause

behavioral changes that alter breeding behaviors or predator avoidance. However, effects on organisms must result in changes to their survival or reproductive output to have any effect on the population. Population level effects of pollutants include changes over time in abundance or density (number of individuals in a defined area), age or sex structure, and production or sustainable rates of harvest (Barnthouse, 2007). Community level attributes affected by pollutants include species richness and abundance (also known as biodiversity), dominance of one species over another, or size (area) of the community. Pollutants may affect communities in ways that are not observable in organisms or populations (Bartell, 2007), including: (1) effects resulting from interactions between species, such as altering predation rates or competitive advantage; (2) indirect effects, such as reducing or removing one species from the assemblage and allowing another to emerge (Petraitis and Latham, 1999); and (3) alterations in trophic structure.

Alternatively, ecosystems may be defined on a functional basis. "Function" refers to the suite of processes and interactions among the ecosystem components and their environment that involve nutrient and energy flow as well as other attributes including water dynamics and the flux of trace gases such as rates of photosynthesis, decomposition, nitrification, or carbon cycling. Pollutants may affect abiotic conditions (e.g., soil chemistry), which indirectly influences biotic structure and function (Bartell, 2007). Feedback loops or networks influence the stability of the system, and can be mathematically described through simplistic or complex process, or energy flow, models (Bartell, 2007). For example, the Comprehensive Aquatic Systems Model (CASM) is a bioenergetics-based multi compartment model that describes the daily production of biomass (carbon) by populations of aquatic plants and animals over an annual cycle (DeAngelis et al., 1989). CASM, originally designed to examine theoretical relationships between food web structure, nutrient cycling, and ecosystem stability, has since been adapted for risk assessments and has been applied to numerous lakes with a variety of pollutants (Bartell, 2007). Likewise, other theoretical ecosystem models are being modified for use in assessing ecological risks from pollutant exposures (Bartell, 2007).

Some ecosystems, and some aspects of particular ecosystems, are less vulnerable to long-term consequences of pollutant exposure. Other ecosystems may be profoundly altered if a single attribute is affected. Thus, spatial and temporal definitions of ecosystem structure and function become an essential factor in defining impacted ecosystem services and critical loads of particular pollutants, either as single pollutants or in combination with other stressors. Both ecosystem services (Section 7.1.2) and critical loads (Section 7.1.3) serve as benchmarks or measures of the impacts of pollutants on ecosystems.

7.1.2 Ecosystem Services

Ecosystem structure and function may be translated into ecosystem services (Daily, 1997). Ecosystem services are the benefits people obtain from ecosystems (UNEP, 2003). Ecosystem services are defined as the varied and numerous ways that ecosystems are important to human welfare and how they provide many goods and services that are of vital importance for the functioning of the biosphere. This concept has gained recent interest and support because it recognizes that ecosystems are valuable to humans, and are important in ways that are not generally appreciated (Daily, 1997). Ecosystem services also provide a context for assessing the collective effects of human actions on a broad range of the goods and services upon which humans rely.

In general, both ecosystem structure and function play essential roles in providing goods and services. Ecosystem processes provide diverse benefits including absorption and breakdown of pollutants, cycling of nutrients, binding of soil, degradation of organic waste, maintenance of a balance of gases in the air, regulation of radiation balance and climate, and fixation of solar energy (WRI, 2000; Daily, 1997; Westman, 1977). These ecological benefits, in turn, provide economic benefits and values to society (Costanza et al., 1997; Pimentel et al., 1997). Goods such as food crops, timber, livestock, fish and clean drinking water have market value. The values of ecosystem services such as flood control, wildlife habitat, cycling of nutrients and removal of air pollutants are more difficult to measure (Goulder and Kennedy, 1997).

Particular concern has developed within the past decade regarding the consequences of decreasing biological diversity (Tilman, 2000; Ayensu et al., 1999; Wall, 1999; Chapin et al., 1998; Hooper and Vitousek, 1997). Human activities that decrease biodiversity also alter the complexity and stability of ecosystems and change ecological processes. In response, ecosystem structure, composition and function can be affected (Daily and Ehrlich, 1999; Wall, 1999; Chapin et al., 1998; Levlin, 1998; Peterson et al., 1998; Tilman, 1996; Tilman and Downing, 1994; Pimm, 1984). Biodiversity is an important consideration at all levels of biological organization, including species, communities, populations, and ecosystems. Human-induced changes in biotic diversity and alterations in the structure and functioning of ecosystems are two of the most dramatic ecological trends of the past century (U.S. EPA, 2004; Vitousek et al., 1997).

Hassan (2005) identified four broad categories of ecosystem services:

- Supporting services are necessary for the production of all other ecosystem services. Some examples include biomass production, production of atmospheric O_2, soil formation and retention, nutrient cycling, water cycling and provisioning of habitat. Biodiversity is a supporting service in that it is

increasingly recognized to sustain many of the goods and services that humans enjoy from ecosystems. These supporting services provide a basis for an additional three higher-level categories of services.

- Provisioning services such as products (Gitay et al., 2001) i.e., food (including game meat, roots, seeds, nuts, and other fruit, spices, fodder), water, fiber (including wood, textiles) and medicinal and cosmetic products.
- Regulating services that are of paramount importance for human society such as (1) carbon sequestration, (2) climate and water regulation, (3) protection from natural hazards such as floods, avalanches, or rock-fall (4) water and air purification, and (5) disease and pest regulation.
- Cultural services that satisfy human spiritual and aesthetic appreciation of ecosystems and their components.

7.1.3 Critical Loads as an Organizing Principle for Ecological Effects of Atmospheric Deposition

A critical load is defined as, "a quantitative estimate of an exposure to one or more pollutants below which significant harmful effects on specified sensitive elements of the environment do not occur according to present knowledge" (Nilsson and Grennfelt, 1988). Critical loads are a powerful organizing principle for information that links atmospheric deposition with ecological impairment. They allow for heterogeneity in ecosystem sensitivity and exposure which often results in critical load values that vary by ecosystem (e.g., aquatic-water; aquatic-sediment; terrestrial), and differ by endpoint of concern. It is important to consider that critical loads are often calculated assuming steady state conditions (i.e., how much input is required to balance the rate of output), and there may be time required to reach the critical load (i.e., the lag time between onset of exposure and induction of measurable effects). The following types of information are required to calculate a critical load, each of which is discussed in more detail in the subsequent sections of this chapter:

- Ecosystem at risk;
- Receptors of concern (plants, animals, etc.);
- Endpoints of concern (organism, population or community responses, changes in ecosystem services or functions);
- Dose (concentration) - response relationships and threshold levels of effects;

- Bioavailability and bioaccumulation rates;
- Naturally occurring (background) Pb (or other metal) concentrations; and
- Biogeochemical modifiers of exposure.

There is no single "definitive" critical load for a pollutant, partly because critical load estimates reflect the current state-of-knowledge and policy priorities, and also because of local or regional differences among ecosystems (U.S. EPA, 2008e). Changes in scientific understanding may include, for example, expanded information about dose-response relationships, better understanding of bioavailability factors, and improved quantitative models for effects predictions. Changes in policy may include new mandates for resource protection, inclusion of perceived new threats that may exacerbate the effects of the pollutant of concern (e.g., climate change), and a better understanding of the value of ecosystem services.

7.1.4 Ecosystem Exposure, Lag Time and Re-entrainment of Historically Deposited Lead

Ecosystem exposure from atmospheric emissions of Pb depends upon the amount of Pb deposited per unit time. Ecosystem response will also depend upon the form in which the Pb is deposited, the areal extent of such deposition, and modifying factors that affect Pb bioavailability in soil, sediments, and water (e.g., pH, organic matter)(Sections 7.2.2. and 7.3.2). However, there is frequently a lag time between when metals are emitted and when an effect is seen, particularly in terrestrial ecosystems and, to a lesser extent, in aquatic sediments; water exposures result in more immediate system responses. This is because the buffering capacity of soils and sediments permits Pb to become sequestered into organic matter, making it less available for uptake by organisms. The lag time from start of emissions to achieving a critical load can be calculated as the time to reach steady state from the time when the Pb was initially added to the system. Excluding erosion processes, the time required to achieve 95% of steady state is about 4 half-lives ($t^{1/2}$)[1] (Smolders et al., 2007). Conversely, once emissions cease, the same amount of time is required to reduce metal concentrations to background levels.

Time to steady state for metals in soils is dependent upon rates of erosion, uptake by plants, and leaching or drainage from soils. Ignoring erosion, half-life of metals can be predicted (Smolders et al., 2007) for a soil as:

[1] Time required to reduce the initial concentration by 50% if metal input is zero.

$$t_{1/2} = \frac{0.69 \times d \times 10{,}000}{y \times TF + \frac{R}{\rho K d}}$$

Equation 7-1

where:

d is the soil depth in meters (m)

y is the annual crop yield (tons/ha·yr)

TF is the ratio of the metal concentration in plant to that in soil

R is the net drainage loss out of the soil depth of concern (m^3/ha·yr)

P is the bulk density of soil [kg(dry weight)/L]

Kd is the ratio of the metal concentration in soil to that in soil pore solution (L/kg)

Metals removed by crops (or plants in general) comprise a very small fraction of the total soil metal and can be ignored for the purpose of estimating time to steady state. Thus, equation 7-1 is simplified to:

$$t_{1/2} = \frac{0.69 \times d \times 10{,}000}{\frac{R}{\rho K d}}$$

Equation 7-2

and becomes a function of soil depth, the amount of rainfall, soil density, and soil properties that affect *Kd*. Pb has a relatively long time to steady state compared to other metals, as shown in Table 7-1.

Table 7-1 Comparison among several metals: Time to achieve 95% of steady state metal concentration in soil; example in a temperate system

Metal	Loading rate (g/ha/yr)	Kd (L/kg)	Time (yr)
Se	100	0.3	1.3
Cu	100	480[a]	1,860[a]
Cd	100	690[a]	2,670[a]
Pb	100	19,000[a]	73,300[a]
Cr	100	16,700[a]	64,400[a]

[a]Mean *Kd* (ratio of total metal concentrations in soils to that in soil pore water); and Time to achieve 95% of steady-state concentration in soil. (49 Dutch soils) (de Groot et al., 1998).

Note: Based on a soil depth of 23 cm, a rain infiltration rate of 3,000 m^3/ha·yr, and the assumption that background was zero at the start of loading.

Source: Smolders, Fairbrother et al. (2007)

In aquatic systems, $t^{1/2}$ for Pb in the water column depends on the ratio of the magnitudes of the fluxes coming from and going into the sediment, the ratio of the depths of the water column and sediment, and the sediment half-life. Sediment $t^{1/2}$ is dependent upon the particulate and dissolved fractions and is calculated as for soils (Equation 7-2).

Re-entrainment of Pb particles via windblown dust from surface soils or dry sediments may occur. Amount and distance of re-entrained particles and deposition rates are dependent upon wind velocity and frequency; size, density, shape, and roughness of the particle; soil or sediment moisture; and terrain features including openness (including amount of vegetation), aspect relative to wind direction, and surface roughness. Resuspension is defined in terms of a resuspension factor, K, with units of m^{-1}, or a resuspension rate (Λ), with units of sec^{-1} (Equation 7-3). The resuspension rate, Λ, is the fraction of a surface contaminant that is released per time and is defined by:

$$\boldsymbol{\Lambda} = \frac{\boldsymbol{R}}{\boldsymbol{C}}$$

Equation 7-3

where:

R is the upward resuspension flux ($\mu g/m^2/sec$)

C is the soil (or dry sediment) Pb concentration ($\mu g/m^2$)

Such emissions may have local impacts, but are not likely to have long-range effects, as particles generally remain low to the ground and are not lifted into the upper atmosphere. Although re-entrainment may alter the particle size distribution in a local area, it generally does not alter the bioavailable fraction, and deposited particles will be subject to the same biogeochemical forces affecting bioavailability. Therefore, exposure via re-

entrainment should be considered additive to exposure from atmospheric particulate deposition in terrestrial and aquatic ecosystems.

7.2 Terrestrial Ecosystem Effects

7.2.1 Introduction to Terrestrial Ecosystem Effects

Numerous studies of the effects of Pb on components of terrestrial systems were reviewed in the 1977 Pb AQCD, the 1986 Pb AQCD and the 2006 Pb AQCD. The focus of this ISA is on the effects of Pb on terrestrial organisms including plants, invertebrates and vertebrates, with particular focus on current ambient level. The most extensive survey of background soil Pb concentration in the contiguous U.S. was conducted between 1961 and 1976, and comprised 1,319 non-urban, undisturbed sampling locations, where 250 cm^3 of soil was collected at a depth of 20 cm (Shacklette and Boerngen, 1984). The lower detection limit was 10 mg Pb/kg, and 14% of the 1,319 samples were below it. The mean Pb concentration was 19.3 mg Pb/kg, the median 15 mg Pb/kg, and the 95th percentile 50 mg/kg. Sixteen locations had Pb concentrations between 100 and 700 mg Pb/kg. These results were in agreement with 3 previous surveys. When creating the Ecological Soil Screening Level (Eco-SSL) guidance document, the U.S. EPA (2007d, 2003b) augmented these data with observations from an additional 13 studies conducted between 1982 and 1997, most of them limited to one state. The resulting data were summarized using state means for each of the fifty states. Those state means ranged between 5 and 38.6 mg Pb/kg, with an overall national mean of 18.9 mg Pb/kg.

No new data on background concentrations of Pb in U.S. soils have been published since 2005. Data on levels of Pb in U.S. soils are reviewed in Section 3.6.1 and summarized in Table 2-1. The literature on terrestrial ecosystem effects of Pb, published since the 2006 Pb AQCD, is considered with brief summaries from the 1977 Pb AQCD, the 1986 Pb AQCD and the 2006 Pb AQCD where relevant. Section 7.2 is organized to consider uptake of Pb and effects at the species level, followed by community and ecosystem level effects. Soil biogeochemistry of Pb is reviewed in Section 7.2.2 Section 7.2.3 considers the bioavailability and uptake of Pb by plants, invertebrates, and vertebrates in terrestrial systems. Biological effects of Pb on terrestrial ecosystem components including plants and lichen, invertebrates, and vertebrates (Section 7.2.4) are followed by data on exposure and response of terrestrial species (Section 7.2.5). Effects of Pb at the ecosystem level of biological organization are discussed in Section 7.2.6 Section 7.2 concludes with a discussion of critical loads in terrestrial systems (Section 7.2.7), soil screening levels (Section 7.2.8), characterization of sensitivity and vulnerability of

ecosystem components (Section 7.2.9), and effects on ecosystem services (Section 7.2.10).

7.2.2 Soil Biogeochemistry and Chemical Effects

According to data presented in the 2006 Pb AQCD, the fraction of soil metal that is directly available to plants is the fraction found in soil pore water, even though the concentration of metals in pore water is small relative to bulk soil concentration. The amount of Pb dissolved in soil solution is controlled by at least six variables: (1) solubility equilibria; (2) adsorption-desorption relationship of total Pb with inorganic compounds (e.g., oxides of Al, Fe, Si, Mn; clay minerals); (3) adsorption-desorption reactions of dissolved Pb phases on soil organic matter; (4) pH; (5) cation exchange capacity (CEC); and (6) aging. Adsorption-desorption of Pb to soil solid phases is largely controlled by total metal loading. Therefore, areas with high Pb deposition will exhibit a lower fraction of total Pb partitioned to inorganic and organic matter. Decreasing soil pH, CEC, and organic matter have been strongly correlated to increases in the concentration of dissolved Pb species. Aging of metals in soils results in decreased amounts of labile metal as the Pb becomes incorporated into the soil solid phase (McLaughlin et al., 2010). Data from recent studies have further defined the impact of pH, CEC, organic matter (OM), and aging on Pb mobilization and subsequent bioavailability in soils.

7.2.2.1 pH, CEC and Salinity

Models of metal bioavailability calibrated from 500+ soil toxicity tests on plants, invertebrates, and microbial communities indicated that soil pH and CEC are the most important factors governing metal solubility and toxicity (Smolders et al., 2009). The variability of derived EC_{50} values was most closely associated with CEC. Smolders et al. (2007) determined that 12 to 18 months of artificial aging of soils amended with metal decreased the soluble metal fraction by approximately one order of magnitude. Miretzky et al. (2007) also showed that the concentration of mobile Pb was increased in acidic soils, and discovered that Pb adsorption to sandy loam clay was a function of weak electrostatic bonds with charged soil surfaces and was influenced by Fe and Mn oxide. Relatedly, lower soil pH in forest environments relative to adjacent agricultural land resulted in higher solubility, and the mobility of smelter-produced metals was found to be greater in forest than in agricultural lands (Douay et al., 2009). Further, decreasing the soil pH via simulated acid rain events increased naturally occurring Pb bioavailability in field tests (Hu et al., 2009b).

Salinity can also alter Pb mobility and bioavailability in soils. Application of $CaCl_2$, MgCl, or NaCl salts to field-collected soils containing 31 to 2,764 mg Pb/kg increased the proportion of mobile metal. As the strength of the salt application was increased from 0.006 to 0.3 M, the proportion of released Pb increased from less than 0.5% to over 2% for $CaCl_2$ and from less than 0.5% to over 1% for MgCl (Acosta et al.). However, the majority of salinity-induced effects occurred in soils containing less than 500 mg Pb/kg, and the proportion of released Pb decreased with increasing total soil Pb concentrations. In addition, the authors noted that Pb release from soils under increasing salinity was reduced at higher carbonate concentrations, indicating that the effect of soil salinity on Pb release is dependent on still other soil factors. A sequential extraction procedure was employed by Ettler et al. (2005) to determine the relative bioavailability of different Pb fractions present in soils collected from a mining and smelting area in the Czech Republic. Five Pb fraction categories were identified: (Fraction A) exchangeable, (Fraction B) acid extractable (bound to carbonates), (Fraction C) reducible (bound to Fe and Mn oxides), (Fraction D) oxidizable (complexed with organic carbon), and (Fraction E) residual (silicates). Tilled agricultural soils were found to have decreased Pb, likely as a result of repeated cultivation, with the majority of Pb represented as the reducible Fraction C. Pb concentration in undisturbed forest soils, however, was largely present as the exchangeable fraction (A), weakly bound to soil OM. However, the validity of associating sequentially extracted fractions with discrete geochemical components has not been definitively established, and as a consequence, the association between fractionation and bioavailability remains uncertain.

7.2.2.2 Organic Matter

Organic matter decreases bioavailability of Pb, but as it is turned over and broken down, pedogenic minerals become more important in Pb sequestration (Schroth et al., 2008). Shaheen and Tsadilas (2009) noted that soils with higher clay content, organic matter, total calcium carbonate equivalent, and total free sesquioxides also exhibited higher total Pb concentration, indicating that less Pb had been taken up by resident plant species. Huang et al. (2008) examined the re-mobilization potential of Pb in forest soils, and determined that mobilization of total Pb was strongly associated with dissolved organic matter (DOM). Groenenberg et al. (2010) used a non-ideal competitive adsorption Donnan model to explain the variability of organic matter binding affinity and uncertainties associated with metal speciation. They found that natural variations in fulvic acid binding properties were the most important variable in predicting Pb speciation. Guo et al. (2006b) determined that the -COOH and -OH groups associated with soil OM were important factors in Pb sequestration in soil, and Pb sorption was increased as pH was

raised from 2 to 8. Because organic content increased the Pb sequestration efficiency of soils, OM content had an inhibitory effect on Pb uptake by woodlouse species *Oniscus asellus* and *Porcellio scaber* (Gál et al., 2008). Vermeulen et al. (2009) demonstrated that invertebrate bioaccumulation of Pb from contaminated soils was dependent on pH and OM, but that other unidentified habitat-dependent factors also contributed. The relationship of bioaccumulation and soil concentration was modified by pH and OM, and also by habitat type. Kobler et al. (2010) showed that the migration of atmospherically deposited Pb in soil matrices was strongly influenced by soil type, indicating that certain soil types may retain Pb for longer periods of time than others. In soils characterized by well-drained substrate and limestone bedrock, Pb concentration decreased over time, likely as a result of water drainage and percolation. The authors contrasted this observation with reports of prolonged residence time in humic soils, particularly at the lower depths of the humus layer. They theorized that the most significant Pb migration route was transportation of particulate-bound Pb along with precipitation-related flow through large soil pores.

A number of recent laboratory studies have further defined the relationship of soil biogeochemical characteristics and Pb uptake by plants. Dayton et al. (2006) established significant negative correlations between log-transformed Pb content of lettuce plants (*Lactuca sativa*), soil organic content, and CEC, and similar negative relationships were also confirmed between soil pH and amorphous Fe and Al oxide content. As part of a metal partitioning study, Kalis et al. (2007) determined that not only did metal concentration in the soil solution decrease as pH increased, but pH-mediated metal adsorption at the root surface of *Lolium perenne* determined root Pb concentration, with concentration in the shoot correlated with root concentration. Interestingly, Kalis et al. (2007) and Lock et al. (2006) also observed that the influx of Pb in the water-soluble fraction had an impact on soil pH. In addition, 1 µM humic acid decreased root Pb concentration in *L. perenne* plants grown in 0.1 and 1 µM Pb solution, likely as a result of Pb complexation and sequestration with the added OM (Kalis et al., 2006). Ma et al. (2010) also reported that long-term agricultural cultivation can decrease the rate of Pb desorption in soil through a gradual OM-enrichment. Phosphorous soil amendments equivalent to 35 mg P/kg soil were observed to reduce the quantity of DPTA-extractable Pb from an average of 19 and 24 mg Pb/kg in unamended soils to 12 to 15 mg Pb/kg in P-amended soils. As a result, maize and soybean seedlings accumulated significantly less Pb: average concentrations in soybean shoot and root ranged from 4.4 to 5.2 mg Pb/kg with P addition (versus 9.21 mg Pb/kg without), while maize shoot concentrations average between 4.8 to 5.3 mg Pb/kg in P-amended soils (as compared with 10.16 mg Pb/kg in controls) (Xie et al., 2011).

7.2.2.3 Aging

Smolders et al. (2007) defined aging as the process responsible for decreasing the bioavailability of metals in soils independently of their persistence. Smolders et al. (2009) reviewed the effects of aging of Pb in soils on the toxicity of Pb to plants and soil invertebrates, with aging achieved in most studies primarily by leaching amended soil, but also through natural binding and complexation. In nearly half of the Pb soil studies reviewed, responses that were observed with freshly amended soil could no longer be detected following soil leaching, indicating that aged soils likely contain less bioavailable Pb. The authors concluded that competitive binding between soil ligands and biotic ligands on plant roots or invertebrate guts can be used to model the relationship of observed availability and toxicity of metals in soils. Because this concept is the basis of the Biotic Ligand Model (BLM) (Section 7.2.3), the authors proposed a terrestrial BLM approach to estimate the risk of metals to terrestrial organisms. However, Antunes et al. (2006) noted that there were several key challenges involved in development of a terrestrial BLM applicable to plants, particularly the reliable measurement of free ion activities and ligand concentration in the rhizosphere, the identification of the organisms' ligands associated with toxicity, and the possible need to incorporate kinetic dissolution of metal-ligand complexes as sources of free ion. Further, Pb in aged field soils has been observed to be less available for uptake into terrestrial organisms, likely as a result of increased sequestration within the soil particles (Antunes et al., 2006). Magrisso et al. (2009) used a bioluminescent strain of the bacterium *Cupriavidus metallidurans* to detect and quantify Pb bioavailability in soils collected adjacent to industrial and highway areas in Jerusalem, Israel, and in individual simulated soil components freshly spiked with Pb. The bacterium was genetically engineered to give off the bioluminescent reaction as a dose-dependent response, and was inoculated in soil slurries for three hours prior to response evaluation. Spiked soil components induced the bioluminescent response, and field-collected components did not. However, the comparability of the simulated soils and their Pb concentration with the field-collected samples was not entirely clear. Lock et al. (2006) compared the Pb toxicity to springtails (*Folsomia candida*) from both laboratory-spiked soils and field-collected Pb-contaminated soils of similar Pb concentrations. Total Pb concentrations of 3,877 mg Pb/kg dry weight and higher always caused significant effects on *F. candida* reproduction in the spiked soils. In field soils, only the soil with the highest Pb concentration of 14,436 mg Pb/kg dry weight significantly affected reproduction. When expressed as soil pore-water concentrations, reproduction was never significantly affected at Pb concentrations of 0.5 mg Pb/L, whereas reproduction was always significantly affected at Pb concentrations of 0.7 mg Pb/L and higher, independent of the soil treatment. Leaching soils prior to use in bioassays had only a slight effect on Pb toxicity to resident springtails, suggesting that

among the processes that constitute aging of Pb in field soils, leaching is not particularly important with respect to bioavailability.

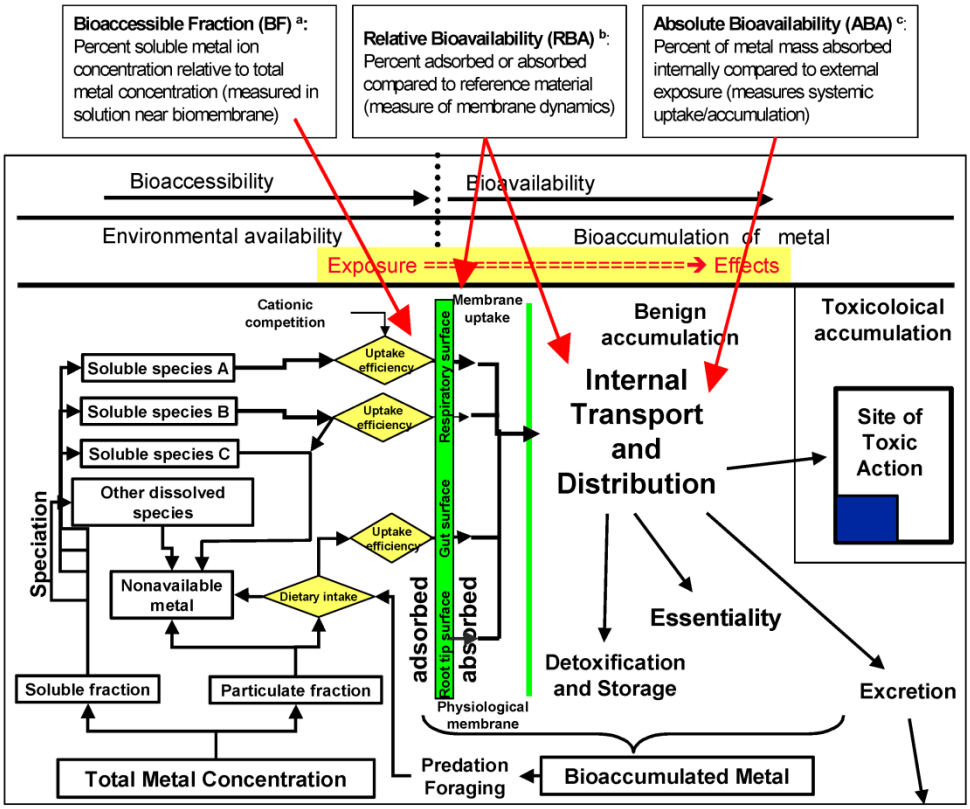
Red-backed salamanders (*Plethodon cinereus*) exposed to Pb-amended soils (553 mg Pb/kg, 1,700 mg Pb/kg, 4,700 mg Pb/kg, and 9,167 mg Pb/kg) exhibited lowered appetite and decreased white blood cell counts at the two highest concentrations, as compared to controls (Bazar et al., 2010). However, salamanders tolerated field-collected, aged soils containing Pb concentration of up to 16,967 mg Pb/kg with no significant deleterious effects.

In summary, studies published during the past 5 years continue to substantiate the important role that soil geochemistry plays in sequestration or release of Pb. Soil pH and CEC have long been known to be the primary controlling factors of the amount of bioavailable Pb in soils, and a recent review of more than 500 studies corroborates these findings (Smolders et al., 2009). Fe and Mn oxides are now known to also play an important role in Pb sequestration in soils. Pb binds to OM, although relatively weakly, and as the OM is broken down the Pb may be released into soil solution. Leaching of metal through soil pores may be the primary route for loss of bioavailable soil Pb; OM may reduce leaching and thus appear to be associated with Pb sequestration. Aging of Pb in soils through incorporation of the metal into the particulate solid phase of the soil results in long term binding of the metal and reduced bioavailability of Pb to plants and soil organisms.

7.2.3 Bioavailability in Terrestrial Systems

Bioavailability was defined in the 2006 Pb AQCD as "the proportion of a toxin that passes a physiological membrane (the plasma membrane in plants or the gut wall in animals) and reaches a target receptor (cytosol or blood)" (U.S. EPA, 2006c). In 2007, EPA took cases of bioactive adsorption into consideration and revised the definition of bioavailability as "the extent to which bioaccessible metals absorb onto, or into, and across biological membranes of organisms, expressed as a fraction of the total amount of metal the organism is proximately exposed to (at the sorption surface) during a given time and under defined conditions" (Fairbrother et al., 2007). The bioavailability of metals varies widely depending on the physical, chemical, and biological conditions under which an organism is exposed (U.S. EPA, 2007c). Characteristics of the toxicant itself that affect bioavailability are: (1) chemical form or species, (2) particle size, (3) lability, and (4) source. The bioavailability of a metal is also dependent upon the bioaccessible fraction of metal. As stated in the Framework for Metals Risk Assessment (U.S. EPA, 2007c), the bioaccessible fraction of a metal is the portion (fraction or

percentage) of environmentally available metal that actually interacts at the organism's contact surface and is potentially available for absorption or adsorption by the organism. The Framework states that "the bioaccessibility, bioavailability, and bioaccumulation properties of inorganic metals in soil, sediments, and aquatic systems are interrelated and abiotic (e.g., organic carbon) and biotic (e.g., uptake and metabolism). Modifying factors determine the amount of an inorganic metal that interacts at biological surfaces (e.g., at the gill, gut, or root tip epithelium) and that binds to and is absorbed across these membranes. A major challenge is to consistently and accurately measure quantitative differences in bioavailability between multiple forms of organic metals in the environment." A conceptual diagram presented in McGeer et al. (2004) and the Framework for Metals Risk Assessment summarizes metals bioavailability and bioaccumulation in aquatic, sediment and soil media (Figure 7-1).



[a]BF is most often measured using in vitro methods (e.g., artificial stomach), but it should be validated by in vivo methods.
[b]RBA is most often estimated as the relative absorption factor, compared to a reference metal salt (usually calculated on the basis of dose and often used for human risk, but it can be based on concentrations).
[c]ABA is more difficult to measure and used less in human risk; it is often used in ecological risk when estimating bioaccumulation or trophic transfer.
Source: ERG (2004) and U.S. EPA (2007c).

Figure 7-1 Conceptual diagram for evaluating bioavailability processes and bioaccessibility for metals in soil, sediment, or aquatic systems.

The BLM attempts to integrate the principal physical and chemical variables that influence Pb bioavailability. The model considers the reactions of Pb with biological surfaces and membranes (the site of action) to predict the bioavailability and uptake of the metal (Figure 7-2), and integrates the binding affinities of various natural ligands and the biological uptake rates of organisms to predict both the bioaccessible and bioavailable fraction of Pb in the environment, and to determine the site-specific toxicity of the bioavailable fraction. In principle, the BLM can be used for determining toxicity in water, sediment, and soil media, however, the parameter values that influence BLM are, in general, characterized to a greater extent in aquatic systems than in terrestrial systems (Section 7.3.4).

Figure 7-2 Schematic diagram of the biotic ligand model.

New information on sources of Pb in terrestrial ecosystems, and their influence on subsequent bioavailability, was reviewed in Chapter 3, while new information on the influence of soil biogeochemistry on speciation and chemical lability was presented in Section 7.2.2. This section summarizes new literature on uptake and subsequent presence of Pb in tissues. The 2006 Pb AQCD extensively reviewed the methods available for quantitative determination of the mobility, distribution, uptake, and fluxes of atmospherically delivered Pb in ecosystems, and they are not reviewed in this section. The 2006 Pb AQCD also reported bioaccumulation factors (BAF) and bioconcentration factors (BCF) for some terrestrial and aquatic biota. BAF is defined as the field measurement of metal concentration in tissues, including dietary exposures, divided by metal concentration in environmental media (Smolders et al., 2007). BCF is defined as the same measurement carried out in artificial media in the laboratory that does not include dietary exposure (Smolders et al., 2007). The EPA Framework for Metals Risk Assessment states that the latest scientific data on bioaccumulation do not currently support the use of BCFs and BAFs when applied as generic threshold criteria for the hazard potential of metals (U.S. EPA, 2007c).

7.2.3.1 Terrestrial Plants

At the time of the 1977 Pb AQCD, it was understood that Pb uptake in plants was influenced by plant species and by the available Pb pool in the soils (U.S. EPA, 1977). The role of humic substances in binding Pb was better characterized by the 1986 Pb

AQCD where it was stated that most plants cannot survive in soil containing 10,000 µg/g (mg Pb/kg) dry weight if the pH is below 4.5 and the organic content is below 5% (U.S. EPA, 1986b). Pb can be absorbed across the leaf surface into internal plant tissues although the vast majority of uptake is via roots (U.S. EPA, 1986b). The 2006 Pb AQCD noted that terrestrial plants accumulate atmospheric Pb primarily via two routes: direct stomatal uptake into foliage, and incorporation of atmospherically deposited Pb from soil into root tissue, followed by variable translocation to other tissues. Foliar Pb may include both incorporated Pb (i.e., from atmospheric gases or particles) and surficial particulate Pb deposition. Although the plant may eventually absorb the surficial component, its main importance is its likely contribution to the exposure of plant consumers. This section will first review recent studies on uptake of Pb by plants through foliar and soil routes, and their relative contribution, followed by the consideration of translocation of Pb from roots to shoots, including a discussion of variability in translocation among species. Data on ambient Pb levels associated with vegetation are summarized in Section 3.6.6.

Leaf and Root Uptake

Although Pb is not an essential metal, it is taken up from soils through the symplastic route, the same active ion transport mechanism used by plants to take up water and nutrients and move them across root cell membranes (U.S. EPA, 2006c). As with all nutrients, only the proportion of a metal present in soil pore water is directly available for uptake by plants. In addition, soil-to-plant transfer factors in soils enriched with Pb have been found to better correlate with bioavailable Pb soil concentration, defined as DTPA-extractable Pb, than with total Pb concentration (U.S. EPA, 2006c).

Field studies carried out in the vicinity of Pb smelters have determined the relative importance of direct foliar uptake and root uptake of atmospheric Pb deposited in soils. Hu and Ding (2009) analyzed ratios of Pb isotopes in the shoots of commonly grown vegetables and in soil at three distances from a point source (0.1, 0.2, 5.0 km). Pb isotope ratios in plants and soil were different at two of those locations, leading the authors to the conclusion that airborne Pb was being assimilated via direct leaf uptake. Soil Pb concentration in the rhizosphere at the three sites ranged between 287 and 379 mg Pb/kg (Site I), 155 and 159 mg Pb/kg (Site II), and 58 and 79 mg Pb/kg (Site III, selected as the control site). The median shoot and root Pb concentrations at each site were 36 and 47 mg Pb/kg, 176 and 97 mg Pb/kg, and 1.3 and 7 mg Pb/kg, respectively, resulting in shoot:root Pb ratios exceeding 1.0 in Site I (for Malabar spinach [*Basella alba]*, ratio = 1.6, and amaranth [*Amaranthus spinosus]*, ratio = 1.1), and in Site II (for the weeds *Taraxacum mongolicum*, ratio = 1.9, and *Rostellaria procumbens*, ratio = 1.7). However, the two species studied at Site II were not studied at Site I or Site III. In the

control site (Site III), no plant was found with a Pb shoot:root ratio greater than 1.0. Hu and Ding (2009) concluded that metal accumulation was greater in shoot than in root tissue, which suggested both high atmospheric Pb concentration and direct stomatal uptake into the shoot tissue.

Cui et al. (2007) studied seven weed species growing in the vicinity of an old smelter (average soil Pb concentration of 4,020 mg Pb/kg) in Liaoning, China, to measure Pb accumulation rates in roots and shoots. Cutleaf groundcherry (*Physalis angulata*) accumulated the most Pb, with root and shoot concentration of 527 and 331 mg Pb/kg, respectively, and velvetleaf (*Abutilon theophrasti*) was the poorest absorber of Pb (root and shoot concentration of 39 and 61 mg Pb/kg, respectively). In all cases, weed species near the smelter accumulated more Pb than plants from non-polluted environments (5 mg Pb/kg), indicating that aerially deposited Pb produced by smelting is bioavailable to plants. However, the ratio of root:shoot Pb concentration varied by species, and the authors presented no data to differentiate Pb taken up from soil from Pb incorporated via foliar uptake. Angelova et al. (2010) examined Pb uptake by rapeseed plants (*Brassica napus*) grown in heavy metal contaminated soils 0.5 km and 15 km from the Non-Ferrous Metal Works, in Bulgaria. Average surface soil Pb concentration decreased with distance from the plant (200.3 and 24.6 mg Pb/kg, respectively), as did average DTPA-extractable Pb (69.7 and 4.9 mg Pb/kg, respectively). Pb content in stems and leaves in rapeseed grown at 0.5 km from the plant averaged 1.73 and 8.69 mg Pb/kg ; average stem and leaf Pb concentrations in rapeseed grown at the more distant location were reported as 0.72 and 1.42 mg Pb/kg, respectively (Angelova et al., 2010).

Pb plant BAFs for plants grown in 70 actively cropped fields in California averaged 0.052 for vegetable crops and 0.084 for grains; the highest reported Pb BAF (0.577) was found in onions. Authors compared the BAFs based on total Pb and Pb in solution and determined that both were accurate predictors of plant uptake (Chen et al., 2009b). Likewise, Zhang et al. (2011) compiled Pb uptake data for several crop species in China, and reported an average BAF for grains (rice) of 0.009 (0.0009-0.03) and 0.41(0.0007-0.17) for leafy vegetables, such as spinach, Chinese cabbage and celery (Zhang et al., 2011). Chrastny et al. (2010) characterized the Pb contamination of an agricultural soil in the vicinity of a shooting range. Pb was predominantly in the form of PbO and $PbCO_3$, and Pb was taken up by plants through both atmospheric deposition onto the plant and by root uptake.

The Pb content of ripe date palm (*Phoenix dactylifera*) fruit collected in Riyadh, Saudi Arabia was determined to be indicative of areas of heavy industrialization and urbanization; Pb concentrations in fruit flesh ranged from 0.34 to 8.87 µg Pb/g dry weight, with the highest Pb date concentrations detected near freeways and industrial

areas (Aldjain et al., 2011). Likewise, Pb concentrations in rosemary (*Rosmarinus officinalis*) flowers, stems, and leaves were significantly higher in the urban areas of Al-Mafraq and Irbid, Jordan than in the smaller town of Ma'an, Jordan (53.6 to 86.5 mg Pb/kg versus 16.2 to 16.7 mg Pb/kg). Authors noted a significant difference between Pb concentrations in washed and unwashed rosemary samples, indicating that aerial deposition and surface dust is likely a significant source of plant-associated lead (El-Rjoob et al., 2008).

Bilberry (*Vaccinium myrtillus*), accumulated the highest amount of Pb out of four total herbaceous species growing in Slovakian spruce ecosystems with variable soil lead concentrations, giving BAFs of 0.09 to 0.44, depending on location (Kuklova et al., 2010). Because of their long life spans, trees can provide essential information regarding the sources of bioavailable Pb. A Scots pine forest in northern Sweden was found to incorporate atmospherically derived Pb pollution directly from ambient air, accumulating this Pb in bark, needles, and shoots (Klaminder et al., 2005). Nearly 50% of total tree uptake was estimated to be from direct adsorption from the atmosphere, as determined using isotopic ratios and a binary mixing model. Further, Aznar et al. (2009b) found that the Pb content of black spruce (*Picea mariana*) needles collected along a metal contamination gradient emanating from a Canadian smelter in Murdochville, Quebec, showed a significant decrease in Pb concentration with increasing distance from the smelter. Interestingly, older needles were determined to accumulate larger quantities of Pb than younger ones. Foliar damage and growth reduction were also observed in the trees (Aznar et al., 2009b). They were significantly correlated with Pb concentration in the litter layer. In addition, there was no correlation between diminished tree growth and Pb concentration in the deeper mineral soil layers, strongly suggesting that only current atmospheric Pb was affecting trees (Aznar et al., 2009a). Similarly, Kuang et al. (2007) noted that the Pb concentration in the inner bark of *Pinus massoniana* trees growing adjacent to a Pb-Zn smelter in the Guangdong province of China was much higher (1.87 mg Pb/kg dry weight) than in reference-area trees. Because concentration in the inner bark was strongly correlated with concentration in the outer bark, they concluded that the origin of the Pb was atmospheric.

Dendrochronology (tree ring analysis) has become an increasingly important tool for measuring the response of trees to Pb exposure (Watmough, 1999). Tree ring studies reviewed in the 1977 Pb AQCD showed that trees could be used as indicators of increasing environmental Pb concentrations with time. Additional studies in the 1986 Pb AQCD indicated that Pb could be translocated from roots to the upper portions of the plant and that the amounts translocated are in proportion to concentrations of Pb in soil (U.S. EPA, 1986b). The advent of laser ablation inductively coupled plasma mass spectrometry has made measurement of Pb concentration in individual tree rings possible

(Witte et al., 2004; Watmough, 1999). This allows for close analysis of the timing of Pb uptake relative to smelter activity and/or changes in soil chemistry. For example, Aznar et al. (2008b) measured Pb concentration in black spruce tree rings to determine the extent and timing of atmospheric deposition near the Murdochville smelter. Variability in tree-ring Pb content seemed to indicate that trees accumulated and sequestered atmospheric Pb in close correlation with the rates of smelter emission, but that sequestration lagged about 15 years behind exposure. However, the ability to determine time of uptake from the location in growth rings is weakened in species that transfer Pb readily from outer bark to inner bark. Cutter and Guyette (1993) identified species with minimal radial translocation from among a large number of tree species, and recommended the following temperate zone North American species as suitable for metal dendrochronology studies: white oak (*Quercus alba*), post oak (*Q. stellata*), eastern red cedar (*Juniperus virginiana*), old-growth Douglas fir (*Pseudotsuga menziesii*), and big sagebrush (*Artemisia tridentata*). In addition, species such as bristlecone pine (*Pinus aristata*), old-growth redwood (*Sequoia sempervirens*), and giant sequoia (*S. gigantea*) were deemed suitable for local purposes. Patrick and Farmer (2006) determined that European sycamore (*Acer pseudoplatanus*) are not suitable for this type of dendrochronological analysis because of the formation of multiple annual rings.

Pb in sapwood and heartwood is more likely a result of soil uptake than of direct atmospheric exposure (Guyette et al., 1991). Differentiation of geogenic soil Pb in tree tissue from Pb that originated in the atmosphere requires measurement of stable Pb isotope ratios (Patrick, 2006). Tree bark samples collected from several areas of the Czech Republic were subjected to stable Pb isotope analysis to determine the source and uptake of atmospheric Pb (Conkova and Kubiznakova, 2008). Results indicated that beech bark is a more efficient accumulator of atmospheric Pb than spruce bark. A decrease in the $^{206}Pb/^{207}Pb$ ratio was measured in bark and attributed to increased usage of leaded gasoline between 1955 and 1990; an increased $^{206}Pb/^{207}Pb$ ratio was ascribed to coal combustion (Conkova and Kubiznakova, 2008). Similarly, Savard et al. (2006) compared isotope ratios of $^{206}Pb/^{207}Pb$ and $^{208}Pb/^{206}Pb$ in tree rings from spruce trees sampled at a control site near Hudson Bay, with those sampled near the Horne smelter active since 1928, in Rouyn-Noranda, Canada. The concentration of total Pb showed a major increase in 1944 and a corresponding decrease of the $^{206}Pb/^{207}Pb$ ratios, suggesting that the smelter was responsible for the increased Pb uptake (Savard et al., 2006). The authors suggested that the apparent delay of 14 years may have been attributable to the residence time of metals in airborne particles the buffering effect of the soils and, to a lesser extent, mobility of heavy metals in tree stems. Furthermore, through the use of the two different isotope ratios, Savard et al. (2006) were able to differentiate three types of Pb in tree rings: natural (derived from the mineral soil horizons), industrial (from coal

burning urban pollution), and mining (typical of the volcanogenic massive sulfide ore deposits treated at the Horne smelter).

Devall et al. (2006) measured Pb uptake by bald-cypress trees (*Taxodium distichum*) growing in a swamp near a petroleum refinery and along a bank containing Pb-contaminated dredge spoils. They measured Pb in tree cores and showed greater uptake of Pb by trees in the swamp than by trees growing on the dredge spoil bank, attributing the difference to exposure source (refinery versus dredge spoils) and differences in soil chemistry between the swamp and the dredge spoil bank (Devall et al., 2006). Similarly, Gebologlu et al. (2005) found no correlation between proximity to roadway and accumulated Pb in tomato and bean plants at sites adjacent to two state roads in Turkey (average Pb concentration 5.4 and 6.0 mg Pb/kg), indicating that uptake may be influenced by multiple factors, including wind direction, geography, and soil chemistry. Average Pb levels in leaves were 0.6 and 0.5 mg Pb/kg for tomato and bean plants, respectively, while fruit concentration averaged 0.4 mg Pb/kg for both species. Conversely, if foliar contamination is due primarily to dust deposition, distance from a source such as a road may be easily correlated with Pb concentration on the plants. For example, Ai-Khlaifat and Al-Khashman (2007) collected unwashed date palm (*Phoenix dactylifera*) leaves at 3-meter trunk height from trees in Jordan to assess the extent of Pb contamination from the city of Aqaba. Whereas relatively low levels of Pb were detected in leaves collected at background sites (41 mg Pb/kg), leaves collected adjacent to highway sites exhibited the highest levels of Pb (177 mg Pb/kg). The authors determined that Pb levels in date palm leaves correlated with industrial and human activities (e.g., traffic density) (Ai-Khlaifat and Al-Khashman, 2007). Likewise, Pb concentrations were significantly enriched in tree bark samples and road dust collected in highly urbanized areas of Buenos Aires, Argentina (approximate average enrichment factors of 30 and 15 versus reference samples) (Fujiwara et al., 2011). However, decreases in tissue Pb concentration with increasing distance from point sources can also follow from decreasing Pb in soil. Bindler et al. (2008) used Pb isotopes to assess the relative importance of pollutant Pb versus natural Pb for plant uptake and cycling in Swedish forested soils. The Pb isotopic composition of needles/leaves and stemwood of different tree species and ground-cover plants indicated that the majority of Pb present in these plant components was derived from the atmosphere, either through aerial interception or actual uptake through the roots. For the ground-cover plants and the needles/leaves, the $^{206}Pb/^{207}Pb$ isotopic ratios (1.12 to 1.20) showed that the majority of Pb was of anthropogenic origin. Stemwood and roots have higher $^{206}Pb/^{207}Pb$ ratio values (1.12 to 1.30) which showed the incorporation of some natural Pb as well as anthropogenic Pb. For pine trees, the isotopic ratio decreased between the roots and the apical stemwood suggesting that much of the uptake of Pb by trees is via aerial exposure. Overall, it was estimated that 60-80% of the Pb in boreal forest vegetation originated from pollution; the

Pb concentrations were, however, quite low – not higher than 1 mg Pb/kg plant material, and usually in the range of 0.01-0.1 mg Pb/kg plant material (while soils had a range of 5 to 10 mg Pb/kg in the mineral horizons and 50 to 150 mg Pb/kg in the O horizons). Overall, the forest vegetation recycles very little of the Pb present in soils (and thus does not play a direct role in the Pb biogeochemical cycle in boreal forest soils).

Fungal species, as represented by mushrooms, accumulate Pb from soils to varying degrees. Based on the uptake of naturally occurring ^{210}Pb, Guillen et al. (2009) established that soil-associated Pb was bioavailable for uptake by mushrooms, and that the highest ^{210}Pb accumulation was observed in *Fomes fomentarius* mushrooms, followed by *Lycoperdon perlatum*, *Boletus aereus*, and *Macrolepiota procera*, indicating some species differences. Benbrahim et al. (2006) also showed species differences in uptake of Pb by wild edible mushrooms, although they found no significant correlations between Pb content of mushrooms and soil Pb concentration. Pb concentrations in mushroom carpophores ranged from 0.4 to 2.7 mg Pb/kg from sites with soil concentrations ranging from 3.6 and 7.6 mg Pb/kg dry soil. Likewise, Semreen and Aboul-Enein (2011), reported the heavy metal uptake of wild edible mushrooms collected in various mountainous regions of Jordan. Pb BCFs ranged between 0.05 *(Russula delica*) and 0.33 (*Bovista plumbea)* for six mushroom species. Pb BAFs for edible mushrooms collected from quartzite acidic soils in central Spain (containing 19.2 mg Pb/kg) ranged from 0.07 (*Macrolepiota procera*) to 0.45 (*Lepista nuda*) (Campos and Tejera, 2011).

Translocation and Sequestration of Lead in Plants

In the 1977 Pb AQCD it was recognized that most Pb taken up from soil remains in the roots and that distribution to other portions of the plant is variable among species (U.S. EPA, 1977). The 2006 Pb AQCD stated that most of the Pb absorbed from soil remains bound in plant root tissues either because (1) Pb may be deposited within root cell wall material, or (2) Pb may be sequestered within root cell organelles. Sequestration of Pb may be a protective mechanism for the plant. Recent findings have been consistent with this hypothesis: Han et al. (2008) observed Pb deposits in the cell walls and cytoplasm of malformed cells of *Iris lactea* exposed to 0 to 10 mM Pb for 28 days. They hypothesized that preferential sequestration of Pb in a few cells, which results in damage to those cells, helps in maintaining normal overall plant activities through the sacrifice of a small number of active cells. Similarly, macroscopic analysis of the roots of broad bean (*Vicia faba*) cultivated in mine tailings (average Pb concentration of 7,772 mg Pb/kg) by Probst et al. (2009) revealed dark ultrastructural abnormalities that were demonstrated to be metal-rich particles located in or on root cell walls. It is unclear whether the presence of these structures had any effect on overall plant health.

Clark et al. (2006) investigated Pb bioavailability in garden soils in Roxbury and Dorchester, MA. The sources of Pb were considered to be Pb from paints and from leaded gasoline additives, with 40 to 80% coming from paint. The average Pb concentration in foliar tissue of bean plants was 14 ± 5 mg Pb/kg while the concentration in the bean pod was only 20.6 mg Pb/kg. For mustard plants, there was a linear relationship (R^2=0.85) between Pb concentration in plant tissues and Pb concentration in the soil (both for plants grown in situ and those grown under greenhouse conditions).

Murray et al. (2009) investigated the uptake and accumulation of Pb in several vegetable species (carrot [*Daucus carota*], radish [*Raphanus sativus*], lettuce [*Lactuca sativa*], soybean [*Glycine max*], and wheat [*Triticum aestivum*]) from metal-contaminated soils, containing 10 to 40 mg Pb/kg and demonstrated that most Pb remained in the roots. No Pb was measured in the above-ground edible soybean and wheat tissues, while carrots, the most efficient accumulator of Pb, contained a maximum Pb tissue concentration of 12 mg Pb/kg dry mass. Similarly, (Cho et al., 2009) showed that green onion (*Allium fistulosum*) plants also take up little Pb when planted in soil spiked with Pb nitrate. No plant tissues contained a Pb concentration greater than 24 mg Pb/kg when grown for 14 weeks in soils of up to 3,560 mg Pb/kg, and the majority of bioavailable Pb was determined to be contained within the roots. Chinese spinach (*Amaranthus dubius*) also translocates very little Pb to stem and leaf tissue, and uptake from Pb-containing soils (28 to 52 mg Pb/kg) is minimal (Mellem et al., 2009). Wang et al. (2011c) determined tissue-specific BCFs for wheat grown in soils containing 93 to 1,548 mg Pb/kg. Although the average calculated root BCF was 0.3, very little Pb was translocated to shoots (average BCF=0.02), shells (0.006), and kernels (0.0007) (Wang et al., 2011c). Sonmez et al. (2008) reported that Pb accumulated by three weed species (*Avena sterilis*, *Isatis tinctoria*, *Xanthium strumarium*) grown in Pb-spiked soils was largely concentrated in the root tissues, and little was translocated to the shoots (Sonmez et al., 2008).

The Pb BCFs for alfalfa (*Medicago sativa*) and crimson clover (*Trifolium incarnatum*) grown in mixtures of heavy metals (Pb concentrations of 10 to 500 µg Pb/kg) were reportedly low. For alfalfa, BCFs ranged from 0.02 to 0.12, while for crimson clover, these values were between 0.04 and 0.06 (Comino et al., 2011). The low shoot-root translocation factors reported for alfalfa (0.17 to 0.43) indicated that plant Pb content was largely contained in root tissue. Businelli et al. (2011) calculated whole-plant Pb BAFs for lettuce, radish, tomato and Italian ryegrass using Pb-spiked soils (average values of 0.025, 0.021, 0.032, and 0.65, respectively). Again, the majority of accumulated Pb was stored in root tissue, with comparatively little translocated to above-ground tissues (Businelli et al., 2011).

Recent research has shown that Pb translocation to stem and leaf tissues does occur at significant rates in some species, including the legume *Sesbania drummondii* (Peralta-Videa et al., 2009) and buckwheat (*Fagopyrum esculentum*) (Tamura et al., 2005). Wang et al. (2006b) noted that Pb soil-to-plant transfer factors were higher for leafy vegetables (Chinese cabbage, pak-choi, and water spinach) than for the non-leafy vegetables tested (towel gourd, eggplant, and cowpea). Tamura et al. (2005) demonstrated that buckwheat is an efficient translocator of Pb. Buckwheat grown in Pb-containing soils collected from a shooting range site (average 1M HCl extractable Pb= 6,643 mg Pb/kg) preferentially accumulated Pb in leaves (8,000 mg Pb/kg) and shoots (4,200 mg Pb/kg), over root tissues (3,300 mg Pb/kg). Although plant growth was unaffected, this level of leaf and shoot accumulation is likely to have significant implications for exposure of herbivores. Similarly, Shaheen and Tsadilas (2009) reported that vegetables (pepper, okra, and eggplant) grown in soils containing 24 to 30 mg Pb/kg total Pb were more likely to accumulate Pb in leaves (range: undetected to 25 mg Pb/kg) rather than in fruits (range: undetected to 19 mg Pb/kg); however, no significant correlation between soil Pb concentration and plant tissue Pb concentration could be established (Shaheen and Tsadilas, 2009). Tobacco plants were also observed to take up significant amounts of Pb into leaf tissue. Field-grown plants in soils containing an average of 19.8 mg Pb/kg contained average lower, middle and upper leaf Pb concentrations of 11.9, 13.3, and 11.6 mg Pb/kg respectively (Zaprjanova et al., 2010). Uptake by tobacco plants was correlated with both total soil Pb concentrations and the mobile Pb fraction (average 3.8 mg Pb/kg soil).

There is broad variability in uptake and translocation among plant species, and interspecies variability has been shown to interact with other factors such as soil type. By studying multiple species in four Pb-Zn mining sites in Yunnan, China, Li et al. (2009d) demonstrated not only significant differences in uptake and translocation among the species studied, but also modification of the effect on species by type of soil. Plants sampled represented nine species from four families—Caryophyllaceae, Compositae, Cruciferae, and Pteridaceae. Overall, soil Pb concentration averaged 3,772 mg Pb/kg dry weight, with the highest site average measured at the Minbingying site (5,330 mg Pb/kg), followed by Paomaping (2,409 mg Pb/kg), Jinding (1,786 mg Pb/kg), and Qilinkeng (978 mg Pb/kg). The highest average shoot Pb concentration (3,142 mg Pb/kg) was detected in *Stellaria vestita* (Caryophyllaceae) collected at Paomaping, while *Sinopteris grevilloides* (Pteridaceae) collected from Minbingying exhibited the lowest shoot Pb concentration (69 mg Pb/kg). A similar trend was detected in root tissues. *S. vestita* root collected from the Paomaping area contained the maximum Pb concentration measured (7,457 mg Pb/kg), while the minimum root Pb levels were measured in *Picris hieraciodides* (Pteridaceae) tissues collected from Jinding. These results indicate significant interspecies differences in Pb uptake, as well as potential soil-specific

differences in Pb bioavailability. *S. vestita*, in particular, was determined to be an efficient accumulator of Pb, with a maximum enrichment coefficient of 1.3. Significant correlations between soil Pb concentration and average shoot and root Pb levels were also established (Li et al., 2009d). Within plant species, the variability in uptake and translocation of Pb may extend to the varietal level. Antonious and Kochhar (2009) determined uptake of soil-associated Pb for 23 unique genotypes from four species of pepper plants (*Capsicum chinense*, *C. frutescens*, *C. baccatum*, and *C. annum*). Soil Pb concentration averaged approximately 0.6 mg Pb/kg dry soil. No Pb was detected in the fruits of any of the 23 genotypes, except two out of seven genotypes of *C. baccatum*, which had 0.9 and 0.8 mg Pb/kg dry weight Pb in fruit.

Recent studies substantiated findings from the 2006 Pb AQCD that plants store a large portion of Pb in root tissue. Pb soil-to-plant transfer factors are higher for leafy vegetables than for the non-leafy vegetables (Wang et al., 2006b) and buckwheat has recently been shown to be an efficient translocator of Pb from soil to above-ground shoots (Tamura et al., 2005).

Field studies carried out in the vicinity of Pb smelters (Hu et al., 2009b) show that Pb may accumulate in shoot tissue through direct stomatal uptake rather than by soil-root-shoot translocation. For instance, Hovmand and Johnsen (2009) determined that about 98% of Pb sequestered in Norway spruce needles and twigs was derived from atmospheric sources, and that less than 2% of Pb was translocated from the roots (Hovmand et al., 2009). Dendrochronology has become more advanced in recent years and is a useful tool for monitoring historical uptake of Pb into trees exposed to atmospheric or soil Pb. Trees accumulate and sequester atmospheric Pb in close correlation with the rate of smelter emissions, although one study indicated that sequestration can lag behind exposure from emissions by 15 years. Pb in the outer woody portion of the tree is more likely the result of direct atmospheric exposure, while Pb in sapwood is more likely a result of soil uptake. This difference provides an important tool for analyzing source apportionment of Pb accumulation in plants (Guyette et al., 1991).

7.2.3.2 Terrestrial Invertebrates

At the time of publication of the 2006 Pb AQCD, little information was available regarding the uptake of atmospheric Pb pollution (direct or deposited) by terrestrial invertebrate species. Consequently, few conclusions could be drawn concerning the Pb uptake rate of particular species although there was some evidence that dietary or habitat preferences may influence exposure and uptake. Recent literature indicates that invertebrates can accumulate Pb from consuming a Pb-contaminated diet and from

exposure via soil, and that uptake and bioaccumulation of Pb by invertebrates is lower than that observed for other metals.

Snails

Pauget et al. (2011) reported that uptake of Pb from soil by the land snail (*Cantareus asperses*) was most significantly influenced by soil pH and organic matter, as increases in these variables were correlated to decreased Pb bioavailability. *Cantareus asperses* snails exposed to dietary Pb at 3.3, 86, and 154 mg/kg of diet (spiked with Pb sulfate) for up to 64 days were found to assimilate a significant proportion of Pb, and feeding rates were unaffected by the presence of the metal (Beeby and Richmond, 2010). While BCFs for Cd were observed to increase over the 64-day study period, the rate of Pb assimilation remained consistent over time and the authors inferred the absence of a regulatory mechanism for uptake of Pb. The authors speculated that uptake is a function of growth or cell turnover instead. *Helix aspersa* snails rapidly accumulated Pb from contaminated soil (1,212 mg Pb/kg) and from eating contaminated lettuce (approximately 90 mg Pb/kg after 16 weeks' growth on Pb-contaminated soil) during the first 2 weeks of exposure, at which point snail body burdens reached a plateau (Scheifler et al., 2006b). There were no observed effects of Pb exposure or accumulation on survival or growth in *C. asperses* or *H. aspersa*. In another study (Ebenso and Ologhobo, 2009b), juvenile *Achatina achatina* snails confined in cages on former Pb-battery waste dump sites were found to accumulate Pb from both plant and soil sources. Soil Pb concentration averaged 20, 200, and 1,200 mg Pb/kg at the three main waste sites, while leaf tissues of radish (*Raphanus sativus*) grown at these sites averaged 7, 30, and 68 mg Pb/kg dry weight, respectively. Concentration of Pb in snail tissues rose with concentration in both soil and plants, and the authors found that for both sources, a log-log relationship could be estimated with a very close fit (r^2 =0.94 and 0.95, respectively). Pb concentration in snail tissues averaged 12, 91, and 468 mg Pb/kg, respectively, at the three sites, which the authors stipulated were above the maximum permissible concentration of Pb for human consumption of mollusks, mussels, and clams (1.5 µg Pb/g tissue) as determined by the U.K. Food Standards Agency. Pb concentration in snail tissues generally is much lower than that of the soil substrates upon which they were reared, but higher than in other soil-dwelling organisms. De Vaufleury et al. (2006) exposed *Helix aspera* snails to standardized (International Organization for Standardization methodology [ISO 11267:1999]) artificial-substrate soils containing 13, 26, 39, or 52 mg Pb/kg for 28 days without supplemental food. After the exposure period, snail foot tissue contained increased levels of Pb—1.9, 1.7, and 1.5 µg Pb/g dry weight versus concentration averaging 0.4 mg Pb/kg in control organisms. Viscera also exhibited increased Pb levels at the two highest exposures, with measured tissue concentration of 1.2 and 1.1 mg Pb/kg, respectively, as

compared with control tissue Pb levels of 0.4 mg Pb/kg. However, there was no significant increase in snail-tissue Pb concentration when natural soil was used in place of ISO medium, and there was no relationship between soil Pb concentration and snail tissue concentration, strongly suggesting the presence of soil variables that modify bioavailability. Notten et al. (2008) investigated the origin of Pb pollution in soil, plants, and snails by means of Pb isotope ratios. They found that a substantial proportion of Pb in both plants and snails was from current atmospheric exposure.

Finally, a study by Coeurdassier et al. (2007) found that the presence of snails was associated with higher Pb content in earthworms, suggesting that snails themselves may have an effect on bioavailability.

Earthworms

Accumulation studies conducted with *Eisenia* sp. earthworms documented the difficulty of extrapolating accumulation kinetic constants from one soil type to another, and showed that many soil physiochemical properties, including pH, organic matter, and CEC, among others, affect metal bioavailability (Nahmani et al., 2009). Source of Pb, and proportion of soil:leaf litter also affect Pb bioavailability. Bradham et al. (2006) examined the effect of soil chemical and physical properties on Pb bioavailability. *Eisenia andrei* earthworms were exposed to 21 soils with varying physical properties that were freshly spiked with Pb to give a standard concentration of 2,000 mg Pb/kg dry weight. Both internal earthworm Pb concentration and mortality rates increased with decreasing pH and CEC although the apparent role of CEC may only have been due to its correlation with other soil characteristics. These data corroborate that Pb bioavailability and toxicity are increased in acidic soils and in soils with a low CEC (Section 7.2.2). This finding was confirmed by Gandois et al. (2010), who determined that the free-metal-ion fraction of total Pb concentration in field-collected soils was largely predicted by pH and soil iron content.

The role of soil profile and preferred depth was studied using eight species of earthworms from 27 locations in Switzerland, representing three ecophysiological groups (Ernst et al., 2008): epigeic (surface-dwelling worms), endogeic (laterally burrowing worms that inhabit the upper soil layers), and anecic (vertically burrowing worms that reach depths of 6 inches). For epigeic and anecic earthworms, the total concentration of Pb in leaf litter and in soil, respectively, were the most important drivers of Pb body burdens. By contrast, the level of Pb in endogeic earthworms was largely determined by soil pH and CEC. As a result of these differences, the authors suggested that atmosphere-sourced Pb may be more bioavailable to epigeic than endogeic species, because it is less dependent on modifying factors. Suthar et al. (2008), on the other hand, found higher Pb

bioaccumulation in the endogeic earthworm *Metaphire posthuma* than in the anecic earthworm species *Lampito mauritii*, and speculated that differences in Pb tissue level arose from differing life-history strategies, such as feeding behaviors, niche preferences, and burrowing patterns, all of which exposed the endogeic species to greater Pb concentration. Garg et al. (2009) reported that the smaller native earthworm *Allolobophora parva* accumulated significantly greater Pb concentrations than *E. fetida*. Subsequently, it was concluded that native earthworm species may exhibit a higher Pb accumulation potential as a result of increased tolerance to the heavy metal (Garg et al., 2009).

Earthworm activity can alter Pb bioavailability and subsequent uptake by earthworms themselves and other organisms. Sizmur and Hodson (2009) speculated that earthworms affect Pb mobility by modifying the availability of cations or anions. The concentration of water-soluble Pb was observed to increase following earthworm (*Lumbricus terrestris*) feeding activity in field-collected soils containing 132.7, 814.9, and 821.4 mg total Pb/kg (calculated BAFs of 0.27, 0.33, and 0.13, respectively) (Alonso-Azcarate et al., 2011). However, Coeurdassier et al. (2007) found that snails did not have a higher Pb content when earthworms were present, and that unexpectedly, Pb was higher in earthworm tissue when snails were present.

Despite significant Pb uptake by earthworms, Pb in earthworm tissue may not be bioavailable to predators. Pb in the earthworm (*Aporrectodea caliginosa*) was determined to be contained largely in the granular fraction (approximately 60% of total Pb), while the remaining Pb body burden was in the tissue, cell membrane, and intact cell fractions (Vijver et al., 2006). However, this may vary by species, as (Li et al., 2008b) found that more than half of the Pb accumulated by *E. fetida* was contained within earthworm tissue and cell membranes. Regardless, Vijver et al. (2006) concluded that only a minority of earthworm-absorbed Pb would be toxicologically available to cause effects in the earthworms or in their predators.

Arthropods

Pb and other metals were analyzed in honeybees (*Apis mellifera*) foraging in sampling sites that included both urban areas and wildlife reserves in central Italy. (Perugini et al., 2011). Pb in whole bees ranged from 0.28 to 0.52 mg Pb/kg with the highest concentration in honeybees caught in hives near an airport. Cicadas pupating in historically Pb-arsenate-treated soils accumulated Pb at concentrations similar to those reported previously for earthworms (Robinson et al., 2007). Likewise, tissue Pb levels measured in Coleoptera specimens collected from areas containing average soil concentration of 45 and 71 mg Pb/kg exhibited a positive relationship with soil Pb

content, although abundance was unaffected (Schipper et al., 2008). By contrast, two grasshopper species inhabiting Pb and Cd-contaminated areas near zinc smelting facilities exhibited different Pb accumulation rates. Locust (*Locusta migratoria*) collected from areas with an average Pb soil concentration of 540mg Pb/kg contained 47 mg Pb/kg, while grasshoppers (*Acrida chinensis*) inhabiting the same area accumulated 93.9 mg Pb/kg (Zhang et al., In Press). This gives respective BAFs of 0.09 and 0.17. Similarly, the Pb sequestration rates that were observed in two woodlouse species, *O. asellus* and *P. scaber*, were species-dependent (Gál et al., 2008). Both species were field collected at Pb-contaminated sites (average concentration, 245 mg Pb/kg dry weight; range, 21-638 mg Pb/kg dry weight), with *O. asellus* Pb levels averaging 43 mg Pb/kg over all sites, while *P. scaber* contained no detectable Pb residues. Pb concentration measured in granivorous rough harvester ants (*Pogonomyrmex rugosus*), in the seeds of some plant species they consume, and in surface soil, were all shown to decline with increasing distance from a former Pb smelter near El Paso, Texas, where soil leachable Pb at the three sites of ant collection ranged from 0.003 to 0.117 mg Pb/kg (Del Toro et al., 2010). Ants accumulated approximately twice as much Pb as was measured in seeds, but the study did not separate the effects of dietary exposure from those of direct contact with soil or respiratory intake.

7.2.3.3 Terrestrial Vertebrates

At the time of the 1977 Pb AQCD few studies of Pb exposure and effects in wild animals other than birds had been conducted. A limited number of rodent trapping studies near roadsides indicated general trends of species differences in Pb uptake and higher concentrations of Pb in habitats adjacent to high-traffic areas (U.S. EPA, 1977). In the 1986 Pb AQCD concentration of Pb in bone tissue was reported for selected herbivore, omnivore and carnivore species [Table 8-2 in (U.S. EPA, 1986b)].

Tissue Pb residues in birds and mammals associated with adverse toxicological effects were presented in the 2006 Pb AQCD. In general, avian blood, liver, and kidney Pb concentrations of 0.2-3 µg Pb/dL, 2-6 mg Pb/kg wet weight, and 2-20 mg Pb/kg wet weight, respectively, were linked to adverse effects. A few additional studies of Pb uptake and tissue residues in birds and mammals conducted since 2006 are reviewed here.

In a study of blood Pb levels in wild Steller's eiders (*Polysticta stelleri*) and black scoters (*Melanitta nigra*) in Alaska, the authors compiled avian blood Pb data from available literature to develop reference values for sea ducks (Brown et al., 2006). The background exposure reference value of blood Pb was <20 µg Pb/dL, with levels between 20 and

59 µg Pb/dL as indicative of Pb exposure. Clinical toxicity was in the range of 60-99 µg Pb/dL in birds while >100 µg Pb/dL results in acute, severe toxicity. In measurement of blood Pb with a portable blood Pb analyzer, only 3% of birds had values indicating exposure and none of the birds had higher blood Pb levels or clinical signs of toxicity. Tissue distribution of Pb in liver, kidney, ovary and testes of rain quail (*Coturnix coramandelica*) following oral dosing of 0.5 mg Pb/kg, 1.25 mg Pb/kg or 2.5 mg Pb/kg Pb-acetate for 21 days indicated that Pb uptake was highest in liver and kidney and low in ovary and testes (Mehrotra et al., 2008). Resident feral pigeons (*Columba livia*) captured in the urban and industrial areas of Korea exhibited increased lung Pb concentration, ranging from 1.6 to 1.9 mg Pb/kg wet weight (Nam and Lee, 2006). However, tissue concentration did not correlate with atmospheric Pb concentration, so the authors concluded that ingestion of particulate Pb (paint chips, cement, etc.) in the urban and industrial areas was responsible for the pigeons' body burden. Similarly, 70% of American woodcock (*Scolopax minor*) chicks and 43% of American woodcock young-of-year collected in Wisconsin, U.S., exhibited high bone Pb levels of 9.6-93 mg Pb/kg dry weight and 1.5-220 mg Pb/kg, respectively, even though radiographs of birds' gastrointestinal tracts revealed no evidence of shot ingestion (Strom et al., 2005). Authors hypothesized that unidentified anthropogenic sources may have caused the observed elevated Pb levels.

In addition to birds, soil-dwelling mammals can also bioaccumulate atmospherically-sourced Pb. Northern pocket gophers (*Thomomys talpoides*) trapped within the Anaconda Smelter Superfund Site were shown to accumulate atmospherically deposited Pb. Gopher liver and carcass Pb concentration averaged 0.3 and 0.4 mg Pb/kg wet weight on low Pb soils (47 mg Pb/kg), 0.4 and 0.9 mg Pb/kg wet weight in medium Pb soils (95 mg Pb/kg) and 1.6 and 3.8 mg Pb/kg wet weight in high Pb soils (776.5 mg Pb/kg) (Reynolds et al., 2006). Likewise, rats trapped in the vicinity of a Kabwe, Zambia Pb-Zn mine had significantly elevated liver and kidney Pb concentrations. Soil Pb concentrations were measured between 9 and 51,188 mg Pb/kg (approximate average of 200 mg Pb/kg dry weight), while rat liver and kidney Pb concentrations ranged between 0.009 and 7.3 mg Pb/kg dry weight and 0.3 and 22.1 mg Pb/kg dry weight, respectively. Consequently, residence in the mining region was correlated to significantly increased Pb body burdens for rats (Nakayama et al., 2011). Angelova et al. (2010) reared rabbits on a fodder mixture containing lead-contaminated rapeseed grown adjacent to a metal works plant. Following a four week exposure, Pb was most heavily concentrated in rabbit kidney tissue (3.9 mg Pb/kg and 1.9 mg Pb/kg, for high and low diet respectively), bone (1.0 and 0.3 mg Pb/kg, respectively), and liver (0.6 and 0.4 mg Pb/kg, respectively). Yucatan micropigs (*Sus scrofa*) and Sprague-Dawley rats (*Rattus norvegicus*) reared on Pb-contaminated soil (5% of 1,000 µg Pb/g soil as dietary component) consumed significantly different amounts of Pb. Over a 30-day period, rats consumed an average of

19.4 mg Pb, while micropig intake averaged 948 mg Pb (Smith et al., 2009a). This resulted in significantly higher Pb accumulation in micropigs, based on liver, blood, kidney and bone Pb concentrations (average concentrations of 1.2, 25, 0.9, and 9 µg Pb/g for micropigs, and 0.2, 7, 0.5, and 1.5 µg Pb/g for rats, respectively).

Casteel et al. (2006) found that bioavailability of Pb from environmental soil samples in swine (*Sus domestica*) depended on Pb form or type, with high absorption of cerussite and manganese-Pb oxides and poor absorption of galena and anglesite. Juvenile swine (approximately 5-6 weeks old and weighing 8-11 kg) were fed Pb-contaminated soils collected from multiple sources for 15 days (concentration range of 1,270 to 14,200 mg Pb/kg) to determine the relative bioavailability. While Pb concentrations were roughly equivalent in blood, liver, kidney, and bone tissues, individual swine exhibited different uptake abilities (Casteel et al., 2006).

Consistent with observations in humans, dietary Ca deficiency (0.45 mg Ca daily versus 4 mg under normal conditions) was linked to increased accumulation of Pb in zebra finches (*Taeniopygia guttata*) that were provided with drinking water containing 20 mg Pb/L (Dauwe et al., 2006). Liver and bone Pb concentration were increased by an approximate factor of three, while Pb concentration in kidney, muscle, and brain tissues were roughly doubled by a Ca-deficient diet. However, it is not known whether this level of dietary Ca deficiency is common in wild populations of birds.

7.2.3.4 Food Web

In addition to the organism-level factors reviewed above, understanding the bioavailability of Pb along a simple food chain is essential for determining risk to terrestrial animals. While the bioavailability of ingested soil or particles is relatively simple to measure and model, the bioavailability to secondary consumers of Pb ingested and sequestered by primary producers and primary consumers is more complex. Kaufman et al. (2007) caution that the use of total Pb concentration in risk assessments can result in overestimation of risk to ecological receptors, and they suggest that the bioaccessible fraction may provide a more realistic approximation of receptor exposure and effects. This section reviews recent literature that estimates the bioaccessible fraction of Pb in dietary items of higher order consumers, and various studies suggesting that Pb may be transferred through the food chain but that trophic transfer of Pb results in gradual attenuation, i.e., lower concentration at each successive trophic level.

Earthworm and plant vegetative tissue collected from a rifle and pistol range that contained average soil Pb concentration of 5,044 mg Pb/kg were analyzed for Pb content and used to model secondary bioavailability to mammals (Kaufman et al., 2007).

Earthworms were determined to contain an average of 727 mg Pb/kg, and the Pb content of unwashed leaf tissues averaged 2,945 mg Pb/kg. Canonical correspondence analysis detected no relationship between earthworm and soil Pb concentration, but did show correlation between unwashed vegetation and soil concentration. The authors noted that the relatively high Pb concentration of unwashed as opposed to washed vegetation indicated the potential importance of aerial deposition (or dust resuspension) in determining total vegetative Pb concentration. Based on the mammalian gastric model, they noted that 50% of vegetation tissue Pb and 77% of earthworm tissue Pb was expected to be bioavailable to consumers. The avian gizzard model indicated that 53% of soil Pb and 73% of earthworm Pb was bioaccessible to birds, and, for both mammals and birds, the bioaccessible fraction of Pb was a function of total Pb concentration.

The transfer of Pb from soils contaminated by a Pb-Zn mine was limited along a soil-plant-insect-chicken food chain (Zhuang et al., 2009). In soils averaging 991 mg Pb/kg, plants of the fodder plant *Rumex patientia X tianschanicus* sequestered an average of 1.6 mg Pb/kg wet weight in the shoot tissue, while larvae of the leafworm *Spodoptera litura* accumulated an average Pb concentration of 3.3 mg Pb/kg wet weight *S. litura*-fed chickens (*Gallus gallus domesticus*) accumulated 0.58 mg Pb/kg and 3.6 mg Pb/kg in muscle and liver tissue, respectively, but only liver Pb burden was increased significantly relative to controls. A large proportion of ingested Pb was excreted with the feces. Likewise, an insectivorous bird species, the black-tailed godwit (*Limosa limosa*) was shown to accumulate Pb from earthworms residing in Pb-contaminated soils (Roodbergen et al., 2008). Pb concentration in eggs and feathers was increased in areas with high soil and earthworm Pb concentration (336 and 34 mg Pb/kg, respectively): egg Pb concentration averaged 0.17 mg Pb/kg and feather concentration averaged 2.8 mg Pb/kg. This suggests that despite a residence breeding time of only a few months, this bird species could accumulate Pb when breeding areas are contaminated.

Rogival et al. (2007) showed significant positive correlations between soil Pb concentration along a gradient (approximately 50 to 275 mg Pb/kg) at a metallurgical plant, and Pb concentration in both acorns (from *Quercus robur*) and earthworms (primarily *Dendrodrilus rubidus* and *Lumbricus rubellus*) collected on site. Acorn and earthworm Pb contents were, in turn, positively correlated with the Pb concentration in the liver, kidney, and bone tissues of locally trapped wood mice (*Apodemus sylvaticus*).

The uptake and transfer of Pb from soil to native plants and to red deer (*Cervus elaphus*) was investigated in mining areas of the Sierra Madrona Mountains in Spain (Reglero et al., 2008). The authors reported a clear pattern between plant Pb concentration and the Pb content of red deer tissues with attenuation (i.e., decreasing concentration) of Pb up the food chain. Interestingly, soil geochemistry likely was affected by mining activity as

holm oak (*Quercus ilex*), gum rockrose (*Cistus ladanifer*), elm leaf blackberry (*Rubus ulmifolius*), and grass (Graminae) tissues collected from mining areas exhibited increased Pb levels (up to 98 mg Pb/kg in grasses and 21 mg Pb/kg in oak) despite the fact that total soil Pb concentrations were not significantly greater than those of the non-mining areas.

Positive relationships were observed between *Cepaea nemoralis* snail tissue Pb levels and Pb concentration measured in *Urtica dioica* leaves in field-collected samples from areas characterized by metal soil contamination (approximately 200 to 400 mg Pb/kg) (Notten et al., 2005). Inouye et al. (2007) found that several invertebrate prey of fence lizards, including *Acheta domestica* crickets, *Tenebrio molitor* beetles, and *P. scaber* isopods, accumulate Pb from dietary exposures (10, 50, 100, 250, 500, 750, and 1,000 mg Pb/kg) lasting between 44 and 72 days. By day 44, Pb body burdens of crickets were 31, 50 and 68 mg Pb/kg (wet weight) at the three highest dietary exposures, respectively. Isopods and beetle larvae accumulated significantly less Pb, with average body burdens of 10, 15, and 14 mg Pb/kg following 56 days of exposure, and 12, 14, and 31 mg Pb/kg following 77 days of exposure, respectively. For all invertebrates tested, Pb was sequestered partly in the exoskeleton, and partly in granules. Exoskeleton Pb may be available to predators, but returns to background level with each shedding, while granular Pb is likely unavailable, at least to other invertebrates (Vijver et al., 2004).

Overall, studies of Pb transfer in food webs have established the existence of pervasive trophic transfer of the metal, but no consistent evidence of trophic magnification. It appears that on the contrary, attenuation is common as Pb is transferred to higher trophic levels. However, many individual transfer steps, as from particular plants to particular invertebrates, result in concentration, which may then be undone when stepping to the next trophic level. It is possible that whether trophic transfer is magnifying or attenuating depends on Pb concentration itself. Kaufman et al. (2007) determined that, at low concentrations of soil Pb, risk to secondary consumers (birds and mammals) was driven by the bioavailability of Pb in worm tissues, while at high soil concentrations, bioavailability of soil-associated Pb was more critical. The authors concluded that incorporation of bioavailability/bioaccessibility measurements in terrestrial risk assessments could lead to more accurate estimates of critical Pb levels in soil and biota. Finally, while trophic magnification does greatly increase exposure of organisms at the higher levels of the food web, these studies establish that atmospherically deposited Pb reaches species that have little direct exposure to it. For those species, detrimental effects are not a function of whether they accumulate more Pb than the species they consume, but of the absolute amount they are exposed to, and their sensitivity to it.

7.2.4 Biological Effects

Various effects can be observed in exposed terrestrial species following uptake and accumulation of Pb. While many of the responses are specific to organism type, induction of antioxidant activities in response to Pb exposure has been reported in plants, invertebrates, and vertebrates. In this section, the observed biological effects caused by exposure to atmosphere-derived Pb will be discussed, while the results of dose-response experimentation will be addressed in Section 7.2.5. Because environmental releases of Pb often include simultaneous release of other metals, it can be difficult to identify Pb-specific effects in field studies, with the exception of effects from leaded gasoline and some Pb smelter deposition. Many laboratory studies that expose organisms to natural soils (or to biosolids-amended soils) also include exposure to multiple metals. There is some information about mechanisms of metal interactions, such as through competition for binding locations on specific enzymes or on cellular receptors, but generally such interactions (particularly of multiple metals) are not well understood (ATSDR, 2004). Despite a few well-known examples of metal antagonism (e.g., Cu and Mo or Cd and Zn), it is common practice to assume additivity of effects (Fairbrother et al., 2007). Because this review is focused on effects of Pb, studies reviewed for this section and the following include only those for which Pb was the only, or primary, metal to which the organism was exposed.

7.2.4.1 Terrestrial Plants and Lichen

Pb exposure has been linked to decreased photosynthesis in affected plants, significant induction of antioxidant activities, genetic abnormalities, and decreased growth. Induction of antioxidant responses in plants has been shown to increase tolerance to metal soil contamination, but at sufficiently high levels, antioxidant capacity is exceeded, and metal exposure causes peroxidation of lipids and DNA damage, eventually leading to accelerated senescence and potentially death (Stobrawa and Lorenc-Plucinska, 2008).

Effects on Photosystem and Chlorophyll

Photosynthesis and mitosis were recognized as targets of Pb toxicity in plants in the 1977 Pb AQCD and additional effects of Pb on these processes were reported in subsequent Pb AQCDs (U.S. EPA, 2006c, 1986b, 1977). The effect of Pb exposure on the structure and function of plant photosystem II was recently studied in giant duckweed, *Spirodela polyrrhiza* (Ling and Hong, 2009). Although this is an aquatic plant, photosystem II is present in all plants. This finding thus provides support for effects on photosystem II

being the cellular-level mechanism that leads to decreases photosynthesis observed in other plants. The Pb concentration of extracted photosystem II particles was found to increase with increasing environmental Pb concentration, and increased Pb concentration was shown to decrease emission peak intensity at 340 nm, amino acid excitation peaks at 230 nm, tyrosine residues, and absorption intensities. This results in decreased efficiency of visible light absorption by affected plants. The authors theorized that Pb^{2+} may replace either Mg^{2+} or Ca^{2+} in chlorophyll or the oxygen-evolving center, inhibiting photosystem II function through an alteration of chlorophyll structure. Consistently with these results, Wu et al. (2008c) demonstrated that Pb exposure interfered with and decreased light absorption by spinach (*Spinacia oleracea*) plants. Spinach seeds were soaked in 5, 12, or 25 mM $PbCl_2$ for 48 hours prior to germination, and following 42 days of growth, plants were sprayed with $PbCl_2$ solutions. Chloroplast absorption peak intensity, fluorescence quantum yield at 680 nm, and whole-chain electron transport rate all decreased with Pb exposure, as did photosystem II photoreduction and oxygen evolution. Similarly, the photosynthetic rate of maize (*Zea mays*) seedlings decreased over 21 days exposure to Pb, and measured leaf Pb concentrations in photosynthetically-depressed seedlings ranged from approximately 0.1 to 0.3 mg Pb/g dry weight (Ahmad et al.). Liu et al. (2010a) observed that chlorophyll *a* and *b* content in wheat grown in soils spiked with Pb nitrate rose with length of exposure until 14 days, at which point chlorophyll decreased. At exposures of 0.1 and 0.5 mM Pb in hydroponic solution for 50 days, concentration of chlorophyll *a* and *b* was decreased in radish (*R. sativus*) (Kumar and Tripathi, 2008). Changes in chlorophyll content in response to Pb were also observed in lichen and moss species following exposures intended to simulate atmospheric deposition (Carreras and Pignata, 2007). *Usnae amblyoclada* lichen was exposed to aqueous Pb solutions of 0.5, 1, 5, and 10 mM Pb nitrate; chlorophyll *a* concentration was shown to decrease with increasing Pb exposure. However, the ratio of lichen dry weight to fresh weight increased following Pb exposures. It should be noted that highly productive *Sphagnum* mosses accumulated atmospheric lead at the same rate as slower growing mosses, indicating that moss growth allowed for further lead uptake, rather than a "dilution" effect (Kempter et al., 2010). As compared to other metals, however, Pb caused less physiological damage, which the authors attributed to the metal's high affinity for binding to and sequestration within cell walls (Carreras and Pignata, 2007).

The effect of Pb exposure on chlorophyll content of the moss and liverwort species *Thuidium delicatulum*, *T. sparsifolium*, and *Ptychanthus striatus* was investigated following immersion in six solutions of Pb Nitrate containing from 10^{-10} to 10^{-2} M Pb (Shakya et al., 2008). Both chlorophyll *a* and total chlorophyll content of the mosses (*T. delicatulum* and *T. sparsifolium*) decreased with increasing Pb exposure. For the liverwort, increasing Pb exposure resulted in decreases in content of chlorophyll *a*, chlorophyll *b*, and total chlorophyll. Further, the total chlorophyll content of *Hypnum*

plumaeforme mosses was decreased by 5.8% following exposure to 10 mM Pb, while lower exposures slightly elevated chlorophyll content.

Response of Antioxidants

Increased antioxidant activity is a common response to Pb exposure, although this endpoint may not necessarily be an indication of deleterious effects on plant vitality. Increases in reactive oxygen species with increasing exposure to Pb from 20 mg Pb/kg soil to 2,000 mg Pb/kg have been demonstrated in broad bean (*Vicia faba*) (Wang et al., 2010c; Wang et al., 2010b; Wang et al., 2008b) and tomato (*Lycopersicon esculentum*) (Wang et al., 2008a), where they were accompanied up to approximately 500mg Pb/kg by proportional increases in superoxide dismutase (SOD), glutathione, guaiacol peroxidase, and lipid peroxidation, as well as decreases in catalase. Spinach seedlings grown in soil containing six increasing concentrations of Pb from 20 to 520 mg Pb /kg exhibited higher production of reactive oxygen species, increased rates of lipid peroxidation and increased SOD concentrations. Many of these responses persisted for 50 days after germination and growth in the Pb-contaminated soil (Wang et al., 2011a). Similarly, the bryophyte mosses *Hypnum plumaeforme*, *Thuidium cymbifolium*, and *Brachythecium piligerum* exposed to Pb solutions of greater than 0.1 mM Pb for 48 hours exhibited increased production of $\bullet O_2^-$ and H_2O_2, although no single moss species could be identified as most sensitive to Pb exposure (Sun et al., In Press). Increased rates of lipid peroxidation were also observed in Pb-exposed mosses; however, SOD and catalase activity was suppressed or unaffected by Pb.

Reddy et al. (2005) found that horsegram (*Macrotyloma uniflorum*) and bengalgram (*Cicer arietinum*) plants exposed to Pb solutions of 200, 500, and 800 mg Pb/kg exhibited increased antioxidant activity: at exposures of 800 mg Pb/kg, root and shoot SOD activity increased to 2–3 times that of controls, and induction was slightly higher in *M. uniflorum.* Similarly, catalase, peroxidase, and glutathione-S-transferase activities were elevated in Pb-stressed plants, but were again higher for *M. uniflorum.* Antioxidant activities were also markedly greater in the root tissues than the shoot tissues of the two plants, and were very likely related to the higher Pb accumulation rate of the roots. The effectiveness of the up-regulation of antioxidant systems in preventing damage from Pb uptake was evidenced by lower malondialdehyde (MDA) (a chemical marker of lipid peroxidation) concentration in *M. uniflorum* versus *C. arietinum*, indicating a lower rate of lipid peroxidation in response to *M. uniflorum's* higher antioxidant activity.

Gupta et al. (2010) contrasted responses of two ecotypes of *Sedum alfredii* (an Asian perennial herb), one an accumulator of Pb and the other not. Glutathione level was increased in both, and root and shoot lengths were decreased following long-term

exposures to Pb up to 200 µM. However, the accumulator plants exhibited greater SOD and ascorbate peroxidase activity, likely as a result of greater Pb uptake and a concurrent increased detoxification capacity. Similar results were reported by Islam et al. (2008): following Pb exposures of 200 µM, catalase, ascorbic acid, and glutathione levels of another Chinese herb, *Elsholtzia argyi*, were increased, while SOD and guaiacol peroxidase activities decreased. Microscopic analysis also showed that affected plants exhibited abnormal chloroplast structures. The response of glutathione was further confirmed in wheat (Liu et al., 2010a) grown in soils spiked with Pb nitrate. Evidence of increasing lipid peroxidation (MDA accumulation) with increasing Pb exposure was also found in mosses (Sun et al., 2009) and lichens. Lichens field-collected from the trunks of poplar (*Populus tremula*) trees in eastern Slovakia were chemically analyzed for metal concentration arising from exposure to smelter pollution (Dzubaj et al., 2008). These concentrations (ranging from 13 to 1,523 mg Pb/kg dry weight) were assessed in relation to physiological variables, including chlorophyll *a* and *b*, carotenoids, photosystem II activity, CO_2 gas exchange (respiration), and MDA content. Lichen Pb levels were significantly correlated only with MDA content. Determination of plant chitinase content following exposure to As, Cd and Pb indicated that while levels of these defense proteins were elevated by As and Cd, chitinase levels were not increased following exposure to Pb (Békésiová et al., 2008).

Growth

Evidence of effects of Pb on higher growth processes in terrestrial plants was reported in early NAAQS reviews. Growth effects of Pb on plants in the 1977 Pb AQCD primarily included visible growth responses observed in laboratory studies with plants grown in artificial nutrient culture (U.S. EPA, 1977). No Pb toxicity was observed in plants growing under field conditions at the time of the 1977 Pb AQCD. Indirect effects of Pb on plant growth (i.e., inhibition of uptake of other nutrients when Pb is present in the plant) were also reported in the 1977 Pb AQCD. In the 1986 Pb AQCD mechanisms of Pb effects on growth included reduction of photosynthetic rate, inhibition of respiration, cell elongation, root development or premature senescence (U.S. EPA, 1986b). All of these effects were observed to occur in isolated cells or in plants grown hydroponically in solutions comparable to 1 to 2 µg Pb/g soil or in soils with 10,000 mg Pb/kg or greater (U.S. EPA, 1986b). Pb effects on other plant processes, especially maintenance, flowering and hormone development had not been studied at the time of the 1986 Pb AQCD and remain poorly characterized.

Both growth and carotenoid and chlorophyll content of *Brassica juncea* (mustard) plants were negatively affected by Pb exposure (John et al., 2009). Pb treatments of 1,500 µM (as Pb-acetate solution) decreased root lengths and stem heights by 50% after 60 days.

Exposure to 600 µM Pb and greater decreased carotenoid content, while chlorophyll *a* was decreased at Pb exposures of 450 µM and higher. However, when smelter ash–spiked soils containing 1,466 mg Pb/kg (and 18.6 mg Cd/kg) or 7,331 mg Pb/kg (98.0 mg/kg Cd) were used to grow maize (*Zea mays*), effects were seen in growth or chlorophyll production only at the higher concentration (Komarek et al., 2009) . Given the low solubility of smelter ash, these observations are consistent with solubility being a key determinant of bioavailability. Similarly, wheat seedling growth was unaffected when exposed to soil leachate containing up to 686 µg Pb/L for six weeks. Lettuce seedling root growth was negatively correlated to leachate Pb concentration, but this correlation was only significant for week 3 and week 6 measurements. Authors concluded that although the total concentrations of multiple metals in tested soils and leachates exceeded Canadian Environmental Quality Guidelines, no toxic or only slightly toxic effects occurred following exposure to the metal mixture (Chapman et al., 2010). Further, 14-day growth bioassays conducted with lettuce seedlings (*Latuca sativa*) and field-collected Pb-arsenate contaminated soil produced an unbounded NOEC value of 390 mg Pb/kg (and 128 mg As/kg) (Delistraty and Yokel, In Press).

Chinese cabbage (*Brassica pekinensis*) exposed to Pb-containing soils exhibited depressed nitrogen assimilation as measured by shoot nitrite content, nitrate reductase activity, and free amino acid concentration (Xiong et al., 2006). The authors planted germinated cabbage seeds in soils spiked with Pb-acetate to give final soil concentrations of 0.2, 4, and 8 mM Pb/kg dry weight total Pb and collected leaf samples for 11 days. At exposures of 4 and 8 mM Pb/kg, leaf nitrite content was decreased by 29% and 20%, while nitrate content was affected only at the highest Pb exposure (70% of control levels). Free amino acid content in exposed plants was 81% and 82% of control levels, respectively. *B. pekinensis* shoot biomass was observed to decrease with increasing Pb exposures, with biomass at the two highest Pb exposures representing 91% and 84% of control growth, respectively.

Nitrogen, potassium, and phosphorus concentrations in the shoot and root tissues of four canola cultivars (*Brassica napus*) also decreased as spiked soil Pb concentrations increased from 0 to 90 mg/kg. At the highest soil Pb concentration, nitrogen concentrations were reduced 56% in roots and 58% in shoots versus control levels, while phosphorous concentrations were reduced 37% and 45%, respectively, and potassium content decreased by 42% in both tissues (Ashraf et al., 2011). Cultivation in Pb-spiked soils was also linked to decreased shoot and root biomass (32% and 62%, respectively at 90 mg Pb/kg).

Genetic and Reproductive Effects

Exposure to Pb also resulted in genetic abnormalities, including bridges, condensed bivalents, and laggards, in the meiotic cells of pea plants (*Lathyrus sativus*) (Kumar and Tripathi, 2008). Seeds were germinated in soils amended with Pb nitrate at concentrations of 25, 50, 100, 200, and 300 mg Pb/kg, and concentrations of 100 mg Pb/kg and greater were found to be genotoxic or detrimental to pea viability. Cenkci et al. (2010) exposed fodder turnip (*B. rapa*) to 0.5 to 5 nM of Pb nitrate for 6 days and showed decreased genetic template stability (as quantified by random amplified polymorphic DNA profiles) and decreased photosynthetic pigments.

Two genotypes of maize seedlings exhibited a significant and concentration-dependent reduction in seed germination following 7 days of Pb treatment in nutrient solution of 10, 100 and 1,000 µg Pb/L as Pb sulfate (Ahmad et al.). Pb exposure also decreased germination rate and growth, and increased pollen sterility in radish grown for 50 days in hydroponic solutions containing 0.5 mM Pb (Kumar and Tripathi, 2008). Plants exposed to Pb exhibited decreased growth, curling and chlorosis of young leaves, and decreased root growth. In addition, Gopal and Rizvi (2008) showed that Pb exposure increased uptake of phosphorus and iron and decreased sulfur concentration in radish tops.

Interestingly, as in zebra finch (Section 7.2.3.3) Ca was found to moderate the effects of Pb in both monocotyledon and dicotyledon plant seedlings, with tomato (*Lycopersicon esculentum*), rye (Lolium sp.), mustard, and maize plants exhibiting increased tolerance to Pb exposures of 5, 10, and 20 mg Pb/L in the presence of Ca concentration of 1.2 mM and higher (Antosiewicz, 2005).

7.2.4.2 Terrestrial Invertebrates

Exposure to Pb also causes antioxidant effects, reductions in survival and growth, as well as decreased fecundity in terrestrial invertebrates as summarized in the 2006 Pb AQCD. In addition to these endpoints, recent literature also indicates that Pb exposure can cause significant neurobehavioral aberrations, and in some cases, endocrine-level impacts. Second-generation effects have been observed in some invertebrate species.

The morphology of γ-aminobutyric acid (GABA) motor neurons in *Caenorhabditis elegans* nematodes was affected following exposure to Pb nitrate for 24 hours (Du and Wang, 2009). The authors determined that exposures as low as 2.5 µM Pb nitrate could cause moderate axonal discontinuities, and observed a significant increase in the number of formed gaps and ventral cord gaps at Pb nitrate exposures of 75 and 200 µM. Younger *C. elegans* larvae were more likely to exhibit neurobehavioral toxicity symptoms in

response to Pb exposure (2.5 µM) (Xing et al., 2009c). Neural degeneration, as demonstrated by dorsal and ventral cord gaps and neuronal loss was also more pronounced in young larval *C. elegans* than in older larvae and adults (Xing et al., 2009b). *C. elegans* nematodes exposed to Pb concentration as low as 2.5 µM for 24 hours also exhibited significantly altered behavior characterized by decreased head thrashes and body bends. Exposures of 50 µM Pb and greater decreased the number of nematode forward turns (Wang and Xing, 2008). Chemotaxis toward NaCl, cAMP, and biotin was also decreased in *C. elegans* nematodes exposed to Pb concentration greater than 2.5 µM (Xing et al., 2009a). This evidence suggests that Pb may exert neurotoxic action in invertebrates as it does in vertebrates. However, it is unclear how these behavioral aberrations would affect fitness or survival (Wang and Xing, 2008).

In a study of *C. elegans* exposed to 4 sub-lethal concentrations of Pb nitrate between 25 and 100 µ*M*, Vigneshkumar et al. (In Press) observed upregulation of both catalase and antimicrobial response-related genes. When challenged with addition of a pathogenic strain of *Pseudomonas aeruginosa*, exposed *C. elegans* showed greater resistance to microbial colonization than controls.

Younger individuals also appear to be more sensitive to the reproductive effects of Pb exposure. Guo et al. (2009) showed that concentrations of 2.5, 50, and 100 µM Pb had greater significant adverse effects on reproductive output when early-stage larval *C. elegans* were exposed. Adult *C. elegans* exhibited decreased brood size only when exposed to the highest Pb concentration.

The progeny of *C. elegans* nematodes exposed to 2.5, 75, and 200 µM Pb nitrate exhibited significant indications of multi-generational toxicity (Wang and Peng, 2007). Life spans of offspring were decreased by increasing parental Pb exposure, and were comparable to the reductions in parental life-spans. Similarly, diminished fecundity was observed in the progeny of *C. elegans* exposed to Pb (9%, 19%, and 31% reductions of control fecundity, respectively), although the decrease was smaller than in the exposed parental generation (reductions of 52%, 58%, and 65%, respectively). Significant behavioral defects affecting locomotion were also observed in the offspring, but these impacts were not determined to be concentration-dependent. Reproductive effects of Pb exposure were also observed in springtails *F. candida* following 10 day exposure to Pb-spiked soils. Egg hatch significantly decreased at concentrations of 1,600 mg Pb/kg dry soil and higher and the EC_{50} for hatching was 2,361 mg Pb/kg dry soils (Xu et al., 2009a).

E. andrei earthworms exposed to 21 different soils, each containing 2,000 mg Pb/kg freshly added Pb, for 28 days exhibited highly variable mortality, ranging from 0% to 100%, (Bradham et al., 2006). Pb body burden of exposed worms ranged from 29 to 782 mg Pb/kg. Internal Pb concentration was also negatively correlated to reproductive

output. CEC and pH were found to be the principal soil characteristics determining the differences in those effects, although the apparent role of CEC may only have been due to its correlation with other soil characteristics. Low soil Pb concentration (5 mg Pb/kg) also decreased the protein content of *E. fetida* earthworms during a 7-day exposure (Li et al., 2009b). Higher Pb concentration had no effect on protein production. However, cellulase activity was increased by the 7-day exposures to Pb at all exposure concentrations (31%, 13%, and 23% of control activity at exposures of 5, 50, and 500 mg Pb/kg, respectively), which the authors reported as an indication of detrimental effects on worm metabolism. By contrast, Svendsen et al. (2007) found that *L. rubellus* earthworms exposed for 42 days to field-collected smelter-polluted soils containing average Pb concentration of 106, 309, and 514 mg Pb/kg dry weight exhibited normal survival and cocoon production rates, even though they accumulated more Pb with increased environmental concentration. The much smaller effect may be explained by the increased aging time undergone by field soil, causing a larger fraction of the total Pb to be complexed and sequestered by organic and inorganic compounds. Similarly, earthworms (*E. fetida*) exposed to field-collected soils with concentrations of Pb and As up to 390 mg/kg and 128 mg/kg, respectively, due to historical treatments of lead-arsenate pesticides, exhibited no change in survival, behavior or morphology (Delistraty and Yokel, In Press). Soil aging (e.g., from of the time of Pb-arsenate applications in 1942 to soil collection in approximately 2009) likely reduced Pb bioavailability to earthworms.

As in plants, induction of metal chelating proteins and antioxidant activity in invertebrates is affected by exposure to Pb. Metallothionein production in earthworms (*Lampito mauritii*) was significantly induced following exposure to Pb-contaminated soil. Tissue metallothionein levels increased after a two week exposure to 75 to 300 mg Pb/kg soil, although by 28 days levels had begun to decrease, perhaps as a result of Pb toxicity (Maity et al., 2011). Further, the induction of antioxidant activity was correlated to standard toxicity measurements in *Theba pisana* snails (Radwan et al., 2010). Topical application of Pb solutions (estimated to be 500 to 2,000 µg Pb per animal) to snails resulted in decreased survival, increased catalase and glutathione peroxidase activities, and decreased glutathione concentration. The 48-hour LD_{50} concentration was determined to be 653 µg per snail, as measured in digestive gland tissue. Snail glutathione content was decreased at exposures of 72.2% of the 48-hour LD_{50} value, while Pb exposure at 40% of the 48-hour LD_{50} value induced catalase and glutathione peroxidase activities.

Dietary exposure to Pb also affected *T. pisana* snail growth. After three weeks on Pb-contaminated diet, snail feeding rates were depressed by all Pb exposures (50 to 15,000 µg Pb/g diet dry weight) (El-Gendy et al., 2011). A five week dietary exposure to 1,000 µg Pb/g and greater resulted in reduced snail growth. Decreased food consumption,

growth, and shell thickness were also observed in juvenile *A. achatina* snails exposed to Pb-contaminated (concentration greater than 134 mg Pb/kg) diet for 12 weeks (Ebenso and Ologhobo, 2009a) . A similar depression of growth was observed in sentinel juvenile *A. achatina* snails deployed at Pb-polluted sites in the Niger Delta region of Nigeria. Although snail mortality was not increased significantly by exposure to soil Pb up to 1,200 mg Pb/kg, a concentration-dependent relationship was established for growth, with significant reduction observed at 12-week exposures to 20 mg Pb/kg (Ebenso and Ologhobo, 2009b). However, consumption of field-collected Pb-polluted *U. dioica* leaves containing 3 mg Pb/kg stopped all reproductive output in *C. nemoralis*. Snails also exhibited diminished food consumption rates when offered leaves with both low (1.5 mg Pb/kg) and high Pb content, but the mechanism of the dietary aversion was not defined (Notten et al., 2006).

Chronic dietary exposure to Pb was also examined in post-embryonic oribatid mites (*Archegozetes longisetosus*) (Kohler et al., 2005). Both algae and bark samples were soaked in 100 mg/L Pb as Pb nitrate and provided as diet and substrate, respectively, to larval mites. In addition to elevated heat shock proteins (hsp70), 90.8% of the protonymphs exhibited significant leg deformities, including abnormal claws, shortened and thickened legs, and translocated setae. Although not specifically discussed, it is very likely that these deformities would decrease mite mobility, prey capture, and reproductive viability. While there is some evidence that oribatid mites exhibit Pb avoidance behavior, this response may not significantly reduce Pb exposure and effects. Although soil-inhabiting mites (*Oppia nitens*) were observed to avoid high Pb concentrations, the EC_{50} for this behavior was approximately five times higher than the chronic EC_{50} for reproduction (8,317 and 1,678 mg Pb/kg, respectively) (Owojori et al., 2011). Consequently, it is unlikely that oribatid mites will avoid soils containing toxic Pb concentrations.

Lock et al. (2006) compared the toxicity of both laboratory-spiked soils and field-collected Pb-contaminated soils to springtails (*F. candida*). The 28-day EC_{50} values derived for *F. candida* ranged from 2,060 to 3,210 mg Pb/kg in leached and unleached Pb-spiked soils, respectively, whereas field-collected soils had no significant effect on springtail reproduction up to (but not including) 14,436 mg Pb/kg (Lock et al., 2006). Consequently, leaching soils prior to use in bioassays had only a slight effect on Pb toxicity to resident springtails, and did not provide an appropriate model for field-weathered, Pb-contaminated soils. This indicates that physiochemical factors other than leaching may be more important determinants of Pb bioavailability. A 4-week exposure to Pb-amended soils containing up to 3,200 mg Pb/kg had no significant effect on *Sinella curviseta* springtail survival or reproduction (Xu et al., 2009b).

Carabid beetles (*Pterostichus oblongopunctatus*) inhabiting soils contaminated by pollution from a Pb-Zn smelter (containing 136 to 2,635 mg Pb/kg) were field-collected and then laboratory-reared for two generations (Lagisz and Laskowski, 2008). While fecundity was positively correlated to soil metal concentration (e.g., more eggs were produced by females collected from contaminated areas), the hatching rate of eggs diminished with increasing soil metal contamination. For the F1 generation, females produced by parents inhabiting highly polluted areas exhibited decreased body mass. The authors stated that these results indicate that invertebrates inhabiting metal- (or Pb-) contaminated soils could face "significantly altered life-history parameters." Similarly, aphids (*Brevicoryne brassicae*) reared on cabbage and radish plants exposed to 0.068 mg Pb daily exhibited altered development and reproduction when compared to those reared on non-exposed plants. Development time was increased by approximately two days, which led to a reduction in relative fecundity (Gorur, 2007). Although the authors noted that study exposures were greater than what would be expected in naturally polluted areas, Pb exposure under field conditions could alter invertebrate life history patterns.

Several studies suggest that Pb may disrupt hormonal homeostasis in invertebrates. Shu et al. (2009) reported that vitellogenin production in both male and female *S. litura* moths was disrupted following chronic dietary exposure to Pb. Adult females reared on diets containing 25, 50, 100, or 200 mg Pb/kg exhibited decreased vitellogenin mRNA induction, and vitellogenin levels were demonstrated to decrease with increasing Pb exposure. Conversely, in a study by Zheng and Li (2009), vitellogenin mRNA was detected at higher levels in males exposed to 12 and 25 mg Pb/kg, although vitellogenin levels were not affected. Similarly, the sperm morphology of the Asian earthworm (*Pheretima guillelmi*) was found to be altered significantly following 2-week exposure to soils containing 1,000, 1,400, 1,800, and 2,500 mg Pb/kg (Zheng and Li, 2009). Common deformities were swollen head and head helices, while head bending was also recorded in some cases. These deformities were observed following exposures to concentration below the 14-day LC_{50} (3,207 mg Pb/kg) and below the concentration at which weight was diminished (2,800 mg Pb/kg). Experimentation with the model organism Drosophila indicates that Pb exposure may increase time to pupation and decrease pre-adult development, both of which are endocrine-regulated (Hirsch et al., 2010).

7.2.4.3 Terrestrial Vertebrates

Pb poisoning is one of the earliest recognized toxicoses of terrestrial vertebrates, occurring primarily through the ingestion of spent shot by birds. While the focus of the ISA is on more environmentally relevant exposures, studies of Pb poisoning provide historical context for the review. The widespread nature of this toxicosis was first noticed

in American waterfowl around the turn of the last century (see (Jones, 1939) for an historical summary). Wetmore (1919) demonstrated that Pb shot caused the observed effects and described in detail the species affected, associated symptoms, and additional factors involved. By 1959, the estimated annual loss of waterfowl to Pb poisoning was 2−3 percent of the fall population (Bellrose, 1959). Smaller numbers of shorebirds and upland game birds were also found poisoned by Pb (Locke and Thomas, 1996).

The first reported Pb poisoning of a bald eagle (*Haliaeetus leucocephalus*) was described by Mulhern et al. (1970), and subsequently several hundred bald eagle lead poisonings were diagnosed throughout the U.S. prior to the ban on use of Pb shot for waterfowl hunting (Kramer and Redig, 1997). Eagles and other raptors are poisoned by consuming Pb pellets imbedded in the flesh of ducks or upland prey species and may also be exposed to other sources of Pb, such as fishing sinkers and weights (Kramer and Redig, 1997). The use of Pb shot for waterfowl hunting was banned in 1991 due to the poisoning of bald eagles, which had been previously added to the endangered species list and were specially protected under the Bald Eagle Protection Act of 1940.

Anderson et al. (2000) reported that by 1997, mallard (*Anas platyrhynchus*) deaths from Pb poisoning in the Mississippi flyway were reduced by 64 percent, and ingestion of toxic pellets had declined by 78 percent. They estimated the ban prevented approximately 1.4 million duck deaths in the first 6-year period. However, Pb exposure remains widespread in bald eagles, although blood lead concentrations have significantly decreased (Kramer and Redig, 1997). The endangered California condor (*Gymnogyps californianus*) also continues to have significantly elevated blood Pb levels as well as Pb-associated mortality resulting from exposure to ammunition fragments contained in food items (Cade, 2007; Church et al., 2006). Although there is a significant amount of information on Pb tissue residues of mammals, there are very few reports of Pb poisoning; exceptions are reports of Pb poisoned bats in a cave in the southern U.S. and small mammals in the vicinity of several smelters (Shore and Rattner, 2001).

At the time of the 1977 Pb AQCD few studies of the effects of exposure to Pb had been conducted in wild animals other than birds, and the majority of those studies were of direct poisoning (U.S. EPA, 1977). Several studies of domestic animals grazing near Pb smelters indicated that horses are more susceptible than cattle to chronic Pb exposure although the findings were not conclusive due to the presence of other metals. Delta-aminolevulinic acid dehydratase (ALAD) was recognized as a sensitive indicator of Pb exposure in rats and waterfowl. In the 1986 Pb AQCD, additional effects of Pb on small mammals and birds were reported. According to the 2006 Pb AQCD, commonly observed effects of Pb on avian and mammalian wildlife include decreased survival, reproduction, and growth, as well as effects on development and behavior. More recent

experimental data presented here expand and support these conclusions, and also indicate that Pb can exert other effects on exposed terrestrial vertebrates, including alteration of hormones and other biochemical variables.

Since the 2006 Pb AQCD, there is additional evidence for hematological effects of Pb exposure in terrestrial vertebrates. Red-backed salamanders (*Plethodon cinereus*) exposed to Pb-amended soils (553, 1,700, 4,700, and 9,167 mg Pb/kg) by Bazar et al. (2010) exhibited lowered appetite and decreased white blood cell counts at the two highest concentrations, but tolerated field-collected, aged soils containing Pb concentrations of up to 16,967 mg Pb/kg with no significant deleterious effects. The white blood cell count of adult South American toads, (*Bufo arenarum)* was also decreased by weekly sublethal i.p. injections of Pb-acetate at 50 mg Pb/kg body weight (Chiesa et al., 2006). The toads also showed altered serum profiles and increased number of circulating blast cells. Final toad blood Pb levels were determined to be 8.6 mg Pb/dL, although it is unclear whether this is representative of Pb concentrations observed in field *B. arenarum* populations exposed to Pb. The authors suggested that, based on these findings, long-term environmental exposure to Pb could affect toad immune response. In western fence lizards (*S. occidentalis*), sub-chronic (60-day) dietary exposure to 10 to 20 mg Pb/kg per day resulted in significant sublethal effects, including decreased cricket consumption, decreased testis weight, decreased body fat, and abnormal posturing and coloration (Salice et al., 2009). Long-term dietary Pb exposures are thus likely to decrease lizard fitness.

Even in cases of high environmental Pb exposures, however, linking Pb body burdens to biological effects can be difficult. Pb tissue concentration in field-collected urban blackbirds (*Turdus merula*) were determined to be 3.2 mg Pb/kg, 4.9 mg Pb/kg, and 0.2 mg Pb/kg wet mass in breast feathers, washed tail feathers, and blood, respectively (Scheifler et al., 2006a). Although these levels were significantly higher than those measured in rural blackbirds, elevated Pb tissue concentration was not significantly correlated to any index of body condition. On the other hand, Hargreaves et al. (2010) showed that Pb tissue concentration of female arctic shorebirds was negatively correlated with reproductive success. Maternal blood Pb levels were negatively associated with hatching success in black bellied plovers (*Pluvialis squatarola*) and ruddy turnstones (*Arenaria interpres*), and with nest duration in all species tested. There was no significant correlation between adult whole-blood or feather Pb concentration and Pb levels in produced eggs.

The long-term effect of atmospheric Pb deposition on pied flycatcher (*Ficedula hypoleuca*) nestlings was determined in native communities residing in the Laisvall mining region of Sweden (Berglund et al., 2010). Moss samples indicated that Pb

deposition in study areas ranged between 100 and 2,000 mg Pb/kg dry weight during operations and 200 and 750 mg Pb/kg when operations ceased. A simultaneous slight reduction was observed in pied flycatcher blood Pb levels, from 0.4 to 0.3 mg Pb/kg). However, clutch size was decreased in pied flycatchers inhabiting the mining area both during and after mining operations, and mean nestling mortality was 2.5 times higher in the mining region than in reference areas during mining operations, and 1.7 higher five years after cessation of mining operations. The authors noted that Pb deposition in the mining region remained elevated even after mining operations ceased, and that stable Pb isotope analysis suggested that smelter Pb remained available to pied flycatcher through the transfer of historically deposited Pb in soil to prey items.

Berglund (Berglund et al., 2010) also analyzed ALAD activity in pied flycatchers at the later period, and found that it was 46% lower at the mine site. Beyer et al. (2004) observed that elevated blood Pb levels in several types of birds inhabiting the Tri-State Mining District (Oklahoma, Kansas, Missouri) were correlated with decreases in ALAD activity. Based on reduction in ALAD activity, robins (*Turdus migratorius*) were most sensitive to Pb exposure (35% reduction), followed by cardinals (*Cardinalis cardinalis*), waterfowl, and bobwhite quail (*Colinus virginianus*) (40%, 41%, and 56% reductions, respectively). Eagle owl (*Bubo bubo*) nestlings living in a historical mining area in Spain also exhibited elevated blood Pb levels (average 8.61 µg/dL as compared to an average reference area value of 3.18 µg/dL), and this was correlated to an approximate 60% reduction in ALAD activity (Gómez-Ramírez et al., 2011). Hansen et al. (2011a) determined that ground-feeding songbirds were frequently exposed to Pb within the Coeur d'Alene, ID mining region. Robins, in particular, were significantly likely to exhibit blood Pb levels in the clinical and severe clinical poisoning ranges (50 to 100 µg/dL and >100 µg/dL, respectively). Ingested soil Pb accounted for almost all of the songbirds' exposure to Pb, with Pb exposure correlated with estimated soil ingestion rates (20% for robins, 17% for song sparrows, and 0.7% for Swanson's thrushes, *Catharus ustulatus*). More than half of the robins and song sparrows from all contaminated sites and more than half of the Swainson's thrushes from highly contaminated sites showed at least 50% inhibition of ALAD. The highest hepatic Pb concentration of 61 mg/kg (dry weight) was detected in a song sparrow (Hansen et al., 2011a).

Blood Pb was significantly elevated in waterfowl in the Lake Coeur d'Alene areas of Blackwell Island and Harrison Slough (mean sediment concentrations of 679 and 3,507 mg Pb/kg dry weight, respectively). Twenty-seven percent of the waterfowl sampled in the Blackwell Island region had blood Pb concentrations suggestive of severe clinical poisoning (average concentration =0.17 µg Pb/g); in the Harrison Slough, 60% of sampled waterfowl had highly elevated blood Pb levels that exceeded the severe clinical poisoning threshold (average concentration= 2,2 µg Pb/g) (Spears et al., 2007). The level

of corticosteroid hormones in field populations of white stork nestlings (*Ciconia ciconia*) in a mining area affected by Pb and other metals was positively correlated with blood Pb levels (Baos et al., 2006). The effect was more pronounced for single nestlings than for multiple-chick broods. Surprisingly, average blood Pb levels in chicks inhabiting reference areas was 91 µg Pb/L (± 51), which was higher than blood Pb levels from the mining area (44 ± 34 µg Pb/L). However, the correlation between blood Pb levels and the corticosteroid stress response in white stork nestlings was observed in both groups of birds. Burger and Gochfeld (2005) exposed herring gull (*Larus argentatus*) chicks to Pb-acetate via an i.p. injection of 100 mg Pb/kg body weight, to produce feather Pb concentration approximately equivalent to those observed in wild gulls. Pb-exposed gulls exhibited abnormal behaviors, including decreased walking and food begging, erratic behavioral thermoregulation, and diminished recognition of caretakers. Interestingly, subchronic exposure of Japanese quail (*Coturnix coturnix japonica*) to 5,000 and 50,000 µg Pb/L in drinking water caused an increase in their immune response. Exposed quail exhibited significantly lower rates of death or health effects (including septicemia, perihepatitis, and pericarditis among others) than control animals following infection with *E.coli*, and the incidence of infection-related effects was dependent on Pb exposure (Nain and Smits, 2011). These observations contrast with immunotoxicology results in mice reported in Section 5.6.4.1.

Again, dietary or other health deficiencies unrelated to Pb exposure are likely to exacerbate the effects of Pb. Ca-deficient female zebra finches (*T. guttata*) had a suppressed secondary humoral immune response following 28-day exposures to 20,000 µg Pb/L in drinking water (Snoeijs et al., 2005). This response, however, was not observed in birds fed sufficient Ca. Although a significant finding, these data are difficult to interpret under field conditions where the overall health of avian wildlife may not be easily determined.

Chronic Pb exposures were also demonstrated to affect several mammalian species. Young adult rats reared on a diet containing 1,500 mg Pb/kg Pb-acetate for 50 days demonstrated less plasticity in learning than non-exposed rats (McGlothan et al., 2008), indicating that Pb exposure caused significant alteration in neurological function. Yu et al. (2005) showed that dietary Pb exposure affected both the growth and endocrine function of gilts (*S. domestica*). Consumption of 10 mg Pb/kg diet resulted in lower body weight and food intake after 120 days of dietary exposure; Pb exposure decreased final weight by 8.2%, and average daily food intake of Pb-exposed pigs was decreased by 6.8% compared to control intake. Additionally, concentration of estradiol, luteinizing hormone, and pituitary growth hormone were decreased (by 12%, 14%, and 27% versus controls, respectively), while blood Pb level was increased by 44% to an average 2.1 µg/dL. In cattle grazing near Pb-Zn smelters in India, blood Pb levels were positively

correlated with plasma levels of the thyroid hormones thyroxine (T4) and tri-iodothyronine (T3) and the hepatic biomarkers alanine transaminase and aspartate transaminase (Swarup et al., 2007). Total lipids, total protein and albumin levels were decreased in the same animals. Rodriguez-Estival et al. (2011) determined that red deer (*Cervus elaphus*) and wild boar (*Sus scrofa*) inhabiting a Pb-contaminated mining area in Spain exhibited increased liver and bone Pb concentrations (geometric means of 0.35 and 0.46 µg Pb/g for red deer, and 0.81 and 7.36 µg Pb/g for wild boar, respectively). These tissue concentrations were correlated to a significant decrease in red deer glutathione production, but corresponded to an increase in wild boar glutathione (Rodríguez-Estival et al., 2011). Authors proposed that the different antioxidant responses may be indicative of different Pb susceptibilities in the two species.

Pb-treated oocytes of buffalo (*Bubalus bubalis*) assessed in vitro at concentrations ranging from 0.5 to 1,000 µg/dL in one-day cultures indicated a significant decline in viability of oocytes at 100 µg/dL (Nandi et al., 2010). Dose-dependent effects on oocyte viability, morphological abnormalities, cleavage, blastocyst yield and blastocyst hatching were observed in Pb-treated oocytes with maturation significantly reduced at 250 µg/dL and 100% oocyte death at 3,200 µg/dL. Similarly, the reproductive viability of the red deer from the Pb-contaminated mining area of Spain studied by Rodriguez-Estival et al. (2011) was shown to be altered, with 11% and 15% reductions in spermatozoa and acrosome integrity observed in male deer from the mining area compared with those residing in reference areas (Reglero et al., 2009b).

7.2.5 Exposure and Response of Terrestrial Species

Evidence regarding exposure-response relationships and potential thresholds for Pb effects on terrestrial populations can inform determination of standard levels that are protective of terrestrial ecosystems. Given that exposure to Pb may affect biota at the organism, population, or community level, determining the rate and concentration at which these effects occur is essential in predicting the overall risk to terrestrial organisms. This section updates available information derived since the 2006 Pb AQCD, summarizing several dose-response studies with soil invertebrates. No new exposure-response information was available for plants, birds, or mammals.

Dose-dependent responses in antioxidant enzymes were observed in adult *L. mauritii* earthworms exposed to soil-associated Pb contamination (75, 150, 300 mg Pb/kg) (Maity et al., 2008). By day seven of exposure, glutathione-S-transferase activity and glutathione disulfide concentration were positively correlated with increasing Pb exposures, while glutathione concentration exhibited a negative dose-response relationship with soil Pb

concentration. However, these trends had become insignificant by the end of the total exposure period (28 days), as a result of normalization of antioxidant systems following chronic exposure. This strongly suggests that changes to earthworm antioxidant activity are an adaptive response to Pb exposures.

Both survival and reproductive success of *E. fetida* earthworms showed concentration-dependent relationships with soil Pb concentration during the course of standard 14- and 56-day toxicity tests (Jones et al., 2009b). Five levels of Pb soil concentration were prepared for the acute 14-day study via spiking with Pb nitrate—0, 300, 711, 1,687, and 2,249 mg Pb/kg, while soil concentration of 0, 355, 593, 989, and 1,650 mg Pb/kg were used in chronic (56-day) earthworm bioassays. A 14-day acute LC_{50} of 2,490 mg Pb/kg was determined from the dose-response relationship, while the approximate 56-day NOEC (no observed effect concentration) and EC_{50} values were about 400 mg Pb/kg and 1,000 mg Pb/kg, respectively. Currie et al. (2005) observed mortality of *E. fetida* after 7 and 14 days in spiked field soil at seven levels of Pb (0 to 10,000 mg Pb/kg). They reported LC_{50} values of 2,662 mg Pb/kg at 7 days and 2,589 mg Pb/kg at 14 days or 2,827 mg Pb/kg at both 7 and 14 days, depending on the number of worms in the experimental enclosure.

Other studies have shown no correlation between Pb concentration in either earthworm tissue or soil, and earthworm survival rate. Although the Pb content of *E. fetida* held in metal-contaminated soils containing between 9.7 and 8,600 mg Pb/kg was positively correlated with Pb concentration of fully aged soil collected from disused mines, there was no statistical relationship with earthworm survival during a 42-day exposure period (Nahmani et al., 2007). However, Pb concentration in soil leachate solution was significantly correlated with decreased earthworm survival and growth (linear regression: $R^2 = 0.64$, $p < 0.0001$). The 42-day Pb EC_{50} for *E. fetida* growth was 6,670 mg Pb/kg.

Langdon et al. (2005) exposed three earthworm species (*E. andrei*, *L. rubellus*, and *A. caliginosa*) to Pb nitrate-amended soils at concentrations of 1,000 to 10,000 mg Pb/kg to determine species variability in uptake and sensitivity. Twenty-eight-day LC_{50} values for the three species were 5,824 mg Pb/kg, 2,867 mg Pb/kg, and 2,747 mg Pb/kg, respectively, indicating that *L. rubellus* and *A. caliginosa* are significantly more vulnerable to Pb contamination than *E. andrei*, a common laboratory species. This is comparable to previous findings by Spurgeon et al. (1994) who reported 14-day LC_{50} of 4,480 mg Pb/kg and 50-day LC_{50} of 3,760 mg Pb/kg for *E. fetida*, another standard laboratory test species. In the more recent study of *E. fetida* sensitivity summarized above, Jones (2009b) reported LC_{50} values for *E. fetida* that are similar to those for *L. rubellus* and *A. caliginosa*. It is likely that these apparent species differences are a result of differential bioavailability of the Pb in test soils. However, the Pb body burden of all

three species in the study by Langdon et al. (2005) increased with increasing environmental concentration, and there were no species differences in Pb tissue content. When given a choice between treated and untreated soils, all worm species exhibited significant avoidance of Pb-contaminated soils, and altering pH (and, consequently, Pb bioavailability) had no impact on avoidance (Langdon et al., 2005). Field earthworms may thus be able to reduce their exposure to Pb through behavior.

Reproductive success of other soil invertebrates is impacted by Pb. The organismal and population-level responses of the springtail *Paronychiurus kimi* to Pb were determined by Son et al. (2007) using artificial soils, following the 1999 ISO methodology. The 7-day Pb LC_{50} was determined to be 1,322 mg Pb/kg dry weight, while the 28-day reproduction EC_{50} was established as 428 mg Pb/kg. The intrinsic rate of population increase was lower at a Pb soil concentration of 1,312 mg Pb/kg, and the authors estimated that, at this level, *P. kimi* populations would be extirpated. The authors noted that, in this case, the reproductive endpoint overestimated the population-level risk for *P. kimi* springtails exposed to Pb, and proposed that more specific measures of population-level endpoints (such as the reduction in intrinsic rate of increase) be used to determine risk to populations. Menta et al. (2006) showed that a nominal soil concentration of 1,000 mg Pb/kg decreased the reproductive output of two collembolans, *Sinella coeca* and *F. candida*. Pb concentration of 50, 100, and 500 mg Pb/kg slightly but significantly depressed *S. coeca* adult survival, while *F. candida* survival was statistically unaffected by Pb exposure. The hatching success of *F. candida* eggs was diminished by 10 day exposure to Pb-spiked soils; the 10-day EC_{50} for hatching success was reported as 2,361 mg/kg Pb (Xu et al., 2009d). However, authors noted that egg development was more sensitive to Cu and Zn exposure, and by comparison, was less susceptible to Pb.

In addition to species variability, physical and chemical factors affecting Pb bioavailability were also demonstrated to significantly influence the toxicity of Pb to terrestrial species. As noted previously in Section 7.2.2, laboratory-amended artificial soils provide a poor model for predicting the toxicity of Pb-contaminated field soils, because aging and leaching processes, along with variations in physiochemical properties (pH, CEC, OM), influence metal bioavailability. Consequently, toxicity values derived from exposure-response experimentation with laboratory-spiked soils probably overestimate true environmental risk, with the possible exception of highly acidic sandy soils. Because toxicity is influenced by bioavailability of soil biogeological and chemical characteristics, extrapolation of toxic concentrations between different field-collected soils will be difficult. Models that account for those modifiers of bioavailability, such as the terrestrial BLM proposed by Smolders et al. (2009), have proven difficult to develop due to active physiological properties of soil organisms affecting either uptake (such as

root phytochelatins) or sequestration of Pb (such as granule formation in root tissues and earthworms, or substitution of Pb for calcium in bones).

7.2.6 Community and Ecosystem Effects

A study reviewed in the 1977 Pb AQCD provided evidence for Pb effects on forest-nutrient cycling and shifts in community composition. Reduced arthropod density, biomass and richness were observed in the vicinity of a smelting complex in southeastern Missouri where Pb, Cd, Zn and Cu were measured in the litter layer and soil (U.S. EPA, 1977; Watson et al., 1976). In the 1986 Pb AQCD it was reported that Pb at environmental concentrations occasionally found near roadsides and smelters (10,000 to 40,000 µg Pb/g dry weight [mg Pb/kg]) can eliminate populations of bacteria and fungi on leaf surfaces and in soil. At soil concentrations of 500 to 1,000 µg Pb/g (mg Pb/kg) or higher, populations of plants, microorganisms, and invertebrates may shift toward Pb-tolerant populations of the same or different species (U.S. EPA, 1986b).

According to the 2006 Pb AQCD, natural terrestrial ecosystems near significant Pb point sources (such as smelters and mines) exhibited a number of ecosystem-level effects, including decreased species diversity, changes in floral and faunal community composition, and decreasing vigor of terrestrial vegetation. These findings are summarized in Table AX7-2.5.2 of the Annex to the 2006 Pb AQCD (U.S. EPA, 2006c). More recent literature explored the interconnected effects of Pb contamination on soil bacterial and fungal community structure, earthworms, and plant growth, in addition to impacts on soil microbial community function.

Inoculation of maize plants with *Glomus intraradices* arbuscular mycorrhizal fungi isolates decreased Pb uptake from soil, resulting in lower shoot Pb concentration and increased plant growth and biomass (Sudova and Vosatka, 2007). Similarly, Wong et al. (2007) showed that the presence of arbuscular mycorrhizal fungi improved vetiver grass (*Vetiveria zizanioides*) growth, and while Pb uptake was stimulated at low soil concentration (10 mg Pb/kg), it was depressed at higher concentration (100 and 1,000 mg Pb/kg). Bojarczuk and Kieliszewska-Rokicka (2010) found that the abundance of ectomycorrhizal fungi was negatively correlated with the concentration of metals, including Pb, in the leaves of silver birch seedlings. Arbuscular mycorrhizal fungi may thus protect plants growing in Pb-contaminated soils. Microbes too may dampen Pb uptake and ameliorate its deleterious effects: biomass of plants grown in metal-contaminated soils (average Pb concentration 24,175 mg Pb/kg dry weight) increased with increasing soil microbial biomass and enzymatic activity (Epelde et al., 2010). However, above certain Pb concentration, toxic effects on both plants and microbial

communities may prevent these ameliorating effects. R.Y. Yang et al. (2008b) found that both the mycorrhizal colonization and the growth of *Solidago canadensis* were negatively affected by soil Pb contamination. They suggested that, more generally, Pb-mediated alterations in plant-fungal dynamics may be the cause of ecological instability in terrestrial vegetative communities exposed to metals.

The presence of both earthworms and arbuscular mycorrhizal fungi decreased the mobility of Pb in mining soils undergoing phytoremediation (Ma et al., 2006). Inoculation with both earthworms and fungi increased plant growth at sites contaminated with mine tailings compared to that observed at sites with 75% less Pb contamination. Most likely, this was a result of the decrease in bioavailable (DTPA-extractable and ammonium acetate-extractable) Pb to 17% to 25% of levels in areas without the earthworm and arbuscular mycorrhizal fungi amendments. The presence of earthworms in metal-contaminated soils decreased the amount of water-soluble Pb (Sizmur and Hodson, 2008), but despite this decrease, ryegrass accumulated more Pb from earthworm-worked soils than soils without worms present. Sizmur and Hodson speculated that increased root dry biomass may explain the increased uptake of Pb in the presence of earthworms. However, Sizmur et al. (2011) found that the presence of anecic (deep-burrowing) earthworms (*L. terrestris*) increased soil leachate Pb concentrations by 190%. The authors observed that worms promoted a faster breakdown of organic matter, which caused a decrease in soil pH and a concurrent increase in Pb solubility. As a result, ryegrass (*L. perenne*) accumulated a greater amount of Pb in systems with earthworms (Sizmur et al., 2011). Further, the presence of earthworms (*Lumbricus terrestris*) was found to increase Pb concentrations in both maize and barley, although growth of these species was unaffected (Ruiz et al., 2011). Authors noted that worm activity increased Pb extraction yields by factors of 4.4 and 7.6, for barley and maize. By contrast, Coeurdassier et al. (2007) found that Pb was higher in earthworm tissue when snails were present, but that snails did not have a higher Pb content when earthworms were present.

Microbial communities of industrial soils containing Pb concentrations of 61, 456, 849, 1,086, and 1,267 mg Pb/kg dry weight were also improved via revegetation with native plants, as indicated by increased abundances of fungi, actinomycetes, gram-negative bacteria, and protozoa, as well as by enhanced fatty acid concentration (Zhang et al., 2006). Increased plant diversity ameliorated the effects of soil Pb contamination (300 and 600 mg Pb/kg) on the soil microbial community (Yang et al., 2007).

The effect of Pb on microbial community function has been quantified previously using functional endpoints such as respiration rates, fatty acid production, and soil acid phosphatase and urease activities, which may provide an estimate of ecological impacts separate from microbial diversity and abundance measurements. Most studies of metal-

induced changes in microbial communities have been conducted using mixtures of metals. However, Akerblom et al. (2007) tested the effects of six metals (Cr, Zn, Mo, Ni, Cd, and Pb) individually. All tested metals had a similar effect on the species composition of the microbial community. Exposure to a high Pb concentration (52 mg Pb/kg) also negatively affected respiration rates. Total phospholipid fatty acid content was determined to negatively correlate with increasing Pb exposure, indicating alteration of the microbial community. When Yang et al. (2006) compared the microbial properties of metal-contaminated urban soils to those of rural soils, significant differences were detected in basal community respiration rates and microbial abundance. The urban soils studied contained multiple metal contaminants, but microbial biomass was the only measured endpoint to be significantly and negatively correlated to Pb concentration. Similarly, the fungal community in a naturally Pb-enriched forest in Norway exhibited differences in community composition and abundance when compared with other, low Pb sites. The number of colony–forming fungal units was diminished by soil Pb, and was approximately 10 times lower in the highest Pb soil concentration (~4.5 mg/g dw). Further, only one fungus species was isolated from both high Pb and control soils, indicating highly divergent communities; species diversity was also reduced by high soil Pb concentrations (Baath et al., 2005). These studies suggest that anthropogenic Pb contamination may affect soil microbial communities, and alter their ecological function. However, (Khan et al., 2010c) reported that it is possible for indicators of microbial activity to recover after an initial period depression. (Khan et al., 2010c) found that following a 2-week exposure to three levels of Pb (150, 300, and 500 mg Pb/kg), the number of culturable bacteria at the highest exposure concentration tested was decreased. Acid phosphatase and urease levels (measures of soil microbial activity) decreased significantly, but they had recovered by the ninth week. Another study (Bamborough and Cummings, 2009) reported that no changes in bacterial and actinobacterial diversity in metallophytic soils containing 909 to 5,280 mg Pb/kg (43 to 147 mg Pb/kg bioavailable Pb (as defined by the study authors).Soil bacteria community structure and basal respiration rates were examined in natural soils with pH values ranging from 3.7 to 6.8 (Lazzaro et al., 2006). Six soil types of differing pH were treated with Pb nitrate concentrations of 0.5, 2, 8, and 32 mM. Basal respiration was decreased in two soil types tested at the highest Pb treatment (32 mM), and in a third at the two highest Pb treatments (8 and 32 mM). Terminal Restriction Fragment Length Polymorphism analysis indicated that bacterial community structure was only slightly altered by Pb treatments. While pH was correlated with the amount of water-soluble Pb, these increases were apparently not significant enough to affect bacterial communities, because there were no consistent relationships between soil pH and respiration rate or microbial community structure at equivalent soil Pb concentration. Pb contamination was also demonstrated to reduce phenol oxidase activity in several type of soils; concentrations between 5 and 50 nM Pb

significantly decreased phenol oxidase activity in all soils tested, while 400 nM and greater completely arrested phenol oxidase activity in one soil tested (a high pH sandy loam) (Carine et al., 2009). Carine (2009) suggested that the decreased soil enzymatic activity resulted from changes in the microbial community following Pb exposure. Pb concentrations between 50 and 500 mg Pb/kg significantly reduced microbial abundance and diversity, and also resulted in lower soil phosphatase, urease, and dehydrogenase activities (Gao et al., 2010b). Further, the weekly soil carbon dioxide evolution rate was significantly reduced by concentrations of 5, 10, and 50 mg Pb/g, which also indicated decreased microbial respiration and adverse effects on the microbial community (Nwachukwu and Pulford, 2011). Gai et al. (2011) examined the microbial activity of three soils via microcalorimetric methods following Pb exposure. They noted an increase in activity immediately following Pb application (giving 10, 20, 40, 80, and 160 µg Pb/g), and theorized that this was a result of rapid mortality of sensitive microbial species, followed by a concurrent proliferation of Pb-tolerant microorganisms. As Pb concentrations increased, however, the calculated microbial growth rate constant decreased, indicating a suppression of microbial activity (Gai et al., 2011). Authors also noted a strong correlation between microcalorimetry estimates and the number of colony forming units isolated from soil samples.

Pb exposure negatively affected the prey capture ability of certain fungal species. Nematophagous fungi are important predators of soil-dwelling nematodes, collecting their prey with sticky nets, branches, and rings. The densities of traps they constructed decreased in soils treated with 0.15 mM Pb chloride (Mo et al., 2008). This suppression caused a subsequent reduction in fungal nematode capturing capacity, and could result in increased nematode abundance.

In a study of microbial communities and enzyme activity, Vaisvalavicius et al. (Vaisvalavicius et al., 2006) observed that high concentration of soil metals were linked to a significant reduction in soil microorganism abundance and diversity. Soil columns spiked with Cu, Zn, and Pb-acetate (total Pb concentration of 278 to 838 mg Pb/kg, depending on depth) exhibited a 10- to 100-fold decrease in microbial abundance, with specific microbe classes (e.g., actinomycetes) seemingly more affected than others (Vaisvalavicius et al., 2006). Concurrently, decreases in soil enzymatic activity were also observed, with saccharase activity decreased by 57–77%, dehydrogenase activity by 95–98%, and urease activity 65–97%. Although this suggests that Pb contamination may alter the nutrient cycling capacity of affected soil communities, it is difficult to separate the impact of Pb in this study from the contributions of Cu and Zn that were also added. In contrast, Zeng et al. (2007) reported that soil concentrations of 300 mg Pb/kg and less stimulated soil enzymatic activity. Both urease and dehydrogenase levels were increased and rice dry weight was unaffected by concentrations of 100 and 300 mg Pb/kg.

However, at 500 mg Pb/kg, both rice and soil enzyme activities and microbial biomass were decreased suggesting impacts at the community level for the soil-rice system. The authors proposed that these concentrations could be considered the critical Pb concentration in rice paddy systems (Zeng et al., 2007).

The microbial communities of soils collected from a Pb-Zn mine and a Pb-Zn smelter were significantly affected by Pb and other metals (e.g., Cd) (Hu et al., 2007b). At a mine site, Pb concentration of 57 to 204 mg Pb/kg and Cd concentration of 2.4 to 227 mg Cd/kg decreased the number of bacteria-forming colonies extracted from soils. Principal component analysis of microbial community structure demonstrated that different communities were associated with different metal soil concentration. Similarly, soil microbial communities exposed to metal contamination from a smelter site (soil Pb concentration ranging from 30 to 25,583 mg Pb/kg dry weight) showed decreased bacterial functional diversity (although fungal functional diversity increased) and no effects on soil respiration rates were observed (Stefanowicz et al., 2008). This led the authors to conclude that bacterial diversity is a more sensitive endpoint and a better indicator of metal exposure than fungal diversity or microorganism activity. In a similar study, Kools et al. (2009) showed that soil ecosystem variables measured after a 6-month exposure to metal-contaminated soil indicated that Pb concentration (536 or 745 mg Pb/kg) was an important driver of soil microbial species biomass and diversity.

Pb-resistant bacterial and fungal communities were extracted regularly from soil samples at a shooting range site in southern Finland (Hui et al., 2009). While bioavailable Pb concentration averaged 100 to 200 mg Pb/kg as determined by water extraction, the total Pb concentrations measured on site were 30,000 to 40,000 mg Pb/kg. To determine Pb tolerance, bacterial colonies extracted and cultured from shooting range and control soils were grown on media containing either 0.4 or 1.8 mM Pb. While bacteria isolated from control soil did not proliferate on high-Pb media, shooting-range soil microbe isolates grew on high-Pb media and were deemed Pb tolerant. The authors noted that bacterial species common in control samples were not detected among the Pb-tolerant species isolated from shooting-range soils. They speculated that if long-term exposure to minimally bioavailable Pb can alter the structure of soil decomposer communities, decomposition rates could be altered. However, this would require that the microbial ecosystem decomposing function be altered along with structure, and the authors provided no evidence for alteration of function.

Microbial communities associated with habitats other than soils are also affected by exposure to atmospherically deposited Pb. Alder (*Alnus nepalensis*) leaf microorganism populations were greater in number at non-affected sites than at sites adjacent to a major Indian highway with increased Pb pollution (Joshi, 2008). The density, species richness,

and biomass of testate amoebae communities grown on *Sphagnum fallax* mosses were significantly decreased following moss incubation in Pb solutions of either 625 or 2,500 µg Pb/L (Nguyen-Viet et al., 2008). More importantly, species richness and density were negatively correlated with Pb concentration accumulated within the moss tissue. The structure of microbial communities associated with lichen surfaces was affected by lichen trace-element accumulation, including Pb content. Lichens collected from industrial areas had elevated Pb concentration (10 to 20 mg Pb/kg versus 5 to 7 mg Pb/kg in urban and rural areas, respectively) and housed bacterial communities characterized by increased cyanobacteria biomass (Meyer et al., 2010).

Following a 28-day exposure to field-collected soils contaminated with metals (including Pb at 426 mg Pb/kg), both population growth and individual growth of the earthworm *L. rubellus* were diminished (Klok et al., 2006). The authors proposed that, although these reductions were unlikely to result in extirpation, avian predators such as the godwit (*Limosa limosa*) that feed heavily on earthworms may be affected by a reduction of available earthworm biomass.

During the past 5 years, there has been increasing interest in the effects of Pb and other metals on the functional aspects of soil microbial communities. Most studies show that Pb decreases diversity and function of soil microorganisms. However, in an example of ecological mutualism, plant-associated arbuscular mycorrhizal fungi were found to protect the host plant from Pb uptake, while fungal viability is protected by the host plants. Similarly, soil microbial communities (bacterial species as well as fungi) in Pb-contaminated soils are improved by revegetation. A few studies have reported on effects of Pb to populations of soil invertebrates. They demonstrated that Pb can decrease earthworm population density, although not to levels that would result in local extinction. There have been no recently reported studies on the potential effects of Pb on terrestrial vertebrate populations or communities, or possible indirect effects through reduction of prey items such as earthworms.

7.2.7 Critical Loads in Terrestrial Systems

The general concept and definition of critical loads is introduced in Section 7.1.3 of this chapter [also see Section 7.3 of the 2006 Pb AQCD (U.S. EPA, 2006c)]. An international workshop was conducted in 2005 on the development of critical loads for metals and other trace elements (Lofts et al., 2007). Among the findings of the workshop it was reported that soil transport and transformation processes are key in controlling the fate of metals and trace elements, thus their importance in the input-output mass balance needs to be considered. The degree to which these processes are understood and can be

quantified varies. Complexation, sorption, ion exchange and precipitation are well understood in the lab, but to a lesser extent in the field (Lofts et al., 2007). Slower processes of weathering and fixation are less well understood or studied than leaching (Lofts et al., 2007).

As noted in previous section, soil pH and organic matter influence Pb availability. De Vries et al. (2007) demonstrate that critical limits, measured as critical reactive metal content, can significantly vary between soil types that differ in pH and organic matter. Critical limits of Pb increased from 30 to 64 (mg Pb/kg) over a pH range of 4-7 when soil organic matter content was 5%, while these limits increased from 187 to 400 (mg Pb/kg) over the same pH range when organic content was 80%. These implications suggest that critical limits increase with increasing soil organic matter. This has important consequences for forest soils because many are covered by an organic layer where roots, fungi and other microorganisms are located. Baath (1989) evaluated the effects of organic matter on critical limits for microorganisms, measured via enzyme synthesis, litter decomposition and soil respiration. Results indicate critical limits are up to four times higher in the organic (135 to 976 mg Pb/kg) than the mineral soil layer (32 to 690 mg Pb/kg) at hazardous concentration ranging from 5-50% of species. In general, De Vries et al. (2007) found support that ecotoxicological critical limits in European soils for Pb decrease with increasing pH.

Several methods are routinely used for Pb risk assessment of terrestrial animals. Buekers et al. (2009) proposed the use of a Tissue Residue Approach as a risk estimation method for terrestrial vertebrates that eliminates the need for quantitative estimation of food intake or Pb species bioavailability. Blood Pb no observed effect concentration (NOEC) and lowest observed effects concentration (LOEC) data derived from 25 studies examining the effects of Pb exposure on growth, reproduction, and hematological endpoints were used to construct a series of species sensitivity distributions for mammals and birds. They also used the HC5 criterion (5th percentile of species NOEC values for collection of species) proposed by Aldenberg and Slob (1993). For mammals, the HC5 values obtained ranged from 11 to 18 µg Pb/dL blood; HC5 values for birds ranged from 65 to 71 µg Pb/dL. The authors proposed the use of 18 and 71 µg Pb/dL as critical threshold values for mammals and birds respectively, which are below the lowest NOEC for both data sets used, and are above typical background Pb values. It is difficult to determine environmental Pb toxicity given the variation of physiochemical and soil properties that alter bioavailability and toxicity. This variability makes it difficult to extrapolate between areas. Furman et al. (2006) proposed the use of a physiologically based extraction test to predict risks posed to waterfowl from environmental Pb contamination. The extraction process was modeled after gastric and intestinal conditions of waterfowl, and was used to gauge the bioavailability of Pb from freshly amended and

aged contaminated soils. The concentration of Pb extracted through the use of the physiologically based extraction test was demonstrated to be significantly correlated to Pb tissue concentration in waterfowl exposed via in vivo studies of the same soils.

There are few critical loads for Pb reported for terrestrial ecosystems in the U.S.; however, work has been conducted in Europe. Given that local conditions (including historic loading, soil transport and transformation processes) are key elements to critical load calculation the utility of critical loads that are developed from other countries for application to U.S. ecosystems is unclear. The most recent European publications on Pb critical loads include assessments of the U.K., Netherlands and Italy. Hall et al. (2006) used the critical load approach to conduct a national risk assessment of atmospheric Pb deposition for the U. K. While specific regions were determined to have low critical load values for Pb (central England, the Pennines, and southern Wales), the authors noted that this approach can be significantly biased, as available ecotoxicological data used in the modeling were from studies that were not conducted in soils representative of all U.K. soils. De Vries et al. (2009) similarly observed that the uncertainty inherent in a critical load approach to Pb risk assessment is influenced by the critical concentration of dissolved metal and the absorption coefficients of exposed soils. However, this approach did indicate that for forest soils in the Netherlands, 29% of the areas would be expected to exceed the critical load, based on currently available toxicity data and Pb pollution data (de Vries and Groenenberg, 2009). Similarly, although Pb soil concentrations in the Bologna Province of Italy were far below concentrations harmful to soil organisms, current atmospheric Pb deposition rates suggest that critical load exceedances are likely in the future, unless annual Pb emissions are decreased (Morselli et al., 2006).

7.2.8 Soil Screening Levels

Developed by EPA, ecological soil screening levels (Eco-SSLs) are maximum contaminant concentrations in soils that are predicted to result in little or no quantifiable effect on terrestrial receptors. These conservative values were developed so that contaminants that could potentially present an unacceptable hazard to terrestrial ecological receptors are reviewed during the risk evaluation process while removing from consideration those that are highly unlikely to cause significant effects. The studies considered for the Eco-SSLs for Pb and detailed consideration of the criteria for developing the Eco-SSLs are provided in the 2006 Pb AQCD (U.S. EPA, 2006c). Preference is given to studies using the most bioavailable form of Pb, to derive conservative values. Soil concentration protective of avian and mammalian diets are calculated by first converting dietary concentration to dose (mg/kg body weight per day) for the critical study, then using food (and soil) ingestion rates and conservatively derived

uptake factors to calculate soil concentration that would result in unacceptable dietary doses. This frequently results in Eco-SSL values below the average background soil concentration [19 mg Pb/kg dry weight (U.S. EPA, 2005b, 2003b)], as is the case with Pb for birds. The Pb Eco-SSL was completed in March 2005 and has not been updated since. Values for terrestrial birds, mammals, plants, and soil invertebrates are 11, 56, 120, and 1,700 mg Pb/kg soil (dry weight), respectively.

7.2.9 Characterization of Sensitivity and Vulnerability

Research has long demonstrated that Pb affects survival, reproduction, growth, metabolism, and development in a wide range of species. The varying severity of these effects depends in part upon species differences in metabolism, sequestration, and elimination rates. Dietary factors also influence species sensitivity to Pb. Because of effects of soil aging and other bioavailability factors discussed above (Section 7.2.2), in combination with differing species assemblages and biological accessibility within prey items, ecosystems may also differ in their sensitivity and vulnerability to Pb. The 2006 Pb AQCD reviewed many of these factors which are updated herein by reference to recent literature.

7.2.9.1 Species Sensitivity

There is wide variation in sensitivity of terrestrial species to Pb exposure, even among closely related organisms. Langdon et al. (2005) showed a two-fold difference in LC_{50} values among three common earthworm species, with the standard laboratory species, *E. andrei*, being the least sensitive. Similarly, 28-day EC_{50} values derived for *F. candida* collembola (springtails) were between 2,060 and 3,210 mg Pb/kg in Pb-spiked soils (Lock et al., 2006), while the springtail species *S. curviseta* exhibited no response to a 28-day exposure to 3,200 mg Pb/kg Pb-spiked soil (Xu et al., 2009b). Mammalian NOEC values expressed as blood Pb levels were shown to vary by a factor of 8, while avian blood NOECs varied by a factor of 50 (Buekers et al., 2009). Age at exposure, in particular, may affect sensitivity to Pb. For instance, earlier instar *C. elegans* were more likely than older individuals to exhibit neurobehavioral toxicity following Pb exposure (Xing et al., 2009c), and also demonstrated more pronounced neural degeneration than older larvae and adults (Xing et al., 2009b).

7.2.9.2 Nutritional Factors

Dietary factors can exert significant influence on the uptake and toxicity of Pb in many species of birds and mammals. The 2006 Pb AQCD describes how Ca, Zn, Fe, vitamin E, Cu, thiamin, P, Mg, fat, protein, minerals, and ascorbic acid dietary deficiencies increase Pb absorption and its toxicity. For example, vitamin E content was demonstrated to protect against Pb-induced lipid peroxidation in mallard ducks. Generally, Pb exposure is more likely to produce behavioral effects in conjunction with a nutrient-deficient diet. As previously reported in the 2006 Pb AQCD, Ca deficiencies may increase the susceptibility of different terrestrial species to Pb, including plant (Antosiewicz, 2005), avian (Dauwe et al., 2006; Snoeijs et al., 2005) and invertebrate species. Antosiewicz determined that, for plants, Ca deficiency decreased the sequestration capacity of several species (tomato, mustard, rye, and maize), and that this likely resulted in an increased proportion of Pb at sites of toxic action. Because Pb ions can interact with plant Ca channel pores, in the presence of low Ca and high Pb concentration, a higher proportion of Pb can interact with these channels and be taken up by plants. A similar phenomenon has been observed in invertebrates, where the metabolic pathway of metals mimics the metabolic pathway of Ca [Simkiss et al. (1982), as cited in Jordaens et al. (2006)]. Hence, in environments with disproportionately high Pb versus Ca concentration, accumulation of Pb may be accelerated, as in plants. Ca deficiency in birds was demonstrated to stimulate the production of Ca-binding proteins in the intestinal tract, which extract more Ca from available diet; however, this response also enhances the uptake and accumulation of Pb from diet and drinking water [Fullmer (1997), as cited in Dauwe et al. (2006)].

7.2.9.3 Soil Aging and Site-Specific Bioavailability

Total soil Pb concentration is a poor predictor of hazards to avian or mammalian wildlife, because site-specific biogeochemical and physical properties (e.g., pH, OM, metal oxide concentration) can affect the sequestration capacity of soils. Additionally, soil aging processes have been demonstrated to decrease the bioavailable Pb fraction; as such, laboratory toxicity data derived from spiked soils often overestimate the environmental risk of Pb. Smolders et al. (2009) compared the toxicity of freshly Pb-spiked soils to experimentally aged spiked soils and field-collected Pb-contaminated soils. Experimental leaching and aging was demonstrated to increase invertebrate Pb EC_{50} values by factors of 0.4 to greater than 8; in approximately half the cases, the proportionality of toxicity to Pb content disappeared following experimental aging of freshly spiked soils through leaching. The leaching-aging factor for Pb was determined to be 4.2, and represented the ratio of ED_{10} values derived in aged soils to freshly spiked soils (factors greater than one

indicate decreased toxicity in aged field soils relative to laboratory spiked soils). Consequently, the sensitivity of terrestrial vertebrates to environmental Pb exposures will be heavily dependent on the relative rate of aging and site-specific bioavailability.

7.2.9.4 Ecosystem Vulnerability

Relative vulnerability of different terrestrial ecosystems to effects of Pb can be inferred from the information discussed above on species sensitivity and how soil geochemistry influences the bioavailability and toxicity of Pb. Soil ecosystems with low pH, particularly those with sandy soils, are likely to be the most sensitive to the effects of Pb. Examples of such systems are forest soils, including oak, beech, and conifer forests. The Pine Barrens in southern New Jersey (also known as the Pinelands) is an example of a highly vulnerable ecosystem: it is a dense coniferous (pine) forest with acidic, sandy, nutrient poor soil. As agricultural areas are taken out of production and revert to old fields and eventually forests, their vulnerability to Pb is likely to increase as a result of decreasing OM and acidification of soils (from discontinuation of fertilizing and liming). On the other hand, increasing density of native or invasive plants with associated arbuscular mycorrhizal fungi will likely act to ameliorate some of the effects of Pb (see previous discussion of studies by Sudova and Vostka (2007) and Wong et al. (2007). It is, however, difficult to categorically state that certain plant or soil invertebrate communities are more vulnerable to Pb than others, as the available toxicity data have not yet been standardized for differences in bioavailability (because of use of different Pb salts, different soil properties, and different lengths of aging of soil prior to testing), nutritional state, or organism age, or other interacting factors. Data from field studies are complicated by the co-occurrence of other metals and alterations of pH, such as acidification from SO_2 in smelter emissions, which are almost universal at sites of high Pb exposure, especially at mine or smelter sites. However, because plants primarily sequester Pb in the roots, uptake by soil invertebrates is the most likely pathway for Pb exposure of higher trophic level organisms. Invertivores are likely at higher risk than herbivores. In fact, estimations of Pb risk at a former Pb smelter in northern France indicated that area Pb concentration presented the greatest threat to insectivorous bird and mammal species, but only minimal risk to soil invertebrate and herbivorous mammals (Fritsch et al., 2010). By extension, birds and mammals in ecosystems with a richer biodiversity of soil invertebrates may be more vulnerable to Pb than those in ecosystems with fewer invertebrates (e.g., arid locations). Regardless, the primary determinant of terrestrial ecosystem vulnerability is soil geochemistry, notably pH, CEC, and amount of OM.

7.2.10 Ecosystem Services

Pb deposited on the surface of, or taken up by organisms has the potential to alter the services provided by terrestrial biota to humans. There are no publications at this time that specifically focus on the ecosystem services affected by Pb in terrestrial systems. The evidence reviewed in this ISA illustrates that Pb can cause ecological effects in each of the four main categories of ecosystem services (Section 7.1.2) as defined by Hassan et al. (2005). These effects are sorted into ecosystem services categories and summarized here:

- Supporting: altered nutrient cycling, decreased biodiversity, decline of productivity, food production for higher trophic levels
- Provisioning: plant yields
- Regulating: decline in soil quality, detritus production
- Cultural: ecotourism and cultural heritage values related to ecosystem integrity and biodiversity, impacts to terrestrial vertebrates.

A few studies since the 2006 Pb AQCD consider the impact of metals in general on ecosystem services. Honeybees are important for provisioning services such as pollination and production of honey. They can be exposed to atmospheric Pb by direct deposition or through Pb associated with plants, water or soil. In a study of heavy metals in honeybees in central Italy, there was a statistically significant difference in Pb between bees collected in wildlife reserves compared to bees collected in urban areas with the highest concentration of Pb detected from bees caught in hives near an airport (Perugini et al., 2011). In a review of the effects of metals on insect behavior, ecosystem services provided by insects such as detritus reduction and food production for higher trophic levels were evaluated by considering changes in ingestion behavior and taxis (Mogren and Trumble, 2010). Pb was shown in a limited number of studies to affect ingestion by insects. Crickets (Chorthippus spp) in heavily contaminated sites reduced their consumption of leaves in the presence of increasing cadmium and Pb concentrations (Migula and Binkowska, 1993). Decreased feeding activity in larval and adult Colorado potato beetle (*Leptinotarsa decemlineata*) were observed as a result of dietary exposures of Pb and Cu (Kwartirnikov et al., 1999), while no effects were found in ingestion studies of Pb with willow leaf beetle, *Lochmaea caprae* (Rokytova et al., 2004) mottled water hyacinth weevil, *Neochetina eichhorniae* (Kay and Haller, 1986) and hairy springtail, *Orchesella cincta* (Van Capelleveen et al., 1986).

Soil health for agricultural production and other soil-associated ecosystem services is dependent upon the maintenance of four major functions: carbon transformations, nutrient cycles, soil structure maintenance, and the regulation of diseases and pests and

these parameters may be altered by metal deposition (Kibblewhite et al., 2008). Pb impacts to terrestrial systems reviewed in the previous sections provide evidence for impacts to supporting, provisioning, and regulating ecosystem services provided by soils. For example, earthworms were shown to impact soil metal mobility and availability, which in turn resulted in changes to microbial populations (biodiversity), pH, dissolved organic carbon, and metal speciation (Sizmur and Hodson, 2009), all of which may directly affect soil fertility.

Pb is bioaccumulated in plants, invertebrates and vertebrates inhabiting terrestrial and aquatic systems that receive Pb from atmospheric deposition. This represents a potential route for Pb mobilization into the food web or into food products. For example, Pb bioaccumulation in leaves and roots of an edible plant may represent an adverse impact to the provisioning of food, an essential ecosystem service. Although there is no consistent evidence of trophic magnification there is substantial evidence of trophic transfer. It is through consumption of Pb-exposed prey or Pb-contaminated food that atmospherically deposited Pb reaches species that may have very little direct exposure to it.

There is limited evidence of Pb impacts to plant productivity. Productivity of gray birch (*Betula populifolia*) was impaired in soils with elevated As, Cr, Pb, Zn and V (Gallagher et al., 2008). Tree growth measured in both individuals and at the assemblage level using satellite imagery and field spectrometry was significantly decreased with increasing metal load in soil.

7.2.11 Summary of Effects in Terrestrial Systems

This summary of the effects of Pb on terrestrial ecosystems covers information from the publication of the 2006 Pb AQCD to present. Refer to Section 7.4: Causal Determinations for Ecological Effects of Lead for a synthesis of all evidence dating back to the 1977 Pb AQCD considered in determining causality.

7.2.11.1 Biogeochemistry and Chemical Effects

The amount of Pb dissolved in soil pore water determines the impact of soil Pb on terrestrial ecosystems to a much greater extent than the total amount present. It has long been established that the amount of Pb dissolved in soil solution is controlled by at least six variables: (1) solubility equilibria; (2) adsorption-desorption relationship of total Pb with inorganic compounds; (3) adsorption-desorption reactions of dissolved Pb phases on soil OM; (4) pH; (5) CEC; and (6) aging. Since 2006, further details have been contributed to the understanding of the role of pH, CEC, OM, and aging. Smolders et al.

(2009) demonstrated that the two most important determinants of both solubility and toxicity in soils are pH and CEC. However, they had previously shown that aging, primarily in the form of initial leaching following deposition, decreases soluble metal fraction by approximately one order of magnitude (Smolders et al., 2007). Since 2006, OM has been confirmed as an important influence on Pb sequestration, leading to longer-term retention in soils with higher OM content, and also creating the potential for later release of deposited Pb. Aging, both under natural conditions and simulated through leaching , was shown to substantially decrease bioavailability to plants, microbes, and vertebrates.

7.2.11.2 Bioavailability and Uptake

Plants

Studies with herbaceous species growing at various distances from smelters added to the existing strong evidence that atmospherically transported Pb is taken up by plants. These studies did not establish the relative proportion that originated from atmospheric Pb deposited in the soil, as opposed to that taken up directly from the atmosphere through the leaves. Studies found that in trees, Pb that is taken up through the roots is then generally translocated from the roots to other parts. However, multiple new studies showed that in trees, the proportion of Pb that is taken up through the leaves is likely to be very substantial. One study attempted to quantify it, and suggested that 50% of the Pb contained in Scots Pine in Sweden is taken up directly from the atmosphere. Studies with herbaceous plants found that in most species tested, soil Pb taken up by the roots is not translocated into the stem and leaves.

Invertebrates

Since the 2006 Pb AQCD, various species of terrestrial snails have been found to accumulate Pb from both diet and soil. New studies with earthworms have found that both internal concentration of Pb and mortality increase with decreasing soil pH and CEC. In addition, tissue concentration differences have been found in species of earthworms that burrow in different soil layers. The rate of accumulation in each of these species may result from layer differences in interacting factors such as pH and CEC. Because earthworms often sequester Pb in granules, some authors have suggested that earthworm Pb is not bioavailable to their predators. There is some evidence that earthworm activity increases Pb availability in soil, but it is inconsistent. In various

arthropods collected at contaminated sites, recent studies found gradients in accumulated Pb that corresponded to gradients in soil with increasing distance from point sources.

Vertebrates

There were few new studies of Pb bioavailability and uptake in birds since the 2006 Pb AQCD. A study of two species of sea ducks in Alaska found that 3% of the birds had tissue levels of Pb that indicated exposure above background. Urban pigeons in Korea were found to accumulate 1.6 to 1.9 mg Pb/kg wet weight Pb in the lungs, while in Wisconsin 70% of American woodcock chicks and 43 % of young-of-year had elevated bone Pb (9.6 to 93 mg Pb/kg dry weight in chicks, 1.5 to 220 mg Pb/kg dry weight in young-of-year). None of the locations for these studies was in proximity to point sources, and none was able to identify the origin of the Pb. A study at the Anaconda Smelter Superfund site found increasing Pb accumulation in gophers with increasing soil Pb around the location of capture. A study of swine fed various Pb-contaminated soils showed that the form of Pb determined accumulation.

Food web

New studies were able to measure Pb in the components of various food chains that included soil, plants, invertebrates, arthropods and vertebrates. They confirmed that trophic transfer of Pb is pervasive, but no consistent evidence of trophic magnification was found.

7.2.11.3 Biological Effects

Plants

Experimental studies have added to the existing evidence of photosynthesis impairment in plants exposed to Pb, and have found damage to photosystem II due to alteration of chlorophyll structure, as well as decreases in chlorophyll content in diverse taxa, including lichens and mosses. A substantial amount of evidence of oxidative stress in response to Pb exposure has also been produced. Reactive oxygen species were found to increase in broad bean and tomato plants exposed to increasing concentrations of soil Pb, and a concomitant increase in superoxide dismutase, glutathione, peroxidases, and lipid peroxidation, as well as decreases in catalase were observed in the same plants. Monocot, dicot, and bryophytic taxa grown in Pb-contaminated soil or in experimentally spiked soil all responded to increasing exposure with increased antioxidant activity. In addition,

reduced growth was observed in some experiments, as well as genotoxicity, decreased germination, and pollen sterility.

Invertebrates

Recently published studies have shown neuronal damage in nematodes exposed to low concentrations of Pb (2.5 μM), accompanied by behavioral abnormalities. Reproductive effects were found at lower exposure in younger nematodes, and effects on longevity and fecundity were shown to persist for several generations. Increased mortality was found in earthworms, but was strongly dependent on soil characteristics including pH, CEC, and aging. Snails exposed to Pb through either topical application or through consumption of Pb-exposed plants had increased antioxidant activity, decreased food consumption, growth, and shell thickness. Effects on arthropods exposed through soil or diet varied with species and exposure conditions, and included diminished growth and fecundity, endocrine and reproductive anomalies, and body deformities. Increasing concentration of Pb in the exposure medium generally resulted in increased effects within each study, but the relationship between concentration and effects varied between studies, even when the same medium, e.g., soil, was used. Evidence suggested that aging and pH are important modifiers.

Vertebrates

Effects on amphibians and reptiles included decreased white blood cell counts, decreased testis weight, and behavioral anomalies. However large differences in effects were observed at the same concentration of Pb in soil, depending on whether the soil was freshly amended, or field-collected from contaminated areas. As in most studies where the comparison was made, effects were smaller when field-collected soils were used. In some birds, maternal elevated blood Pb level was associated in recent studies with decreased hatching success, smaller clutch size, high corticosteroid level, and abnormal behavior. Some species show little or no effect of elevated blood Pb level. Effects of dietary exposure were studied in several mammalian species, and cognitive, endocrine, immunological, and growth effects were observed.

7.2.11.4 Exposure Response

Evidence reviewed in previous sections demonstrates clearly that increased exposure to Pb is generally associated with increases in observed effects in terrestrial ecosystems. It also demonstrates that many factors, including species and various soil physiochemical

properties, interact strongly with concentration to modify those effects. In these ecosystems, where soil is generally the main component of the exposure route, Pb aging is a particularly important factor, and one that may be difficult to reproduce experimentally. Without quantitative characterization of those interactions, characterizations of exposure-response relationships would likely not be transferable outside of experimental settings. Since the 2006 Pb AQCD, a few studies of exposure-response have been conducted with earthworms, and results have been inconsistent.

7.2.11.5 Community and Ecosystem Effects

New evidence of effects of Pb at the community and ecosystem levels of biological organization include several studies of the ameliorative effects of mycorrhizal fungi on plant growth, attributed to decreased uptake of Pb by plants, although both mycorrhizal fungus and plant were negatively affected. The presence of both earthworms and mycorrhizal fungi decreased solubility and mobility of Pb in soil in one study, but the presence of earthworms was associated with higher uptake of Pb by plants in another. The presence of snails increased uptake of Pb by earthworms, but not vice-versa. Most recently published research on community and ecosystem effects of Pb has focused on soil microbial communities, which have been shown to be impacted in both composition and activity. Many recent studies have been conducted using mixtures of metals, but have tried to separate the effects of individual metals when possible. One study compared the effects of 6 metals individually (Akerblom et al., 2007), and found that their effects on community composition were similar. In studies that included only Pb, or where effects of Pb could be separated, soil microbial activity was generally diminished, but in some cases recovered over time. Species and genotype composition were consistently altered, and those changes were long-lasting or permanent.

7.2.11.6 Critical Loads, Sensitivity and Vulnerability

Over the longer term, terrestrial systems may be more affected particularly by those metals with a long soil residence time, such as Pb. Exploratory studies of critical load approaches for risk assessment for Pb have been recently conducted in the U.K., the Netherlands, and Italy. Their authors suggested that the main limitations of critical loads approaches in those countries were gaps and uncertainty in both ecotoxicological and Pb deposition data. The most visible indication of the need for improvement was that critical load values were often below background values. Smolders (2009) suggested that correcting for aging and other interacting factors would likely raise predicted-no-effect concentrations, and others proposed basing risk management on tissue residue in

organisms, or creating extraction methods that more closely mimic uptake and accumulation.

Given the heterogeneity of ecosystems affected by Pb, and the differences in expectations for ecosystem services attached to different land uses, it is expected that there will be a range of critical load values for Pb for soils within the U.S.

Recent studies have addressed differences in sensitivity explicitly, and clearly demonstrated high variability between related species, as well as within larger taxonomic groupings. Mammalian NOEC values expressed as blood Pb levels were shown to vary by a factor of 8, while avian blood NOECs varied by a factor of 50 (Buekers et al., 2009). Protective effects of dietary Ca have been found in plants, birds, and invertebrates.

7.3 Aquatic Ecosystem Effects

7.3.1 Introduction to Aquatic Ecosystem Effects

This section of the Pb ISA reviews the new literature since the 2006 Pb AQCD (U.S. EPA, 2006c) on the effects of Pb on freshwater and marine ecosystems. Freshwater and marine/estuarine systems are considered separately due to differences in Pb speciation, bioavailability of Pb, and salinity as modifying factors for Pb toxicity. The focus is on the effects of Pb, with particular focus on ambient level, to aquatic organisms including algae, aquatic plants, invertebrates, vertebrates, and other biota with an aquatic lifestage (e.g., amphibians). Pb from atmospheric sources can be directly deposited over a water surface or enter aquatic systems through runoff from terrestrial systems. Pb loadings to aquatic ecosystems, especially freshwater systems, are primarily derived from the runoff and erosional transport from terrestrial systems (U.S. EPA, 2006c). Wet and dry deposition of Pb to land and water (Section 3.3.1.2), Pb in runoff (Section 3.3.2.4) and Pb in water and sediment (Section 3.3.2.3) are considered in Section 3.3 Fate and Transport of Pb. The flux of Pb in aquatic ecosystems is therefore influenced by the dynamic physical and chemical interactions within a watershed. Data on ambient Pb concentrations in rain, snow, natural waters, and sediment are summarized in Section 3.6.

7.3.2 Biogeochemistry and Chemical Effects of Pb in Freshwater and Saltwater Systems

Quantifying Pb speciation in aquatic environments is critical for determining the toxicity of the metal to aquatic organisms. As reviewed in the 2006 Pb AQCD and discussed in

detail in Section 3.3 of this assessment (Fate and Transport), the speciation process is controlled by many environmental factors. Although aerially deposited Pb largely consists of the labile Pb fraction, once the atmospherically-derived Pb enters surface waters its fate and bioavailability are influenced by Ca concentration, pH, alkalinity, total suspended solids, and dissolved organic carbon (DOC), including humic acids. In sediments, Pb is further influenced by the presence of sulfides and Fe and Mn oxides. For instance, in neutral to acidic aquatic environments, Pb is typically present as $PbSO_4$, $PbCl_4$, Pb^{2+}, cationic forms of Pb hydroxide, and ordinary hydroxide [$Pb(OH)_2$], while in alkaline waters, common forms of Pb include Pb carbonates [$Pb(CO_3)$] and hydroxides [$Pb(OH)_2$]. In freshwater systems, Pb complexes with inorganic OH^- and CO_3^{2-} and forms weak complexes with Cl^-; conversely, Pb speciation in seawater is a function of chloride concentration and the primary species are $PbCl_3$, $PbCO_3$, $PbCl_2$, and $PbCl^+$. In many, but not all aquatic organisms, Pb dissolved in water can be the primary exposure route to gills or other biotic ligands. The toxicity associated with Pb in the water column or sediment pore waters is directly affected by the competitive binding of Pb to the anions listed above.

Currently, national and state ambient water quality criteria for Pb attempt to adjust measured concentrations to better represent the bioavailable free ions, and express the criteria value as a function of the hardness (i.e., amount of Ca and Mg ions) of the water in a specific aquatic system. Models such as the BLM (Paquin et al., 2002) include an aquatic speciation model (WHAM V; see below) combined with a model of competitive binding to gill surfaces, and provides a more comprehensive method for expressing Pb concentrations at specific locations in terms of the bioavailable metal. Sediment quality criteria have not been established, although the EPA has developed methods based on equilibrium partitioning theory to estimate sediment benchmarks for Pb and a few other metals (U.S. EPA, 2005d). The approach is based on the ratio of the sum of simultaneously extracted metals and amount of AVS, adjusted for the fraction of organic carbon present in the sediments, and is reviewed in detail in the 2006 Pb AQCD (U.S. EPA, 2006c). It is important to note that this method cannot accurately predict which sediments are toxic or which metal is the primary risk driver.

A more detailed understanding of the biogeochemistry of Pb in aquatic systems (both the water column and sediments) is critical to accurately predicting toxic effects of Pb to aquatic organisms. It should be recognized, however, that in addition to exposure via sediment and water, chronic exposures to Pb also include dietary uptake, even though the toxicokinetics of this exposure pathway are not yet well understood in aquatic organisms and the influence of the bioavailability factors described above is unknown. Furthermore, changes in environmental factors that reduce the bioaccessible Pb fraction can result in either sequestration in sediments or subsequent release as mobile, bioaccessible forms.

This section provides updated information about the influence of chemical parameters that affect Pb bioaccessibility in the aquatic environment (in sediments and the water column).

Several models are available for estimating the speciation of dissolved Pb. These models were tested by Balistrieri and Blank (2008) by comparing the speciation of dissolved Pb in aquatic systems affected by historical mining activities with that predicted by several models, including Windermere humic aqueous model (WHAM VI), non-ideal competitive absorption Donnan-type model (NICA-Donnan), and Stockholm humic model (SHM). Accurate prediction of labile Pb concentrations was achieved only with SHM, although other metal concentrations were better described by the WHAM model. Whereas both WHAM VI and NICA-Donnan predicted that the bulk of Pb contamination would be complexed with iron, SHM predicted Pb speciation predominantly characterized by both iron and inorganic Pb complexes. Predicted dynamic Pb concentrations developed with the WHAM VI and NICA-Donnan methods overestimated Pb concentrations measured using diffusive gradients in thin-films in Lake Greifen (Switzerland), but underestimated concentrations in Furbach stream (both in the Coeur D'Alene River Basin in Idaho), indicating that such models may not be able to accurately describe metal speciation under all environmental conditions (Balistrieri and Blank, 2008).

Quantification of different sediment metal-binding phases, including sulfide, organic C, Fe, and Mn phases, is important to fully understand the bioaccessible fraction of Pb and the toxicity to benthic organisms (Simpson and Batley, 2007). However, physical disturbance, pH change, and even the biota themselves also alter sediment binding or release of Pb. Atkinson et al. (2007) studied the effects of pH on sequestration or release of Pb from sediments. Although high and circumneutral water pH (8.1 and 7.2) did not affect the release of sequestered Pb from sediments, lowering the pH to 6 increased the concentration of Pb in overlying waters from less than 100 µg Pb/L to 200-300 µg Pb/L. Physical sediment disturbance also increased the amount of sediment-bound Pb released into the aqueous phase. When Pb-contaminated sediment was physically disturbed, the dissolved oxygen content of the overlying water was observed to significantly impact Pb mobilization, with greater Pb mobilization at lower dissolved oxygen levels (3 to 9 mg/L O_2) (Atkinson et al., 2007). In addition, although Pb concentrations in the sediments of a mine-impacted wetland in Hezhang, China, were determined to be strongly associated with organic/sulfide and residual fractions (e.g., 34 to 82% of total Pb), the presence of aquatic macrophytes altered the Pb speciation, increasing the fraction of Pb bound to Fe-Mn oxides (42% to 47% of total Pb) (Bi et al., 2007). This phenomenon was investigated in greater depth by Sundby et al. (2005), who determined that release of oxygen from

macrophyte roots resulted in the oxidation of sediment-bound Pb, leading to the release of bioaccessible Pb fractions (Sundby et al., 2005).

7.3.2.1 Other Metals

Multiple metals are present simultaneously in many aquatic environments and may interact with one another influencing Pb uptake and toxicity. Interactions of Pb with other metals were reviewed in the 2006 Pb AQCD and new evidence in this ISA supports previous findings of altered bioavailability associated with metal mixtures. Komjarova and Blust (2008) looked at the effect of the presence of Cd^{2+} on the uptake of Pb by the freshwater cladoceran *Daphnia magna*. While Pb uptake rates were not affected by Cu, Ni or Zn, enhanced Pb accumulation was observed in the presence of 0.2 µM Cd. The highest Pb concentrations (0.25 µM) in turn facilitated Cu uptake. Area-specific and whole organism Pb transport rates were greatest in the mid-intestine. It was concluded that Pb-induced disruptions of ion homeostasis and metal absorption processes might be a possible explanation of stimulated Pb uptake in the presence of Cd, as well as the increase in Cu uptake rates provoked by presence of Pb at its highest studied concentration. Komjarova and Blust (2009b) then considered the effect of Na, Ca and pH on simultaneous uptake of Cd, Cu, Ni, Pb and Zn. Cd and Pb showed increased uptake rates at high Na concentration. It was thought that increased Na uptake rates promoted Pb entrance to the cell. With respect to the effect of pH, reduced proton competition begins to influence Pb uptake in waters with high pH. A clear suppression of Cd, Ni, Pb and Zn uptake was observed in the presence of Ca (2.5 mM). Ca has been reported to have a protective effect in other studies (involving other organisms). The presence of other metals may also affect the uptake of Pb by fish. At low concentrations, Cd in a Pb-Cd mixture out-competed Pb at gill tissue binding sites in rainbow trout (*Oncorhynchus mykiss*), resulting in a less-than additive toxicity when fish were exposed to both metals in tandem (Birceanu et al., 2008). Evidence for the presence of Pb influencing the uptake of other metals was observed in the marine bivalves *Macomona liliana* and *Austrovenus stutchburyi*. Significantly, more Zn bioaccumulated in the presence of Pb in these mussels than with Zn alone following a 10-day exposure to spiked sediments (Fukunaga and Anderson, 2011).

7.3.2.2 Biofilm

Farag et al. (2007) measured Pb concentrations in various media (water, colloids, sediment, biofilm) as well as invertebrates and fish collected within the Boulder River watershed, MT, U.S. They concluded that the fraction of Pb associated with Fe-oxides

was most frequently transferred to biofilms and the other biological components of the sampled systems (Farag et al., 2007). Consequently, an increase in the Pb Fe-oxide fraction could signify a potential increase in the bioaccessible pool of Pb. The authors also noted that this fraction may promote downstream transport of Pb contamination. Ancion et al. (2010) investigated whether urban runoff metal contaminants could modify biofilm bacterial community structure and diversity and therefore potentially alter the function of biofilms in stream ecosystems. They found that accumulation rates for metals in biofilm were maximal during the first day of exposure and then decreased with time. Equilibrium between metal concentrations in the water and in the biofilm was reached for all metals after 7-14 days of exposure. The affinity of the biofilm for Pb was, however, much greater than for Cu and Zn. With respect to recovery, the release of metals was slow and after 14 days in clean water 35% of Pb remained in the biofilm. By retaining and releasing such metal pollutants, biofilms may play a key role in determining both the concentration of the dissolved metals in the water column and the transfer of the metals to invertebrates and fish grazing on them. An enrichment factor of 6,000:1 for Pb between the biofilm and the water was measured after 21 days exposure to synthetic urban runoff. The relatively slow release of such metal may greatly influence the transfer of Pb to organisms feeding on the biofilms. This may be of particular importance during storm events when large amounts of Pb are present in the urban runoff. It was suggested that biofilms constitute an integrative indicator of metal exposure over a period of days to weeks.

7.3.2.3 Carbonate

An investigation of heavy metal concentrations in an industrially impacted French canal (Deule canal) indicated that total extractable Pb in sediments ranged from 27 to 10,079 mg Pb/kg, with 52.3% present in Fe-Mn oxide fractions, 26.9% as organic sulfide fraction, 10.7% in carbonates, and 10.1% in the residual fraction (Boughriet et al., 2007). The relatively high fraction of Pb associated with carbonates was not observed at other sites, as sediments in these areas contained low proportions of carbonates. Hence, addition of carbonates (either from anthropogenic or natural sources) can significantly impact Pb speciation in sediments, and potential bioavailability to resident organisms. In addition, increased surface water carbonate concentrations also reduced the bioaccessible Pb fraction as measured by chronic Pb accumulation in the fathead minnow, (*Pimephales promelas*) (Mager et al., 2010), and by Pb toxicity to fathead minnow and the cladoceran *Ceriodaphnia dubia* (Mager et al., 2011b).

7.3.2.4 Dissolved Organic Matter (DOM)

Uptake of Pb by water-column organisms is affected by the concentration of DOM (Mager et al., 2011a; Mager et al., 2010). In a 7-day chronic study with *C. dubia*, DOM protected against toxicity while water hardness was not protective (Mager et al., 2011a). The specific composition of DOM has been shown to affect the bioaccessibility of environmental Pb. Humic acid-rich DOM resulted in decreased free Pb ion concentration when compared to systems containing DOM with high concentrations of polysaccharides (Lamelas and Slaveykova, 2008). When the sequestering abilities of various components of DOM were compared, humic acid again was shown to be most efficient at reducing the Pb free ion concentration, followed by fulvic acid, alginic acid, polygalacturonic acid, succinoglycan, and xanthan (Lamelas et al., 2005). Lamelas et al. (2009) considered the effect of humic acid on Pb(II) uptake by freshwater algae taking account of kinetics and cell wall speciation. The uptake flux was described by a Michaelis-Menten type equation. Comparison of Cu(II), Cd(II) and Pb(II) uptake by green freshwater algae, *Chlorella Kessleri*, in the presence of either citric acid or humic acid was made. The uptake fluxes, percentage adsorbed and percentage internalized for Cu and Cd were identical in the presence of either citric or humic acid. In contrast, however, there was a ten-fold increase in the respective values for Pb. The increase in adsorbed Pb was attributed to the increase in adsorption sites from the adsorbed humic acid on the surface of the algae. Two hypotheses were considered to explain the increase in internalized Pb and the internalization flux: (1) direct interaction of Pb-humic acid complexes with the internalization sites, and (2) uptake of Pb(II) after dissociation from the Pb-humic acid complex. The authors favor the former hypothesis but no evidence is presented for the proposed ternary Pb-humic acid-internalized site complexes, nor is there an explanation as to why this behavior is not observed for Cd or Cu.

There is evidence, however, that DOC/DOM does not have the same effect on free Pb ion concentration in marine systems as in freshwater systems. No correlation was observed between DOM concentration or composition and Pb toxicity when examined using the sea urchin *Paracentrotus lividus* embryo-larval bioassay (Sanchez-Marin et al., 2010b). For marine invertebrates, the presence of humic acid increased both the uptake and toxicity of Pb, despite the fact that a larger fraction of Pb is complexed with humic acid (25 to 75%). Although the authors could not provide a precise explanation for this, they theorized that in marine environments, addition of humic acid could induce and enhance uptake of Pb via membrane Ca^{2+} channels (Sanchez-Marin et al., 2010a). This mechanism was observed in the marine diatom *Thalassiosira weissflogii*, in that humic acids absorbed to cell surfaces increased metal uptake; however, water column Pb-humic acid associations did appear to reduce free Pb ion concentrations (Sanchez-Marin et al., 2010a). Formation of a ternary complex that is better absorbed by biological membranes

was another proposed mechanism that could describe the increased bioaccessibility to marine invertebrates of Pb bound to humic acid (Sánchez-Marín et al., 2007).

Sanchez-Marin et al. (2011) subsequently have shown that different components of DOM have different effects on Pb bioavailability in marine systems. Their initial research using commercially-derived humic acid found that increasing humic acid concentrations increased Pb uptake by mussel gills and increased toxicity to sea urchin larvae in marine environments (Sánchez-Marín et al., 2007). In contrast, a subsequent investigation found that fulvic acid reduced Pb bioavailability in marine water (Sánchez-Marín et al., 2011). The contradictory effects of different components of DOM on marine bioavailability likely reflect their distinct physico-chemical characteristics. More hydrophobic than fulvic acid, humic acid may adsorb directly with cell membranes and enhance Pb uptake through some (still unidentified) mechanism (Sánchez-Marín et al., 2011).

As little as 1 µmol of humic acid introduced into surface waters was sufficient to reduce Pb uptake by perennial ryegrass, *Lolium perenne*, grown in nutrient solution. This resulted from a decrease in the concentration of the free Pb fraction by several orders of magnitude following complexation with the OM. Pb content on the root surface was reduced to 8 µmol/g from 20 µmol/g following humic acid addition, and relative Pb absorption (absorption in the presence of humic acid divided by absorption in the absence of humic acid) was determined to be approximately 0.2 (Kalis et al., 2006). Conversely, humic acid may increase the bioaccessible Pb fraction for green algae through formation of a ternary complex that promotes algal uptake of the metal. Lamelas and Slaveykova (2007) found that aqueous Pb formed complexes with humic acid, which in turn would become adsorbed to *C. kesslerii* algal surfaces, and that the presence of Pb sorbed to humic acid did not interfere with humic acid-algae complexation. The authors concluded that humic acids bound to algae acted as additional binding sites for Pb, thus increasing the concentrations associated with the algal fraction (Lamelas and Slaveykova, 2007).

Based on the above, the recent literature indicates the existence of a number of deviations from current models used to predict bioaccessibility of Pb. In marine aquatic systems, for instance, surface water DOM was found to increase (rather than decrease) uptake of Pb by fish gill structures, potentially through the alteration of membrane Ca-channel permeability. This phenomenon would not be accurately predicted by a BLM developed using data from freshwater organisms. Further, in both freshwater and marine environments, algal biosorption of labile Pb fraction was also increased by humic acid and DOM, likely through the formation of ternary complexes that increase Pb binding sites on the algal surface. Although it is unclear whether Pb in this form is available for toxic action on algae, it is likely to comprise a significant source of dietary Pb for primary consumers. Moreover, the attempted field verification of freshwater

bioaccessibility models was conducted at sites with distinct point-sources of Pb contamination, and only one model (SHM) adequately predicted Pb bioaccessibility.

7.3.2.5 Sulfides

In sediments, Pb bioavailability is further influenced by sulfides. In the presence of sulfides, most of the reactive metal in sediments will form insoluble metal sulfide that is not bioavailable for uptake by benthic organisms. Acid volatile sulfide (AVS) has been used to predict the toxicity of Pb and other metals in sediments (Ankley et al., 1996; Di Toro et al., 1992) and in the development of sediment quality criteria (Section 7.3.3). The role of sulfides in the flux of Pb from sediments is discussed further in Section 3.3.2.3.

7.3.3 Introduction to Bioavailability and Biological Effects of Pb in Freshwater Ecosystems

Freshwater ecosystems across the U.S. encompass many habitats including ponds, streams, rivers, wetlands and lakes. Representative median and range of Pb concentrations in surface waters (median 0.50 µg Pb/L, range 0.04 to 30 µg Pb/L), sediments (median 28 µg Pb/g dry weight, range 0.5 to 12,000 µg Pb/g dry weight) and fish tissues (median 0.59 µg Pb/g dry weight, range 0.08 to 23 µg Pb/g dry weight [whole body]) in the U.S. based on a synthesis of National Water Quality Assessment (NAWQA) data reported in the previous 2006 Pb AQCD (U.S. EPA, 2006c). Additional information on ambient Pb levels in waters, sediments and biota is presented in Section 3.6.5 and Table 2-1 including new data from the Western Airborne Contaminants Assessment Project (WACAP) on Pb in environmental media and biota from remote ecosystems in the Western U.S. WACAP assessed concentrations of semi-volatile organic compounds and metals in up to seven ecosystem components (air, snow, water, sediment, lichen, conifer needles and fish) in watersheds of eight core national parks during a multi-year project conducted from 2002-2007 (Landers et al., 2008). The goals of the study were to assess where these contaminants were accumulating in remote ecosystems in the Western U.S., identify ecological receptors for the pollutants, and to determine the source of the air masses most likely to have transported the contaminants to the parks.

The 2006 Pb AQCD provided an overview of regulatory considerations for water and sediments in addition to consideration of biological effects and major environmental factors that modify the response of aquatic organisms to Pb exposure. Regulatory guidelines for Pb in water and sediments have not changed since the 2006 Pb AQCD and

are summarized below with consideration of limited new information on these criteria since the last review. This section is followed by new information on biogeochemistry, bioavailability and biological effects of Pb since the 2006 Pb AQCD.

The most recent ambient water quality criteria (AWQC) for Pb in freshwater were released in 1985 (U.S. EPA, 1985) by the EPA Office of Water which employed empirical regressions between observed toxicity and water hardness to develop hardness-dependent equations for acute and chronic criterion. These criteria are published pursuant to Section 304(a) of the Clean Water Act and provide guidance to states and tribes to use in adopting water quality standards for the protection of aquatic life and human health in surface water. The ambient water quality criteria for Pb are expressed as a criteria maximum concentration (CMC) for acute toxicity and criterion continuous concentration (CCC) for chronic toxicity (U.S. EPA, 2010b). In freshwater, the CMC is 65 µg Pb/L and the CCC is 2.5 µg Pb/L at a hardness of 100 mg/L.

The 2006 Pb AQCD summarized two approaches for establishing sediment criteria for Pb based on either bulk sediment or equilibrium partitioning (Section 7.2.1, Table 7-2 and Section AX7.2.1.4). The first approach is based on empirical correlations between metal concentrations in bulk sediment and associated biological effects to derive threshold effect concentrations (TEC) and probable effects concentrations (PEC) (MacDonald et al., 2000). The TEC/PEC approach derives numeric guidelines to compare against bulk sediment concentrations of Pb. The other approach in the 2006 Pb AQCD was the equilibrium partitioning procedure published by the EPA for developing sediment criteria for metals (U.S. EPA, 2005d). The equilibrium partitioning approach considers bioavailability by relating sediment toxicity to pore water concentration of metals. The amount of simultaneously extracted metal (SEM) is compared with the metals extracted via AVS since metals that bind to AVS (such as Pb) should not be toxic in sediments where AVS occurs in greater quantities than SEM.

Since the 2006 Pb AQCD both of these methods, for estimating sediment criteria for metals, they have continued to be used and refined. The SEM approach was further refined in the development of the sediment BLM (Di Toro et al., 2005). The BLM is discussed further in Sections 7.2.3 and 7.3.4. Comparison of empirical approaches with AVS-SEM in metal contaminated field sediments shows that samples where either method predicted there should be no toxicity due to metals, no toxicity was observed in chronic amphipod exposures (Besser et al., 2009; MacDonald et al., 2009). However, when the relationship between invertebrate habitat (epibenthic and benthic) and environmental Pb bioaccumulation was investigated, De Jonge et al. (2010) determined that different environmental fractions of Pb were responsible for invertebrate uptake and exposure. Pb uptake by benthic invertebrate taxa was not significantly correlated to AVS

Pb levels, but rather to total sediment concentrations (De Jonge et al., 2009). Conversely, epibenthic invertebrate Pb body burdens were better correlated to AVS concentrations, rather than total Pb sediment concentrations (De Jonge et al., 2010).

In the following sections, new information since the 2006 Pb AQCD on Pb in aquatic ecosystems will be presented. Throughout the sections, brief summaries of conclusions from the 1977 Pb AQCD, the 1986 Pb AQCD and 2006 Pb AQCD are included where appropriate. The sections are organized to consider uptake of Pb and effects at the species level, followed by community and ecosystem level effects. Freshwater ecosystem effects are considered first, followed by corresponding sections on effects in saltwater ecosystems. New research on the bioavailability and uptake of Pb into freshwater organisms including plants, invertebrates and vertebrates is presented in Section 7.3.4 Effects of Pb on the physiology of freshwater fauna and biota (Section 7.3.5) are followed with data on exposure and response of freshwater organisms (Section 7.3.6). Responses at the community and ecosystem levels of biological organization are reviewed in Section 7.3.7 followed by a brief consideration of critical loads in freshwater systems (Section 7.3.8), and characterization of sensitivity and vulnerability of ecosystem components (Section 7.3.9). Corresponding sections for saltwater ecosystems include bioavailability (Section 7.3.11), biological effects of Pb in saltwater (Section 7.3.12) and exposure and response of saltwater species (Section 7.3.13). Community and ecosystem level effects in saltwater are considered in Section 7.3.14, followed by characterization of sensitivity and vulnerability in saltwater species (Section 7.3.15). Finally, the effects of Pb on ecosystem services associated with aquatic environments are discussed in Section 7.3.16 and an overall summary of aquatic effects is presented in Section 7.3.17.

7.3.4 Bioavailability in Freshwater Systems

Bioavailability was defined in the 2006 Pb AQCD as "the proportion of a toxin that passes a physiological membrane (the plasma membrane in plants or the gut wall in animals) and reaches a target receptor (cytosol or blood)." In 2007, EPA took cases of bioactive adsorption into consideration and revised the definition of bioavailability as "the extent to which bioaccessible metals absorb onto, or into, and across biological membranes of organisms, expressed as a fraction of the total amount of metal the organism is proximately exposed to (at the sorption surface) during a given time and under defined conditions" (Fairbrother et al., 2007).

The bioavailability of metals varies widely depending on the physical, chemical, and biological conditions under which an organism is exposed (U.S. EPA, 2007c). The bioavailability of a metal is also dependent upon the bioaccessible fraction of metal. The

bioaccessible fraction of a metal is the portion (fraction or percentage) of environmentally available metal that actually interacts at the organism's contact surface and is potentially available for absorption or adsorption by the organism (U.S. EPA, 2007c). The processes for evaluating bioavailability and bioaccessibility are presented in Figure 7-1 and in Section 7.2.3. In brief, trace metals, and their complexes, must first diffuse from the external medium to the surface of the organism (mass transport). Metal complexes may dissociate and re-associate in the time that it takes to diffuse to the biological surface. These processes are considered further in Chapter 3. To have an effect on the organism, metals must then react with a sensitive site on the biological membrane (adsorption/desorption processes), often but not necessarily followed by biological transport (internalization). Any of these processes may be the rate limiting step for the overall biouptake process. Internalization is, however, the key step in the overall biouptake process. Although the transport sites often have a high affinity for required metals they do not always have high selectivity and so a toxic metal may bind to the site of an essential metal with a similar ionic radius or co-ordination geometry, e.g., Pb^{2+}, Cd^{2+} and Zn^{2+} are similar to Ca^{2+}. At the molecular level, there are three major classes of transition metal transporter: P-type ATPases, Zn regulated transporter/iron-regulated transporter, and natural resistance associated macrophage proteins (Worms et al., 2006). Of these, natural resistance associated macrophage proteins have been shown to promote the uptake of various metals including Pb. This type of trace metal transport can be described by Michaelis-Menten uptake kinetics and equilibrium considerations.

Routes of Exposure

According to the 2006 Pb AQCD, Pb adsorption, complexation, chelation, etc., are processes that alter its bioavailability to different aquatic species, and it was suggested that multiple exposure routes may be important in determining overall bioavailability of Pb. Given its low solubility in water, bioaccumulation of Pb by aquatic organisms may preferentially occur via exposure routes other than direct absorption from the water column, including ingestion of contaminated food and water, uptake from sediment pore waters, or incidental ingestion of sediment. If uptake and accumulation are sufficiently faster than depuration and excretion, Pb tissue levels may become sufficiently high to result in physiological effects (Luoma and Rainbow, 2005). Pb accumulation rates are controlled, in part, by metabolic rate. Other factors that influence bioavailability of Pb to organisms in aquatic systems are reviewed in Section 7.3.2. As summarized in the 2006 Pb AQCD, organisms exhibit three Pb accumulation strategies: (1) accumulation of significant Pb concentrations with low rate of loss resulting in substantial accumulation; (2) balance between excretion and bioavailable metal in the environment; and (3) very low metal uptake rate without significant excretion, resulting in weak net accumulation

(Rainbow, 1996). Uptake experiments with aquatic plants, invertebrates and vertebrates reviewed in the 2006 Pb AQCD showed increases in Pb uptake with increasing Pb in solution. The 2006 Pb AQCD findings included consideration of bioaccumulation in different trophic levels. Pb concentrations were found to be typically higher in algae and benthic organisms and lower in higher trophic-level consumers.

In this section:

1) Recent information on bioavailability and uptake in algae, plants, invertebrates and vertebrates from freshwater systems are reviewed with summary material from the 2006 Pb AQCD where appropriate.

2) An overview of the BLM is presented as the most widely used method for predicting both the bioaccessible and bioavailable fractions of Pb in the aquatic environment. This is followed by a discussion of

3) Bioavailability in algae, plants, invertebrates and vertebrates. As reviewed by Wang and Rainbow (2008), aquatic organisms exhibit distinct patterns of metal bioaccumulation. The authors suggest that the observed differences in accumulation, body burden, and elimination between species are due to metal biogeochemistry and physiological and biological responses of the organism. The studies presented below generally support the observations of Wang and Rainbow (2008) that closely related species can vary greatly in bioaccumulation of Pb and other non-essential metals.

The bioaccumulation and toxicity of Pb to aquatic organisms are closely linked to the environmental fate of the metal under variable environmental conditions (Section 3.3) as they are highly dependent upon the relative proportion of free metal ions in the water column. However, information is lacking on the uptake of Pb through ingestion of Pb-sorbed particles or dietary exposure to biologically-incorporated Pb. Such routes of exposure are not included in models such as the BLM that predict toxicity as a function of Pb concentration in the water column. This uncertainty may be greater for Pb than for other more soluble metals (such as Cu) as a greater proportion of the total mass of Pb in an aquatic ecosystem is likely to be bound to particulate matter. Therefore, estimating chronic toxicity of Pb to aquatic receptors may have greater uncertainty than predicting acute effects.

BLM Models

In addition to the biogeochemical effects that govern the environmental pool of accessible Pb, reactions of Pb with biological surfaces and membranes determines the

bioavailability and uptake of the metal by aquatic organisms. The BLM (Figure 7-2) predicts both the bioaccessible and bioavailable fraction of Pb in the aquatic environment, and can be used to estimate the importance of environmental variables such as DOC in limiting uptake by aquatic organisms (Alonso-Castro et al., 2009). The BLM integrates the binding affinities of various natural ligands in surface waters and the biological uptake rates of aquatic organisms to determine the site-specific toxicity of the bioavailable fraction.

In the 2006 Pb AQCD, limitations of the use of BLM in developing air quality criteria were recognized including the focus of this model on acute endpoints and the absence of consideration of dietary uptake as a route of exposure. Atmospheric deposition of Pb to aquatic systems and subsequent effects on ecosystem receptors is likely characterized as a chronic, cumulative exposure rather than an acute exposure. Recommendations from the 2006 Pb AQCD included developing both chronic toxicity BLMs and BLMs that consider the dietary route of Pb uptake. The EPA recently incorporated the BLM into the Framework for Metal Risk Assessment (U.S. EPA, 2007c) and has published an ambient freshwater criteria document for Cu based on the BLM model (U.S. EPA, 2007a). This section reviews the literature from the past 5 years on applications of the BLM to predicting bioavailability of Pb to aquatic organisms. However, the primary focus of initial BLMs has been acute toxicity endpoints for fish and invertebrates following gill or cuticular uptake of metals.

Di Toro et al. (2005) constructed BLMs for metals exposure in sediments, surface water, and sediment pore water to determine how to most accurately predict the toxicity of metals-contaminated sediments. Results from models were compared with literature-derived acute toxicity values for benthic and epibenthic invertebrates to establish the accuracy of the developed models. Although the models tended to overestimate the toxicity of aqueous and sediment-bound Pb in freshwater environments, it was determined that the model significantly underestimated Pb toxicity to marine invertebrates (Di Toro et al., 2005). This may be because pore water metal concentrations were not modeled. Consequently, these results may suggest that either 1) mobilization of Pb concentrations from sediments into pore water is greater in marine environments, or 2) marine invertebrates are significantly more sensitive to Pb exposures than are freshwater species.

A number of deviations from results predicted by Pb exposure models (such as the BLM) were documented by Ahlf et al. (2009). They highlighted that uptake of metals by sediment-dwelling bivalves was significantly greater than predicted, because bivalves accumulate Pb from multiple sources not included in the model, such as ingestion of algae, bacteria, and colloidal matter. Species-specific dietary assimilation of ingested

particulate-bound metals is also likely to play a role in the toxicity of Pb to aquatic organisms, yet insufficient data are available to permit modeling of this additional factor (Ahlf et al., 2009). The authors outlined the need for additional data in developing bioavailability models for chronic metal exposures. As recent evidence suggests that the hydrophobic DOC fraction (e.g., humic and fulvic acids) sequesters the greatest fraction of Pb in aquatic systems (Pernet-Coudrier et al., 2011), understanding the influence of this adsorption on Pb toxicity is critical for the prediction of chronic aquatic Pb toxicity. For instance, although the presence of humic acid is considered to reduce the bioavailable fraction of metals in surface water, green algae uptake and biosorption of metals, including Pb, was actually increased by humic acid. The authors determined that humic acid bound to algal surfaces served to increase the total number of metal binding sites over those afforded solely by the algal surface (Lamelas and Slaveykova, 2007). This highlights the complexity of modeling chronic metals bioavailability through multiple exposure routes, as humic acid would decrease gill or cuticular uptake of metals from the water column, but could potentially enhance dietary exposure by increasing algal metal content. Slaveykova and Wilkinson (2005) also noted that humic acid is likely to interact with other biological membranes and alter their permeability to metals, especially in acidic environments. Further, they observed that increased surface water temperatures can not only increase membrane permeability but also change metabolic rates, both of which can enhance metals uptake and assimilation; however, this factor is not included in bioavailability models such as the BLM (Slaveykova and Wilkinson, 2005). Despite this, the authors noted that, in most cases, the BLM could predict acute metals toxicity with a reasonable degree of accuracy.

7.3.4.1 Freshwater Plants and Algae

In the 1977 Pb AQCD, the root system of plants was recognized as the major route of uptake for Pb (U.S. EPA, 1977). Aquatic macrophytes and algae can accumulate Pb from either the water column or sediments, based on their specific microhabitats. For instance, rooted macrophytes may be more likely to accumulate Pb from sediment sources, while floating macrophytes or algae will take up Pb suspended or dissolved in the water column. However, significant species-dependent differences in bioaccumulation rates, as well as concentrations of sequestered metals within different parts of the plants (shoots versus roots), have also been observed and some authors have concluded that the plant species is a more important determinant of Pb uptake than is habitat type. Plants that are hyperaccumulators of Pb and other metals may be used for phytoremediation at highly contaminated sites and there is a large body of literature on uptake of very high concentrations of metals by different species, however, this chapter focuses on

environmentally relevant concentrations of Pb and also those studies with doses or exposures in the range of one or two orders of magnitude above current or ambient conditions, as described in the Preamble**.** Uptake and translocation studies of Pb in plants and algae reviewed in the 1977 Pb AQCD and the 2006 Pb AQCD indicated that plants tend to sequester larger amounts of Pb in their roots than in their shoots. Recent studies on bioavailability of Pb to plants support the findings of the previous Pb AQCDs and provide additional evidence for species-dependent differences in responses to Pb in water and sediments.

The microalgae *Spirulina platensis* was demonstrated to accumulate Pb from Zarrouk culture medium, with 2.7, 6.9, 19, 45 and 145 µg Pb/mg accumulated at high Pb concentrations of 5,000, 10,000, 30,000, 50,000 and 100,000 µg Pb/L, following a 10-day incubation period (Arunakumara et al., 2008). Pb concentrations accumulated by algae appeared to decrease when culture time increased from 2 to 10 days. This may have occurred as a result of a gradual recovery of growth and an addition of biomass that would have reduced the concentration of Pb in algal tissue. An aquatic moss, *Fontinalis antipyretica*, accumulated up to an average of 3 µmol Pb/g dry weight over a 7-day exposure to 100 µmol Pb, despite saturation of intracellular Pb concentrations after 5 days of exposure (Rau et al., 2007). Interestingly, experimentation with concurrent Cu and Pb exposure indicated that the presence of Cu increased the uptake of Pb by the green algae *Chlamydomonas reinhardtii* (Chen et al., 2010c). The authors noted that, in the case of Cu-Pb binary exposures, uptake rates of Pb exhibited complex non-linear dynamics in other aquatic organisms as well. When exposed to water concentrations of up to 100 µmol Pb/L, floating (non-rooted) coontail plants (*Ceratophyllum demersum*) accumulated an average Pb concentration of 1,748 mg Pb/kg after 7 days, although this was not significantly higher than levels accumulated in the first day of exposure (Mishra et al., 2006b). Induction of the antioxidant system improved the tolerance of the aquatic plant *Najas indica* for bioaccumulated Pb, allowing for increased biomass and the potential to accumulate additional Pb mass. High Pb accumulation (3,554 mg Pb/kg dry weight tissue following a 7-day exposure to 100 µmol Pb/L) was considered to be a function of plant morphology; as a submerged, floating plant, *N. indica* provides a large surface area for the absorption of Pb (Singh et al., 2010). Pb bioaccumulation in curly pondweed (*Potamogeton crispus*) was observed to be dose-dependent, with plants accumulating 3.3, 5.5, 15.4, and 23.6 µg Pb/g, at aquatic concentrations of 10, 20, 30, 40, and 50 mM Pb (Xu et al., 2011).

Given that atmospherically-derived Pb is likely to become sequestered in sediments, uptake by aquatic macrophytes is a significant route of Pb removal from sediments, and a potential route for Pb mobilization into the aquatic food web. The rooted aquatic macrophyte *Eleocharis acicularis* was determined to be a hyperaccumulator of Pb in an

11-month bioaccumulation experiment with mine tailings. When grown in sediments containing 1,930 mg Pb/kg, the maximum concentration of Pb in *E. acicularis* was determined to be 1,120 mg Pb/kg dry weight. However, calculated BCFs for Pb were all less than one, indicating that Pb uptake, although high, was less efficient than for other metals present (Ha et al., 2009).

Aquatic plants inhabiting a wetland containing an average sediment Pb concentration of 99 mg Pb/kg exhibited variable Pb tissue concentrations, but these do not appear to be related to macrophyte type (e.g., submerged, floating, emergent, etc.). Consequently, the authors concluded that uptake of Pb by aquatic plants appears to be dependent on species, at the exclusion of habitat or type. For instance, among the submerged plant species, *Ceratophyllum demersum* accumulated the greatest amount of Pb (22 µg/g dry weight), while *Potamogeton malainus* tissue contained the least amount of Pb, 2.4 µg/g dry weight (Bi et al., 2007). Tissues of the floating plants *Azolla imbricata* and *Spirogyra communis* were found to contain 12 and 20 mg Pb/kg dry weight, respectively, while emergent macrophytes *Scirpus triqueter* and *Alternanthera philoxeroides* accumulated 1.4 and 10 mg Pb/kg dry weight. Fritioff and Greger (2006) determined that anywhere from 24–59% of the total Pb taken up by *Potamogeton natans* aquatic plants was sequestered in the cell wall fraction, depending on plant tissue and environmental Pb concentration. More importantly, no translocation of Pb was observed when plant tissues (leaf, stem, root) were exposed to Pb solutions separately (Fritioff and Greger, 2006).

Dwivedi et al. (2008) reared nine different species of aquatic plants in a fly-ash contaminated medium containing approximately 7 mg Pb/kg dry weight. Not only did species exhibit different Pb accumulation efficiencies but they also compartmentalized sequestered Pb differently. The submerged macrophyte *Hydrilla verticillata* accumulated the greatest amount of Pb (approximately 180 mg Pb/kg dry weight tissue), but Pb was sequestered solely in the shoot tissue. In contrast, other plant species accumulated between 15 and 100 mg Pb/kg dry weight (*Ranunculus scloralus* and *Marsilia quadrifolia*) with the majority compartmentalizing the metal in root tissue, except for *C. demersum* and *M. quadrifolia*, which also utilized shoot tissue for Pb storage (Dwivedi et al., 2008).

Pb concentrations in the root, leaf, and stem tissues of three aquatic plant species were found to correlate most closely with the concentration of the exchangeable Pb fraction (e.g., the fraction of Pb that is easily and freely leachable from the sediment). Authors noted that seasonal variations can alter the amount of Pb present in the exchangeable fraction, and that Pb was more likely than Cd or Cu to remain tightly bound to sediments, and therefore the relationship between total sediment Pb and Pb in aquatic plant tissues was weaker (Ebrahimpour and Mushrifah, 2009).

Lemna sp., a free floating macrophyte, incubated in a water extract of waste ash containing 19 µg Pb/L accumulated 3.5 mg Pb/kg dry weight over 7 days of exposure. Slight toxic effects, including suppression of growth, were observed over this exposure period, but this may have been a result of exposures to multiple metals in the water extract, including Cr, Mn, Cu, and Zn (Horvat et al., 2007). Lemna sp. was also demonstrated to be effective in the biosorption of Pb from solution, even in the presence of sediments (1 g per 700 mL water). Over 7 days of exposure to 5 and 10 mg Pb/L, plant biomass was found to contain an average of 2.9 and 6.6 mg Pb, respectively, versus 0.2 and 0.3 mg in sediment (Hurd and Sternberg, 2008).

Young *Typha latifolia*, another rooted macrophyte, were grown in 5 and 7.5 mg/L Pb-spiked sediment for 10 days to determine their value as metal accumulators. Within the exposure period, plants exposed to the lower concentration were able to remove 89% of Pb, while 84% of the Pb present in the higher treatment was taken up by *T. latifolia*. Pb concentrations measured in root and leaf tissue ranged from 1,365 to 4,867 mg Pb/kg and 272 to 927 mg Pb/kg, respectively, and were higher at the greater environmental Pb exposure (Alonso-Castro et al., 2009).

Common reeds (*Phragmites australis*) grown in metal-impacted aquatic environments in Sicily, Italy, preferentially accumulated Pb in root and rhizome tissues (Bonanno and Lo Giudice, 2010). Environmental Pb concentrations in water and sediment averaged 0.4 µg Pb/L and 2.7 mg Pb/kg. These levels yielded root and rhizome concentrations of 17 and 15 mg Pb/kg, respectively, whereas stem and leaf Pb concentrations were lower (9.9 and 13 mg Pb/kg). These tissue concentrations were significantly correlated to both water and sediment concentrations (Bonanno and Lo Giudice, 2010). Conversely, the semi-aquatic plant *Ammania baccifera*, grown in mine tailings containing 35 to 78 mg Pb/kg, did not accumulate analytically detectable levels of Pb in either root or shoot tissues, despite the fact that other metals (Cu, Ni, Zn) were bioaccumulated (Das and Maiti, 2007). This would indicate that at low/moderate environmental Pb concentrations, some plant species may not bioaccumulate significant (or measurable) levels of Pb.

The average concentration of Pb in the tissues of rooted aquatic macrophytes (*Callitriche verna*, *P. natans*, *C. demersum*, *Polygonum amphibium*, *Veronica beccabunga*) collected from two metals-polluted streams in Poland (average sediment concentration 38 to 58 mg Pb/kg) was less than 30 mg Pb/kg. Pb bioaccumulation in plants was significantly correlated with sediment Pb concentrations (Samecka-Cymerman and Kempers, 2007). A similar significant correlation was established between reed sweet grass root Pb concentration and sediment Pb concentrations (Skorbiowicz, 2006).

Pb tissue concentrations of aquatic plants *P. australis* and *Ludwigia prostrata* collected from wetlands containing an average of 52 mg Pb/kg in surficial sediments were

predominantly in root tissues, indicating poor translocation of Pb from roots. In the former, Pb decreased from an average of 37 mg Pb/kg in roots to 17, 14, and 12 mg Pb/kg in rhizome, stem and leaf tissues, respectively, while *L. prostrata* Pb tissue concentrations decreased from 77 mg Pb/kg in fibrous root to 7 and 43 mg Pb/kg in stem and leaf tissues (Yang et al., 2008a). The authors proposed that this diminished transfer ability explained the relatively low BCFs for Pb uptake in these two species, when compared with those of other metals.

Despite no significant seasonal effect on surface water Pb concentrations, shining pondweed (*Potamogeton lucens*), a rooted aquatic macrophyte grown in an urbanized metal-contaminated lake in Turkey, exhibited seasonal alterations in Pb tissue concentrations. Average measured water Pb concentrations were 28 µg Pb/L in spring, 27 µg Pb/L in summer, and 30 µg Pb/L in autumn. Over this same time period, root tissue Pb concentrations significantly increased from 6 mg Pb/kg dry weight in spring, to 9 mg Pb/kg dry weight in summer, and to 10 mg Pb/kg dry weight in autumn (Duman et al., 2006). No differences were detected in stem Pb concentrations between spring and summer (approximately 4 mg Pb/kg dry weight), but stem Pb concentrations were found to be significantly higher in autumn (6 mg Pb/kg dry weight). In the same system, *P. australis* plants accumulated the most Pb during winter: 103, 23, and 21 mg Pb/kg dry weight in root, rhizome, and shoot tissue, respectively, in sediments containing 13 mg Pb/kg dry weight. By contrast, *Schoenoplectus lacustris* accumulated maximum rhizome and stem Pb concentrations of 5.1 and 7.3 mg Pb/kg dry weight in winter, but sequestered the greatest amount of Pb in root tissues during the spring (30 mg Pb/kg dry weight) at a comparable sediment concentration, 18 mg Pb/kg dry weight (Duman et al., 2007). The authors suggest that this indicated that metal uptake was regulated differently between species.

Tree species that inhabit semi-aquatic environments have also been shown to absorb Pb from Pb-contaminated sediments. Bald-cypress trees (*Taxodium distichum*) growing in sediments of a refinery-impacted bayou in Louisiana accumulated significantly greater amounts of Pb than did trees of the same species growing in bankside soil, despite the lower Pb concentrations of sediments. Bankside soils contained greater than 2,700 mg Pb/kg versus concentrations of 10 to 424 mg Pb/kg in sediments, yet Pb concentrations in trees averaged 4.5 and 7.8 mg Pb/kg tissue, respectively (Devall et al., 2006). The authors theorized that Pb was more readily released from sediments and that soil dispersion to the swamp sediments provides additional, if periodic, loads of Pb into the system. Willow seedlings planted in Pb-contaminated sediment were more effective at removing Pb from the media than a diffusive gradient in thin film technique predicted (Jakl et al., 2009). The authors proposed that the plant's active mobilization of nutrients from soil during growth also resulted in increased Pb uptake and sequestration.

Given that sediments are a significant sink for Pb entering aquatic systems, it is not surprising that rooted macrophytes bioaccumulate significant quantities of the metal. Although there are some similarities to Pb accumulation observed in terrestrial plants (e.g., preferential sequestration of the metal in root tissue), Pb appears to be more bioavailable in sediment than it is in soil. This may be a result of differences in plant physiology between aquatic and terrestrial plants (e.g., more rapid growth or more efficient assimilation of nutrients and ions from a water-saturated medium). While rooted macrophytes are likely to be chronic accumulators of Pb sequestered in sediments, aerial deposition of Pb into aquatic systems may result in pulsed inputs of labile Pb that would be available for uptake by floating macrophytes and algae.

7.3.4.2 Freshwater Invertebrates

Uptake and subsequent bioaccumulation of Pb in freshwater invertebrates varies greatly between species and across taxa as previously characterized in the 2006 Pb AQCD. This section expands on the findings from the 1986 Pb AQCD and 2006 Pb AQCD on bioaccumulation and sequestration of Pb in aquatic invertebrates. In the case of invertebrates, Pb can be bioaccumulated from multiple sources, including the water column, sediment, and dietary exposures, and factors such as proportion of bioavailable Pb, lifestage, age, and metabolism can alter the accumulation rate. In this section, new information on Pb uptake from freshwater and sediments by invertebrates will be considered, followed by a discussion on dietary and water routes of exposure and factors that influence species-specific Pb tissue concentrations such as invertebrate habitat and functional feeding group.

In a new uptake study in freshwater mussels available since the 2006 Pb AQCD, the Eastern elliptio mussel (*Elliptio complanata*) was shown to accumulate Pb rapidly from water and then reach an equilibrium with exposure level and tissue concentration by two weeks following exposures to 1, 4, 14, 57 or 245 µg Pb/L as Pb-nitrate (Mosher et al., In Press). Tissue concentrations of Pb increased at an exposure-dependent rate for the first 14 days and then did not change significantly for the remainder of the 28-day exposure although mussels continued to accumulate Pb. At the end of the exposure period, average Pb in tissue ranged from 0.33 to 898 µg Pb/g. The authors concluded that the mussels were likely eliminating Pb via pseudo feces and through storage of Pb in shell.

The 2006 Pb AQCD summarized studies of uptake of Pb from sediment by aquatic invertebrates and noted that sediment pore water, rather than bulk sediment, is the primary route of exposure. However, a recent study suggests that in the midge, *Chironomus riparius*, total metal concentrations in bulk sediment are better predictors of

metal accumulation than dissolved metal concentrations in sediment pore water based on bioaccumulation studies using contaminated sediments from six different sites (Roulier et al., 2008a). Vink (2009) studied six river systems and found that, for a range of metals, uptake by benthic organisms (the oligochaete, Limnodrilus (Family Tubificidae) and the midge, *C. riparius*) from the sediment pore water (as compared with surface water) was observed only occasionally, and solely for Pb. The physiological mechanisms of Pb uptake are still unclear but it is suggested that uptake and elimination of Pb obey different mechanisms than for other heavy metals.

The 2006 Pb AQCD recognized the potential importance of the dietary uptake pathway as a source of Pb exposure for invertebrates. Specifically, in a study with the freshwater amphipod *Hyalella azteca,* dietary exposure was found to contribute to the chronic toxicity of Pb, while acute toxicity was unaffected (Besser et al., 2004). Since the 2006 Pb AQCD, additional studies have considered the relative importance of water and dietary uptake of Pb in aquatic invertebrates. A stable isotope technique was used to simultaneously measure uptake of environmentally relevant concentrations of Pb (0.05 µmol Pb in the water column) by the freshwater cladoceran *D. magna* directly from water and through food, the green algae *Pseudokirchneriella subcapitata*. (Komjarova and Blust, 2009a). *D. magna* accumulated the metal from both sources, but the relative proportion of uptake from each source changed over the exposure period. After the first day of exposure, 12% of accumulated Pb was determined to have been absorbed from dietary (algal) sources, but this percentage decreased by day four of exposure to 4%. Pb absorbed from water exposure only resulted in Daphnia body burdens of approximately 300 µmol Pb/kg dry weight, and was similar to the amount absorbed by algae (Komjarova and Blust, 2009a). In a comparison of dietary and waterborne exposure as sources of Pb to aquatic invertebrates, no correlation between Pb uptake and dietary exposure was observed in the amphipod *H. azteca* (Borgmann et al., 2007).

Stable isotope analysis was to used measure uptake and elimination simultaneously in net-spinning caddisfly larvae (Hydropsyche sp.) exposed to aqueous Pb concentrations of 0.2 to 0.6 µg Pb/L for 18 days (Evans et al., 2006). The measured uptake constant for Pb in this study was 7.8 g/dry weight·day and the elimination rate constant of 0.15/day for Pb-exposed larvae was similar in both presence and absence of the metal in the water. Measured tissue concentrations ranged from approximately 15 to 35 µg Pb/g. Hydropsychid Pb BCFs ranged from 41 to 65, and averaged 54, indicating a relatively high accumulation rate when compared to other metals tested (average BCF of 17 for Cd, 7.7 for Cu, and 6.3 for Zn) (Evans et al., 2006).

Recent reports on Pb distribution in freshwater organisms generally support the findings of the 2006 Pb AQCD that Pb is primarily sequestered in the gills, hepatopancreas, and

muscle. Uptake of Pb by the crayfish *Cherax destructor* exposed to 5,000 µg Pb/L for 21 days resulted in accumulation at the highest concentration in gill, followed by exoskeleton > mid-gut gland > muscle >hemolymph (Morris et al., 2005). Body burden analysis following 96 hour exposure to 50, 100 and 500 µg Pb/L in the freshwater snail *Biomphalaria glabrata* indicated that bioaccumulation increased with increasing concentrations of Pb and the highest levels were detected in the digestive gland (Ansaldo et al., 2006).

When the relationship between invertebrate habitat (epibenthic and benthic) and environmental Pb bioaccumulation was investigated, De Jonge et al. (2010) determined that different environmental fractions of Pb were responsible for invertebrate uptake and exposure. Pb uptake by benthic invertebrate taxa was not significantly correlated to AVS Pb levels, but rather to total sediment concentrations (De Jonge et al., 2009). Conversely, epibenthic invertebrate Pb body burdens were better correlated to AVS concentrations, rather than total Pb sediment concentrations (De Jonge et al., 2010). For instance, the biologically available Pb (e.g., bound to metal-rich granules or metallothioneins) accumulated by the oligochaete *Tubifex tubifex* was determined to correlate with sediment SEM-AVS Pb concentrations (De Jonge et al., 2011). Similarly, Desrosiers et al. (2008) reported that Pb accumulation by chironomid larvae from St. Lawrence river sediments was significantly correlated to both total Pb and reactive Pb sediment concentrations.

Both inter- and intra-specific difference in Pb uptake and bioaccumulation may occur in macroinvertebrates of the same functional-feeding group. Cid et al. (2010) reported significant differences in Pb bioaccumulation between field collected *Ephoron virgo* mayflies and Hydro psyche sp, caddisflies, with only the mayfly exhibiting increased Pb tissue concentrations when collected from Pb-contaminated sites; the caddisfly Pb tissue concentrations were similar between reference and Pb-contaminated areas. The authors also examined the lifestage specific accumulation of Pb for *E. virgo* mayflies, and although there was no statistical difference in Pb tissue concentrations between different lifestages, Pb bioaccumulation did change as mayflies aged (Cid et al., 2010).

Reported BAF values for Pb in aquatic invertebrates from the 2006 Pb AQCD ranged from 499 to 3,670 [Table AX7-2.3.2 (U.S. EPA, 2006c)]. Since the 2006 Pb AQCD, additional BAF values have been established for invertebrates in field studies which tend to be higher than BCF values calculated in laboratory exposures (Casas et al., 2008; Gagnon and Fisher, 1997). A complicating factor in establishing BAF values is that laboratory studies usually assess uptake in water-only or sediment only exposures while field studies take into account dietary sources of Pb as well as waterborne Pb resulting in BAF values that are frequently 100-1,000 times larger than BCF values for the same

metal and species (DeForest et al., 2007). The EPA Framework for Metals Risk Assessment states that the latest scientific data on bioaccumulation do not currently support the use of BCFs and BAFs when applied as generic threshold criteria for the hazard potential of metals (U.S. EPA, 2007c).

7.3.4.3 Freshwater Vertebrates

Uptake of Pb by vertebrates considered here includes data from fish species as well as a limited amount of new information on amphibians and aquatic mammals. In fish, Pb is taken up from water via the gills and from food via ingestion. Amphibians and aquatic mammals are exposed to waterborne Pb primarily through dietary sources. In the 2006 Pb AQCD, dietary Pb was recognized as a potentially significant source of exposure to all vertebrates since Pb adsorbed to food, particulate matter and sediment can be taken up by aquatic organisms.

Since the 2006 Pb AQCD, tissue accumulation of Pb via gill and dietary uptake has been further characterized in vertebrates, and new techniques such as the use of stable isotopes have been applied to further elucidate bioaccumulation of Pb. For example, patterns of uptake and subsequent excretion of Pb in fish as measured by isotopic ratios of Pb in each tissue can determine whether exposure was due to relatively long term sources (which favor accumulation in bone) or short term sources (which favors accumulation in liver) (Miller et al., 2005). New information since the 2006 Pb AQCD on uptake of Pb by fish from freshwater is reviewed below, followed by studies on dietary uptake as a route of Pb exposure. Next, tissue accumulation patterns in fish species are reported with special consideration of the anterior intestine as a newly identified target of Pb from dietary exposures.

Freshwater Fish

Pb uptake in freshwater fish is accomplished largely via direct uptake of dissolved Pb from the water column through gill surfaces and by ingestion of Pb-contaminated diets. According to the data presented in the 2006 Pb AQCD, accumulation rates of Pb are influenced by both environmental factors, such as water pH, DOC, and Ca concentrations, and by species-dependent factors, such as metabolism, sequestration, and elimination capacities. The effects of these variables on Pb bioaccumulation in fish are largely identical to the effects observed for invertebrates (discussed above).

Pb in fish is primarily found in bone, gill, blood, kidney and scales (Spry and Wiener, 1991). Since the 2006 Pb AQCD, multiple studies on uptake of Pb from water by fathead

minnow and subsequent tissue distribution have been conducted. Spokas et al. (2006) showed that Pb accumulates to the highest concentration in gill when compared to other tissues over a 24 day exposure. This pattern was also observed in larval fathead minnows exposed to 26 µg Pb/L for 10-30 days, where gill exhibited the highest Pb concentration compared to carcass, intestine, muscle and liver (Grosell et al., 2006b). In the larval minnows, Pb concentration in the intestine exhibited the highest initial accumulation of all tissues on day 3 but then decreased for the remainder of the experiment while concentrations in the other organs continued to increase. By day 30, gill tissue exhibited the highest Pb concentration (approximately 120 µg Pb/g), followed by whole fish and carcass (whole fish minus gill, liver, muscle and intestine) Pb concentrations (approximately 70 to 80 µg Pb/g). However, in considering overall internal Pb body burden, nearly 80% was largely concentrated in the bone tissue, while gill contributed <5%.

In another study with fathead minnow, chronic (300 day) exposure to 120 µg Pb/L resulted in accumulation of approximately 200 nmol Pb/g tissue, although this number was decreased from initial body burdens of greater than 500 nmol Pb/g at test initiation (Mager et al., 2010). Tissue distribution at 300 days was consistent with Grosell et al. (2006b) with highest concentration in gill, followed by kidney, anterior intestine, and carcass. Addition of humic acid and carbonate both independently reduced uptake of Pb in these fish over the exposure time period. Interestingly, fathead minnow eggs collected daily during 21 day breeding assays that followed the chronic exposure described above accumulated similar levels of Pb from the test solutions regardless of Pb concentration or water chemistry (e.g., addition of humic acid and carbonate) (Mager et al., 2010). Direct acute exposure from water rather than parental transfer accounted for the majority of the Pb accumulation in eggs. Similarly, exposure of fish to 157 nM Pb in base water for 150 days resulted in fathead minnow whole body concentrations of approximately 150 nmol Pb/g tissue, with the most rapid accumulation rate occurring within the first 10 days of exposure, followed by an extended period of equilibrium (Mager et al., 2008). In this same study, fish were tested in two additional treatments: 177 nM Pb in hard water (Ca^{2+} 500 µM) or 187 nM Pb in humic acid supplemented water (4 mg/L). While the addition of humic acid significantly reduced Pb bioaccumulation in minnows (to approximately 50 nmol Pb/g on a whole body basis), Ca sulfate did not alter uptake. Despite the fact that Ca-mediated Pb toxicity occurred in larval fathead minnow, there was no concurrent effect on whole body Pb accumulation.

Uptake studies in other teleosts of Pb from freshwater have generally followed the pattern of uptake described above for fathead minnow. In the cichlid, Nile tilapia (*Oreochromis niloticus*) Pb accumulated significantly in gill (45.9 ±34.4 µg/g dry weight at 10 µM, 57.4 ±26.1 µg/g dry weight at 20 µM) and liver (14.3 µg/g dry weight at 10 µM and 10.2 µg/g

dry weight at 20 µM) during a 14-day exposure (Atli and Canli, 2008). In rainbow trout exposed to 100 µg Pb/L for 72 hours, the accumulation in tissues was gill > kidney > liver and this same pattern was observed in all concentrations tested (100-10,000 µg Pb/L) (Suicmez et al., 2006). In contrast to uptake in teleosts, in Pb-uptake studies with the Chondrostei fish Chinese Sturgeon (*Acipenser sinensis*), muscle tissue accumulated higher levels of Pb than gills (Hou et al., 2011).

Sloman et al. (2005) investigated the uptake of Pb in dominant-subordinate pairings of rainbow trout exposed to 46 µg/L or 325 µg/L Pb-nitrate for 48 hours. Significant Pb accumulation in gill, liver and kidney was only observed in the highest concentration. Pb accumulated preferentially in liver of subordinate trout when compared to dominant trout. Brown trout (*Salmo trutta*) exposed to aqueous Pb concentrations ranging from 15 to 46 µg Pb/L for 24 days accumulated 6 µg Pb/g dry weight in gill tissue and Pb concentrations in liver tissue reached 14 µg Pb/g dry weight. Interestingly, Pb in gill tissue peaked on day 11 and decreased thereafter, while liver Pb concentrations increased steadily over the exposure period, which may indicate translocation of Pb in brown trout from gill to liver (Heier et al., 2009).

Zebrafish (*Danio rerio*) Pb uptake rates from media containing 0.025 µmol Pb was significantly increased by neutral pH (versus a pH of 6 or 8) and by Ca concentrations of 0.5 mmol; uptake rate of Pb was increased from 10 L/kg·h to 35 L/kg·h by increasing pH from 6 to 7, and from 20 L/kg·h to 35 L/kg·h by increasing Ca concentration from 0.1 mmol to 0.5 mmol (Komjarova and Blust, 2009c). This study also demonstrated that zebrafish gill tissue is the main uptake site for the metal, as Pb concentrations in these tissues were up to eight times as high as that in other tissues.

The Eurasian silver crucian carp (*Carassius auratus*) collected from a pond containing an average of 1,600 mg Pb/kg in the sediments exhibited increased Pb body burdens ranging from 12 to 68 mg Pb/kg dry weight (Khozhina and Sherriff, 2008). Pb was primarily sequestered in skin, gill, and bone tissues, but was also detected at elevated levels in muscle and liver tissues, as well as in eggs. Two fish species (*Labeo rohita* and *Ctenopharyngodon idella*) collected from the Upper Lake of Bhopal, India with average Pb concentration 30 µg Pb/L in the water column contained elevated Pb tissue concentrations (Malik et al., 2010). However, while liver and kidney Pb concentrations were similar between the two species (1.5 and 1.1 µg Pb/g tissue and 1.3 and 1.0 µg Pb/g tissue for *C. idella* and *L. rohita*, respectively), they accumulated significantly different amounts of Pb in gill and muscle tissues. *C. idella* accumulated more than twice the Pb in these tissues (1.6 and 1.3 µg Pb/g) than did *L. rohita* (0.5 and 0.4 µg Pb/g).

The studies reviewed above generally support the conclusions of the 2006 Pb AQCD that the gill is a major site of Pb uptake in fish and that there are species-dependent

differences in the rate and pattern of Pb accumulation. As indicated in the 2006 Pb AQCD, exposure duration can be a factor in Pb uptake from water. In a 30 day exposure study, Nile tilapia fingerlings had a three-fold increase in Pb uptake at the gill on day 30 compared to Pb concentration in gill at day 10 and 20 (Kamaruzzaman et al., 2010). In addition to uptake at the gill, a time-dependent uptake of Pb into kidney in rainbow trout exposed to 570 µg Pb/L for 96 hours (Patel et al., 2006) was observed. Pb was accumulated preferentially in the posterior kidney compared to the anterior kidney. A similar pattern was observed by Alves and Wood (2006) in a dietary exposure. In catla (*Catla catla*) fingerlings, the accumulation pattern of Pb was kidney > liver > gill > brain > muscle in both 14 day and 60 day Pb exposures (Palaniappan et al., 2009). In multiple studies with fathead minnow at different exposure durations, tissue uptake patterns were similar at 30 days (Grosell et al., 2006b) and 300 days (Mager et al., 2010). In the larval minnows, Pb concentration in the intestine exhibited the highest initial accumulation of all tissues on day 3 but then decreased for the remainder of the experiment while concentrations in the other organs continued to increase (Grosell et al., 2006b). By day 30, gill tissue exhibited the highest Pb concentration followed by whole fish and carcass (whole fish minus gill, liver, muscle and intestine). The most rapid rate of Pb accumulation in this species occurs within the first 10 days of exposure (Mager et al., 2008). African catfish (*Clarias gariepinus*) exposed to aqueous Pb concentrations of 50 to 1,000 µg Pb/L (as Pb nitrate) for 4 weeks accumulated significant amounts of Pb in heart (520-600 mg Pb/kg), liver (150-242 mg Pb/kg), and brain (120-230 mg Pb/kg) tissues (Kudirat, 2008). Doubling the exposure time to 8 weeks increased sequestration of Pb in these tissues as well as in skin (125-137.5 mg Pb/kg) and ovaries (30-60 mg Pb/kg).

Since the 2006 Pb AQCD, several studies have focused on dietary uptake of Pb in teleosts. Metals have been shown to assimilate differently in tissues depending on the exposure route (Meyer et al., 2005; Rozon-Ramilo et al., In Press). Alves et al. (2006) administered a diet of three concentrations of Pb (7, 77 and 520 µg Pb/g dry weight) to rainbow trout for 21 days. Doses were calculated to be 0.02 µg Pb/day (control), 3.7 µg Pb/day (low concentration), 39.6 µg Pb/day (intermediate concentration) and 221.5 µg Pb/day (high concentration). Concentrations in the study were selected to represent environmentally relevant concentrations in prey. After 21 days exposure to the highest concentration, Pb accumulation was greatest in the intestine, followed by carcass, kidney and liver leading the authors to hypothesize that the intestine is the primary site of exposure in dietary uptake of Pb. All tissues, (gill, liver, kidney, intestine, carcass) sequestered Pb in a dose-dependent manner. The gills had the greatest concentration of Pb on day 7(8.0 µg Pb/g tissue wet weight) and this accumulation decreased to 2.2 µg Pb/g tissue wet weight by the end of the experiment suggesting that the Pb was excreted or redistributed (Alves et al., 2006). Furthermore, with increasing dietary concentrations, the percentage of Pb retained in the fish decreased. Additionally, in this

study red blood cells were identified as a reservoir for dietary Pb. Plasma did not accumulate significant Pb (0.012 µg Pb g wet weight in the high dose), however, Pb was elevated in blood cells (1.5 µg Pb g wet weight in the high dose) (Alves et al., 2006).

Additional studies have supported the anterior intestine as a target for Pb in fish. Nile tilapia exposed to dietary Pb for 60 days (100, 400, and 800 µg Pb/g dry weight) accumulated the greatest concentration of Pb in the intestine, followed by the stomach and then the liver (Dai et al., 2009b). The amount of Pb in tissue increased with increasing dietary Pb concentration. In a 42 day chronic study of dietary uptake in rainbow trout, fish fed 50 or 500 µg Pb/g, accumulated Pb preferentially in anterior intestine (Alves and Wood, 2006). Pb accumulation in the gut was followed by bone, kidney, liver, spleen, gill, carcass, brain and white muscle (Alves and Wood, 2006). Ojo and Wood (2007) investigated the bioavailability of ingested Pb within different compartments of the rainbow trout gut using an in vitro gut sac technique. Although a significant increase in Pb uptake was observed in the mid-intestines, this was determined to be much lower than Pb uptake rates via gill surfaces. However, given that intestinal uptake rate for Pb did not significantly differ from those derived for essential metals (e.g., Cu, Zn, and Ni), this uptake route is likely to be significant when aqueous Pb concentrations are low and absorption via gill surfaces is negligible (Ojo and Wood, 2007).

Following a chronic 63-day dietary exposure to Pb, male zebrafish had significantly increased Pb body burdens, but did not exhibit any significant impairment when compared with controls. Fish were fed diets consisting of field-collected *Nereis diversicolor* oligochaetes that contained 1.7 or 33 mg Pb/kg dry weight. This resulted in a daily Pb dose of either 0.1 or 0.4 mg Pb/kg (Boyle et al., 2010). At the end of the exposure period, tissue from male fish reared on the high-Pb diet contained approximately 0.6 mg Pb/kg wet weight, as compared with approximately 0.48 mg Pb/kg wet weight in the low-Pb dietary exposure group. Pb level was elevated in female fish fed the high-Pb diet, but not significantly so.

Ciardullo et al. (2008) examined bioaccumulation of Pb in rainbow trout tissues following a 3-year chronic dietary exposure to the metal. Diet was determined to contain 0.19 µg Pb/g wet weight. Fish skin accumulated the greatest Pb concentrations (0.02 to 0.05 µg Pb/g wet weight), followed by kidney, gills, liver, and muscle. Pb accumulation in muscles (5 ng Pb/g) remained constant over all sampled growth stages (Ciardullo et al., 2008). The authors concluded that dietary Pb was poorly absorbed by rainbow trout. Comparison of dietary and water-borne exposures suggest that although accumulation of Pb can occur from dietary sources, toxicity does not correlate with dietary exposure, but does correlate with gill accumulation from waterborne exposure (Alves et al., 2006).

Comparison of uptake rates across the gut and gill have shown that transporter pathways in the gill have a much higher affinity for Pb than do similar pathways in the gut (Ojo and Wood, 2007).

Since the 2006 Pb AQCD, several field studies have considered Pb uptake and bioaccumulation in fish as a tool for environmental assessment. Pb tissue concentrations were elevated in several species of fish exposed in the field to Pb from historical mining waste, and blood Pb concentrations were highly correlated with elevated tissue concentrations, suggesting that blood sampling may be a useful and potentially non-lethal monitoring technique (Brumbaugh et al., 2005).

This review of the recent literature indicates that the primary and most efficient mode of Pb absorption for freshwater fish is assimilation of labile Pb via gill surfaces; recent research indicates that chronic dietary Pb exposure may result in some Pb bioaccumulation although it is not the predominant route of exposure. Nevertheless, if benthic invertebrates comprise a large portion of fish diets in chronically contaminated systems, assimilated Pb loads may be significant. This was demonstrated by Boyle et al. (2010), who showed that laboratory diets consisting of less than one third field-collected Pb-contaminated invertebrates were sufficient to raise fish tissue Pb levels. However, data from field sites suggest that fish accumulation of Pb from dietary sources is highly variable and may be strongly dependent on the physiology of individual species and absorption capacities.

Amphibians

Since the 2006 Pb AQCD, there are a few new field measurements and laboratory-based studies that consider uptake of Pb in amphibians. Whole body Pb measured in three species of field-collected tadpoles in the Mobile-Tensaw River Delta in Alabama averaged 1.19 µg Pb/g dry weight in *Rana clamitans*, 0.65 µg Pb/g dry weight in *Rana catesbeiana* and 1.32 µg Pb/g dry weight in *Hyla cinerea* (Albrecht et al., 2007). Blood-Pb levels in Ozark hellbenders (*Cryptobranchus alleganiensis alleganiensis*), a candidate species for the Endangered Species Act, ranged from 0.04 to 0.06 µg/g dry whole blood weight, in three rivers in Missouri (Huang et al., 2010). In the same study, Pb-blood levels were measured from Eastern hellbenders (*Cryptobranchus alleganiensis bishopi*), a species of concern, collected from four rivers and ranged from 0.075 to 0.088 µg Pb/g dry whole blood weight.

In a chronic laboratory-based study with tadpoles of the Northern Leopard frog (*Rana pipiens*), Pb tissue concentrations were evaluated following exposures to 3, 10, and 100 µg Pb/L from embryo to metamorphosis. The tadpole tissue concentrations ranged

from 0.1 to 224.5 mg Pb/kg dry mass and were positively correlated to Pb concentrations in the water (Chen et al., 2006b). Dose-dependent bioaccumulation of Pb was observed in the livers of tadpoles of the African clawed frog (*Xenopus laevis*) exposed to concentrations ranging from 0.001 to 30 mg Pb/L (2.91 to 114.5 Pb µg/g wet weight) for 12 days (Mouchet et al., 2007). Pb concentrations were measured in livers, bodies without liver and whole bodies in Southern leopard frog (*Rana sphenocephala*) tadpoles exposed to Pb in sediment (45 to 7,580 mg Pb/kg dry weight) with corresponding pore water concentrations of 123 to 24,427 µg Pb/L from embryonic stage to metamorphosis (Sparling et al., 2006). There was 100% mortality at 3,940 mg Pb/kg and higher. In all body residues analyzed there was a significant positive correlation between Pb in sediment and Pb in sediment pore water. Concentrations of Pb in liver were similar to results with whole body and bodies without liver indicating that Pb is not preferentially sequestered in liver.

Reptiles

New field surveys of Pb in water snakes since the 2006 Pb AQCD indicate that Pb is bioaccumulated in several species. Water snakes spend time in terrestrial and aquatic habitats and could potentially be exposed to atmospherically deposited-Pb in both environments. Average Pb levels in whole body samples of Eastern Ribbon Snakes (*Thamnophis sauritus*) collected from the Mobile-Tensaw River, a large watershed that drains more than 75% of Alabama were 0.35 ± 0.12 µg Pb/g dry weight) (Albrecht et al., 2007). Burger et al. (2007) measured Pb levels in blood, kidney, liver, muscle and skin from water snakes, *Nerodia sepedon*, collected from an urban/suburban canal in New Jersey. Pb was highest in skin (0.467 µg Pb/g wet weight) followed by kidney (0.343 µg Pb/g wet weight) blood (0.108 µg Pb/g wet weight), muscle (0.103 µg Pb/g wet weight) and liver (0.063 µg Pb/g wet weight). No interspecies differences were observed in blood Pb (range 0.04 to 0.1 µg Pb/g) from field-collected banded water snakes (*Nerodia fasciata*), brown water snakes (*N. taxsipilota*) and cottonmouth (*Agkistrodon piscivorus*) from a reference area and an area contaminated by chemical and radiation releases from the 1950's to the 1980's at the Department of Energy Savannah River site in South (Burger et al., 2006). Cottonmouth and brown water snake from the exposed site had significantly higher levels of Pb in tail muscle when compared to the reference creek.

Mammals

Pb bone levels in Eurasian otters (*Lutra lutra*) measured in dead individuals collected in southwest England fell by 73% between 1992 and 2004 (Chadwick et al., 2011). Annual mean bone Pb levels were 446 µg Pb/kg in 1992 and 65 µg Pb/kg in 2004. The 73%

decline of Pb in otter bones from 1992 to 2004 was found to coincide with legislative controls on Pb emissions implemented in the U.K. starting in 1986. A positive correlation with stream sediment Pb and bone Pb was also observed in this study. The strength of this correlation decreased with increasing Ca in streams.

7.3.4.4 Food Web

In the 2006 Pb AQCD, trophic transfer of Pb through aquatic food chains was considered to be negligible (U.S. EPA, 2006c). Measured concentrations of Pb in the tissues of aquatic organisms were found to be generally higher in algae and benthic organisms and lower in higher trophic-level consumers indicating that Pb was bioaccumulated but not biomagnified (U.S. EPA, 2006c; Eisler, 2000). New literature since the 2006 Pb AQCD provides evidence of the potential for Pb to be transferred in aquatic food webs. Other studies indicate Pb is decreased with increasing trophic level. This section incorporates recent literature on transfer of Pb through freshwater aquatic food chains including the application of stable isotope techniques to trace the accumulation and dilution of metals through producers and consumers.

Pb was transferred through at least one trophic level in El Niagara reservoir, Aguascalientes, Mexico, a freshwater ecosystem that lacks fishes (Rubio-Franchini et al., 2008). Pb was measured in sediment, water, and zooplankton samples of this freshwater system. BAFs were calculated for predatory and grazing zooplanktonic species. The BAF of the rotifer *A. brightwellii* (BAF 49,300) was up to four times higher than the grazing cladocerans *D. similis* (BAF 9,022) and *M. micrura* (BAF 8,046). According to the authors, since *M. micrura* are prey for *A. brightwellii* this may explain the biomagnifications of Pb observed in the predatory rotifer and provides evidence that Pb biomagnifies at intermediate trophic levels.

The relative contribution of water and food as source of trace metals including Pb was investigated in the larvae of the alderfly *Sialis velata* (Croisetiere et al., 2006). Its prey, the midge (*C. riparius*) was reared in the laboratory and then exposed to trace elements in a metal-contaminated lake for one week prior to being fed to *S. velata*. During the one-week exposure period of *C. riparius* to the contaminated water, five of six trace elements, including Pb, reached steady state within *C. riparius*. Alderfly larvae were held in the lab in uncontaminated lake water and feed one of the treated *C. riparius* per day for up to six days to measure Pb uptake via prey. A separate group of alderfly larvae were exposed directly to the contaminated lake water for six days and fed uncontaminated *C. riparius* while a third group was exposed to Pb via prey and water. Trace metal concentrations in *S. velata* that consumed contaminated *C. riparius* increased significantly compared to *S.*

velata in water-only exposures. Food was concluded to be the primary source of Pb (94%) to these organisms, not Pb in the water.

The trophic transfer of Pb from the sediment dwelling polychaete worm *N. diversicolor* to the invertebrate polychaete predator *Neris virens* provides additional evidence for assimilation of Pb by a predator and the potential for further transport up the food chain (Rainbow et al., 2006). *N. virens* significantly accumulated Pb from a diet of *N. diversicolor* and there was a significant inverse linear relationship between the trophic transfer coefficient and prey Pb concentration. In the same study, another predator, the decapod *Palaemonetes varians*, did not significantly accumulate Pb from *N. diversicolor* indicating that trophic transfer is dependent on species-specific differences in metal assimilation efficiencies and accumulation patterns.

In a recent dietary metal study, field-collected invertebrates representing ecologically relevant sources of Pb were fed to zebrafish, to assess bioavailability of this metal via food. The polychaete worm *N. diversicolor* was collected from two sites; an estuary contaminated with Pb and a reference site with low metal concentrations (Boyle et al., 2010). Male zebrafish fed Pb-enriched *N. diversicolor* had significant increases in whole-body Pb burden when compared to zebrafish fed prey from the reference site, brine shrimp or flake food diets. There was a trend toward increased Pb levels in females under the same dietary regimen. In this study, deposit feeding invertebrates were shown to mobilize sediment-bound metals in the food chain since zebrafish were exposed only to biologically incorporated metal.

The concentration of Pb in the tissues of various aquatic organisms was measured during the biomonitoring of mining-impacted stream systems in Missouri, U.S. Generally, Pb concentrations decreased with increasing trophic level: detritus contained 20 to 60 µg Pb/g dry weight, while periphyton and algae contained 1 to 30 µg Pb/g dry weight; invertebrates and fish collected from the same areas exhibited Pb tissue concentrations of 0.1 to 8 µg Pb/g dry weight (Besser et al., 2007). In addition, Pb concentrations in invertebrates (snails, crayfish, and other benthos) were negatively correlated with Pb concentrations in detritus, periphyton, and algae. Fish tissue concentrations, however, were consistently correlated only with detritus Pb concentrations (Besser et al., 2007).

Other studies have traced Pb in freshwater aquatic food webs and have found no evidence of biomagnification of Pb with increasing trophic level. Watanabe et al. (2008) observed decreasing Pb concentrations through a stream macroinvertebrate food web in Japan from producers to primary and secondary consumers. In a Brazilian freshwater coastal lagoon food chain, Pb was significantly higher in invertebrates than in fishes (Pereira et al., 2010).

Introduction of exotic species into an aquatic food web may alter Pb concentrations at higher tropic levels. In Lake Erie, the invasive round goby (*Neogobius melanostomus*) and the introduced zebra mussel (*Dreissena polymorpha*) have created a new benthic pathway for transfer of Pb and other metals (Southward Hogan et al., 2007). The goby is a predator of the benthic zebra mussel, while the endemic smallmouth bass (*Micropterus dolomieui*) feed on goby. Since the introduction of goby into the lake, total Pb concentrations have decreased in bass. The authors attribute this decrease of Pb in bass to changes in food web structure, changes in prey contaminant burden or declines in sediment Pb concentrations.

7.3.5 Biological Effects of Pb in Freshwater Systems

This section focuses on the studies of biological effects of Pb on freshwater algae, plants, invertebrates, fish and other biota with an aquatic lifestage (e.g., amphibians) published since the 2006 Pb AQCD. Key studies from the 1977 Pb AQCD, the 1986 Pb AQCD and the 2006 Pb AQCD on biological effects of Pb are summarized where appropriate. Waterborne Pb is highly toxic to aquatic organisms with toxicity varying depending upon the species and lifestage tested, duration of exposure, the form of Pb tested, and water quality characteristics. The 2006 Pb AQCD noted that the physiological effects of Pb in aquatic organisms can occur at the biochemical, cellular, and tissue levels of organization and include inhibition of heme formation, alterations of blood chemistry, and decreases in enzyme levels. A review of the more recent literature corroborated these findings, and added information about induction of oxidative stress by Pb, alterations in chlorophyll, and changes in production and storage of carbohydrates and proteins.

New studies available since the 2006 Pb AQCD further consider effects of Pb on reproduction and development, growth and survival of aquatic organisms. Alterations to these endpoints can lead to changes at the community and ecosystem levels of biological organization such as decreased abundance, reduced taxa richness, and shifts in species composition. In this ISA, effects on reproduction, growth and survival are reported in additional species with some effects occurring in sensitive biota at or near ambient levels of Pb. Because this review is focused on effects of Pb, studies reviewed for this section include only those for which Pb was the only, or primary, metal to which the organism was exposed. Areas of research not addressed here include literature related to exposure to Pb from ingestion of shot or pellets. Biological effects of Pb on freshwater algae and plant species are considered below, followed by information on effects on freshwater invertebrates and vertebrates.

7.3.5.1 Freshwater Plants and Algae

The toxicity of Pb to algae and plants has been recognized in earlier agency reviews of this metal. In the 1977 Pb AQCD, differences in sensitivity to Pb among different species of algae were observed and concentrations of Pb within the algae varied among genera and within a genus (U.S. EPA, 1977). The 1986 Pb AQCD (U.S. EPA, 1986b) reported that some algal species (e.g., Scenedesmus sp.) were found to exhibit physiological changes when exposed to high Pb concentrations in situ. The observed changes included increased numbers of vacuoles, deformations in cell organelles, and increased autolytic activity. Effects of Pb on algae reported in the 2006 Pb AQCD included decreased growth, deformation and disintegration of algae cells, and blocking of the pathways that lead to pigment synthesis, thus affecting photosynthesis. Observations in additional algal species since the 2006 Pb AQCD support these findings and indicate that Pb exposure is associated with oxidative stress.

The effect of Pb exposure on the structure and function of plant photosystem II was studied in giant duckweed, *S. polyrrhiza* (Ling and Hong, 2009). The Pb concentration of extracted photosystem II particles was found to increase with increasing environmental Pb concentration, and increased Pb concentration was shown to decrease emission peak intensity at 340 nm, amino acid excitation peaks at 230 nm, tyrosine residues, and absorption intensities. This results in decreased efficiency of visible light absorption by affected plants. The authors theorized that Pb^{2+} may replace either Mg^{2+} or Ca^{2+} in chlorophyll or the oxygen-evolving center, inhibiting photosystem II function through an alteration of chlorophyll structure.

Pb exposure in microalgae species has been linked to several effects, including disruption of thylakoid structure and inhibition of growth in both *Scenedesmus quadricauda* and *Anabaena flos-aquae* (Arunakumara and Zhang, 2008). Arunakumara et al. (2008) determined the effect of aqueous Pb on the algal species *S. platensis* using solutions of Pb-nitrate. Exposures at 5,000 µg Pb/L stimulated 10-day algal growth, growth was inhibited at higher concentrations of 10,000 30,000 50,000 and 100,000 µg Pb/L by 5, 40, 49, and 78%, respectively. In addition to growth inhibition, algal chlorophyll *a* and *b* content were significantly diminished at the three highest Pb exposures (Arunakumara et al., 2008). Although no specific morphological abnormalities were linked to Pb exposure, filament breakage was observed in *S. platensis* at Pb concentrations >50,000 µg Pb/L. Since the 2006 Pb AQCD, the production of reactive oxygen species following Pb exposure has been measured directly in cells of the freshwater algae *Chlamydomonas reinhardtii* at environmentally relevant concentrations of Pb (0.1 to 250 nmol/L) with the greatest response at 3.15 times more stained cells compared to the control sample (Szivak et al., 2009).

At the time of the 1977 Pb AQCD, there was limited information available on Pb effects on aquatic macrophytes. For plants in general, Pb was recognized to affect photosynthesis, mitosis, and growth, however, the majority of studies reporting Pb toxicity were not conducted with plants grown under field conditions (U.S. EPA, 1977). The mechanism for Pb inhibition of photosynthesis was further elucidated in the 1986 Pb AQCD. Additional evidence of Pb effects on plant growth was also observed, however, the available studies were conducted under laboratory conditions at concentrations that exceeded Pb levels in the environment except near smelters or roadsides (U.S. EPA, 1986b). In the 1986 Pb AQCD, EC_{50} values for plant growth were available for several aquatic plants with the lowest EC_{50} of 1,100 µg Pb/L in *Azolla pinnata* exposed to Pb-nitrate for 4 days. Effects of Pb on metabolic processes in aquatic plants reviewed in the 2006 Pb AQCD included nitrate uptake, nitrogen fixation, ammonium uptake and carbon fixation at concentrations of 20,000 µg Pb/L and higher.

New information is available on Pb effects on oxidative stress endpoints such as changes in antioxidant enzymes, lipid peroxidation and reduced glutathione in aquatic plant, algae, and moss species exposed to Pb. An aquatic moss, *F. antipyretica*, exhibited increased SOD and ascorbate levels following a 2-day exposure to Pb-chloride solutions of concentrations of 1, 10, 100, and 1,000 µmol. When exposure duration was increased to 7 days, only SOD activity remained significantly increased by Pb exposure (Dazy et al., 2009). Bell-shaped concentration-response curves were commonly observed for the induction of antioxidant enzymes in *F. antipyretica*. The chlorophyll, carotenoid, and protein contents of the aquatic macrophyte *Elodea canadensis* were significantly reduced following Pb accumulation at exposures of 1,000 10,000 and 100,000 µg Pb/L (Dogan et al., 2009). This, along with the induction of some antioxidant systems and the reduction of growth at the highest two exposures, indicated that exposure to the metal caused significant stress, and that toxicity increased with exposure. In addition, native *Myriophyllum quitense* exhibited elevated antioxidant enzyme activity (glutathione-S-transferase, glutathione reductase, peroxidase) following transplantation in anthropogenically polluted areas containing elevated Pb concentrations. These were correlated with sediment Pb concentrations in the range of 5 to 23 mg Pb/g dry weight (Nimptsch et al., 2005).

Since the 2006 Pb AQCD, toxicity and oxidative stress were also observed in coontail (*C. demersum*) rooted aquatic macrophytes following 7-day exposures to aqueous Pb (1 to 100 µmol), with increasing effects observed with greater exposure concentrations and times. Chlorosis and leaf fragmentation were evident following a 7-day exposure to the highest concentration, while induction of antioxidant enzymes (glutathione, superoxide dismutase, peroxidases, and catalase) was observed at lower exposure concentrations and times. However, as the duration and concentration of Pb exposure was increased,

activities of these antioxidant enzymes decreased (Mishra et al., 2006b). Similarly, curly pondweed (*P. crispus*) exposed to lead (10 to 50 mM) exhibited increased generation of reactive oxygen species (Xu et al., 2011).

Sobrino et al. (2010) observed reductions in soluble starch stores and proteins with subsequent increases in free sugars and amino acids in *Lemna gibba* plants exposed to Pb (50,000 to 300,000 µg Pb/L); total phenols also increased with increasing Pb exposure. Authors noted that this species exhibited similar responses under extreme temperatures, drought, and disease. According to Odjegba and Fasidi (2006), exposure to 0.3 mmol of Pb for 21 days was sufficient to induce a gradual reduction of both chlorophyll and protein content in the macrophyte *Eichhornia crassipes*. Decreased proteins were theorized to be related to inefficient protein formation following disruption of nitrogen metabolism after Pb exposure (Odjegba and Fasidi, 2006). Foliar proline (which is thought to act as an antioxidant) concentrations were found to increase in a concentration-dependent manner as Pb concentrations increase from 0.1 to 5.0 mmol.

Following 72-hour aqueous exposure to 41 µmol Pb-nitrate, phytochelatin and glutathione concentrations in the freshwater algae *Scenedesmus vacuolatus* were significantly increased over that of non-exposed algal cultures (Le Faucheur et al., 2006). The 72-hour Pb exposure also significantly reduced *S. vacuolatus* growth, and of all the metals tested (Cu, Zn, Ni, Pb, Ag, As, and Sb), Pb was determined to be the most toxic to the algae species. In the algae *Chlamydomonas reinhardtii*, phytochelatin concentrations were lower than intracellular Pb and not sufficient to bind to accumulated metal following 72-hour exposure (Scheidegger et al., 2011).

In addition to oxidative stress responses, there is new information since the 2006 Pb AQCD on growth effects observed at high concentrations of Pb. Root elongation was significantly reduced in a number of wetland plant species (*Beckmannia syzigachne*, *Juncus effusus*, *Oenanthe javanica*, *Cyperus flabelliformis*, *Cyperus malaccensis*, and *Neyraudia reynaudiana*) following Pb exposures of 20,000 µg Pb/L (Deng et al., 2009). Further, while both Zn and Fe exposures exerted some selective pressure on plants, the authors did not observe the same with Pb, leading them to theorize that concentrations of bioavailable Pb were not present in high enough quantities to have such an effect. However, while Lemna sp. aquatic plants were determined to effectively sequester aqueous Pb, the plant growth rate was not significantly different from zero following exposures of 5,000 and 10,000 µg Pb/L, while exposure to 15,000 µg Pb/L was associated with notable plant mortality (Hurd and Sternberg, 2008). In fact, Paczkowska et al. (2007) observed that low Pb exposures (0.1 to 1.0 mmol for 9 days) stimulated the growth of *Lemna minor* cultures, although there was concurrent evidence of chlorosis and induction of antioxidant enzymes. Additionally, Cd was found to be more toxic than Pb,

although the authors determined that this resulted from poor uptake of Pb by *L. minor* (Paczkowska et al., 2007). Pb exposure (as Pb-nitrate) caused oxidative damage, growth inhibition, and decreased biochemical parameters, including photosynthetic pigments, proteins, and monosaccharides, in *Wolffia arrhiza* plants. Fresh weight of plants was reduced following both 7- and 14-day exposures to Pb concentrations greater than 10 mmol, while chlorophyll *a* content was decreased at concentrations greater than 1 mmol Pb (Piotrowska et al., 2010).

All of the observed effects on aquatic macrophytes and algae occur at concentrations not typically encountered in surface waters.

7.3.5.2 Freshwater Invertebrates

Few studies on biological effects of Pb in freshwater invertebrates had been conducted at the time of the 1977 Pb AQCD. One study reported an effect on reproduction in *Daphnia magna* at 30 µg Pb/L (U.S. EPA, 1977). In the 1986 Pb AQCD, increased mortality was observed in the freshwater snail *Lymnaea palustris* as low as 19 µg Pb/L and reproductive impairment was reported as low as 27 µg Pb/L for Daphnia sp. Endpoints of effects of Pb on aquatic invertebrates reviewed in the 2006 Pb AQCD included metabolism, reproduction, growth, and survival. Pb was recognized to be more toxic in longer-term exposures than shorter-term exposures with chronic toxicity thresholds for reproduction in water fleas (*D. magna*) ranging as low as 30 µg Pb/L. In aquatic invertebrates, Pb has also been shown to affect stress responses and osmoregulation. New evidence that supports previous findings of Pb effects on reproduction and growth in invertebrates is reviewed here as well as limited studies on changes in gene expression and behavioral effects associated with Pb exposure.

Recent literature strengthens the evidence indicating that Pb affects enzymes and antioxidant activity in aquatic invertebrates. These alterations at the suborganismal level may serve as biomarkers for effects at the organism level and higher. In invertebrate species that have hemoglobin, ALAD activity can be measured as a biomarker for Pb exposure. In the freshwater mussel *B. glabrata* and the freshwater oligochaete *Lumbriculus variegatus* a significant negative correlation between whole body tissue ALAD enzyme activity and increasing Pb was observed following 48 hour exposure to varying concentrations of the metal (Aisemberg et al., 2005). The concentration at which 50% of enzyme inhibition was measured was much lower in *B. glabrata* (23 to 29 µg Pb/L) than in *L. variegatus* (703 µg Pb/L). A significant negative correlation was also observed between ALAD activity and metal accumulation by the organisms. Sodium and potassium-ATPase (NA, K-ATPase) activity in gills of Eastern elliptio mussels was

significantly reduced following a 28-day exposure to 57 µg Pb/L and 245 µg Pb/L (Mosher et al., In Press). A significant reduction in Na^{2+} and significant increase in Ca^{+} in hemolymph was only observed at the highest concentration.

Studies of stress responses to Pb in invertebrates, conducted since the 2006 Pb AQCD, include induction of heat shock proteins and depletion of glycogen reserves. Induction of heat shock proteins in zebra mussel exposed to 500 µg Pb/L for 10 weeks exhibited a 12-fold higher induction rate as compared to control groups (Singer et al., 2005). Energetic reserves in the freshwater snail *B. glabrata* in the form of glycogen levels were significantly decreased by 20%, 57% and 78% in gonads compared to control animals following 96-hour exposures to 50, 100 and 500 µg Pb/L, respectively (Ansaldo et al., 2006). Decreases in glycogen levels were also observed in the pulmonary and digestive gland region at 50 and 100 µg Pb/L treatment levels. Pb did not exacerbate the effects of sustained hypoxia in the crayfish (*C. destructor*) exposed to 5,000 µg Pb/L for 14 days while being subjected to decreasing oxygen levels in water (Morris et al., 2005). The crayfish appeared to cope with Pb by lowering metabolic rates in the presence of the metal.

The effect of Pb on the osmoregulatory response has been studied since the 2006 Pb AQCD. The combined effects of Pb and hyperosmotic stress on cell volume regulation was analyzed in vivo and in vitro in the freshwater red crab, *Dilocarcinus pagei* (Amado et al., 2006). Crabs held in either freshwater or brackish water lost 10% of their body weight after one day when exposed to 2,700 µg Pb^{2+}/L. This weight loss was transient and was not observed during days 2-10 of the exposure. In vitro, muscle from red crabs exposed to hyperosmotic saline solution had increased ninhydrin-positive substances and muscle weight decreased in isosmotic conditions upon exposure to Pb indicating that this metal affects tissue volume regulation in crabs although the exact mechanism is unknown.

Recently, genomic-level responses to Pb-exposure have been observed in Daphnia. The effects of Pb on *D. magna* hemoglobin gene expression was measured in daphnids exposed for 24 hours to 25, 250, or 2,500 µg Pb/L as Pb-nitrate (Ha and Choi, 2009). A significant induction in all four genes tested was observed at the highest concentration with a two-fold change in two of the genes. Hemoglobin expression was also significantly elevated above the controls in one gene at 25 µg Pb/L and in two genes at 250 µg Pb/L although this expression was less than two-fold when compared to the controls. Changes in gene expression can lead to changes at the whole organism level although these links are frequently not established.

Behavioral responses of aquatic invertebrates to Pb reviewed in the 2006 Pb AQCD included avoidance. A limited number of new studies have considered additional

behavioral endpoints. Feeding rate of the blackworm *L. variegatus* was significantly suppressed by day 6 of a 10 day sublethal test in Pb-spiked sediments (Penttinen et al., 2008) as compared to feeding rates at the start of the experiment. However, this decrease of approximately 50% of the initial feeding rate was also observed in the controls; therefore it is likely caused by some other factor other than Pb exposure. Aqueous soil leachates containing multiple metals, including Pb, had no effect on *D. magna* mobility. Authors noted that although concentrations (13 to 686 µg Pb/L) exceeded Canadian Environmental Quality Guidelines, no significant correlation could be established between Pb exposure and *D. magna* mobility; in fact, the cladocerans were more sensitive to Fe and Al in the leachate than to Pb (Chapman et al., 2010).

New evidence of reproductive and developmental effects of Pb on freshwater invertebrates available since the 2006 Pb AQCD include data from previously untested species as well as further characterization of reproductive effects in commonly tested organisms such as Daphnia sp. Sublethal concentrations of Pb negatively affected the total number of eggs, hatching success and embryonic survival of the freshwater snail *B. glabrata* exposed to 50, 100, or 500 µg Pb/L (Ansaldo et al., 2009). Following exposure of adult snails for 96 hours, adults were removed and the eggs were left in the Pb solutions. The total number of eggs was significantly reduced at the highest concentration tested (500 µg Pb/L). Time to hatching was doubled and embryonic survival was significantly decreased at 50 and 100 µg Pb/L, while no embryos survived in the highest concentration. Theegala et al. (2007) observed that the rate of reproduction was significantly impaired in *Daphnia pulex* at >500 µg Pb/L in 21 day exposures. In a 21-day reproductive test in *D. magna* the number of neonates born per female was significantly reduced at 25, 250, and 2,500 µg Pb/L (Ha and Choi, 2009). *C. dubia* reproduction was also impacted by a seven-day exposure to 50 to 500 µg Pb/L. Both DOC, and, to a lesser degree, alkalinity were observed to ameliorate the effects of Pb on *C. dubia* reproduction. As DOC increased from 100 µmol C/L to 400 and 600 µmol C/L, the calculated mean EC_{50} values for *C. dubia* reproduction increased from approximately 25 µg Pb/L to 200 µg Pb/L and greater than 500 µg Pb/L, respectively (Mager et al., 2011a).

Reproductive variables including average lifespan, rate of reproduction, generation time and rate of population increase were adversely affected in the rotifer *Brachionus patulus* under conditions of increasing turbidity and Pb concentration (Garcia-Garcia et al., 2007).

In larvae of the mosquito, C*ulex quinquefasciatus*, exposed to 50 µg Pb/L, 100 µg Pb/L or 200 µg Pb/L, Pb-nitrate exposure was found to significantly reduce hatching rate and egg-production at all concentrations and larval emergence rate at 200 µg Pb/L

(Kitvatanachai et al., 2005). Larval emergence rates of 78% (F0), 86% (F1) and 86% (F2) were observed in the control group while emergence rates decreased in each generation 46% (F0), 26% (F1) and 58% (F2) in mosquitoes reared in a concentration of 200 µg Pb/L. The time to first emergence also increased slightly to 10 days in the Pb-exposed group as compared to the control group where emergence was first observed on day 9. In the F2 generation of parents exposed to 200 µg Pb/L, the ratio of female to male offspring was 3.6:1.0. No effects were observed on oviposition preference of adult females, larval weight or larval deformation.

As noted in the 2006 Pb AQCD, Pb exposure negatively affects the growth of aquatic invertebrates. Some studies reviewed in the previous Pb AQCD suggested that juveniles do not discriminate between the uptake of essential and non-essential metals (Arai et al., 2002). In new literature, the freshwater pulmonate snail *Lymnaea stagnalis* has been identified as a species that is extremely sensitive to Pb exposure. Growth of juveniles was inhibited at EC_{20} <4 µg Pb/L. (Grosell and Brix, 2009; Grosell et al., 2006a). In *L. stagnalis* exposed to 18.9 µg/L Pb for 21 days, Ca^{2+} influx was significantly inhibited and model estimates indicated 83% reduction in growth of newly hatched snails after 30 days at this exposure concentration (Grosell and Brix, 2009). The authors speculate that the high Ca^{2+} demand of juvenile *L. stagnalis* for shell formation and interference of the Ca^{2+} uptake pathway by Pb result in the sensitivity of this species.

In a study of the combined effects of temperature (22^0C or 32^0C), Pb concentration (50, 100 and 200 µg Pb/L) and presence of a competitor, the population growth rate of two freshwater rotifer species, *Brachionus havanaensis* and *B. rubens*, as measured by quantifying the number of live rotifers for 15 days responded to presence of stressors (Montufar-Melendez et al., 2007). At the lowest temperature, *B. rubens* suppressed population growth of *B. havanaensis* at 50 µg Pb/L and higher and *B. rubens* population growth did not increase at any Pb concentration at 32^0C, a temperature more suited for *B. havanaensis*. In situ toxicity testing with the woodland crayfish (*Orconectes hylas*) indicated that crayfish survival and biomass were significantly lower in streams impacted by Pb mining and that concentrations of Pb and other metals in water, detritus, macroinvertebrates, fish and crayfish were significantly higher at mining sites (Allert et al., 2009a).

Although Pb is known to cause mortality when invertebrates are exposed at sufficiently high concentrations, species that are tolerant of Pb may not exhibit significant mortality even at high concentrations of Pb. In freshwater habitats, odonates are highly tolerant of Pb with no significant differences in survival time of dragonfly larvae *Pachydiplax longipennis* and *Erythemis simplicicollis* exposed to concentrations as high as 185 mg

Pb/L (185,000 µg Pb/L) (Tollett et al., 2009). Other species are more sensitive to Pb in the environment and these responses are reviewed in Section 7.3.6.

7.3.5.3 Freshwater Vertebrates

The 1977 Pb AQCD reported on Pb effects to domestic animals, wildlife and aquatic vertebrates. The available Pb studies were from exposure to Pb via accidental poisoning or ingestion of Pb shot. Studies on aquatic vertebrates reviewed in the 1986 Pb AQCD were limited to hematological, neurological and developmental responses in fish. In the 2006 Pb AQCD, effects on freshwater vertebrates included new data for fish specifically considering the effects of water quality parameters on toxicity, as well as limited information on sensitivity of aquatic stages of frogs and turtles to Pb. Biological effects of Pb on freshwater fish that have been studied since the 2006 Pb AQCD report are reviewed here, and limited new evidence of Pb effects on amphibians are considered. This section also presents new information available on the mechanism of Pb as a neurotoxicant in fish and effects of this metal on blood chemistry. Additional mechanisms of Pb toxicity have been elucidated in the gill and the renal system of fish since the 2006 Pb AQCD. Further supporting evidence of reproductive effects of Pb on fish is discussed along with limited new information on behavioral effects of Pb. Finally, limited new information since the 2006 Pb AQCD on physiological effects of Pb on amphibians and marine mammals is presented.

Freshwater Fish

Evidence of toxicity of Pb and other metals to freshwater fish goes back to early observations whereby contamination of natural areas by Pb mining lead to extirpation of fish from streams (U.S. EPA, 1977). At the time of the 1977 Pb AQCD, documented effects of Pb on fish included mucous secretion, anemia, functional damage to inner organs, physical deformities and growth inhibition. Additionally, the role of temperature, pH, hardness and other water quality parameters on Pb toxicity was discussed in the 1977 Pb AQCD. The 1986 Pb AQCD reported that hematological and neurological responses were the most commonly observed effects in fish and the lowest exposure concentration causing either hematological or neurological effects was 8 µg Pb/L. These findings were additionally supported in the 2006 Pb AQCD, where observed effects of Pb on fish included inhibition of heme formation, alterations in brain receptors, effects on blood chemistry, and decreases in some enzyme activities (U.S. EPA, 2006c). Functional responses resulting from Pb exposure included increased production of mucus, changes in growth patterns, and gill binding affinities. According to Eisler (2000) and reviewed in

the 2006 Pb AQCD, the general symptoms of Pb toxicity in fish include production of excess mucus, lordosis, anemia, darkening of the dorsal tail region, degeneration of the caudal fin, destruction of spinal neurons, ALAD inhibition, growth inhibition, renal pathology, reproductive effects, growth inhibition and mortality.

Evidence of Pb effects on fish available since the 2006 Pb AQCD generally support the findings in previous Pb reviews and elucidate the mechanisms of Pb-associated toxicity on some physiological responses. At the sub-organism level, new information on Pb effects on DNA, specific enzymes, ionoregulation and other biochemical responses is presented followed by a discussion of new information on organism-level endpoints including behavior and reproduction. Since the 2006 Pb AQCD evidence of direct interaction of Pb with fish DNA has become available as well as additional studies on the genotoxic effects of Pb exposure to fish. Hong et al. (2007a) observed covalent binding of Pb with kidney DNA from silver crucian carp (*Carassius auratus gibelio*) though extended X-ray absorption fine structure spectroscopy. In the freshwater fish *Prochilodus lineatus*, blood, liver, and gill cells were sampled from fish treated with nominal concentration of 5,000 µg Pb/L as Pb-nitrate for 6, 24 and 96-hours and then DNA damage was assessed by comet assay (Monteiro et al., 2011). DNA breaks were observed in all cell types after 96-hour exposure.

Upregulation of antioxidant enzymes in fish is a well-recognized response to Pb exposure. Since the last review, additional studies demonstrating antioxidant activity as well as evidence for production of reactive oxygen species following Pb exposure are available. Silver crucian carp injected with 10, 20 or 30 mg Pb/kg wet weight Pb-chloride showed a significant increase in the rate of production of superoxide ion and hydrogen peroxide in liver (Ling and Hong, 2010). In the same fish, activities of liver SOD, catalase, ascorbate peroxidase, and glutathione peroxidase were significantly inhibited. Both glutathione and ascorbic acid levels decreased and malondialdehyde content increased with increasing Pb dosage, suggesting that lipid peroxidation was occurring and the liver was depleting antioxidants. In fathead minnow, three genes, glucose-6-phosphate dehydrogenase, glutathione-S-transferase and ferritin were upregulated, in microarray analysis, during 30 day exposures to Pb in base water (33µg Pb/L), or (37µg Pb/L [hard]-water supplemented with 500 µM Ca^{2+}) or (39 µg Pb/L [DOC]-water supplemented with 4 mg/L humic acid). However, no changes in whole body ion concentrations were observed (Mager et al., 2008).

In the freshwater fish Nile tilapia, liver catalase, liver alkaline phosphatase, NA, K-ATPase and muscle Ca-ATPase activities were quantified in various tissues following a 14 day exposure to 5, 10, and 20 µM concentrations of Pb nitrate (Atli and Canli, 2007). Liver catalase activity significantly increased in the 5 and 20 µM concentrations while

liver alkaline phosphatase activity was significantly increased only at the 20 µM concentration. No significant change in alkaline phosphatase activity was observed in intestine or serum. Ca-ATPase activity was significantly decreased in muscle. Na, K-ATPase was elevated in gill in the highest concentration of Pb while all concentrations resulted in significant decreases of this enzyme in intestine. Serum alanine aminotransferase and aspartate aminotransferase activities were elevated in Nile tilapia exposed to 50 µg Pb/L in 4 and 21 day aqueous exposures while elevations in alkaline phosphatase and lactate dehydrogenase were only observed at 21 days (Fırat et al., In Press). In another study with Nile tilapia, Pb had no effect on glutathione measured in liver, gill, intestine, muscle and blood and liver metallothionein levels following a 14 day exposure to 5, 10, and 20 µM concentrations of Pb nitrate (Atli and Canli, 2008).

Metabolic enzyme activity in teleosts has also been measured following dietary exposures. Alves and Wood (2006) in a 42 day chronic dietary Pb study with 50 to 500 µg Pb/g found that gill Na, K-ATPase activity was not affected in rainbow trout while increased Na, K-ATPase was observed in the anterior intestine. Metabolic activities measured in liver and kidney of Nile tilapia following 60 day dietary administration of 100, 400, and 800 µg Pb/g indicated that alanine transaminase, aspartate transaminase, and lactate dehydrogenase activities significantly decreased in kidney in a concentration-dependent manner (Dai et al., 2009a) and increased in liver with increasing concentration of dietary Pb. In a subsequent study using the same exposure paradigm, the digestive enzymes amylase, trypsin and lipase in tilapia were inhibited by dietary Pb in a concentration-dependent manner (Dai et al., 2009b). Lesions were also evident in histological sections from livers of Pb-exposed fish from this study and included irregular hepatocytes, cell hypertrophy, and vacuolation although no quantification of lesions by dose-group was presented.

Pb was shown to inhibit hepatic cytochrome P450 in carp (*C. carpio*), silver carp (*Hypothalmichtys molitrix)* and wels catfish (*Silurus glanis*) in a concentration-dependent manner from 0-4.0 µg/mL (Pb^{2+}) (Henczova et al., 2008). The concentrations of Pb that resulted in 50% inhibition of EROD and 7-ethoxycoumarin-o-deethylase (ECOD) isoenzymes varied with the fish species. Silver carp was the least sensitive to the inhibitory effects of Pb (EROD 1.21, ECOD 1.52 µg Pb/L) while carp EROD activity was inhibited at 0.76 µg Pb/L. Interaction of Pb with cytochrome P450 was verified by spectral changes using Fourier Transform Infrared (FTIR) spectroscopy. Liver damage to African catfish exposed to Pb (50-1,000 µg Pb/L) for 4 or 8 weeks included hepatic vacuolar degeneration followed by necrosis of hepatocytes (Adeyemo, 2008b). The severity of observed histopathological effects in the liver was proportional to the duration of exposure and concentration of Pb.

In environmental assessments of metal-impacted habitats, ALAD is a recognized biomarker of Pb exposure (U.S. EPA, 2006c). For example, lower ALAD activity has been significantly correlated with elevated blood Pb concentrations in wild caught fish from Pb-Zn mining areas although there are differences in species sensitivity (Schmitt et al., 2007b; Schmitt et al., 2005). Suppression of ALAD activity in brown trout transplanted to a metal contaminated stream was linked to Pb accumulation on gills and in liver in a 23 day exposure (Heier et al., 2009). Costa et al. (2007) observed inhibition of ALAD in hepatocytes of the neotropical traira (*Hoplias malabaricus*) following dietary dosing of 21 µg Pb/g every 5 days for 70 days. Cytoskeletal and cytoplasmic disorganization were observed in histopathological examination of affected hepatocytes. In fathead minnow exposed to Pb in either control water (33 µg Pb/L), $CaSO_4$ (37 µg Pb/L) or (39 µg Pb/L) humic acid-supplemented water and subsequently analyzed by quantitative PCR analysis there were no significant changes in ALAD mRNA gene response leading the authors to speculate that water chemistry alone does not influence this gene response (Mager et al., 2008).

In fish, changes in blood chemistry associated with Pb exposure were noted in the 2006 Pb AQCD and limited new literature since the last Pb review support these findings. In the African catfish, packed cell volume decreased with increasing concentration of Pb (25,000 to 200,000 µg Pb/L as Pb-nitrate) and platelet counts increased in a 96-hour exposure (Adeyemo, 2007). Red blood cell counts also decreased in some of the treatments when compared to controls, although the response was not dose-dependent and so may not have been caused by Pb exposure. In traira exposed to dietary doses (21 µg Pb/g via prey [Astyanax sp.]) for five days, there were no significant changes to leukocytes or hemoglobin concentration and volume (Oliveira Ribeiro et al., 2006). Significant differences in area, elongation and roundness of erythrocytes were observed in the Pb-exposed individuals using light microscopy image analysis.

Disruption of ionoregulation is one of the major modes of action of Pb toxicity. The gill has long been recognized as a target of Pb in teleosts. Acute Pb toxicity at the fish gill primarily involves disruption of Ca homeostasis as previously characterized in the 2006 Pb AQCD (Rogers and Wood, 2004; Rogers and Wood, 2003). In addition to this mechanism, Pb was found to induce ionoregulatory toxicity at the gill of rainbow trout through a binding of Pb with Na-K, ATPase and rapid inhibition of carbonic anhydrase activity thus enabling noncompetitive inhibition of Na^+ and Cl^- influx (Rogers et al., 2005). Alves et al. (2006) administered a diet of three concentrations of Pb (7, 77 and 520 µg Pb/g dry weight) to rainbow trout for 21 days, and measured physiological parameters including Na^+ and Ca^+ influx rate from water. Dietary Pb had no effect on brachial Na^+ and Ca^+ rates except on day 8 where Na^+ influx rates were significantly elevated. These studies suggest that Pb is intermediate between purely Ca antagonists

such as Zn and Cd and disruptors of Na and Cl balance such as Ag and Cu. This finding has implications for BLM modeling since it suggests that both Ca and Na need to be considered as protective cations for Pb toxicity. Indeed, protection from Pb toxicity by both Na and Ca have been documented in freshwater fish (Komjarova and Blust, 2009b).

Long-term exposures of Pb can impact gill structure and function. Histopathological observations of gill tissue in the catfish (*C. gariepinus*) following an 8-week aqueous exposure to Pb nitrate revealed focal areas of epithelial hyperplasia and necrosis at the lower exposure concentrations (50 µg Pb/L and 100 µg Pb/L) (Adeyemo, 2008a). Hyperplasia of mucous cells and epithelial cells were apparent in the tissue from fish exposed the highest concentrations of Pb in the study (500 µg Pb/L and 1,000 µg Pb/L). In vitro incubation of gill tissue from fathead minnow with Pb concentrations of 2.5, 12.5 and 25 mg Pb/L decreased the ratio of reduced glutathione to oxidized glutathione, indicating that lipid peroxidation at the gill likely contributes to Pb toxicity at low water hardness (Spokas et al., 2006).

In addition to recent evidence of Pb interruption of Na^+ and Cl^- at the gill (Rogers et al., 2005), Pb can interfere with the ionoregulation of Na^+ and Cl^- and tubular reabsorption of Ca^+, Mg^{2+}, glucose, and water in the teleost kidney (Patel et al., 2006). Renal parameters including urine flow rate, glomerular filtration rate, urine pH, and ammonia excretion were monitored in a 96-hour exposure of rainbow trout to 1,200 µg Pb/L as Pb nitrate. Rates of Na^+ and Cl^- excretion decreased by 30% by 48 hours while Mg excretion increased two-to-three fold by 96 hours. Urine flow rate was not altered by Pb exposure, although urinary Pb excretion rate was significantly increased. After 24 hours of Pb exposure, the urine excretion rate of Ca^+ increased significantly by approximately 43% and remained elevated above the excretion rate in the control group for the duration of the exposure. Glomerular filtration rate significantly decreased only during the last 12 hours of the exposure. Ammonia excretion rate increased significantly at 48 hours as urine pH correspondingly decreased. At the end of the experiment glucose excretion was significantly greater in Pb-exposed fish. Although the exposures in this study approached the 96-hour LC_{50}, nephrotoxic effects of Pb indicate the need to consider additional binding sites for this metal in the development of biotic ligand modeling (Patel et al., 2006). Additional evidence for Pb effects on ion levels were observed in serum of Nile tilapia; Na^+ and Cl^- were decreased and K^+ levels were elevated following a 21 day exposure to 50 µg Pb/L (Fırat et al., In Press).

Additional evidence of the neurotoxic effects of Pb on teleosts has become available since the 2006 Pb AQCD. The mitogen-activated protein kinases (MAPK), extracellular signal-regulated kinase (ERK)1/2 and $p38^{MAPK}$ were identified for the first time as possible molecular targets for Pb neurotoxicity in a teleost (Leal et al., 2006). The

phosphorylation of ERK1/2 and $p38^{MAPK}$ by Pb was determined in vitro and in vivo in the catfish (*Rhamdia quelen*). *R. quelen* exposed to 1,000 µg Pb/L acetate for two days showed a significant increase in phosphorylation of ERK1/2 and $p38^{MAPK}$ in the nervous system. Incubation of cerebellar slices for 3 hours in 5 and 10µM Pb-acetate also showed significant phosphorylation of MAPKs. The observed effects of Pb on the MAPK family of signaling proteins have implications for control of brain development, apoptosis and stress response. In the neotropical fish traira, muscle cholinesterase was significantly inhibited after 14 dietary doses of 21 µg Pb/g wet weight (Rabitto et al., 2005). Histopathological observations of brains of African catfish exposed to 500 µg Pb/L or 1,000 µg Pb/L Pb for 4 weeks included perivascular edema, focal areas of malacia, and diffuse areas of neuronal degeneration (Adeyemo, 2008b).

Evidence from the 2006 Pb AQCD and earlier Pb reviews indicate that Pb can impair both cognitive and motor function in fish. Reduced locomotion and foraging ability were observed in Chinese sturgeon juveniles exhibiting abnormal body curvature following exposure to either 800 or 1,600 µg Pb/L for 112 days (Hou et al., 2011). These chondrostei fish gradually recovered from deformities during a depuration period and were able to swim and forage effectively 6 weeks after transfer into clean water.

Since the 2006 Pb AQCD, several studies integrating behavioral and physiological measures of Pb toxicity have been conducted on fish. Sloman et al. (2005) investigated the effect of Pb on hierarchical social interactions and the corresponding monoaminergic profiles in rainbow trout. Trout were allowed to establish dominant-subordinate relationships for 24 hours, and then were exposed to 46 µg Pb/L or 325 µg Pb/L (Pb-nitrate) for 48 hours to assess effects on behavior and brain monoamines. In non-exposed fish, subordinate individuals had higher concentrations of circulating plasma cortisol and telencephalic 5-hydroxyindoleacetic acid/5-hydroxytryptamine (serotonin) (5-HIAA/5-HT) ratios. In the high concentration of Pb, there was significant uptake of Pb into gill, kidney and liver when compared with the control group and dominant fish appeared to have elevated hypothalamic 5-HIAA/5HT ratios. Uptake of Pb into the liver was higher in subordinate fish when compared to the dominant fish. No significant differences were observed in cortisol levels or behavior after metal exposure.

Mager et al. (2010) conducted prey capture assays with 10 day old fathead minnow larvae born from adult fish exposed to 120 µg Pb/L for 300 days, then subsequently tested in a breeding assay for 21 days. The time interval between 1st and 5th ingestion of 10 prey items (*Artemia nauplii*) was used as a measure of behavior and motor function of offspring of Pb-exposed fish. Larvae were offered 10 Artemia and the number ingested within 5 minutes was scored. The number of larvae ingesting 5 Artemia decreased within

the time period in offspring of Pb-exposed fish as compared to the control group, leading the authors to suggest this behavior is indicative of motor/behavioral impairment.

In another study with fathead minnows, swimming performance measured as critical aerobic swim speed was significantly impaired in minnows in 24-hour acute (139 µg Pb/L) and chronic 33 to 57 day (143 µg Pb/L) exposures, however, no significant difference in swim speed was observed in chronic exposures to 33 µg Pb/L (Mager and Grosell, 2011).

Zebrafish embryos exposed to low concentrations of Pb (10nM or 30 nM) until 24 hours post-fertilization and then subsequently tested as larvae or adult fish exhibited behavioral disruptions in response to mechanosensory and visual stimuli (Rice et al., 2011). Startle response time in larvae measured as maximum head turn velocity and escape time decreased in a concentration-dependent pattern following a directional, mechanical stimulus (tapping). The pattern of escape swimming was altered in larvae of Pb-exposed embryos compared to controls. In adult fish hatched from Pb-exposed embryos (30 nM), visual response to a rotating black bar against a white background (ability to detect contrast) was significantly degraded. In another study with zebrafish embryos exposed to higher concentration of Pb (200,000 nM) from 0 to 6 days post hatch, swim movements and escape action were also significantly slower than the control group (Dou and Zhang, 2011).

Reproductive and developmental effects of Pb in fish have been reported for several decades. In the 1977 Pb AQCD, second generation brook trout (*Salvelinus fontinalis*) exposed to 235 or 474 µg Pb/L were shown to develop severe spinal deformities (scoliosis) (U.S. EPA, 1977). Pb concentration of 120 µg Pb/L produced spinal curvature in rainbow trout (*Oncorhynchus mykiss*) and spinal curvatures were observed in developing eggs of killifish as reviewed in the 1986 Pb AQCD (U.S. EPA, 1986b). Limited new studies on reproductive effects of Pb in fish from oocyte formation to spawning are available. The effects of metals on embryonic stage of fish development in *C. carpio* and other species were reviewed in Jezierska et al. (2009) and included developmental abnormalities during organogenesis as well as embryonic and larval malformations. The authors concluded that the initial period of embryonic development, just after fertilization, and the period of hatching are the times at which developing embryos are most sensitive to metals. A significant concentration-dependent increase in morphological malformations was observed in African catfish embryos exposed to 100 µg Pb/L, 300 µg Pb/L or 500 µg Pb/L Pb-nitrate from 6 hours post-fertilization to 168 hours post-fertilization (Osman et al., 2007b). Hatching was delayed with increasing Pb concentration and hatch success of the embryos decreased from 75% in the controls to 40% in the group exposed to 500 µg Pb/L. Chinese sturgeon exposed to nominal

concentrations of 200 µg Pb/L, 800 µg Pb/L or 1,600 µg Pb/L for 112 days (96 hour post-fertilized eggs through juvenile stages) exhibited body curvatures in the two highest concentrations (Hou et al., 2011). During a 42 day depuration period in clean water following exposure, the degree of curvature in affected individuals decreased with decreasing tissue concentrations of Pb.

Reproductive performance of zebrafish as measured by incidence of spawning, numbers of eggs per breeding pair or hatch rate of embryos was unaffected following a 63 day diet of field-collected Pb-contaminated polychaetes that were representative of a daily dose of 0.3-0.48 g Pb/kg·day (dry weight diet/wet weight fish) through food (Boyle et al., 2010). Mager et al. (2010) conducted 21 day breeding exposures at the end of chronic 300 day toxicity testing with fathead minnow. Non-exposed breeders were switched to water containing Pb and Pb-exposed breeders were moved to control tanks and effects on egg hatchability and embryo Pb accumulation were assessed. Fish in the high Pb concentration (120 µg Pb/L) reduced total reproductive output, while a significant increase in average egg mass was observed in the high Pb HCO_3^- and DOC treatments as compared to egg mass size in controls and in low HCO_3^- and DOC treatments with Pb. No significant differences were present between treatments in egg hatchability.

Reproductive and endocrine effects of Pb have also been observed at the cellular level in fish, including alterations in gonadal tissue and hormone secretions that are associated with Pb-exposure. Histopathological observations of ovarian tissue in the African catfish following an 8-week aqueous exposure to Pb nitrate indicated necrosis of ovarian follicles at the lowest concentration tested (50 µg Pb/L) (Adeyemo, 2008a). Severe degeneration of ovarian follicles was observed in the highest concentrations of 500 µg Pb/L and 1,000 µg Pb/L. Chaube et al. (2010) considered the effects of Pb on steroid levels through 12 and 24 hour in vitro exposures of post-vitellogenic ovaries from the catfish (*Heteropneustes fossilis*) to Pb-nitrate (0, 001, 0.1, 1, 3, and 10 µg Pb/mL). Progesterone, 17-hydroxyprogesterone, 17, 20 beta-dihydroxyprogesterone, corticosterone, 21-deoxycortisol and deoxycorticosterone were inhibited in a dose-dependent manner. Pb was stimulatory on the steroids estradiol-17-β, testosterone and cortisol at low concentrations, and inhibitory at higher concentrations. The disruption of steroid production and altered hormone secretion patterns observed at the low concentrations of Pb in this study are suggestive of the potential for impacts to fish reproduction (Chaube et al., 2010).

There is also evidence for alterations in steroid levels associated with Pb exposure in other species of fish. Carp (*Cyprinus carpio*) exposed for 35 days to nominal concentration of 410 µg Pb/L experienced altered plasma cortisol and prolactin levels. Plasma cortisol levels significantly increased throughout the study period while plasma

prolactin increased up to day 14 and then declined and was not significantly different from controls by the end of the experiment (Ramesh et al., 2009). Cortisol levels were significantly decreased in Nile tilapia exposed to 50 µg Pb/L for 4 days but were followed by a return to control levels at 21 days of exposure (Fırat et al., In Press). Vitellogenin was significantly induced in juvenile goldfish (*Carassius auratus*) following 96-hour exposure to 1 x 10^{-9} and 1 x10^{-10} M Pb when compared to control fish (Isidori et al., 2010). In the same study, estrogenicity of Pb was detected in vitro using a proliferation assay with estrogen receptor-positive human MCF-7 cells.

Reduction of growth in fish was noted as an effect of Pb exposure in the 2006 Pb AQCD. New studies available since the 2006 Pb AQCD do not present consistent evidence of growth reduction in fish associated with Pb. In a series of exposures in which Ca^{+2}, DOC and pH were varied to assess effects on Pb toxicity to fathead minnows, Grosell et al. (2006b) observed a significant increase in growth in some groups exposed to higher concentrations, however, the increase in body mass was noted to have occurred in tanks with high mortality earlier in the exposure (Grosell et al., 2006b). Fathead minnows exposed to 33 µg Pb/L to test swimming performance had significantly greater body length and body mass compared to control fish following a mean Pb exposure duration of 41 days (range 33 to 57 days) (Mager and Grosell, 2011). In 30 day chronic tests in which a range of pH values (6.4, 7.5 and 8.3) were tested with low (25-32 µg Pb/L), intermediate (82-156 µg Pb/L) and high (297-453 µg Pb/L) concentrations of Pb, Mager et al. (2011b) did not observe growth impairment in fathead minnows at environmentally relevant concentrations of Pb.

No effects on growth rates were observed in rainbow trout administered a diet containing three concentrations of Pb (7, 77 and 520 µg Pb/g dry weight) for 21 days (Alves et al., 2006) or in Nile tilapia fed diets with 100, 400, or 800 µg/g Pb dry weight for 60 days (Dai et al., 2009b). Growth and survival were not significantly affected in juvenile rainbow trout, fathead minnow and channel catfish (*Ictalurus punctatus*) fed a live diet of *L. variegatus* contaminated with Pb (850-1,000 µg Pb/L·g dry mass for 30 days. (Erickson et al., 2010). Two 60-day early lifestage tests with rainbow trout showed differences in LOEC for reduced growth (Mebane et al., 2008). In the first test, a 69 day exposure, the LOECs for mortality and reduced growth were the same (54 µg Pb/L). In the second test, a 62 day exposure of Pb to rainbow trout, the LOEC for fish length was 18 µg Pb/L with an EC_{20} of >87 µg Pb/L. Faster growth rates were associated with lower whole-body trace element concentrations in salmon (*Salmo salar*) across several streams in New Hampshire and Massachusetts, U.S., regardless of whether accumulation was from prey items or from water (Ward et al., 2010). In sites where conditions in the streams were conducive to rapid salmon growth, Pb concentrations were 86% lower than in streams where salmon were smaller.

Amphibians

Amphibians move between terrestrial and aquatic habitats and can therefore be exposed to Pb both on land and in water. The studies reviewed here are all aquatic or sediment exposures. Biological effects of Pb on amphibians in terrestrial exposure scenarios are reviewed in Sections 7.2.3.3 and 7.2.4.3. Amphibians lay their eggs in or around water making them susceptible to water-borne Pb during swimming, breeding and development. In the 2006 Pb AQCD amphibians were considered to be relatively tolerant to Pb. Observed responses to Pb exposure included decreased enzyme activity (e.g., ALAD reduction) and changes in behavior summarized in Table AX7-2.4.3 (U.S. EPA, 2006c). Since the 2006 Pb AQCD, studies conducted at environmentally relevant concentrations of Pb have indicated sublethal effects on tadpole endpoints including growth, deformity, and swimming ability. Genotoxic and enzymatic effects of Pb following chronic exposures have been assessed in laboratory bioassays.

Various sublethal endpoints (growth, deformity, swimming ability, metamorphosis) were evaluated in northern leopard frog (*R. pipiens*) tadpoles exposed to nominal concentrations of 3, 10, and 100 µg Pb/L as Pb nitrate from embryonic stage to metamorphosis (Chen et al., 2006b). In this chronic study, the concentrations represent the range of Pb found in surface freshwaters across the U.S. The lowest concentration of 3 µg Pb/L approaches the EPA chronic criterion for Pb of 2.5 µg Pb/L at a hardness of 100 mg/L or 4.5 µg Pb/L at a hardness of 170 mg/L (U.S. EPA, 2002c). No effects were observed in the lowest concentration. In the 100 µg Pb/L treatment, tadpole growth rate was slower (Gosner stages 25-30), 92% of tadpoles had lateral spinal curvature (compared with 6% in the control) and maximum swimming speed was significantly slower than the other treatment groups. In this study, Pb concentrations in the tissues of tadpoles were quantified and the authors reported that they were within the range of reported tissue concentrations from wild-caught populations.

The effects of Pb-contaminated sediment on early growth and development were assessed in the southern leopard frog (Sparling et al., 2006). Tadpoles exposed to Pb in sediment (45, 75, 180, 540, 2,360, 3,940, 5,520, and 7,580 mg Pb/kg dry weight) with corresponding sediment pore water concentrations of 123, 227, 589, 1,833, 8,121, 13,579, 19,038 and 24,427 µg Pb/L from embryonic stage to metamorphosis exhibited sublethal responses to Pb in sediment at levels below 3,940 mg Pb/kg. There was 100% mortality in the 3,940, 5,520 and 7,580 mg Pb/kg exposures by day 5. The authors noted that the most profound effects of Pb on the tadpoles were on skeletal development. At 75 mg Pb/kg, subtle effects on skeletal formation such as clinomely and brachydactyly were observed. Skeletal malformations increased in severity at 540 mg Pb/kg and included clinodactyly, brachymely and spinal curvature and these effects persisted after metamorphosis. At the highest concentration with surviving tadpoles (2,360 mg Pb/kg)

all individuals displayed severe skeletal malformations that impacted mobility. Other sublethal effects of Pb observed in this study were reduced rates of early growth of tadpoles at concentrations ≤ 540 mg Pb/kg and increased time to metamorphosis in the 2,360 mg Pb/kg (8,121 µg Pb/L sediment pore water) treatment. Conversely, no effects were observed on organogenesis in *X. laevis* embryos exposed to a range of Pb concentrations from 8,600 to 220,500 µg Pb/L using the Frog Embryo Teratogenesis Assay (Gungordu et al., 2010).

Endpoints of oxidative damage were measured in testes of the black-spotted frog (*Rana nigromaculata*) treated with 100 µg Pb/L, 200 µg Pb/L, 400 µg Pb/L, 800 µg Pb/L or 1,600 µg Pb/L Pb-nitrate by epidermal absorption for 30 days (Wang and Jia, 2009). All doses significantly increased MDA, a product of oxidative stress, and glutathione levels were elevated in all but the lowest treatment group. In the same study, damage to DNA assessed by DNA tail length showed effects at >200 µg Pb/L and DNA tail movement showed effects at >400 µg Pb/L. The authors concluded that the effects on endpoints of oxidative stress and DNA damage detected in testes indicated a possible reproductive effect of Pb to black-spotted frogs.

The genotoxic potential of Pb to larvae of the frog (*X. laevis*) was assessed by determining the number of micronucleated erythrocytes per thousand (MNE) following a 12 day exposure (Mouchet et al., 2007). The lowest Pb concentrations with *X. laevis* (10 and 100 µg Pb/L) did not exhibit genotoxic effects while both 1,000 and 10,000 µg Pb/L significantly increased MNE to 14 and 202, respectively compared to the control (6 MNE). In another chronic genotoxic study, erythrocytic micronuclei and erythrocytic nuclear abnormalities were significantly increased with increasing Pb concentrations (700 µg Pb/L , 1,400 µg Pb/L , 14,000 µg Pb/L, 70,000 µg Pb/L) during 45, 60, and 75 day exposures of tadpoles *Bufo raddei* (Zhang et al., 2007b). The authors noted that the erythrocytic micronuclei and erythrocytic nuclear abnormalities frequencies generally decreased with increasing exposure time and that this may be indicative of regulation of genotoxic factors by tadpoles.

Birds

As reviewed in Koivula and Eeva (2010) measurement of enzymes associated with oxidative stress in birds is a well-established biomarker of exposure to metals, however, little is known about the effects of this stress response in wild populations or at higher levels of ecological organization. Changes in ALAD activity and other oxidative stress biomarkers at low levels of Pb exposure were recently documented in mallards and coots (*Fulica atra*) from a lagoon in Spain impacted by Pb shot (Martinez-Haro et al., 2011). ALAD ratio in mallards decreased linearly with blood Pb levels between 6 and 40 µg

Pb/dL, and at Pb levels of < 20 µg Pb/dL effects on several antioxidant enzymes were observed in coots. Although the primary route of exposure to the birds was via ingestion of Pb shot, effects were observed lower than 20 µg Pb/dL, the background level frequently applied to Pb exposures in birds (Martinez-Haro et al., 2011; Brown et al., 2006).

Consideration of toxicity of Pb to vertebrate embryos that develop surrounded by a protective egg shell has been expanded since the 2006 Pb AQCD. Pb treatment of mallard duck (*Anas platyrhynchos*), eggs by immersion in 100 µg Pb/L for 30 minutes on day 0 of development did not increase malformations or mortality of embryos (Kertész and Fáncsi, 2003). However, immersion of eggs in 2,900 µg Pb/L under the same experimental conditions resulted in increased rate of mortality and significant malformations including hemorrhages of the body, stunted growth, and absence of yolk sac circulatory system (Kertesz et al., 2006). The second study was conducted to emulate environmental levels of Pb following a dam failure in Hungary.

7.3.6 Exposure and Response of Freshwater Species

Evidence regarding exposure-response relationships and potential thresholds for Pb effects on aquatic populations can inform determination of standard levels that are protective of aquatic ecosystems. The Annex of the 2006 Pb AQCD (U.S. EPA, 2006c) summarized data on exposure-response functions for invertebrates (Table AX7-2.4.1) and fish (Table AX7-2.4.2). The recent exposure-response studies in this section expand on the findings from the 2006 Pb AQCD with information on newly-tested organisms (including microalgae, invertebrate, amphibian and fish species). Overall, new data for freshwater invertebrates generally supports the previous finding of sensitivity of juvenile lifestages and indicates some effects of Pb observed in some species at environmentally relevant concentrations.

The aquatic freshwater microalgae *Scenedesmus obliquus* was significantly more sensitive to Pb exposure than *Chlorella vulgaris* algae, although these authors stated that both appeared to be very tolerant of the heavy metal. Laboratory 48-hour standard toxicity tests were performed with both of these species and respective EC_{50} values of 4,000 and 24,500 µg Pb/L for growth as measured by cell division rate were derived (Atici et al., 2008). The aquatic macrophyte *Lemna minor* (duckweed) exhibited a EC_{50} for growth inhibition of 6,800 µg Pb/L in a 4-day exposure and 5,500 µg Pb/L for a 7-day exposure to a range of Pb concentrations from 100 to 10,000 µg Pb/L (Dirilgen, 2011). Experiments with the blue-green algae *Spirulina platensis* produced a LC_{50} value of 75,300 µg Pb/L (95% CI: 58.5, 97.0) (Arunakumara et al., 2008).

In the 2006 Pb AQCD, effects of Pb-exposure in amphipods (*H. azteca*) and water fleas (*D. magna*) were reported at concentrations as low as 0.45 µg Pb/L. Effective concentrations for aquatic invertebrates were found to range from 0.45 to 8,000 µg Pb/L. Since the 2006 Pb AQCD, recent studies have identified the freshwater snail *L. stagnalis* as a species that is extremely sensitive to Pb exposure (Grosell and Brix, 2009; Grosell et al., 2006a). Growth of juvenile *L. stagnalis* was inhibited below the lowest concentration tested resulting in an EC_{20} of < 4 µg Pb/L. In the same study, the NOEC was 12 µg Pb/L and the LOEC was 16 µg Pb/L. In contrast, freshwater juvenile ramshorn snails *M. cornuarietis* were less sensitive to Pb with the same LOEC for hatching rate and $LC_{50,}$ calculated to be about 10,000 µg Pb/L (Sawasdee and Köhler, 2010).

Additional studies on Pb effects in aquatic invertebrates published since the 2006 Pb AQCD have indicated differences in sensitivity of different lifestages of aquatic organisms to Pb. In the freshwater mussel, *Lampsilis siliquoidea* (fatmucket) a Pb concentration response was observed in which newly transformed (5-day-old) juveniles were the most sensitive lifestage in a 96-hour toxicity test when compared to acute and chronic results with other lifestages (Wang et al., 2010e). The 96-hour EC_{50} values for the 5-day-old *L. siliquoidea* in two separate toxicity tests were 142 and 298 µg Pb/L (mean EC_{50} 220 µg Pb/L) in contrast to older juveniles (2 months old) with an EC_{50} >426 µg/L. The 24-hour median effect concentration for glochidia (larvae) of *L. siliquoidea* in 48-hour acute toxicity tests was >299 µg/L. A 28 day exposure chronic value of 10 µg Pb/L was obtained from 2-month-old *L. siliquoidea* juveniles, and was the lowest genus mean chronic value ever reported for Pb (Wang et al., 2010e). A 96-hour test on newly transformed juveniles was also conducted on *Lampsilis rafinesqueana* (Neosho mucket), a mussel that is a candidate for the endangered species list. The EC_{50} for this species was 188 µg Pb/L.

Different lifestages of chironomids have been shown to have varying sensitivity to Pb exposure in several studies available since the 2006 Pb AQCD. The acute toxicity of Pb to first-instar *C. riparius* larvae was tested in soft water, with hardness of 8 mg/L as $CaCO_3$ (Bechard et al., 2008). The 24-hour LC_{50} of 610 µg Pb/L for first instar *C. riparius* larvae was much lower than previous values reported for later instars in harder water. In a chronic test with *Chironomus tentans*, (8 day-old larvae exposed to Pb until emergence [approximately 27 days]), the NOEC was 109, and the LOEC was 497 µg Pb/L (Grosell et al., 2006a). The EC_{20} for reduced growth and emergence of the midge *Chironomus dilutus* was 28 µg Pb/L, observed in a 55-day exposure, while the same species had a 96-hour LC_{50} of 3,323 µg Pb/L (Mebane et al., 2008). In fourth instars of the freshwater midge larvae *Chironomus javanus* the 24, 48, 72 and 96 hour LC_{50}'s were 20,490, 6,530, 1,690 and 720 µg Pb/L, respectively (Shuhaimi-Othman et al., In Press). This was

comparable to the 96-hour LC_{50} (420 µg Pb/L) in *Chironomus plumosus (*Vedamanikam and Shazilli, 2008a*).*

Cladocerans are commonly tested aquatic organisms, with data from three species: *D. magna*, *D. pulex* and *Ceriodaphnia dubia*, representing approximately 70% of available metal toxicological literature on this group (Wong et al., 2009). Recent studies have been conducted with *C. dubia* and acute toxicity values for other cladocerans as well as sublethal endpoints for *D. magna* are available. In a series of 48 hour acute toxicity tests with *C. dubia* conducted in a variety of natural waters across North America, LC_{50} values ranged from 29 to 180 µg Pb/L and were correlated with DOC (Esbaugh et al., 2011). Median lethal concentrations for *Moina micrura* (LC_{50} 690 µg Pb/L), *Diaphanosoma birgei* (LC_{50} 3,160 µg Pb/L), and *Alona rectangular* (LC_{50} 7,000 µg Pb/L) indicate differences in sensitivity to Pb in these freshwater cladocerans from Mexico (Garcia-Garcia et al., 2006). An acute study of Pb with *D. pulex* identified a 48-hour LC_{50} of 4,000 µg/L for this species (Theegala et al., 2007). The EC_{50} for swimming inhibition in neonate *D. magna* exposed to Pb-nitrate for 24 hours was 18,153 µg Pb/L (Ha and Choi, 2009).

Rotifers are among the most sensitive aquatic genera to Pb with wide variation in LC_{50} values reported between species (Pérez-Legaspi and Rico-Martínez, 2001). For example, in the rotifer genus *Lecane*, a 22-fold difference in LC_{50} values was observed in 48-hour exposure to Pb between *L. hamata, L. luna* and *L. quadridentata*. (Pérez-Legaspi and Rico-Martínez, 2001). *L. luna* was most sensitive to Pb toxicity with a 48-hour LC_{50} of 140 µg Pb/L. In a 48-hour toxicity test with the rotifer *Brachionus calyciflorus*, an NOEC (194 µg Pb/L), a LOEC (284 µg Pb/L), and an EC_{20} of 125 µg Pb/L was established for this species (Grosell et al., 2006a). The freshwater rotifer *Euchlanis dilatata* 48 hour LC_{50} was 35 µg Pb/L using neonates hatched from asexual eggs (Arias-Almeida and Rico-Martínez, 2011). In contrast, for rotifer *Brachionus patulus* neonates, the 24-hour LC_{50} was 6,150 µg Pb/L (Garcia-Garcia et al., 2007) .

Exposure-response assays on other freshwater species have been conducted since the 2006 Pb AQCD. The 24-hour LC_{50} for larvae of *C. quinquefasciatus* mosquitoes was 180 µg Pb/L (Kitvatanachai et al., 2005). A 48-hour LC_{50} of 5,200 µg Pb/L was observed in water-only exposures of the blackworm *Lumbriculus variegatus* (Penttinen et al., 2008). In the mayfly *Baetis tricaudatus*, the 96-hour LC_{50} was 664 µg Pb/L (Mebane et al., 2008). An EC_{20} value of 66 µg Pb/L was derived for *B. tricaudatus* by quantifying the reduction in the number of molts over a 10-day exposure to Pb (Mebane et al., 2008). The number of molts was significantly less than the control (average of 14 molts over 10 days) at concentrations of 160 µg Pb/L and higher with the lowest number of molts (average of 5.3 molts over 10 days) observed in the highest concentration (546 µg Pb/L).

In the freshwater ostracod *Stenocypris major*, the 96-hour LC_{50} was 526.2 µg Pb/L (Shuhaimi-Othman et al., In Press). In another freshwater crustacean, the prawn *Macrobrachium lancesteri*, the 96-hour LC_{50} was 35 µg Pb/L in soft water (<75 mg/L as $CaCO_3$) (Shuhaimi-Othman et al., 2011).

In the studies reviewed for the 2006 Pb AQCD, freshwater fish demonstrated adverse effects at concentrations ranging from 10 to >5,400 µg Pb/L, generally depending on water quality parameters (e.g., pH, hardness, salinity) (U.S. EPA, 2006c). Pb tended to be more toxic in longer-term exposures and correlated to Pb-uptake in tissues. Table AX7-2.4.2 of the 2006 Pb AQCD summarizes effects of Pb to fish. A series of studies published since the 2006 Pb AQCD have been conducted and have further elucidated the influence of water chemistry parameters on Pb uptake and toxicity in fathead minnow resulting in additional dose-response data for this species. Grosell et al. (2006a) conducted a series of 30-day exposures with larval fathead minnow in which varying concentrations of Ca^{2+} (as $CaSO_4$) and DOC were tested. The effects of reduced pH (6.7) and increased pH (8.1) compared to a control pH of 7.4 on Pb toxicity were also assessed in this study. DOC, $CaSO_4$ and pH influenced Pb toxicity considerably over the range of water parameters tested. The 30-day LC_{50} for low hardness (19 mg $CaSO_4$/L) in basic test water was 39 µg dissolved Pb/L and the highest LC_{50} value (obtained from the protection from increased concentrations of DOC and $CaSO_4$) was 1,903 µg dissolved Pb/L (Grosell et al., 2006b).

Mager et al. (2010) conducted 300-day chronic toxicity tests at 35 and 120 µg Pb/L with fathead minnow under conditions of varied DOC and alkalinity to assess the effects of these water quality parameters on fish growth and Pb-uptake. In additional tests with fathead minnow, Mager et al. (2011b) conducted both 96-hour acute and 30-day chronic tests to further characterize Ca^{2+}, DOC, pH, and alkalinity values on Pb toxicity. Increased Ca^{2+}, DOC and $NaHCO_3$ concentration afforded protection to minnows in acute studies. The role of pH in Pb toxicity is complex and likely involves Pb speciation and competitive interaction of H^+ with Pb^{2+} (Mager et al., 2011b). In a series of 96-hour acute toxicity tests with fathead minnow conducted in a variety of natural waters across North America, LC_{50} values ranged from 41 to 3,598 µg Pb/L and no Pb toxicity occurred in three highly alkaline waters (Esbaugh et al., 2011).

In the 2006 Pb AQCD, fish lifestage was recognized as an important variable in determining the sensitivity of these organisms to Pb. New data available since the 2006 Pb AQCD support the findings of increased sensitivity of juvenile fish to Pb when compared to adults. Acute (96-hour) and chronic (60-day) early-lifestage test exposures were conducted with rainbow trout to develop ACR's for this species (Mebane et al., 2008). Two early-lifestage chronic tests were conducted, the first with an exposure range

of 12-384 µg Pb/L (69 days) at 20 mg $CaCO_3$/L water hardness and the second with an exposure range of 8 to 124 µg Pb/L (62 days) and a water hardness of 29 mg $CaCO_3$/L. In the 69-day test, the following chronic values were observed for survival: NOEC=24 µg Pb/L, maximum acceptable toxicant concentration=36 µg Pb/L, EC_{10}=26 µg Pb/L, EC_{20}=34 µg Pb/L, and LC_{50}=55 µg Pb/L. Results from the 62-day test, with fish length as the endpoint, were NOEC=8 µg Pb/L, MATC=12 µg Pb/L, EC_{10}=7µg Pb/L, EC_{20}=102 µg Pb/L and LC_{50}=120 µg Pb/L. In acute tests with rainbow trout run concurrently with the chronic tests, 96-hour LC_{50} values were 120 and 150 µg Pb/L, respectively. Data from this study resulted in ACR's for trout lower than previously reported. The low ACR values were due to the acute tests which produced LC_{50} values that were 10 to 25 times lower than earlier studies with trout (Mebane et al., 2008). The authors speculated that the lower LC_{50} values were due to the age of the fish used in the study (two to four week old fry) and that testing with larger and older fish may not be protective of more sensitive lifestages.

There have been only a few new exposure-response studies in amphibians since the 2006 Pb AQCD. Southern leopard frog tadpoles exposed to Pb in sediment (45 to 7,580 mg Pb/kg dry weight) with corresponding sediment pore water concentrations from 123 to 24,427 µg Pb/L from embryonic stage to metamorphosis exhibited concentration-dependent effects on survival (Sparling et al., 2006). The LC_{50} value for Pb in sediment was 3,738 mg Pb/kg, which corresponds to 12,539 µg Pb/L in sediment pore water. In the same study, concentration-dependent effects on skeletal development were observed. The 40 day-EC_{50} for deformed spinal columns in the tadpoles was 1,958 mg Pb/kg (corresponding to 6,734 µg Pb/L sediment pore water) and the 60 day-EC_{50} was 579 mg Pb/kg (corresponding to 1,968 µg Pb/L sediment pore water) (Sparling et al., 2006). A 96-hour LC_{50} of 96,100 µg Pb/L was determined for *X. laevis* embryos exposed to a range of Pb concentrations from 8,600 to 220,500 µg Pb/L using the Frog Embryo Teratogenesis Assay (Gungordu et al., 2010).

7.3.7 Freshwater Community and Ecosystem Effects

As discussed in the 1986 Pb AQCD and the 2006 Pb AQCD, exposure to Pb is likely to have impacts in aquatic environments via effects at several levels of ecological organization (organisms, populations, communities, or ecosystems). These effects resulting from toxicity of Pb would be evidenced by changes in species composition and richness, in ecosystem function, and in energy flow. The 2006 Pb AQCD concluded that, in general, there was insufficient information available for single materials in controlled

studies to permit evaluation of specific impacts on higher levels of organization (beyond the organism). Furthermore, Pb rarely occurs as a sole contaminant in natural systems making the effects of Pb difficult to ascertain. New information on effects of Pb at the population, community and ecosystem level is reviewed below.

In laboratory studies reviewed in the 2006 Pb AQCD and this ISA, Pb exposure has been demonstrated to alter predator-prey interactions, as well as feeding and avoidance behaviors. In aquatic ecosystems there are field studies reviewed in the 1977 Pb AQCD, the 1986 Pb AQCD, the 2006 Pb AQCD and this ISA on reductions of species abundance, richness or diversity particularly in benthic macroinvertebrate communities coexisting with other metals where the sources of Pb were from mining or urban effluents. Additionally, field studies have linked Pb contamination to reduced primary productivity and respiration, and to altered energy flow and nutrient cycling. However, because of the complexity inherent in defining such effects, there are relatively few available population, community, or ecosystem level studies that conclusively relate Pb exposure to aquatic ecosystem effects. In addition, most of the available work is related to point-source Pb contamination, with very few studies considering the effects of diffuse Pb pollution.

Microcosm evaluations of the effects of Pb on aquatic cyanobacteria communities indicated that exposure to 25 mM Pb reduced bacterial biomass and diversity. After one week of Pb exposure, total bacteria biomass was reduced from an average of 9.3 mg carbon/cm^3 sediment to 1.3 mg carbon/cm^3 (Burnat et al., 2009). Pb exposure impacted individual cyanobacteria species differently, with *Microcoleus* sp. experiencing a greater decrease in abundance than *Halomicronema*-like cyanobacteria.

Both plant species and habitat type were determined to be factors affecting the rate of Pb accumulation from contaminated sediments. While the rooted aquatic plant *E. canadensis* was observed to accumulate the highest concentrations of Pb, the authors concluded that submerged macrophytes (versus emergent plants) as a group were the most likely to accumulate Pb and other heavy metals (Kurilenko and Osmolovskaya, 2006). This would suggest that certain types of aquatic plants, such as rooted and submerged species, may be more susceptible to aerially-deposited Pb contamination, resulting in shifts in plant community composition as a result of Pb pollution.

Alteration of macrophyte community composition was demonstrated in the presence of elevated surface water Pb concentrations at three lake sites impacted by mining effluents (Mishra et al., 2008). A total of 11 species of macrophytes were collected. Two sites located 500 m and 1,500 m downstream from the mining point-source (study sites 2 and 3) exhibited similar dissolved Pb concentrations (78 to 92 µg Pb/L, depending on season) and contained six and eight unique macrophyte species, respectively. The site nearest the

discharge point of the mine effluent (study site 1) had the highest Pb concentrations (103 to 118 µg Pb/L) and the lowest number of resident macrophyte species; these included *E. crassipes*, *L. minor*, *Azolla pinnata* and *S. polyrrhiza*. Based on analysis of plant tissue Pb concentrations, the authors theorized that certain species may be more able to develop Pb tolerant eco-types that can survive at higher Pb concentrations (Mishra et al., 2008).

Exposure to three levels of sediment Pb contamination (322, 1,225, and 1,465 µg Pb/g dry weight) had variable effects on different species within an aquatic nematode community (Mahmoudi et al., 2007). Abundance, taxa richness, and species dominance indices were altered at all Pb exposures when compared with unexposed communities. Further, while the species *Oncholaimellus mediterraneus* dominated control communities (14% of total abundance), communities exposed to low and medium Pb concentrations were dominated by *Oncholaimus campylocercoides* (36%) and *Marylynnia stekhoveni* (32%), and *O. campylocercoides* (42%) and *Chromadorina metulata* (14%), respectively. Communities exposed to the highest Pb sediment concentrations were dominated by *Spirinia gerlachi* (41%) and *Hypodontolaimus colesi* (29%). Given this, the authors concluded that exposure to Pb significantly reduced nematode diversity and resulted in profound restructuring of the community structure.

In field studies available for certain freshwater habitats, exposure to Pb has been shown to result in significant alterations of invertebrate communities. Macroinvertebrate community structure in mine-influenced streams was determined to be significantly correlated to Pb sediment pore water concentrations. Multiple invertebrate community indices, including Ephemeroptera, Plecoptera, Trichoptera (EPT) taxa richness, Missouri biotic index, and Shannon-Wiener diversity index, were integrated into a macroinvertebrate biotic condition score (Poulton et al., 2010). These scores were determined to be significantly lower at sample sites downstream from mining sites where Pb pore water and bulk sediment concentrations were elevated. Sediment Pb, Cd, and Zn levels were inversely correlated to mussel taxa richness in the Spring River basin encompassing sites in Kansas, Missouri and Oklahoma overlapping a former Pb and Zn mining and processing area (Angelo et al., 2007). In sites upstream of the mining area, 21 to 25 species of mussels were present whereas in sites downstream, only 6 to 8 species were observed.

Rhea et al. (2006) examined the effects of multiple heavy metals in the Boulder River, MT, U.S., watershed biofilm on resident macroinvertebrate assemblages and community structure, and determined that, among all the metals, biofilm Pb concentrations exerted the greatest influence on the macroinvertebrate community indices. Pb biofilm concentrations were significantly correlated with reduced EPT taxa richness, reduced EPT abundance, and an increase in Diptera species abundance. Interestingly, Pb

concentrations in invertebrate tissues were correlated to an increase in Hydropsychidae caddisfly abundance, but this may have resulted from the intrinsically high variability in tissue Pb concentrations. The authors concluded that Pb-containing biofilm represented a significant dietary exposure for impacted macroinvertebrate species, thus altering invertebrate community metrics (Rhea et al., 2006).

Kominkova and Nabelkova (2005) examined ecological risks associated with metal contamination (including Pb) in small urban streams. Although surface water Pb concentrations in monitored streams were determined to be very low, concentrations of the metal in sediment were high enough to pose a risk to the benthic community (e.g., 34 to 101 mg Pb/kg). These risks were observed to be linked to benthic invertebrate functional feeding group, with collector-gatherer species exhibiting larger body burdens of heavy metals than other groups (Kominkova and Nabelkova, 2005). In contrast, benthic predators and collector-filterers accumulated significantly lower metals concentrations. Consequently, it is likely that sediment-bound Pb contamination would differentially affect members of the benthic invertebrate community, potentially altering ecosystems dynamics.

Invertebrate functional feeding group may also affect invertebrate Pb body burdens in those systems where Pb bioconcentration occurs. The predaceous zooplanktonic rotifer, *A. brightwellii* collected from a Pb-impacted freshwater reservoir in Mexico, contained 384 ng Pb/mg and exhibited a water-to-tissue BCF of 49,344. The authors theorized that Pb biomagnification may have been observed in this case because the cladoceran *M. micrura* is both a known Pb accumulator and a favorite prey item of the rotifer (Rubio-Franchini et al., 2008). They showed that *M. micrura* had twice the Pb body burden of *D. similis*, another grazing cladoceran species present in the reservoir. These two species exhibited average Pb tissue concentrations of 57 and 98 ng Pb/mg, respectively, with respective water column BCFs of 9,022 and 8,046. Conversely, an examination of the simultaneous uptake of dissolved Pb by the algae *P. subcapitata* and the cladoceran *D. magna* suggests that the dietary exposure route for the water column filter-feeder is minor. Although Pb accumulated in the algal food source, uptake directly from the water column was determined to be the primary route of exposure for *D. magna* (Komjarova and Blust, 2009c).

For many invertebrate species, sediment Pb concentrations may be the most important driver in determining Pb uptake. For instance, while Hg and Cd body burdens in lentic invertebrates were affected by lake ecological processes (e.g., eutrophication), a similar effect was not observed for Pb concentrations in crayfish tissue, despite a high variability between sites. Although this may be a result of differing bioaccumulation tendencies, the

authors suggested that other factors, including the potential for sediment exposures, may be responsible for Pb uptake in lentic invertebrates (Larsson et al., 2007).

A field survey of fishes in the Viburnum Trend Pb-Zn mining district in southeast Missouri available since the 2006 Pb AQCD found that species richness and species density of riffle-swelling benthic fishes were negatively correlated with metal concentrations in pore water and in fish in mining impacted streams (Allert et al., 2009b). Density of Ozark sculpin (*Cottus hypselurus*) and banded sculpin (*Cottus carolinae*) were positively correlated with distance from mining sources.

In addition to the ecological effects discussed above, there is additional evidence that Pb exposure could alter bacterial infection (and potentially disease transmission) in certain fish species. Following 96-hour exposures to 4,000 µg Pb/L, bacterial density in *Channa punctatus* fish was observed to be significantly altered when compared to non-exposed fish. Bacteria population densities in fish spleen, gills, liver, kidneys and muscle tissues were higher following Pb exposure, with bacterial abundance in the gills too numerous to quantify (Pathak and Gopal, 2009). In addition, bacteria inhabiting Pb-exposed fish were more likely to exhibit antibacterial resistance than colonies isolated from non-exposed fish. Although the mechanism remains unknown, this study suggests that Pb exposure may increase the likelihood of infection in fish, potentially affecting fish abundance and recruitment.

In summary, despite the fact that alterations of macrophyte communities may be highly visible effects of increased sediment Pb concentrations, several recently published papers propose that ecological impacts on invertebrate communities are also significant, and can occur at environmental Pb concentrations lower than those required to impact plant communities. High sediment Pb concentrations were linked to shifts in amphipod communities inhabiting plant structures, and potentially to alterations in ecosystem nutrient processing through selective pressures on certain invertebrate functional feeding groups (e.g., greater bioaccumulation and toxic effects in collector-gatherers versus predators or filter-feeders). Increased sediment pore water Pb concentrations were demonstrated to likely be of greater importance to invertebrate communities, as well. Interestingly, recent research also suggests that Pb exposure can alter bacterial infestations in fish, increasing both microbial density and resilience, and potentially increasing the likelihood of serious disease outbreak.

7.3.8 Critical Loads in Freshwater Aquatic Systems

The general concept and definition of critical loads is introduced in Section 7.1.3 of this chapter [also see Section 7.3 of the 2006 Pb AQCD (U.S. EPA, 2006c)]. Critical load

values are linked to critical limits of Pb for endpoints/receptors of interest in the ecosystems, such as blood Pb. Some important critical limits for lead in aquatic ecosystems are discussed in this section along with information on aquatic critical loads for Pb.

Unit World Models (UWM) have been used to calculate critical loads for metals in aquatic ecosystems. These models couple an ecotoxicity model, the BLM, to a speciation/complexation model, the Windermere Humic Adsorption Model (WHAM), then to the multi-species fate model, TRANsport-SPECiation (TRANSPEC). Gandhi et al. (In Press) apply the UWM to estimate speciation/complexation, fate and critical loads using lakes of three different trophic status. A high percentage of colloidal-bound Pb was found in the eutrophic and mesotrophic lakes (75-80%) vs. the oligotrophic lakes (2%), owing the high affinity of Pb to DOM. Pb concentrations were lowest for mesotrophic and highest for oligotrophic systems. Critical loads were not calculated for Pb; however, for the other metals tested the critical load was lowest in the oligotrophic and highest in the eutrophic systems.

A critical load of 39.0 g $Pb/m^2 \cdot yr$ was calculated for a generalized lake in the Sudbury area of the Canadian Shield using TICKET-UWM based on acute toxicity data for *D. magna*. (Farley et al., 2011). The model was set up to calculate critical loads of metals by specifying free metal ion activity or the critical biotic ligand concentration. This critical load for Pb was an order of magnitude higher than for Cu, Ni and Zn and the authors attribute this difference to the strong binding of Pb to particulate organic matter and the sequestration of $PbCO_3$ in sediment. Refer to Section 7.3.6 of the 2006 Pb AQCD for additional discussion of critical loads of Pb in aquatic systems.

7.3.9 Characterization of Sensitivity and Vulnerability in Freshwater Systems

Data from the literature indicate that exposure to Pb may affect survival, reproduction, growth, metabolism, and development in a wide range of freshwater aquatic species. Often, species differences in metabolism, sequestration, and elimination rates control relative sensitivity and vulnerability of exposed organisms. Diet and lifestage at the time of exposure also contribute significantly to the determination of sensitive and vulnerable populations and communities. Further, environmental conditions in addition to those discussed as affecting bioavailability (Sections 7.3.3 and 7.3.4) may also alter Pb toxicity. The 2006 Pb AQCD reviewed the effects of genetics, age, and body size on Pb toxicity. While genetics appears to be a significant determinant of Pb sensitivity, effects of age and body size are complicated by environmental factors that alter metabolic rates of

aquatic organisms. A review of the more recent literature corroborated these findings, and identified seasonally-affected physiological changes and lifestage as other important determinants of differential sensitivity to Pb.

7.3.9.1 Seasonally-Affected Physiological Changes

A study by Duman et al. (2006) identified species and seasonal effects of Pb uptake in aquatic plants. *P. australis* accumulated higher root Pb concentrations than *S. lacustris*. Additionally, the *P. australis* Pb accumulation factor was significantly higher during the winter versus other seasons, while the Pb accumulation factor for *S. lacustris* was greatest in spring and autumn. The Pb accumulation factor for a third species, *P. lucens*, was greatest in autumn (Duman et al., 2006). Most significantly, these changes in bioaccumulation were not linked with biomass increases, indicating that species-dependent seasonal physiological changes may control Pb uptake in aquatic macrophytes (Duman et al., 2007). Significant interspecies differences in Pb uptake were observed for plants representing the same genus (Sargassum), indicating that uptake of Pb by aquatic plants also may be governed by highly species-dependent factors (Jothinayagi and Anbazhagan, 2009).

Heier et al. (2009) established the speciation of Pb in water draining from a shooting range in Norway and looked at the time dependent accumulation in brown trout. They found that high molecular weight (>10 kDaltons) cationic Pb species correlated with high flow episodes and accumulation of Pb on gills and in the liver. Thus, high flow episodes can remobilize metals from a catchment and induce stress to aquatic organisms.

7.3.9.2 Increased Nutrient Uptake

Singh et al. (2010) proposed that metal-resistant plants have the capacity to not only up-regulate antioxidant synthesis, but also have the ability to increase nutrient consumption and uptake to support metal sequestration and detoxification via production of antioxidants (Singh et al., 2010). Therefore, it is likely that such plant species would be significantly less susceptible to Pb exposure than those species without those abilities.

7.3.9.3 Temperature and pH

Water temperature also appears to affect the toxicity of Pb to aquatic organisms, with higher temperatures leading to greater responses. Pb toxicity to crayfish increased 7 to

10% when the water temperature was increased by 4 °C, and by 14% when the temperature increased by 7 °C. The authors determined that the increased toxicity was a result of the negative impact of Pb on crayfish respiration, which was exacerbated by the lower dissolved oxygen concentrations at higher water temperatures (Khan et al., 2006). In a study of the combined effects of temperature and Pb concentration on two freshwater rotifer species, *Brachionus havanaensis* and *B. rubens*, population growth was measured in three concentrations of Pb (50, 100 and 200 µg Pb/L) for 15 days at either 22^0C or 32^0C (Montufar-Melendez et al., 2007). At 22^0C, population growth of *B. havanaensis* was suppressed by *B. rubens* regardless of Pb treatment. At the higher temperature, there was no population increase of *B. rubens* at any Pb concentration. In the controls, population growth rates of *B. havanaensis, but not B. rubens, increased with an increase in temperature. These studies highlight the role of temperature in Pb toxicity in organisms adapted to low temperatures.*

The sequestration ability of *L. minor* macrophytes was similarly impacted by increased surface water temperature; plants absorbed a maximum Pb concentration of 8.6 mg /g at 30 °C, while uptake at 15 °C was only 0.3 mg/g (Uysal and Taner, 2009). Decreased pH was also demonstrated to increase the uptake of environmental Pb in aquatic plants (Wang et al., 2010a; Uysal and Taner, 2009). Additionally, Birceanu et al. (2008) determined that fish (specifically rainbow trout) were more susceptible to Pb toxicity in acidic, soft waters characteristic of sensitive regions in Canada and Scandinavia. Hence, fish species endemic to such systems may be more at risk from Pb contamination than fish species in other habitats.

7.3.9.4 Lifestage

It is clear that certain stages of a life cycle are more vulnerable to Pb. A comparison of *C. riparius* Pb LC_{50} values derived from toxicity tests with different instars indicates a significant effect of lifestage on Pb sensitivity for aquatic invertebrates. Bechard et al. (2008) calculated a first instar *C. riparius* 24-hour LC_{50} value of 613 µg Pb/L, and contrasted this value with the 24-hour and 48-hour LC_{50} values derived using later instar larvae—350,000 and 200,000 µg Pb/L, respectively. This disparity would suggest that seasonal co-occurrence of aquatic Pb contamination and sensitive early instars could have significant population-level impacts (Bechard et al., 2008). Similarly, Wang et al. (2010e) demonstrated that the newly transformed juvenile mussels, *L. siliquoidea* and *L. rafinesqueana*, at 5 days old were more sensitive to Pb exposure than were glochidia or two to six month- old juveniles, suggesting that Pb exposure at particularly sensitive lifestages could have a significant influence on population viability (Wang et al., 2010e).

Evidence for differences in susceptibility to Pb at distinct lifestages is also available for freshwater fish. In chronic (60-day) early-lifestage test exposures conducted with rainbow trout to develop ACR's for this species the study resulted in ACR's for rainbow trout lower than previously reported due to the acute tests which produced LC_{50} values that were 10 to 25 times lower than earlier studies with trout. (Mebane et al., 2008). The authors speculated that the lower LC_{50} values were due to the age of the fish used in the study (two to four week old fry) and that testing with larger and older fish may not be protective of more sensitive lifestages. Post-hatching stages of the African catfish were more sensitive than the embryonic stage to Pb-exposure and the authors attributed this apparent protective effect to the presence of a hardened chorion in embryos (Osman et al., 2007a).

7.3.9.5 Species Sensitivity

Species-specific Ca requirements have been shown to affect the vulnerability of aquatic organisms to Pb. The snail, *L. stagnalis*, exhibits an unusually high Ca demand due to $CaCO_3$ formation required for shell production and growth, and exposure to Pb prevents the uptake of needed Ca, leading to toxicity. Consequently, aquatic species that require high assimilation rates of environmental Ca for homeostasis are likely to be more sensitive to Pb contamination (Grosell and Brix, 2009). Grosell and colleagues also noted that reduced snail growth following chronic Pb exposure was likely a result of reduced Ca uptake (Grosell et al., 2006a).

There is some indication that molting may comprise an additional sequestration and excretion pathway for aquatic animals exposed to Pb (Soto-Jiménez et al., 2011b; Mohapatra et al., 2009; Tollett et al., 2009; Bergey and Weis, 2007). Libellulidae dragonfly nymphs (Tollett et al., 2009) have been shown to preferentially sequester Pb in exoskeleton tissue. Consequently, aquatic arthropod species and those species that shed their exoskeleton more frequently may be able to tolerate higher environmental Pb concentrations than non-arthropods or slow-growing molting species, as this pathway allows them to effectively lower Pb body burdens.

In contrast, the effect of Pb exposure on fish bacterial loads demonstrated by Pathak and Gopal (2009) suggest that infected fish populations may be more at risk to the toxic effects of Pb than healthier species. Aqueous Pb was demonstrated to both increase bacteria density in several fish organs and to improve the likelihood of antibacterial resistance (Pathak and Gopal, 2009).

Tolerance to prolonged Pb exposure may develop in aquatic invertebrates and fish. Multi-generational exposure Pb appears to confer some degree of metal tolerance in

invertebrates such as *C. plumosus* larvae; consequently, previous population Pb exposures may decrease species' susceptibility to Pb contamination (Vedamanikam and Shazilli, 2008b). However, the authors noted that metal tolerant larvae were significantly smaller than larvae reared under clean conditions, and that transference of Pb-tolerant *C. plumosus* larvae to clean systems resulted in a subsequent loss of tolerance. Evidence of acclimation to elevated Pb in fathead minnow was suggested in the variations in ionoregulatory parameters that were measured on day 10 and 30 in fish exposed to 115 µg Pb/L for 30 days. At the end of the experiment, whole body Ca^{2+} was elevated while Na^{+} and K^{+} recovered from elevated levels at 30 days (Grosell et al., 2006b).

A series of species sensitivity distributions constructed by Brix et al. (2005) in freshwater systems indicated that sensitivity to Pb was greatest in crustacean species, followed by coldwater fish, and warmwater fish and aquatic insects, which exhibited a similar sensitivity. Further, analysis of both acute and chronic mesocosm data sets indicated that Pb-contaminated systems exhibited diminished species diversity and taxa richness following both types of exposure (Brix et al., 2005). Wong et al. (2009) constructed Pb species sensitivity distributions for both cladoceran and copepod freshwater species. A comparison of the two curves indicated that cladoceran species, as a group, were more sensitive to the toxic effects of Pb than were copepods, with respective hazardous concentration values for 5% of the species (HC5) values of 35 and 77 µg Pb/L. This difference in sensitivities would indicate that cladoceran species are more likely to be impacted at lower environmental Pb concentrations than copepods, potentially altering community structures or ecosystem functions (Wong et al., 2009).

7.3.9.6 Ecosystem Vulnerability

Relative vulnerability of different aquatic ecosystems to effects of Pb can be inferred from the information discussed above on species sensitivity and the influence of water quality variables on the bioavailability and toxicity of Pb. It is, however, difficult to categorically state that certain plant, invertebrate or vertebrate communities are more vulnerable to Pb than others, since toxicity is dependent on many variables and data from field studies are complicated by co-occurrence of other metals and alterations of pH, such as in mining areas. Aquatic ecosystems with low pH and low DOM are likely to be the most sensitive to the effects of atmospherically-deposited Pb. Examples of such systems are acidic, soft waters such as sensitive regions in Canada and Scandinavia (Birceanu et al., 2008). In the U.S., aquatic systems that may be more sensitive to effects of Pb include habitats that are acidified due to atmospheric deposition of pollutants, runoff from mining activities or lakes and streams with naturally occurring organic acids. Hence, fish and

invertebrate species endemic to such systems may be more at risk from Pb contamination than corresponding species in other habitats.

7.3.10 Introduction to Bioavailability and Biological Effects of Pb in Saltwater Ecosystems

Saltwater ecosystems include salt marsh, estuaries, beaches and other coastal areas that may receive Pb contributions from direct atmospheric deposition and/or via runoff from terrestrial systems. A range of 0.005-0.4 µg Pb/L for saltwater was reported in by Leland and Kuwabara (1985) and 0.01 to 27 µg Pb/L by Sadiq (1992) with the higher values associated with sites involving human activity. Levels of Pb in the North Atlantic and North Pacific surface waters ranged from 0.005 to 0.05 µg Pb/L but the range of values in coastal waters and estuaries were approximately equal to the range of Pb in freshwater. Additional information on Pb levels in water is available in Section 3.6. The 2006 Pb AQCD provided an overview of regulatory considerations for water and sediments in addition to consideration of biological effects and major environmental factors that modify the response of marine organisms to Pb exposure. Regulatory guidelines for Pb in saltwater have not changed since the 2006 Pb AQCD and are summarized below. This section is followed by new information on bioavailability and biological effects of Pb in saltwater since the 2006 Pb AQCD.

The most recent ambient water quality criteria (AWQC) for Pb in saltwater were released in 1985 (U.S. EPA, 1985) by the EPA Office of Water which employed empirical regressions between observed toxicity and water hardness to develop hardness-dependent equations for acute and chronic criteria. These criteria are published pursuant to Section 304(a) of the Clean Water Act and provide guidance to states and tribes to use in adopting water quality standards for the protection of aquatic life and human health in surface water. The ambient water quality criteria for Pb are currently expressed as a criteria maximum concentration (CMC) for acute toxicity and criterion continuous concentration (CCC) for chronic toxicity (U.S. EPA, 2010b). In saltwater, the CMC is 210 µg Pb/L and the CCC is 8.1 µg Pb/L. The 2006 Pb AQCD summarized two approaches for establishing sediment criteria for Pb based on either bulk sediment or equilibrium partitioning as reviewed in this ISA in Section 7.3.2.

In the following sections, new information available since the 2006 Pb AQCD on Pb in marine and estuarine ecosystems will be presented. Throughout the sections, brief summaries of conclusions from the 1977 Pb AQCD, the 1986 Pb AQCD and the 2006 Pb AQCD are included where appropriate. The sections are organized to consider uptake of

Pb and effects at the species level, followed by community and ecosystem level effects. New research on the bioavailability and uptake of Pb into saltwater organisms including plants, invertebrates and vertebrates is presented in Section 7.3.11. Effects of Pb on the physiology of marine fauna and biota (Section 7.3.12) are followed with data on exposure and response of saltwater organisms (Section 7.3.13). Responses at the ecosystem level of biological organization are reviewed in Section 7.3.14 followed by characterization of sensitivity and vulnerability of ecosystem components (Section 7.3.15).

7.3.11 Bioavailability of Pb in Saltwater Systems

Bioavailability was defined in the 2006 Pb AQCD as "the proportion of a toxin that passes a physiological membrane (the plasma membrane in plants or the gut wall in animals) and reaches a target receptor (cytosol or blood)". In 2007, EPA took cases of bioactive adsorption into consideration and revised the definition of bioavailability as "the extent to which bioaccessible metals absorb onto, or into, and across biological membranes of organisms, expressed as a fraction of the total amount of metal the organism is proximately exposed to (at the sorption surface) during a given time and under defined conditions" (Fairbrother et al., 2007).

Factors affecting bioavailability of Pb to marine organisms are the same as those in freshwater systems. However, although routes of exposure and physiological mechanisms for storage and excretion influence uptake of metals by all organisms, they may be different in marine organisms, particularly for ion transport mechanisms (Niyogi and Wood, 2004). Marine environments are characterized by higher levels of ions, such as Na^{+}, Ca^{2+}, and Mg^{2+}, which compete for potential binding sites on biotic ligands such as gills, thereby generally reducing the effective toxicity of metal ions as compared to freshwater environments. However, because the concentrations of these ions are relatively constant, bioavailability may be more predictable in marine systems than in freshwater systems, varying mostly with amount and type of dissolved organic matter. BLMs (Figure 7-2) now being developed for marine organisms are functionally similar to those applied to freshwater organisms (Section 7.3.4).

Although in freshwater systems the presence of humic acid is considered to reduce the bioavailable fraction of metals in freshwater, there is evidence that DOC/DOM does not have the same effect on free Pb ion concentration in marine systems (see Section 7.3.2.4 for detailed discussion). For the sea urchin *P. lividus*, the presence of humic acid increased both the uptake and toxicity of Pb possibly by enhancing uptake of Pb via membrane Ca^{2+} channels (Sanchez-Marin et al., 2010a). This also was observed in the marine diatom *Thalassiosira weissflogii*, where humic acids absorbed to cell surfaces

increased metal uptake (Sanchez-Marin et al., 2010a). Formation of a ternary complex that is better absorbed by biological membranes was another proposed mechanism that could describe the increased bioavailability to marine invertebrates of Pb bound to humic acid (Sánchez-Marín et al., 2007).

Sanchez-Marin et al. (2011) subsequently have shown that different components of DOM have different effects on Pb bioavailability in marine systems. Their initial research using commercially-derived humic acid found that increasing humic acid concentrations increased Pb uptake by mussel gills and increased toxicity to sea urchin larvae in marine environments (Sánchez-Marín et al., 2007). In contrast, a subsequent investigation found that fulvic acid reduced Pb bioavailability in marine water (Sánchez-Marín et al., 2011). The contradictory effects of different components of DOM on marine bioavailability likely reflect their distinct physico-chemical characteristics. More hydrophobic than fulvic acid, humic acid may adsorb directly with cell membranes and enhance Pb uptake through some (still unidentified) mechanism (Sánchez-Marín et al., 2011). Pb AVS-measurements were also determined to accurately predict uptake by mussels (*Mytilus* sp.) in the presence of 2.5 to 20 mg/L fulvic acid (Sánchez-Marín et al., 2011). However, the effects of DOM on Pb bioavailability to mussels were underpredicted by AVS lead concentration measurements, potentially as a result of adsorption of DOM-Pb complexes.

Based on the above, BLMs used to predict bioavailability of Pb to aquatic organisms (Di Toro et al., 2005), may require modifications for application to marine organisms. Of particular importance is the finding that in marine aquatic systems, surface water DOM was found to increase (rather than decrease) uptake of Pb by fish gill structures, potentially through the alteration of membrane Ca channel permeability. Veltman et al. (2010) proposed an integrating BLM and bioaccumulation models in order to more accurately predict metal uptake by fish and invertebrates, and calculated metal absorption efficiencies for marine fish species from both types of models. They noted that affinity constants for Ca, Cd, Cu, Na, and Zn were highly similar across different aquatic species, including fish and invertebrates (Veltman et al., 2010). These findings suggest that the BLM can be integrated with bioaccumulation kinetics to account for both environmental chemical speciation and biological and physiological factors in both marine and freshwater systems.

7.3.11.1 Saltwater Plants and Algae

In the 1977 Pb AQCD, the cordgrass *Spartina alterniflora* was found to reduce by a small amount the quantity of Pb in sediments (U.S. EPA, 1977). Limited data on marine algal species reviewed in the 1986 Pb AQCD and 2006 Pb AQCD provided additional

evidence for Pb uptake. New data available since the 2006 Pb AQCD includes Pb bioaccumulation studies conducted with five species of marine algae, (*Tetraselmis chuii*, *Rhodomonas salina*, *Chaetoceros* sp., *Isochrysis galbana* and *Nannochloropsis gaditana*). In this study it was demonstrated that bioaccumulation rates varied with species. *I. galbana* accumulated the lowest concentrations of Pb (0.01 and 0.6 pg Pb/cell at water concentrations of 51 and 6,348 µg Pb/L), while *Chaetoceros* sp. was observed to be the most efficient Pb bioaccumulator, adsorbing 0.04 and 54 pg Pb/cell at 1.4 and 6,348 µg Pb/L (Debelius et al., 2009).

New uptake studies of Pb in plants associated with marine environments are also available. The roots of two salt marsh species, *Sarcocornia fruticosa* and *Spartina maritima*, significantly accumulated Pb, to maximum concentrations of 2,870 mg Pb/kg and 1,755 mg Pb/kg, respectively (Caetano et al., 2007). Roots had similar isotopic signature to those of sediments in vegetated zones indicating that Pb uptake by plants reflects the input in sediments. BCFs for Pb in root tissue from mangrove tree species range between 0.09 and 2.9, depending on the species and the habitat, with an average BCF of 0.84. The average BCF for mangrove species leaf tissue was considerably less (0.11), as these species are poor translocators of Pb (MacFarlane et al., 2007).

7.3.11.2 Saltwater Invertebrates

Uptake and subsequent bioaccumulation of Pb in marine invertebrates varies greatly between species and across taxa as previously characterized in the 2006 Pb AQCD. This section expands on the findings from the 2006 Pb AQCD on bioaccumulation and sequestration of Pb in saltwater invertebrates. In the case of invertebrates, Pb can be bioaccumulated from multiple sources, including the water column, sediment, and dietary exposures, and factors such as proportion of bioavailable Pb, lifestage, age, and metabolism can alter the accumulation rate. In this section, new information on Pb uptake and subsequent tissue and subcellular distribution will be considered, followed by a discussion on dietary and water routes of exposure and strategies for detoxification of Pb in marine invertebrates.

The gills were the main sites of Pb accumulation in pearl oyster, *Pinctada fucata* followed by mantle, in 72-hour exposures to 103.5 µg Pb/L (Jing et al., 2007). Following a 10 day exposure to 2,500 µg Pb/L as Pb nitrate, accumulation of Pb was higher in gill than digestive gland of *Mytilus edulis*: after a 10 day depuration, Pb content was decreased in the gills and digestive gland of these mussels (Einsporn et al., 2009). In blue crabs, *Callinectes sapidus*, collected from a contaminated and a clean estuary in New

Jersey, U.S., the hepatopancreas was found to be the primary organ for Pb uptake (Reichmuth et al., 2010).

There is more information now on the cellular and subcellular distribution of Pb in invertebrates than there was at the time of writing the 2006 Pb AQCD. Specifically, localization of Pb at the ultrastructural level has been assessed in the marine mussel (*M. edulis*) through an antibody-based detection method (Einsporn et al., 2009; Einsporn and Koehler, 2008). Dissolved Pb was detected mainly within specific lysosomal structures in gill epithelial cells and digestive gland cells and was also localized in nuclei and mitochondria. Transport of Pb is thought to be via lysosomal granules associated with hemocytes (Einsporn et al., 2009). In the digestive gland of the variegated scallop *(Chlamys varia*), Pb was also mainly bound to organelles, (66% of the total metal burden) (Bustamante and Miramand, 2005). In the digestive gland of the cephalopod *Sephia officinalis*, (cuttlefish) most of the Pb was found in the organelles (62%) (Bustamante et al., 2006). In contrast, only 7% of Pb in the digestive gland of the octopus (*Octopus vulgaris*) was associated with the fraction containing nuclei, mitochondria, lysosome and microsomes: the majority of Pb in this species was found in cytosolic proteins (Raimundo et al., 2008).

Metian et al. (2009) investigated the uptake and bioaccumulation of ^{210}Pb in variegated scallop and king scallop to determine the major accumulation route (seawater or food) and then assess subsequent tissue distribution. Dietary Pb from phytoplankton in the diet was poorly assimilated (<20%) while more than 70% of Pb in seawater was retained in the tissues. In seawater, ^{210}Pb was accumulated more rapidly in variegated scallop than king scallop and soft tissue distribution patterns differed between the species. Variegated scallop accumulated Pb preferentially in the digestive gland (50%) while in king scallop, Pb was equally distributed in the digestive gland, kidneys, gills, gonad, mantle, intestine, and adductor muscle with each tissue representing 12-30% of ^{210}Pb body load. An additional test with Pb-spiked sediment in *king scallop* showed low bioaccumulation efficiency of Pb from spiked sediment.

Recently, several studies have attempted to establish biodynamic exposure assessments for various contaminants. In an in situ metal kinetics field study with the mussel *M. galloprovincialis*, simultaneous measurements of metal concentrations in water and suspended particles with mussel biometrics and physiological indices were conducted to establish uptake and excretion rates in the natural environment (Casas et al., 2008). The mean logarithmic ratio of metal concentration in mussels (ng/kg of wet-flesh weight) to metal concentration in water (ng/L) was found to be 4.3 in *M. galloprovincialis*, based on the rate constants of uptake and efflux in a series of transplantation experiments between

contaminated and clean environments. Equilibrium concentrations of Pb in mussels leveled out at approximately 30 days with a concentration of 6.7 mg Pb/kg.

The protective barrier against Pb toxicity formed by the egg structure in some invertebrates was recognized in the 2006 Pb AQCD. Consideration of toxicity of Pb to embryos that develop surrounded by a protective egg shell has been expanded since the 2006 Pb AQCD. In a study with cuttlefish (*S. officinalis*) eggs, radioisotopes were used to assess the permeability of the egg to Pb at low exposure concentrations (^{210}Pb activity concentration corresponding to 512 µg/L Pb) (Lacoue-Labarthe et al., 2009). Retention and diffusion properties of the cuttlefish egg change throughout the development of the embryo and since the eggs are fixed on substrata in shallow coastal waters they may be subject to both acute and chronic Pb exposures. In the radiotracer experiments, ^{210}Pb was never detected in the internal compartments of the egg during the embryonic development stage, while concentrations in the eggshell increased throughout the 48 day exposure. These results are consistent with a study of cuttlefish eggs collected from natural environments in which Pb was only detected in the eggshell. These studies indicate that the cuttlefish egg provides a protective barrier from Pb toxicity (Miramand et al., 2006).

Aquatic invertebrate strategies for detoxifying Pb were reviewed in the 2006 Pb AQCD and include sequestration of Pb in lysosomal-vacuolar systems, excretion of Pb by some organisms, and deposition of Pb to molted exoskeleton. Molting of the exoskeleton can result in depuration of Pb from the body (see Knowlton et al. (1983) and Anderson et al. (1997), as cited in the 2006 Pb AQCD). New research has provided further evidence of depuration of Pb via molting in invertebrates. Mohapatra et al. (2009) observed that Pb concentrations in body tissues were lower in the newly molted mud crabs (*Scylla serrata*) than in the pre-molt, hard-shelled crabs. However, the carapace of hard shelled crabs had lower concentrations of Pb than the exuvium of the soft shell crabs, leading the authors to speculate that some of the metal might be partially excreted during the molting process, rather than entirely through shedding of the previous exoskeleton. Bergey and Weis (2007) showed that differences in the proportion of Pb stored in exoskeleton and soft tissues changed during intermolt and immediate postmolt in two populations of fiddler crabs (*Uca pugnax*) collected from New Jersey. One population from a relatively clean estuary eliminated an average of 56% of Pb total body burden during molting while individuals from a site contaminated by metals eliminated an average of 76% of total Pb body burden via this route. Pb distribution within the body of crabs from the clean site shifted from exoskeleton to soft tissues prior to molting. The authors observed the opposite pattern of Pb distribution in fiddlers from the contaminated site where larger amounts of Pb were depurated in the exoskeleton. The exact dynamics of Pb depuration through molting in crabs are thus still not completely characterized.

7.3.11.3 Saltwater Vertebrates

Saltwater Fish

In comparison to freshwater fish, fewer studies have been conducted on Pb uptake in marine fish. Since marine fish drink seawater to maintain osmotic homeostasis, Pb can be taken up via both gills and intestine (Wang and Rainbow, 2008). Pb was significantly accumulated in gill, liver, plasma, kidney, rectal gland, intestine, skin, and muscle of the elasmobranch spotted dogfish (*Scyliorhinus canicula*) exposed to 2,072 µg Pb/L for one week (De Boeck et al., 2010). In contrast to Pb distribution patterns in freshwater teleosts, high Pb concentrations were present in this species in the skin and rectal gland. Egg cases of the spotted dogfish exposed to ^{210}Pb in seawater for 21 days, accumulated radiolabeled Pb rapidly and the metal was subsequently detected in embryos indicating the permeability of shark eggs to Pb in coastal environments (Jeffree et al., 2008). A study of Pb bioaccumulation in five marine fish species (*Chloroscombrus chrysurus*, *Sardinella aurita*, *Ilisha africana*, *Galeoides decadactylus*, *Caranx latus*) found that *C. chrysurus* was an especially strong bioaccumulator, yielding Pb concentrations of 6 to 10 mg Pb/kg (Gnandi et al., 2006). However, C. *chrysurus* metal content was not correlated to the Pb concentrations along the mine tailings gradient from which they were collected (8.5 and 9.0 µg Pb/L for minimum and maximum tissue concentrations, respectively). This lack of correlation was also observed for fish species that were considered to be weaker Pb bioaccumulators, indicating that unidentified sources of Pb (e.g., in sediments or in dietary sources) may be contributing to Pb uptake by marine fish.

In grunt fish *H. scudderi*, exposed to Pb via dietary uptake through a simulated marine food chain, mean total Pb body burden increased from 0.55 to 3.32 µg Pb/g in a 42-day feeding study (Soto-Jiménez et al., 2011a). Pb was accumulated to the highest relative concentration in liver with less than 3% of total Pb accumulated in gills. Most of the Pb based on total body mass was accumulated in skeleton, skin, scales and muscle.

The 2006 Pb AQCD considered detoxification mechanisms in fish including mucus production and Pb removal by shedding of scales in which Pb is chelated with keratin. Since the 2006 review, additional Pb detoxification mechanisms in marine fish have been further elucidated. Mummichog (*Fundulus heteroclitus*) populations in metal-polluted salt marshes in New York exhibited different patterns of intracellular partitioning of Pb although body burden between sites was not significantly different (Goto and Wallace, 2010). Mummichogs at more polluted sites stored a higher amount of Pb in metal rich granules as compared to other detoxifying cellular components such as heat-stable proteins, heat-denaturable proteins and organelles.

Marine Mammals

Studies that consider uptake of Pb in aquatic mammals are limited. Kannan et al. (2006) compared trace element concentrations in livers of free-ranging sea otters (*Enhydra lutris nereis*) found dead along the California coast. They detected Pb in all individuals sampled (N=80) in a range of 0.019 to 1.06 µg Pb/g. The otters were classified by cause of death (infectious causes, non-infectious causes, emaciated condition) and trace element patterns of tissue distribution were compared. Livers from emaciated otters had significantly elevated levels of Pb compared to non-diseased individuals.

7.3.11.4 Marine Food Web

As discussed in Section 7.3.4.4 trophic transfer of Pb through aquatic food chains was considered to be negligible in the 2006 Pb AQCD (U.S. EPA, 2006c). Measured concentrations of Pb in the tissues of aquatic organisms were found to be generally higher in algae and benthic organisms and lower in higher trophic-level consumers, indicating that Pb was bioaccumulated but not biomagnified (U.S. EPA, 2006c; Eisler, 2000). New literature since the 2006 Pb AQCD provides evidence of the potential for Pb to be transferred in marine food webs while other studies indicate Pb is decreased with increasing trophic level. This section incorporates recent literature on transfer of Pb through aquatic marine chains.

In a dietary study using environmentally realistic concentrations of Pb in prey through four levels of a simplified marine food chain, biological responses including decreased growth and survival and changes in behavior were observed at different trophic levels. However, the concentration of Pb did not increase along the trophic gradient (Soto-Jiménez et al., 2011a; Soto-Jiménez et al., 2011b). The base of the simulated food chain was the microalgae *Tetraselmis suecica* (phytoplankton) grown in 20 µg Pb/L. Pb-exposed cultures of *T. suecica* had significantly less cell divisions per day (growth), biomass and total cell concentrations than control microalgae at 72 hours of exposure. The microalgal cultures were then fed to *Artemia franciscana* (crustacean, brine shrimp) which were then fed to *Litopenaeus vannamei* (crustacean white shrimp) and finally to *Haemulon scudderi* (fish, grunt). Effects on behavior, growth and survival were observed in shrimp and in grunt fish occupying the intermediate and top levels of the simulated marine food chain. The authors speculate that the species used in the simulated food chain were able to regulate and eliminate Pb (Soto-Jiménez et al., 2011a).

Partial evidence for biomagnification was observed in a subtropical lagoon in Mexico with increases of Pb concentration occurring in 14 of the 31 (45.2%) of trophic interactions considered (Ruelas-Inzunza and Páez-Osuna, 2008). The highest rate of

transference of Pb as measured in muscle tissue occurred between the prey species white shrimp (*Litopenaeus vannimei*) and mullet (*Mugil cephalus*) to pelican (*Pelecanus occidentalis*).

Other studies have traced Pb in aquatic food webs and have found no evidence of biomagnification of Pb with increasing trophic level. In the southeastern Gulf of California, Mexico, Pb was not positively transferred (biomagnification factor <1) through primary producers (seston, detritus) and 14 consumer species in a lagoon food web (Jara-Marini et al., 2009). In a planktonic food web in Bahia Blanca estuary, Argentina, Pb levels in macrozooplankton and mesozooplankton exhibited temporal fluctuations, however no biomagnification was observed between mesozooplankton and macrozooplankton (Fernández Severini et al., 2011). It is important to note, however, that even in the absence of biomagnification, aquatic organisms can bioaccumulate relatively large amounts of metals and become a significant source of dietary metal to their predators (Fairbrother et al., 2007; Reinfelder et al., 1998).

7.3.12 Biological Effects of Pb in Saltwater Systems

This section focuses on the studies of biological effects of Pb on marine and estuarine algae, plants, invertebrates, fish and mammals published since the 2006 Pb AQCD. Key studies from the 1977 Pb AQCD, the 1986 Pb AQCD and the 2006 Pb AQCD on biological effects of Pb are summarized where appropriate. Biological effects of Pb on saltwater algae and plant species are considered below, followed by information on effects on marine invertebrates and vertebrates. In general, Pb toxicity to saltwater organisms is less well characterized than toxicity of Pb in freshwater ecosystems due to the fewer number of available studies on marine species. Because this review is focused on effects of Pb, studies reviewed for this section include only those for which Pb was the only, or primary, metal to which the organism was exposed.

7.3.12.1 Saltwater Algae and Plants

New evidence in this ISA on toxicity of Pb to marine algae indicates that species exhibit varying sensitivities to Pb in saltwater. Pb tested at concentrations up to 10 µmol/L did not affect photosynthetic activity in seven species of marine macroalgae (*Ascophyllum nodosum, Fucus vesiculosus, Ulva intestinalis, Cladophora rupestris, Chondrus crispus, Palmaria palmate, Polysiphonia lanosa*) as measured by pulse amplitude modulation chlorophyll fluorescence yield although Pb was readily accumulated by these species (Baumann et al., 2009). The lowest 72-hour EC_{50} for growth inhibition reported for

marine algae was 105 µg Pb/L in *Chaetoceros* sp (Debelius et al., 2009). In a recent review of the production of phytochelatins and glutathione by marine phytoplankton in response to metal stress, Kawakami et al. (2006) included several studies in which Pb exposure was shown to induce glutathione and phytochelatin at high concentrations in a few species.

7.3.12.2 Saltwater Invertebrates

No studies with marine invertebrates were reviewed in the 1977 Pb AQCD or the 1986 Pb AQCD. Effects of Pb on marine invertebrates reported in the 2006 Pb AQCD included impacts on embryo development in bivalves with an EC_{50} of 221 µg Pb/L for embryogenesis, gender differences in sensitivity to Pb in copepods and increasing toxicity with decreasing salinity in mysids. As in freshwater invertebrates, the antioxidant system, survival, growth and reproduction are affected by Pb in marine organisms. In aquatic invertebrates, Pb has also been shown to affect stress responses and osmoregulation. New evidence on reproduction and growth in invertebrates is also reviewed here.

Recent literature strengthens the evidence indicating that Pb affects enzymes and antioxidant activity in marine invertebrates. Activity of enzymes associated with the immune defense system in the mantle of pearl oyster were measured at 0, 24, 48 and 72 hour exposure to 104 µg Pb/L (Jing et al., 2007). Activity of AcPase, a lysosomal marker enzyme, was detected at 24 hours and subsequently decreased. Phenoloxidase activity was depressed compared with controls and remained significantly lower than control after 72 hours of exposure to Pb. Increased SOD activity was observed in the mantle but decreased with time, although always remaining higher than in the control animals. (Jing et al., 2007). Activity of Se-dependent glutathione peroxidase did not change with Pb exposure. SOD, catalase, and glutathione peroxidase were significantly reduced at environmentally relevant concentrations of Pb (2 µg Pb/L as measured in Bohai Bay, China) in the digestive gland of the bivalve *Chlamys farreri* (Zhang et al., 2010c). In contrast, Einsporn et al. (2009) observed no change in catalase activity in the digestive gland and gill of blue mussel *M. edulis* following exposures to 2,500 µg Pb/L as Pb nitrate for 10 days and again following a 10 day depuration period. However, in this same species, glutathione-S-transferase activity was elevated in the gills after Pb exposure and remained active during depuration while no changes to glutathione-S-transferase activity were observed in the digestive gland. In black mussel (*M. galloprovincialis*) exposed 10 days to sublethal concentrations of Pb, fluctuations in SOD activity were observed over the length of the exposure and MDA levels were increased in mantle and gill (Vlahogianni and Valavanidis, 2007). Catalase activity was decreased in the mantle of

these mussels but fluctuated in their gills, as compared with the control group. In the bivalve *C. farreri* exposed to Pb, there was induction of lipid peroxidation measured as MDA of 24% and a 37% reduction in 7-ethoxyresorufin-o-deethylase (EROD) activity when compared to controls (Zhang et al., 2010c). In red fingered marsh crab, *Parasesarma erythrodactyla*, collected from sites along an estuarine lake in New South Wales, Australia, elevated glutathione peroxidase activity was correlated with individuals with higher metal body burdens (MacFarlane et al., 2006).

ALAD is a recognized biomarker of exposure across a wide range of taxa including bacteria (Korcan et al., 2007), invertebrates and vertebrates. Since the 2006 Pb AQCD, there are additional studies measuring changes in ALAD activity in field-collected bivalves and crustaceans. In the bivalve *Chamelea gallina* collected from the coast of Spain, ALAD inhibition was greater with higher concentrations of Pb measured in whole tissue (Kalman et al., 2008). In another study conducted in Spain, ALAD activity was negatively correlated with total Pb concentration in seven marine bivalves (*C. gallina*, *Mactra corallina*, *Donax trunculus*, *Cerastoderma edule*, *M. galloprovincialis*, *Scrobicularia plana* and *Crassostrea angulata*). However, the authors of this study indicated the need to consider variability of responses between species when using ALAD as a biomarker for Pb (Company et al., 2011). Pb content varied significantly among species and was related to habitat (sediment versus substrate) and feeding behavior.

Behavioral responses of aquatic invertebrates to Pb reviewed in the 2006 Pb AQCD included avoidance. A limited number of new studies have considered additional behavioral endpoints in marine organisms. Valve closing speed was used as a measure of physiological alterations due to Pb exposure in the Catarina scallop (Sobrino-Figueroa and Caceres-Martinez, 2009). The average valve closing time increased from under one second in the control group to 3 to 12 seconds in juvenile scallops exposed to Pb (40 µg/L to 400 µg/L) for 20 days. Damage to sensory cilia of the mantle was observed following microscopic examination of Pb-exposed individuals.

Since the 2006 Pb AQCD, limited studies on marine invertebrates have indicated effects of Pb on reproduction. In a long term (approximately 60 days) sediment multigenerational bioassay with the estuarine-sediment dwelling amphipod *Elasmopus laevis*, onset to reproduction was significantly delayed at 118 µg Pb/g compared to controls. In the higher concentrations, start of offspring production was delayed further; 4 days in 234 µg Pb/g and 8 days in 424 µg Pb/g (Ringenary et al., 2007). Fecundity and time of first offspring production was also reduced with increasing Pb concentration in sediment above 118 µg Pb/g. The authors indicate that this concentration is below the current marine sediment regulatory guideline for Pb (218 µg Pb/g sediment) (NOAA,

1999) and that reproductive endpoints are more sensitive than survival. Exposure of gametes to Pb prior to fertilization resulted in a decrease of the fertilization rates of the marine polychaete *Hydroides elegans* (Gopalakrishnan et al., 2008). In sperm pretreated in 100 µg Pb/L filtered seawater for 20 minutes, fertilization rate decreased by approximately 70% compared to controls. In a separate experiment, eggs were pretreated with Pb prior to addition of an untreated sperm suspension. The fertilization rate of eggs pretreated in 50 µg Pb/L filtered seawater decreased to 20% of the control. In another test with *H. elegans* in which gametes were not pre-treated, but instead added directly to varying concentrations of Pb for fertilization, there appears to be a protective effect following fertilization due to the formation of the fertilization membrane during the first cell division that may prevent Pb from entering the oocytes (Gopalakrishnan et al., 2007).

As noted in the 2006 Pb AQCD and supported by new studies reviewed in this ISA, Pb exposure negatively affects the growth of aquatic invertebrates. Wang et al., (2009d) observed growth of embryos of the Asian Clam (*Meretrix meretrix*) was significantly reduced by Pb with an EC_{50} of 197 µg/L. In juvenile Catarina scallop, *Argopecten ventricosus*, exposed to Pb for 30 days, the EC_{50} for growth was 4,210 µg Pb/L (Sobrino-Figueroa et al., 2007). Rate of growth of the deposit feeding *Capitella* sp. polychaetes decreased significantly with increasing concentrations of Pb associated with sediment (Horng et al., 2009).

Although Pb is known to cause mortality when invertebrates are exposed to sufficiently high concentrations, some species may not exhibit significant mortality even at high concentrations. In a 10-day Pb-spiked sediment exposure (1,000 mg Pb/kg), 100% of individuals of the Australian estuarine bivalve *Tellina deltoidalis* survived (King et al., 2010). In the deposit feeding *Capitella* sp., polychaetes, exposure to varying concentrations of Pb associated with sediment up to 0.41 µmol/g had no effect on survival (Horng et al., 2009). Other species are more sensitive to Pb in the environment and these responses are reviewed in Section 7.3.13.

7.3.12.3 Saltwater Vertebrates

Saltwater Fish

There is a dearth of information in previous Pb AQCDs on Pb effects in saltwater fish. New data available since the 2006 Pb AQCD includes a study with a marine elasmobranch. De Boeck et al. (2010) exposed the spotted dogfish (*S. canicula*) to 2,072 µg Pb/L for one week and measured metallothionein induction in gill and liver tissue, and the electrolytes Na, K, Ca and Cl, in plasma. No effects were observed in Pb-

exposed fish for any of the physiological variables measured in this study, although Pb was detected in all organs (De Boeck et al., 2010).

Since the 2006 Pb AQCD, several studies integrating behavioral and physiological measures of Pb toxicity have been conducted on marine fish. The ornate wrasse (*Thalassoma pavo*) was exposed to sublethal (400 µg Pb/L) or a maximum acceptable toxicant concentration (1,600 µg Pb/L) dissolved in seawater for one week to assess the effects of Pb on feeding and motor activities (Giusi et al., 2008). In the sublethal concentration group, hyperactivity was elevated 36% over controls. In the high concentration, a 70% increase in hyperactivity was observed and hyperventilation occurred in 56% of behavioral observations. Elevated expression of heat shock protein 70/90 orthologs was detected in the hypothalamus and mesencephalic areas of the brains of Pb-treated fish. No changes in feeding activity were noted between non-treated and treated fish.

Additional behavioral studies in fish consider effects of dietary Pb. The grunt fish *H. scudderi*, occupying the top level of a simulated marine food chain, exhibited lethargy and decreased food intake during the last week of a 42-day feeding study (Soto-Jiménez et al., 2011a). The fish were fed white shrimp exposed to Pb via brine shrimp that were in turn fed microalgae cultured at an environmentally-relevant concentration of 20 µg Pb/L. The authors noted a few of the fish exposed to Pb via dietary transfer through the food chain were observed surfacing and speculated that this behavior was air breathing as a response to stress.

Limited new studies on reproductive effects of Pb in marine fish are available. Decreased oocyte diameter and density in the toadfish (*Tetractenos glaber*) were associated with elevated levels of Pb in the gonad of field-collected fish from contaminated estuaries in Sydney, Australia (Alquezar et al., 2006). The authors state this is suggestive of a reduction in egg size which ultimately may lead to a decline in female reproductive output.

Mammals

Although Pb continues to be detected in tissues of marine mammals in U.S. coastal waters (Bryan et al., 2007; Stavros et al., 2007; Kannan et al., 2006) few studies exist that consider biological effects associated with Pb exposure. Pb effects on immune variables, including cell viability, apoptosis, lymphocyte proliferation, and phagocytosis were tested in vitro on phagocytes and lymphocytes isolated from the peripheral blood of bottlenose dolphin (*Tursiops truncates*) (Cámara Pellissó et al., 2008). No effects on viability of immune cells, apoptosis, or phagocytosis were observed in 72 hour exposure to

concentrations of 1, 10, 20 and 50 mg Pb/L. Proliferative response of bottlenose dolphin leukocytes was significantly reduced at 50 mg Pb/L, albeit by only 10% in comparison to the control.

7.3.13 Exposure and Response of Saltwater Species

Evidence regarding exposure-response relationships and potential thresholds for Pb effects on aquatic populations can inform determination of standard levels that are protective of aquatic ecosystems. The Annex of the 2006 Pb AQCD (U.S. EPA, 2006c) summarized data on exposure-response functions for invertebrates (Table AX7-2.4.1) (Table AX7-2.4.2). The recent exposure-response studies reviewed in this section expand on earlier findings with information on microalgal and invertebrate species.

A series of 72-hour Pb toxicity tests were conducted with five marine microalgae species (*T. chuii, R. salina*, Chaetoceros sp., *I. galbana* and *N. gaditana*) to determine the relative Pb sensitivities as measured by growth inhibition. The respective 72-hour EC_{50} values derived were 2,640, 900, 105, 1,340, and 740 µg Pb/L (Debelius et al., 2009). The authors noted that species cellular size, sorption capacity, or taxonomy did not explain differences in sensitivity to Pb, leaving the mechanism of response still open to question.

Other studies of marine invertebrates published since the 2006 Pb AQCD have indicated differences in sensitivity of different lifestages of aquatic organisms to Pb. In a series of seawater and sediment exposures using adult and juvenile amphipods *Melita plumulosa*, juveniles were more sensitive to Pb than adults (King et al., 2006). In the seawater-only exposures, the 96-hour LC_{50} for adults was 3,000 µg Pb/L and 1,520 µg Pb/L for juveniles. Ten-day exposures of juveniles in seawater resulted in an LC_{50} of 1,270 µg Pb/L, an NOEC of 190 µg Pb/L and a LOEC of 390 µg Pb/L. In comparison, the LC_{50}, NOEC, and LOEC value for the adults exposed in sediment was 3,560 µg Pb/L. Juvenile sediment tests results were LC_{50} 1,980, NOEC 580 and LOEC 1,020 µg Pb/L. A 24-hour LC_{50} of 4,500 µg Pb/L for adult black mussel (*M. galloprovincialis*) suggests that, in general, juvenile bivalves are more sensitive to Pb exposure than adults (Vlahogianni and Valavanidis, 2007).

Since the 2006 Pb AQCD, Pb toxicity to larval stages of marine species has been assessed at sublethal and lethal concentrations. The effective concentrations at which Pb resulted in 50% of abnormal embryogenesis of the Asian clam (*M. meretrix*) was 297 µg Pb/L. The 96-hour LC_{50} for larvae of the same species was 353 µg Pb/L (Wang et al., 2009d). In comparison, juvenile Catarina scallop (*A. ventricosus*) had a LC_{50} of 830 µg Pb/L in a 96-hour exposure (Sobrino-Figueroa et al., 2007). Morphological deformities were observed in 50% of veliger larvae of blacklip abalone (*Haliotis rubra*) at 4,100 µg

Pb/L following a 48-hour exposure to Pb, suggesting this species is not as sensitive to Pb as other marine invertebrate larvae (Gorski and Nugegoda, 2006). In the marine polychaete *H. elegans*, EC_{50} values of gametes, embryos, larvae (blastula to trochophore and larval settlement), and adults, exhibited dose-responses to Pb that reflected the differential sensitivity of various lifestages of this organism (Gopalakrishnan et al., 2008). The EC_{50} values for sperm and egg toxicity were 380 and 690 µg Pb/L respectively. Larval settlement measured as the metal concentration causing 50% reduction in attachment was most sensitive to Pb with an EC_{50} of 100 µg Pb/L, while the EC_{50} for abnormal development of embryos was 1,130 µg Pb/L. The LC_{50} values for adult worms in 24-hour and 96-hour tests were 25,017 and 946 µg Pb/L, respectively. Manzo et al. (2010) established a LOEC of 500 µg Pb/L and a maximum effect at 3,000 µg Pb/L in an embryotoxicity assay with sea urchin *P. lividus*. The EC_{50} for developmental defects in this species was 1,150 µg Pb/L with a NOEL of 250 µg Pb/L.

7.3.14 Community and Ecosystem Effects in Saltwater Systems

As discussed in the 1986 Pb AQCD and the 2006 Pb AQCD, exposure to Pb is likely to have impacts in aquatic environments via effects at several levels of ecological organization (organisms, populations, communities, or ecosystems). But fewer studies explicitly consider community and ecosystem-level effects in marine and brackish waters than in freshwater. Reduced species abundance and biodiversity of protozoan and meiofauna communities were observed in laboratory microcosm studies with marine water and marine sediments reviewed in the 2006 Pb AQCD as summarized in Table AX7-2.5.2 (U.S. EPA, 2006c). In a laboratory study with larval mummichogs reviewed in the 2006 Pb AQCD, feeding and predator avoidance behaviors were altered in this marine fish species following a 4 week exposure to Pb. Observations from field studies reviewed in the 2006 Pb AQCD included findings of a negative correlation between Pb and species richness and diversity indices of macroinvertebrates associated with estuary sediments and changes in species distribution and abundance in fish, crustaceans and macroinvertebrates correlated with Pb levels in marine sediments. The 2006 Pb AQCD concluded that, in general, information from controlled studies for single pollutants was insufficient to permit evaluation of specific impacts on higher levels of organization (beyond the organism). In studies from natural saltwater ecosystems, Pb rarely occurs as a sole contaminant in saltwater ecosystems making its effects difficult to ascertain. New information on effects of Pb at the population, community and ecosystem level in coastal ecosystems is reviewed below.

The faunal composition of seagrass beds in a Spanish coastal saltwater lagoon was found to be impacted by Pb in sediment, plants, and biofilm (Marín-Guirao et al., 2005).

Sediment Pb concentrations ranged from approximately 100 to 5,000 mg Pb/kg and corresponding biofilm concentrations were 500 to 1,600 mg Pb/kg, with leaf concentrations up to 300 mg Pb/kg. Although multiple community indices (abundance, Shannon-Wiener diversity, Simpson dominance index) did not vary from site to site, multivariate analysis and similarity analysis indicated significant differences in macroinvertebrate communities between sites with different sediment, biofilm, and leaf Pb concentrations. Differences were largely attributable to three amphipod species (*Microdeutopus* sp., *Siphonoecetes sabatieri*, *Gammarus* sp.). This indicates that, although seagrass abundance and biomass were unaffected by Pb exposure, organisms inhabiting these plants still may be adversely impacted.

Caetano et al. (2007) investigated the mobility of Pb in salt marshes using total content and stable isotope signature. They found that roots had similar isotopic signature to sediments in vegetated zones indicating that Pb uptake by plants reflects the input in sediments. At one site, there was a high anthropogenic Pb content while at the other natural mineralogical sources dominated. The roots of *S. fruticosa* and *S. maritima* significantly accumulated Pb, having maximum concentrations of 2,870 mg Pb/kg and 1,755 mg Pb/kg, respectively, indicating that below-ground biomass played an important role in the biogeochemical cycling of Pb.

In a laboratory microcosm experiment with spiked sediments collected from the Swartkop River estuary, South Africa, the effects of Pb (3 to 6,710 µg/Pb g sediment dry weight) on meiobenthos was tested alone and in combination with Cu, Fe, and Zn (Gyedu-Ababio and Baird, 2006). Total meiofauna density decreased after 32 days in Pb-treated sediments (range 3 to 5 taxa) compared to control (9 taxa). Nematode diversity and community structure was altered with a mean number of 8 genera present in microcosms contaminated with Pb compared to the control with 20 genera, however, the synergistic effect of the four metals on nematode community structure was greater than the individual metals and the effects of Pb could not be distinguished from Cu, Fe and Zn.

7.3.15 Characterization of Sensitivity and Vulnerability in Saltwater Species

Species differences in metabolism, sequestration, and elimination rates have been shown to control relative sensitivity and vulnerability of exposed organisms and effects on survival, reproduction, growth, metabolism, and development. Diet and lifestage at the time of exposure also contribute significantly to the determination of sensitive and vulnerable populations and communities. Further, environmental conditions in addition to those discussed as affecting bioavailability may also alter Pb toxicity. The 2006 Pb

AQCD reviewed the effects of genetics, age, and body size on Pb toxicity. While genetics appears to be a significant determinant of Pb sensitivity, effects of age and body size are complicated by environmental factors that alter metabolic rates of saltwater organisms. A review of the more recent literature corroborated these findings, and identified seasonal physiological changes and lifestage as other important determinants of differential sensitivity to Pb.

7.3.15.1 Seasonally Affected Physiological Changes

Couture et al. (2010) investigated seasonal and decadal variations in Pb sources to mussels (*M. edulis*) from the French Atlantic shoreline. Pb concentrations in the mussels were 5-66 times higher than the natural background value for the north Atlantic. The $^{206}Pb/^{207}Pb$ signature indicated that the bioaccumulated Pb was anthropogenic in origin. The signature was not, however, the same as that emitted in western Europe, as a result of leaded gasoline combustion, although that was a major emission source to the atmosphere during a large part of the study period (1985-2005). Instead, it was most similar to that of Pb released into the environment from wastewater treatment plants, municipal waste incinerators and industries such as metal refineries and smelters. Thus continental runoff rather than atmospheric deposition was identified as the main source of Pb to the French coastal area. The strong seasonal variations in $^{206}Pb/^{208}Pb$ were used to conclude that resuspension of Pb triggered by high river runoff events was a key factor affecting bioaccumulation of Pb in *M. edulis*.

In another biota monitoring study, Pearce and Mann (2006) investigated variations in concentrations of trace metals in the U.K. including Pb in the shells of pod razor shell (*Ensis siliqua*). Pb concentration varied from 3.06-36.2 mg Pb/kg and showed a regional relationship to known sources, e.g., former metal mining areas such as Cardigan Bay, Anglesey, and industrial activity in Liverpool Bay. Seasonal variations were also found for Pb in both Cardigan Bay and Liverpool Bay, relating to increased winter fluxes of Pb (and other metals) into the marine environment. In contrast, levels of Pb and other metals were highest in summer and lowest in winter in oysters *Crassostrea corteziensis* collected from Sonora, Mexico (García-Rico et al., 2010).

Carvalho et al. (2011) measured ^{210}Pb in *M. galloprovincialis* sampled at coastal locations in Portugal and noted that the apparent seasonal fluctuation in radionuclide concentrations in mussel soft tissues was mostly attributable to changes in physiological condition (i.e., fat content , gonadal development) and not to radionuclide body burden fluctuation. The authors caution that since concentrations of contaminants are dependent

upon tissue composition, corrections for mussel physiological condition are need to compare results from different seasons and different locations.

7.3.15.2 Lifestage

Lifestages of the marine polychaete *H. elegans* including embryogenesis, sexual maturation, and offspring development were shown to be differentially affected by Pb exposure. Pb water concentrations of 100 µg Pb/L and greater significantly affected fertilization and embryonic development, but the greatest effects were exhibited by 24-hour-old larvae (Gopalakrishnan et al., 2007). The authors suggested that timing of Pb exposure may have different impacts on marine polychaete populations, if life cycles are offset (Gopalakrishnan et al., 2007). Further, given that the adult lifestage is sedentary, reduction of the mobile early lifestage as a result of Pb exposures may disproportionally affect sessile polychaetes. For instance, larval settlement was significantly reduced at Pb exposures of 50 µg Pb/L and greater (Gopalakrishnan et al., 2008).

7.3.15.3 Species Sensitivity

Both inter- and intra-specific differences in Pb uptake and bioaccumulation may occur in macroinvertebrates of the same functional feeding group. Data from 20 years of monitoring of contaminant levels in filter-feeding mussels of the *Mytilus* species and *Crassostrea virginica* oysters in coastal areas of the U.S. through the National Oceanic and Atmospheric Administration (NOAA) Mussel Watch program indicate that Pb is on average three times higher in mussels than in oysters (Kimbrough et al., 2008). Limpet (Patella sp.) from the Lebanese Coast had Pb BAF values ranging from 2,500 to 6,000 and in the same field study Pb BAF values for a mussel (*Brachidontes variabilis*) ranged from 7,500-8,000 (Nakhle et al., 2006).

There is some indication that molting may comprise an additional sequestration and excretion pathway for aquatic animals exposed to Pb (Soto-Jiménez et al., 2011b; Mohapatra et al., 2009; Tollett et al., 2009; Bergey and Weis, 2007). Crab species *U. pugnax* (Bergey and Weis, 2007) and *Scylla serrata* (Mohapatra et al., 2009), and white shrimp *L. vannamei* (Soto-Jiménez et al., 2011b) have been shown to sequester Pb preferentially in exoskeleton tissue, where it is later shed along with other tissue. Consequently, aquatic arthropod species and those species that shed their exoskeleton more frequently may be able to tolerate higher environmental Pb concentrations than non-arthropods or slow-growing molting species, as this pathway allows them to effectively lower Pb body burdens.

Some tolerant species of fish (e.g., mummichog) have the ability to sequester accumulated Pb in metal-rich granules or heat-stable proteins (Goto and Wallace, 2010). Fish with such abilities are more likely to thrive in Pb-contaminated environments than other species.

7.3.16 Ecosystem Services Associated with Freshwater and Marine Systems

Pb deposited on the surface of, or taken up by organisms has the potential to alter the services provided by aquatic biota to humans. At this time, a few publications address Pb impacts on ecosystem services associated with aquatic systems, mostly estuaries, salt marsh and freshwater wetlands rather than lakes and streams. The evidence reviewed in the ISA illustrates that Pb can affect the ecological effects in each of the four main categories of ecosystem services (Section 7.1.2) as defined by Hassan et al. (2005). These effects are sorted into ecosystem services categories and summarized here:

- Supporting: food for higher trophic levels, biodiversity
- Provisioning: clean drinking water, contamination of food by heavy metals, decline in health of fish and other aquatic species
- Regulating: water quality
- Cultural: ecosystem and cultural heritage values related to ecosystem integrity and biodiversity, wildlife and bird watching, fishing

A few recent studies explicitly consider the impact of Pb and other heavy metals on ecosystem services provided by salt marsh (Gedan et al., 2009) and estuaries (Smith et al., 2009b). These systems are natural sinks for metals and other contaminants. Pb can be toxic to salt marsh plant species and decaying plant detritus may result in resuspension of Pb into the aquatic food chain (Gedan et al., 2009). Salt marsh and estuaries provide habitat and breeding areas for both terrestrial and marine wildlife and are locations for bird watching. Using a modeling approach designed to assess the degree of risk of Pb and Hg to wading birds in estuarine habitats in the U.K., the authors found a high probability that Pb poses an ecologically relevant risk to dunlin, *Calidris alpina* (Smith et al., 2009b). However, the authors noted that a major source of uncertainty in this study was the NOAEL values for Pb.

Ecological services provided by freshwater wetlands are similar to those provided by estuaries and are sinks for atmospheric Pb as well as Pb from terrestrial runoff (Landre et al., 2010; Watmough and Dillon, 2007). Several studies have addressed the response of natural wetlands to Pb (Odum, 2000; Gambrell, 1994). Recent reviews of pollution

control (Mander and Mitsch, 2009) or removal of metals (Marchand et al., 2010) by constructed wetlands and phytoremediation of metals by wetland plants (Rai, 2008) indicate that these systems can remove Pb from the aquatic environment and are important for water quality, sediment stabilization, nutrient cycling and shelter for aquatic biota. The use of plants as a tool for immobilization of Pb and other metals from the environment is not limited to wetland species. Recent advances in the phytoremediation of metals are reviewed in Dickinson et al. (2009).

The impact of Pb on ecological services provided by specific components of aquatic systems has been considered in a limited number of studies. Recent research has suggested that dietary Pb (i.e., Pb adsorbed to sediment, particulate matter, and food) may contribute to exposure and toxicity in primary and secondary order consumers (including humans). Aquatic fauna can take up and bioaccumulate metals. If the bioaccumulating species is a food source, the uptake of metals may make it toxic or more dangerous for people or other wildlife to consume. For example, oysters and mussels bioaccumulate Pb from anthropogenic sources, including atmospheric deposition, and are a food source that is widely consumed by humans and wildlife (Couture et al., 2010). Their capacity to bioaccumulate Pb makes them good bioindicators of environmental contamination and they have been used as monitors of coastal pollutants by the NOAA Mussel Watch program since 1986. Although bioaccumulation may render aquatic fauna toxic to consumers, bioaccumulation is a way to sequester the metals and remove them from waters and soils. Sequestration for this purpose is itself an ecosystem service and has been quantified. For example, the total ecological services value of a constructed intertidal oyster (*Crassostrea* sp.) reef in improving water quality and sequestering metals including Pb was calculated in the Yangtze River estuary to be about $500,000 per year (Quan et al., 2009). Other aquatic organisms have been considered for their role in remediation of Pb in the environment. Theegala et al. (2007) discuss the high uptake rate of Pb by *D. pulex* as the basis for a possible Daphnia-based remediation for aquatic systems.

7.3.17 Summary of Aquatic Effects

This summary of the effects of Pb on aquatic ecosystems covers information from the publication of the 2006 Pb AQCD to present. Refer to Section 7.4: Causality determinations for Pb in Terrestrial and Aquatic Systems for a synthesis of all evidence dating back to the 1977 Pb AQCD considered in determining causality.

7.3.17.1 Biogeochemistry and Chemical Effects

Atmospherically-derived Pb can enter aquatic ecosystems by direct deposition or via watershed processes. Once the Pb enters surface waters its fate and bioavailability are influenced by Ca concentration, pH, alkalinity, and total suspended solids, and DOC, including humic acids. Once in sediments, Pb bioavailability may be influenced by the presence of sulfides and Fe and Mn oxides, physical disturbance, the presence of other metals, biofilm and organisms. In many, but not all aquatic organisms, Pb dissolved in the water can be the primary exposure route to gills or other biotic ligands. A more detailed understanding of the biogeochemistry of Pb in aquatic systems (both the water column and sediments) is critical to accurately predicting toxic effects of Pb to aquatic organisms. As recognized in the 2006 Pb AQCD and further supported in this review, chronic exposures to Pb may also include dietary uptake, and there is an increasing body of evidence showing that differences in uptake and elimination of Pb vary with species. Currently available models for predicting bioavailability focus on acute toxicity and do not consider all possible routes of uptake. They are therefore of limited applicability, especially when considering species-dependent differences in uptake and bioaccumulation of Pb.

7.3.17.2 Bioavailability

There is evidence over several decades of research previously reviewed in Pb AQCDs and in recent studies reviewed in this ISA that Pb bioaccumulates in plants, invertebrates and vertebrates in aquatic systems, just as it does in terrestrial systems. According to the 2006 Pb AQCD, and further supported in this review, Pb adsorption, complexation, chelation, etc., are processes that alter bioavailability to aquatic biota. Given the low solubility of Pb in water, bioaccumulation of Pb by aquatic organisms may preferentially occur via exposure routes other than direct absorption from the water column, including ingestion of contaminated food and water, uptake from sediment pore waters, or incidental ingestion of sediment.

As reviewed by Wang and Rainbow (2008) and supported by additional studies reviewed in this ISA, there are considerable differences between species in the amount of Pb taken up from the environment and in the levels of Pb retained in the organism. The bioaccumulation and toxicity of Pb to aquatic organisms are closely linked to the environmental fate of the metal under variable environmental conditions (Section 3.3) as they are highly dependent upon the proportion of free metal ions in the water column.

Recent studies on bioavailability of Pb in aquatic plants and algae support the findings of previous Pb AQCDs that plants tend to sequester larger amounts of Pb in their roots than in their shoots and provide additional evidence for species differences in compartmentalization of sequestered Pb and responses to Pb in water and sediments. Given that atmospherically-derived Pb is likely to become sequestered in sediments, uptake by aquatic plants is a significant route of Pb removal from sediments, and a potential route for Pb mobilization into the aquatic food web. Although there are some similarities to Pb accumulation observed in terrestrial plants (e.g., preferential sequestration of the metal in root tissue), Pb appears to be more bioavailable in sediment than it is in soil. Trees that inhabit semi-aquatic environments have also been shown to absorb Pb from contaminated sediments.

In the case of invertebrates, Pb can be bioaccumulated from multiple sources, including the water column, sediment, and dietary exposures, and factors such as amount of bioavailable Pb, lifestage, age, and metabolism can alter the accumulation rate. Additional studies have considered the relative importance of water versus dietary uptake of Pb in aquatic invertebrates. Use of stable isotopes has enabled simultaneous measurement of uptake and elimination in several aquatic species to assess the relative importance of water versus dietary uptake. In uptake studies of various invertebrates, Pb was mainly found in the gills and digestive gland/hepatopancreas.

Tissue accumulation of Pb via gill and dietary uptake has been further characterized since the 2006 Pb AQCD in aquatic vertebrates and stable isotope techniques have been applied to further elucidate bioaccumulation of Pb. The conclusions of the 2006 Pb AQCD (that the gill is a major site of Pb uptake in fish and that there are species differences in the Pb accumulation and distribution of Pb within the organism) are supported in this review. In general, the accumulation of Pb in fish tissues is observed to be gill>kidney>liver. The anterior intestine has been newly identified as a site of uptake of Pb through dietary exposure studies (Alves et al., 2006). Additional detoxification strategies for Pb have been elucidated since the 2006 Pb AQCD. Mummichogs at more polluted sites stored a higher amount of Pb in metal rich granules as compared to other detoxifying cellular components such as heat-stable proteins, heat-denaturable proteins and organelles (Goto and Wallace, 2010). There is more information now on the cellular and subcellular distribution of Pb in invertebrates than there was at the time of writing the 2006 Pb AQCD. Specifically, localization of Pb at the ultrastructural level has been assessed in the marine mussel (*M. edulis*), scallop and cuttlefish and was found to be bound principally to organelles (Einsporn et al., 2009; Einsporn and Koehler, 2008).

There are few new studies on Pb uptake by amphibians and mammals. In the 2006 Pb AQCD, trophic transfer of Pb through aquatic food chains was considered to be

negligible. Measured concentrations of Pb in the tissues of aquatic organisms were generally higher in algae and benthic organisms than in higher trophic-level consumers indicating that Pb was bioaccumulated but not biomagnified (U.S. EPA, 2006c; Eisler, 2000). Some studies published since the 2006 Pb AQCD support the potential for Pb to be transferred in aquatic food webs, while other studies indicate that Pb concentration decreases with increasing trophic level (biodilution).

7.3.17.3 Biological Effects

Evidence in this review further supports the findings of the previous Pb AQCDs that waterborne Pb is highly toxic to aquatic organisms, with toxicity varying with species and lifestage, duration of exposure, form of Pb, and water quality characteristics.

Effects of Pb on algae reported in the 2006 Pb AQCD included decreased growth, deformation and disintegration of algae cells, and blocking of the pathways that lead to pigment synthesis, thus affecting photosynthesis. Observations in additional algal species since the 2006 Pb AQCD support these findings. Effects on plants supported by additional evidence in this review and evidence from previous reviews include oxidative damage, decreased photosynthesis and reduced growth. The mechanism of Pb toxicity in plants is likely mediated by damage to photosystem II through alteration of chlorophyll structure. Elevated levels of antioxidant enzymes are commonly observed in aquatic plant, algae, and moss species exposed to Pb.

As observed in terrestrial invertebrates, upregulation of antioxidant enzymes is a common biomarker of Pb exposure in aquatic invertebrates. Since the 2006 Pb AQCD, there is additional evidence for Pb effects on antioxidant enzymes, lipid peroxidation, stress response and osmoregulation. Studies of reproductive and developmental effects of Pb in aquatic invertebrates in this review provide further support for findings in the 2006 Pb AQCD. These new studies include reproductive endpoints for rotifers and freshwater snails as well as multigenerational effects of Pb in mosquito larvae. Growth effects are observed at lower concentrations in some aquatic invertebrates since the 2006 Pb AQCD, including juveniles of the freshwater snail *L. stagnalis* where growth is affected at <4 µg Pb/L (Grosell et al., 2006a). Behavioral effects of Pb in aquatic invertebrates reviewed in this ISA include decreased valve closing speed in scallops and slower feeding rate in blackworms.

Additional mechanisms of Pb toxicity have been elucidated in the gill and the renal system of fish since the 2006 Pb AQCD. Further supporting evidence of reproductive, behavioral, growth effects and effects on blood parameters have become available since the 2006 Pb AQCD. The mitogen-activated protein kinases, ERK1/2 and $p38^{MAPK}$ were

identified for the first time as possible molecular targets for Pb neurotoxicity in a teleost (Leal et al., 2006). Pb toxicity at the fish gill primarily involves disruption of Ca homeostasis as previously characterized in the 2006 Pb AQCD (Rogers and Wood, 2004; Rogers and Wood, 2003). In addition to this mechanism, Pb was found to induce ionoregulatory toxicity at the gill of rainbow trout through a binding of Pb with Na-K, ATPase and rapid inhibition of carbonic anhydrase activity thus enabling noncompetitive inhibition of Na^+ and Cl^- influx. Recent studies on fish behavior associated with Pb exposure include decreased prey capture rate (Mager et al., 2010) and swim speed (Mager and Grosell, 2011) in fathead minnow and decline in startle response and visual contrast in zebrafish (Rice et al., 2011).

In the 2006 Pb AQCD amphibians were considered to be relatively tolerant to Pb. Observed responses to Pb exposure included decreased enzyme activity (e.g., ALAD reduction) and changes in behavior summarized in Table AX7-2.4.3 of the 2006 Pb AQCD (U.S. EPA, 2006c). Since the 2006 Pb AQCD, studies conducted at concentrations approaching environmental levels of Pb have indicated sublethal effects on tadpole endpoints including growth, deformity, and swimming ability.

7.3.17.4 Exposure and Response

Concentration-response data on plants, invertebrates and vertebrates is consistent with findings in previous reviews of species differences in sensitivity to Pb in aquatic systems. Growth in plants continues to be a commonly measured endpoint affected by Pb exposure. The lowest EC_{50} for growth observed in marine microalgae and freshwater microalgae was in the range of 100 µg Pb/L.

In the 2006 Pb AQCD, concentrations at which effects were observed in aquatic invertebrates ranged from 5 to 8,000 µg Pb/L. Several studies in this review have provided evidence of effects at lower concentrations. Among the most sensitive species, growth of juvenile freshwater snails *L. stagnalis* was inhibited at an EC_{20} of <4 µg Pb/L. (Grosell and Brix, 2009; Grosell et al., 2006a). A chronic value of 10 µg Pb/L obtained in 28-day exposures of 2-month-old *L. siliquoidea* juveniles was the lowest genus mean chronic value ever reported for Pb (Wang et al., 2010e). In a series of 48 hour acute toxicity tests with the cladoceran *C. dubia* conducted in a variety of natural waters across North America, LC_{50} values ranged from 29 to 180 µg Pb/L and were most significantly influenced by DOC and water ionic strength (Esbaugh et al., 2011).

In the 2006 Pb AQCD, effects were reported in freshwater fish at concentrations ranging from 10 to >5,400 µg Pb/L, generally depending on water quality variables (e.g., pH, hardness, salinity). Additional testing of Pb toxicity under conditions of varied alkalinity,

DOC, and pH has been conducted since the last review. However, effects in fish observed in recent studies fall within the range of concentrations observed in the previous Pb AQCD.

7.3.17.5 Community and Ecosystem Effects

Since the 2006 Pb AQCD, additional evidence for community and ecosystem level effects of Pb have been observed primarily in microcosm studies or field studies with other metals present. One ecological effect reported in previous Pb AQCDs is a shift in community composition in Pb-impacted habitats toward more Pb-tolerant species. New studies in this ISA provide evidence in additional habitats for community composition shifts associated with Pb. Alteration of aquatic plant community composition was demonstrated in the presence of elevated surface water Pb concentrations at three lake sites impacted by mining effluents. Lakes with the highest levels of Pb had the lowest number of aquatic plant species when compared to sites with lower Pb concentrations. In an aquatic macrophyte community, both plant species and type of habitat were determined to be factors affecting the rate of Pb accumulation from contaminated sediments. While the rooted macrophyte *E. canadensis* was observed to accumulate the highest concentrations of Pb, the authors concluded that submerged macrophytes (versus emergent plants) as a group were the most likely to accumulate Pb and other heavy metals (Kurilenko and Osmolovskaya, 2006). This would suggest that certain types of aquatic plants, such as rooted and submerged species, may be most susceptible to atmospherically-deposited Pb, resulting in shifts in plant community composition as a result of Pb pollution.

Despite the fact that alterations of macrophyte communities may be highly visible effects of increased sediment Pb concentrations, several recently published papers propose that ecological impacts on invertebrate communities are also significant, and can occur at environmental Pb concentrations lower than those required to impact plant communities. High sediment Pb concentrations were linked to shifts in amphipod communities inhabiting plant structures, and potentially to alterations in ecosystem nutrient processing through selective pressures on certain invertebrate functional feeding groups.

Sensitive species may become locally extinct from habitats where Pb toxicity is greater. Birceanu et al. (2008) determined that fish, specifically rainbow trout, were more susceptible to Pb toxicity in acidic, soft waters characteristic of sensitive regions in Canada and Scandinavia. Hence, fish species endemic to such systems may be more at risk from Pb contamination than fish species in other habitats. A series of freshwater species sensitivity distributions constructed by Brix et al. (2005) indicated that sensitivity

to Pb was greatest in crustacean species, followed by coldwater fish, and warmwater fish and aquatic insects, which exhibited a similar sensitivity.

7.3.17.6 Critical Loads, Sensitivity and Vulnerability

In the short term, metal emissions generally have greater effects on biota in aquatic systems than in terrestrial systems because metals are more readily immobilized in soils than in sediment. However, over the longer term, terrestrial systems may be more affected particularly by those metals with a long soil residence time, such as Pb. Thus, for a particular locale, either the terrestrial or the aquatic ecosystem at that site may have the lower critical load. Given the heterogeneity of ecosystems affected by Pb, and the differences in expectations for ecosystem services attached to different land uses, it is expected that there will be a range of critical load values for Pb for soils and waters within the U.S.

Recent studies have identified seasonally-affected physiological changes and lifestage as important determinants of differential sensitivity to Pb in aquatic organisms. These factors are in addition to species differences in metabolism, sequestration, and elimination rates, diet, lifestage, genetics, age, and body size that were considered in the 2006 Pb AQCD. Although evidence is available to support Pb impacts to supporting, provisioning, regulating and cultural ecosystem services, there is insufficient data available to adequately quantify these effects.

7.4 Causal Determinations for Ecological Effects of Lead

This section presents key conclusions regarding causality for welfare effects of Pb (Table 7-2). Evidence considered in establishing causality was drawn from recent studies summarized in this ISA, integrated with findings presented in the 1977 (U.S. EPA, 1977), 1986 (U.S. EPA, 1986a) and 2006 Pb AQCDs (U.S. EPA, 2006c) for Pb. The causal statements for terrestrial and aquatic effects are arranged according to ecologically meaningful levels of biological organization (organism, population, community, ecosystem). As recognized in EPA's Framework for Ecological Risk Assessment (U.S. EPA, 1992), and in the adverse outcome pathway (AOP) framework (Ankley et al., 2010) endpoints that are measured at one level of organization may be related to an endpoint at a higher level. The AOP conceptual framework was proposed to link mechanistic data from initiating events at the molecular level, through a series of higher order biological responses, to survival and to developmental and reproductive endpoints that can be used in ecological risk assessment, i.e., at the population level and higher. Fecundity, growth,

and survival are organism-level attributes that lead to population-level (e.g., abundance, production, extirpation), community-level (taxa richness, relative abundance) and ecosystem-level responses (Ankley et al., 2010; Suter et al., 2005). In the case of Pb, physiological stress, hematological effects and neurobehavioral alterations are likely to decrease the overall fitness of an organism, even though their connection to effects at higher levels of biological organization may not have been characterized. Furthermore, the effects of Pb on ecosystems necessarily begin with some initial effects at the molecular level of specific organisms within the ecosystem (U.S. EPA, 1986b). There are many different molecular and cellular level effects, and chronic toxicity of Pb in ecosystems is thus likely attained through multiple modes of action.

Relevant sources of information on ecological effects of Pb include controlled exposures in the laboratory, microcosm experiments and field observations. Controlled exposure studies in laboratory or small-to medium-scale field settings provide the most direct evidence for causality, but their scope of inference may be limited. In contrast, microcosms and field studies where exposure is not controlled also include potentially confounding factors (e.g., other metals, environmental conditions), thus increasing the uncertainty in associating effects with exposure to Pb specifically. The vast majority of available Pb studies are laboratory toxicity tests on single species, in which an organism is exposed to a known concentration of Pb and the effect on a specific endpoint is evaluated. Potential effects of Pb at the population, community and ecosystem level are often, of necessity, inferred from organism-level studies (U.S. EPA, 2006c). Considering the various types of ecological evidence available, effects determined to be causal at the organism or species level of biological organization contribute to the body of evidence for causal effects at the community and ecosystem levels of biological organization. For some ecological endpoints, support for causality is additionally supported by toxicological findings reviewed in the chapters of the ISA that evaluate evidence for human health effects associated with Pb exposure, particularly when a common mode of action is documented.

For aquatic biota, generally, the number of studies available on freshwater organisms is greater than on saltwater organisms, covering more taxa as well as more endpoints. The causal determinations for aquatic biota are, therefore, based primarily on evidence from freshwater species. When available, data from saltwater ecosystems are discussed separately under the appropriate causal endpoint. For most of the endpoints under consideration, evidence is inadequate to establish causality in saltwater species. When sufficient evidence is available for marine organisms, data on concentrations at which effects are observed are presented.

Table 7-2 Summary of Pb causal determinations for plants, invertebrates and vertebrates

Effect	Terrestrial	Aquatic[a]
Physiological Stress-All organisms	Causal	Causal
Hematological Effects-Invertebrates	Inadequate	Causal
Hematological Effects-Vertebrates	Causal	Causal
Neurobehavioral Effects-Invertebrates and Vertebrates	Likely Causal	Likely Causal
Developmental and Reproductive Effects-Plants	Inadequate	Inadequate
Developmental and Reproductive Effects-Invertebrates and Vertebrates	Causal	Causal
Growth-Plants	Causal	Causal
Growth-Invertebrates	Inadequate	Causal
Growth-Vertebrates	Inadequate	Inadequate
Survival-Plants	Inadequate	Inadequate
Survival- Invertebrates and Vertebrates	Causal	Causal
Community and Ecosystem Level Effects	Likely Causal	Likely Causal

[a]Causal determinations for aquatic biota are based primarily on evidence from freshwater organisms.

Characterization of environmental concentrations of Pb in terrestrial and aquatic systems is important for identification of levels of exposure to organisms. Information on ambient Pb concentrations in non-air media and biota is reported in Section 3.6 and Table 2-1. A survey of 1,319 locations in the conterminous U.S. found an average background soil concentration of 19.3 mg Pb/kg , with a 95th percentile of 50 mg Pb/kg, and 16 locations between 100 and 700 mg Pb/kg (Shacklette and Boerngen, 1984). The U.S.EPA's Eco-SSL Guidance documents (2007d, 2003b) augmented these data with observations from an additional 13 studies conducted between 1982 and 1997, most of them limited to one state. The national average of state-level soil averages was 18.9 mg Pb/kg. The range of the state mean soil Pb concentrations was from 5 mg Pb/kg to 38.6 mg Pb/kg. Representative median and range of Pb concentrations in surface waters (median 0.50 µg Pb/L, range 0.04 to 30 µg Pb/L) and sediments (median 28 µg Pb/g dry weight, range 0.5 to 12,000 µg Pb/g dry weight) in the U.S. based on a synthesis of NAWQA data was reported in the previous 2006 Pb AQCD (U.S. EPA, 2006c). The range of Pb levels in saltwater are available from several studies although the values are not specific to the U.S. A range of 0.005-0.4 µg Pb/L for salt water was reported by Leland and Kuwabara (1985) and 0.01 to 27 µg Pb/L by Sadiq (1992). In general, Pb in seawater is higher in coastal areas and estuaries since these locations are closer to sources of Pb contamination and loading from terrestrial systems (Sadiq, 1992).

The level at which Pb elicits a specific effect is difficult to establish in terrestrial and aquatic systems due the influence of other environmental variables on Pb bioavailability and toxicity and substantial species differences in Pb sensitivity. In the 1977 Pb AQCD,

no correlation could be established between toxic effects in invertebrates, fish, birds and small mammals and environmental concentrations of Pb. At the time of the 1986 Pb AQCD additional data were available on toxicity but there was still little information on the levels of Pb that can cause toxic effects in small mammals or birds (U.S. EPA, 1986b). In the 2006 Pb AQCD several studies on effects of Pb exposure on natural ecosystem structure and function advanced the characterization of Pb levels in the environment near point sources (i.e., smelters, mining). According to the 2006 Pb AQCD, natural terrestrial ecosystems near significant Pb point sources exhibited a number of ecosystem-level effects, including decreased species diversity, changes in floral and faunal community composition, and decreasing vigor of terrestrial vegetation. These findings are summarized in Table AX7-2.5.2 of the Annex to the 2006 Pb AQCD (U.S. EPA, 2006c). The 2006 Pb AQCD concluded that, in general, there was insufficient information available for single materials in controlled studies to permit evaluation of specific impacts on higher levels of organization (beyond the organism). Furthermore, Pb rarely occurs as a sole contaminant in natural systems making the effects of Pb difficult to ascertain. New information available since the 2006 Pb AQCD includes additional field studies in both terrestrial and aquatic ecosystems, but the connection between air concentration and ecosystem exposure continues to be poorly characterized for Pb and the contribution of atmospheric Pb to specific sites is not clear.

The key conclusions and causal determinations for welfare effects of Pb are presented in ascending order of the level of ecological organization to which they apply, moving from responses in organisms (physiological stress, hematological effects, neurobehavioral effects) to endpoints relevant to population, community, and ecosystem-level processes (development and reproduction, growth, survival). They focus on studies where effects of Pb exposure are observed at or near ambient levels of Pb and studies generally within the range of one to two orders of magnitude above current conditions were also considered in the body of evidence. Studies at higher concentrations were used to the extent they informed our understanding of modes of action and illustrated the wide range of sensitivity to Pb across taxa.

7.4.1 Causal Determinations for Lead in Terrestrial Systems

7.4.1.1 Physiological Stress-Terrestrial Biota

Induction of enzymes associated with oxidative stress response in terrestrial biota is a recognized effect of Pb exposure (U.S. EPA, 2006c). Several studies from the 2006 Pb AQCD in birds and plants provide evidence that Pb induces lipid peroxidation, however,

exposures in these studies were higher than would be found generally in the environment (U.S. EPA, 2006c). Building on the body of evidence presented in the 2006 Pb AQCD, recent studies provide evidence of upregulation of antioxidant enzymes and increased lipid peroxidation associated with Pb exposure in many species of plants, invertebrates and vertebrates. In plants, increases of antioxidant enzymes with Pb exposure occur in some terrestrial species at concentrations approaching the average Pb concentrations in U.S. soils (18.9 mg Pb/kg). For example, in a series of studies Wang et al. observed increases in reactive oxygen species with increasing exposure to Pb from 20 mg Pb/kg soil to 2,000 mg Pb/kg in broad bean (*Vicia faba*) (Wang et al., 2010c; Wang et al., 2010b; Wang et al., 2008b) and tomato (*Lycopersicon esculentum*) (Wang et al., 2008a), where they were accompanied up to approximately 500mg Pb/kg by proportional increases in SOD, glutathione, guaiacol peroxidase, and lipid peroxidation, as well as decreases in catalase. Spinach seedlings grown in soil containing six increasing concentrations of Pb from 20 to 520 mg Pb/kg exhibited higher production of reactive oxygen species, increased rates of lipid peroxidation and increased SOD concentrations. (Wang et al., 2011a). Markers of oxidative damage are also observed in terrestrial invertebrates, including snails and earthworms, and in terrestrial mammals. Across these biota, there are differences in the induction of antioxidant enzymes that appear to be species-dependent.

The oxidative stress responses associated with Pb exposure in terrestrial biota are consistent with responses in aquatic organisms (Section 7.4.2.1), in experimental animal studies, and in humans (Section 5.2.4). This oxidative stress is characterized by increased presence of reactive oxygen species and membrane and lipid peroxidation that can promote tissue damage, cytotoxicity, and dysfunction. Increases in reactive oxygen species are often followed by a compensatory and protective upregulation in antioxidant enzymes, such that this upregulation is itself indicative of oxidative stress conditions. Continuous production of reactive oxygen species may overwhelm this defensive process, leading to further oxidative stress and injury.

Upregulation of antioxidant enzymes and increased lipid peroxidation are considered reliable biomarkers of stress, and provide evidence that Pb exposure induces a stress response in those organisms which may itself increase susceptibility to other stressors and reduce individual fitness. Evidence is sufficient to conclude that there is a causal relationship between Pb exposures and physiological stress in terrestrial plants, invertebrates and vertebrates.

7.4.1.2 Hematological Effects-Terrestrial Biota

Hematological responses are commonly reported effects of Pb exposure in vertebrates in terrestrial systems. In the 1977 Pb AQCD, ALAD was recognized as the most sensitive indicator of Pb exposure in rats (U.S. EPA, 1977). Furthermore, inhibition of ALAD was associated with death of waterfowl following ingestion of Pb shot. In the 1986 Pb AQCD, decreases in red blood cell ALAD activity were documented in birds and mammals near a smelter (Beyer et al., 1985). Additional evidence for effects on blood parameters and their applicability as biomarkers of Pb exposure in terrestrial birds and mammals were presented in the 2005 Ecological Soil Screening Levels for Lead, the 2006 Pb AQCD and the current ISA (U.S. EPA, 2006c, 2005b). Field studies available since the 2006 Pb AQCD include evidence for elevated blood Pb levels correlated with decreased ALAD activity in songbirds and owls living in historical mining areas (Gómez-Ramírez et al., 2011; Hansen et al., 2011a).

This evidence is strongly coherent with evidence from aquatic biota (Section 7.4.2.2) and observations from human epidemiologic and animal toxicology studies showing that exposure to Pb induces effects on hematological endpoints, including altered heme synthesis mediated through decreased ALAD and ferrochelatase activities, decreased red blood cell survival and function, and increased red blood cell oxidative stress. Taken together, the overall weight of human epidemiologic and animal toxicological evidence is sufficient to conclude that a causal relationship exists between exposure to Pb and hematological effects in humans and in laboratory animals (Section 5.7). Based on observations in terrestrial birds and mammals and additionally supported by observations in aquatic organisms, and toxicological and epidemiological findings in laboratory animals and humans evidence is sufficient to conclude that there is a causal relationship between Pb exposures and hematological effects in terrestrial vertebrates. The evidence is **i**nadequate to conclude that there is a causal relationship between Pb exposures and hematological effects in terrestrial invertebrates.

7.4.1.3 Neurobehavioral Effects-Terrestrial Biota

The central nervous system of animals was recognized as a target of Pb toxicity in the 1977 Pb AQCD and subsequent Pb reviews have provided additional supporting evidence of Pb as a neurotoxicant in terrestrial biota (U.S. EPA, 1977). Effects of Pb on neurological endpoints in terrestrial animal taxa include changes in behaviors that may

decrease the overall fitness of the organism such as food consumption, prey capture ability and avoidance behaviors.

Some organisms exhibit behavioral avoidance while others do not seem to detect the presence of Pb (U.S. EPA, 2006c). Decreased food consumption of Pb-contaminated diet has been demonstrated in some invertebrates (snails) and vertebrates (lizards, pigs). Decreased food consumption, growth, and shell thickness were observed in juvenile *A. achatina* snails exposed to Pb-contaminated (concentration greater than 134 mg Pb/kg) diet for 12 weeks (Ebenso and Ologhobo, 2009a). Similarly, feeding rate in *T. pisana* snails was depressed in 3 week dietary exposures of 50 to 15,000 mg Pb/kg (El-Gendy et al., 2011), while other snails exposed to Pb at similar concentrations have shown no effects on feeding rate (Beeby and Richmond, 2010). Consumption of 10 mg/Pb kg diet resulted in lower body weight and food intake after 120 days of dietary exposure in pigs (*S. domestica*) (Yu et al., 2005).

In limited studies available on worms there is evidence that Pb may affect the ability to escape or avoid predation. For example, the motility of nematodes was disrupted in Pb-contaminated soils (Wang and Xing, 2008). Additionally, there is new evidence for neurotoxic action of Pb in invertebrates with exposure to Pb observed to cause changes in the morphology of GABA motor neurons in nematodes (*C. elegans*) (Du and Wang, 2009).

There is limited evidence for additional behavioral endpoints altered by Pb exposure. In a laboratory study, Pb-exposed gull chicks exhibited abnormal behaviors such as decreased walking, erratic behavioral thermoregulation and food begging that could make them more vulnerable in the wild (Burger and Gochfeld, 2005). The chicks were exposed to Pb via injection to reach a Pb concentration in feathers equivalent to Pb levels in feathers of wild gull populations. Lizards exposed to Pb through diet of 10 to 20 mg Pb/kg per day for 60 days in the laboratory exhibited abnormal coloration and posturing behaviors.

These findings in terrestrial biota are coherent with findings from studies in aquatic biota that showed neurobehavioral alterations in various species of fish, and also in some aquatic invertebrates (Section 7.4.2.3). They are also coherent with findings in laboratory animals (Section 5.3) that show that Pb induces changes in learning, memory, attention and motor skills. New behaviors induced by exposure to Pb are detailed in that section, including hyperactivity and mood disorders, effects on visual and auditory sensory systems, changes in structure and function of neurons and supporting cells in the brain, and effects on the blood brain barrier. Mechanisms that include the displacement of physiological cations, oxidative stress and changes in neurotransmitters and receptors are also reviewed. Human epidemiological evidence, based on several cohort and cross-sectional studies in diverse populations provides clear and consistent evidence of

association between blood Pb concentrations and decrements in neurodevelopmental outcomes in young children (Section 5.3). In addition to the consistency of findings in children, the evidence is strengthened by the coherence of findings with toxicological studies and by coherence of association of blood Pb with a spectrum of related endpoints including IQ, verbal and reading skills, motor coordination, mood and attention problems, and behavioral problems. The evidence presented in the health chapter is sufficient to conclude that there is a causal relationship between Pb exposure and neurobehavioral effects (Section 5.3). Data from ecological studies are highly coherent with these human health-related data, especially neurobehavioral findings and evidence of structural changes. Overall, the evidence from aquatic and terrestrial systems is sufficient to conclude that there is a likely causal relationship between Pb exposures and neurobehavioral effects in invertebrates and vertebrates in terrestrial ecosystems.

7.4.1.4 Developmental and Reproductive Effects-Terrestrial Biota

In terrestrial biota, evidence from Chapter 7 of this ISA and in previous Pb AQCDs indicates an association between reproductive effects and Pb exposure. Impaired fecundity at the organismal level can result in a decline in abundance and/or extirpation of populations, decreased taxa richness, and decreased relative or absolute abundance at the community level (Suter et al., 2005; U.S. EPA, 2003a). Evaluation of the literature on Pb effects in terrestrial species indicates that exposure to Pb is associated with reproductive effects. Various endpoints have been measured in various taxa of terrestrial organisms to assess the effect of Pb on development, fecundity and hormone homeostasis and although reproductive effects were demonstrated, no single endpoint in a single taxon has been extensively studied.

In terrestrial plants, few studies are available that specifically address reproductive effects of Pb exposure. Two genotypes of maize seedlings exhibited a significant and concentration-dependent reduction in seed germination following 7 days of Pb treatment in nutrient solution of 10, 100 or 1,000 µg Pb/L as Pb sulfate (Ahmad et al.).

In terrestrial invertebrates, Pb can alter developmental timing, hatching success, sperm morphology and hormone homeostasis. However, effects are observed in a limited number of species and at concentrations that typically exceed Pb levels in U.S. soils. In fruit flies, Pb exposure increased time to pupation and decreased pre-adult development at high Pb concentrations (Hirsch et al., 2010). An increase in development time (approximately two days) and a reduction in relative fecundity was observed in aphids feeding on plants exposed to high concentrations of Pb (Gorur, 2007). Hatching success of the collembolan *F. candida* was decreased following 10 day exposure to Pb-spiked

soils (EC_{50} 2,361 mg Pb/kg dry soils) (Xu et al., 2009a). Sperm morphology in Asian earthworms was significantly altered following 2-week exposures to soils containing 1,000, 1,400, 1,800 and 2,500 mg Pb/kg soil (Zheng and Li, 2009). Pb may also disrupt hormonal homeostasis in invertebrates as studies with moths have suggested (Shu et al., 2009). Adult female moths reared on diets containing 25, 50, 100, or 200 mg Pb/kg exhibited decreased vitellogenin mRNA induction, and vitellogenin levels were demonstrated to decrease with increasing Pb exposure. Evidence of multi-generational toxicity effects of Pb is also present in terrestrial invertebrates, specifically springtails, mosquitoes, carabid beetles and nematodes where decreased fecundity in progeny of Pb-exposed individuals was observed. No significant changes to the number of juveniles were noted in the collembolan *Proisotoma minuta* exposed for 42 days to 300, 750, 1,500 or 3,000 mg Pb/kg in acidic sandy loam soil (Nursita et al., 2005) in agreement with a previous study with collembolans in which a NOEC of 2,000 mg Pb/kg and LOEC of 5,000 mg Pb/kg was determined for reproduction (Sandifer and Hopkin, 1996).

In terrestrial vertebrates, there is evidence for reproductive effects associated with Pb exposure in this ISA and previous Pb AQCDs. Reproductive effects observed in birds near areas of Pb-contamination or where Pb tissue concentration has been correlated with effects include declines in clutch size, number of young hatched, number of young fledged, decreased fertility, and decreased eggshell thickness (U.S. EPA, 2006c). Decreased testis weight was observed in lizards administered a sublethal dose of 10 or 20 mg Pb/kg day by oral gavage for 60 days (Salice et al., 2009). Few studies in the field have addressed reproductive effects of Pb specifically in mammals, due to most available data in wild or grazing animals being from near smelters, where animals are co-exposed to other metals. The reproductive viability of red deer (*C. elaphus*) inhabiting a Pb-contaminated mining area of Spain was shown to be altered, with 11% and 15% reductions in spermatozoa and acrosome integrity observed in male deer from the mining area compared with those residing in reference areas (Reglero et al., 2009b).

Evidence from aquatic invertebrates, amphibians, and fish is sufficient to conclude that there is a causal relationship between Pb exposure and reproductive effects in aquatic invertebrates and vertebrates (Section 7.4.2.4). In Chapter 5, evidence obtained using mammals in the context of human health research demonstrates a consistency of adverse effects of Pb on sperm (Section 5.8.2.1) and the onset of puberty in males and females (Sections 5.8.1.3 and 5.8.2.4) with strong evidence from both toxicology and epidemiology studies. Other reproductive endpoints including spontaneous abortions, pre-term birth, embryo development, placental development, low birth weight, subfecundity, hormonal changes, and teratology were also affected, but less consistently (Section 5.8).

The evidence presented in Section 7.4.1.4 is thus highly coherent with evidence from aquatic ecosystems and laboratory animal studies, and sufficient to conclude that there is a causal relationship between Pb exposures and developmental and reproductive effects in terrestrial invertebrates and vertebrates.

In terrestrial plants, the evidence is inadequate to conclude a causal relationship between Pb exposures and plant developmental and reproductive effects.

7.4.1.5 Growth Effects-Terrestrial Biota

Alterations in growth which is an organism-level variable can have impacts at the population, community and ecosystem levels. In terrestrial ecosystems, evidence for effects of Pb on growth is strongest in terrestrial plants, although these effects are typically observed in laboratory studies with high exposure concentrations or in field studies near point sources. Growth effects observed in both invertebrates and vertebrates, where juvenile organisms are generally more sensitive than adults, underscore the importance of lifestage to overall Pb susceptibility.

In terrestrial plants, there is evidence over several decades of research that Pb inhibits photosynthesis and respiration, all of which can reduce the growth of the plant (U.S. EPA, 2006c, 1986a, 1977). Specifically, Pb has been shown to affect photosystem II with the hypothesized mechanism being that Pb may replace either Mg or Ca in chlorophyll, altering the pigment structure and decreasing the efficiency of visible light absorption in exposed plants. Decreases in chlorophyll *a* and *b* content have been observed in various algal and plant species. Many laboratory toxicity studies report effects on the growth of plants in synthetic growing media, but observed effects typically occur at concentrations higher than the average background concentrations in U.S. soils (19 mg Pb/kg dry weight) (U.S. EPA, 2005b) and there are few field studies. Effects on plant growth can result in reduced productivity and decreased biomass. The 2006 Pb AQCD relied heavily on the Ecological Soil Screening Levels for Lead (U.S. EPA, 2005b) document regarding ecotoxicological effects of Pb for which growth (biomass) was considered the most sensitive and ecologically relevant endpoint for plants.

Evidence for growth effects in terrestrial fauna is sparse. In the 1986 Pb AQCD, a study was reviewed in which the F1 and F2 generations of the springtail *Onychiurus armatus* fed a diet of Pb-exposed fungi (0.008 to 3.1 mg Pb/g) experienced a delay in achieving maximum length (Bengtsson et al., 1983). The authors suggested that the reduced growth may be accompanied by delayed sexual maturity. Reduced growth of garden snail *T. pisana*, was observed following a five week dietary exposure of 1,000 µg Pb/g and greater (El-Gendy et al., 2011). In previous AQCDs, growth effects of Pb have been

reported in birds (changes in juvenile weight gain), at concentrations typically higher than currently found in the environment.

Evidence is sufficient to conclude that there is a causal relationship between Pb exposures and growth effects in terrestrial plants. Evidence is inadequate to establish causal relationship between Pb exposures and growth effects in terrestrial invertebrates and vertebrates.

7.4.1.6 Survival-Terrestrial Biota

The relationship between Pb exposure and survival has been well demonstrated in terrestrial species as presented in Sections 7.2.5 of this ISA and in the previous Pb AQCDs. Pb exposure can either be lethal or produce sublethal effects that diminish survival probabilities. In the 1977 Pb AQCD, deaths from Pb poisoning in domestic animals caused by emissions from stationary sources were reported (U.S. EPA, 1977). Additional studies in the 1986 and 2006 Pb AQCDs and current ISA provide evidence for an exposure-response relationship between Pb exposure and mortality in terrestrial biota. Survival is a biologically important response that may have direct impact on population size. However, the typically reported concentration where there is 50% mortality of test organisms (LC_{50}) is a poor measure for comparing environmental concentrations. LC_{50} is applicable to acute toxicity whereas Pb effects on ecosystem receptors is likely characterized as a chronic, cumulative exposure rather than an acute exposure. The scenario where half of test animals die in a laboratory situation would be unacceptable from an ecological perspective. From the LC_{50} data on Pb in this review and previous Pb AQCDs, a wide range of sensitivity to Pb is evident across taxa and within genera. However, the LC_{50} is usually much higher than current environmental levels of Pb in the U.S, even though physiological dysfunction that adversely impacts the fitness of an organism often occurs well below concentrations that result in mortality. When available, LC_{10}, NOEC or LOEC is reported.

Pb is generally not phytotoxic to plants at concentrations found in the environment away from point sources, probably due to the fact that plants often sequester large amounts of Pb in roots, and that translocation to other parts of the plant is limited.

Survival of soil-associated organisms is adversely affected by Pb exposure. In the 1986 Pb AQCD it was reported that Pb at environmental concentrations occasionally found near roadsides and smelters (10,000 to 40,000 µg Pb/g dry weight [mg Pb/kg]) can eliminate populations of bacteria and fungi on leaf surfaces and in soil. Alterations to bacterial and fungal communities can lead to inhibited or delayed decomposition of organic matter and disruption of energy flow through the food chain. As reviewed in the

2006 Pb AQCD, the LC_{50} values for soil nematodes vary from 10-1,550 mg Pb/kg dry weight dependent upon soil OM content and soil pH (U.S. EPA, 2006c). In earthworms, 14 and 28 day LC_{50} values typically fall in the range of 2,400-5,800 mg Pb/kg depending upon the species tested.

In terrestrial avian and mammalian species, toxicity is observed in laboratory studies over a wide range of doses (<1 to >1,000 mg Pb/kg body weight-day) as reviewed for the development of Eco-SSL's (U.S. EPA, 2005b). The NOAELs for survival ranged from 3.5 to 3,200 mg Pb/kg-day. The association of Pb exposure with mortality in vertebrates is coherent with observations in aquatic biota and with the observation of consistently positive associations between Pb exposure and mortality observed in human epidemiologic studies (Section 5.4.5).

The evidence is inadequate to conclude that there is a causal relationship between Pb exposures and survival in terrestrial plants.

The evidence is sufficient to conclude that there is a causal relationship between Pb exposures and survival in terrestrial invertebrates and vertebrates.

7.4.1.7 Community and Ecosystem Level Effects-Terrestrial Biota

Most direct evidence of community and ecosystem level effects is from near point sources where Pb concentrations are higher than typically observed environmental concentrations for this metal. Impacts of Pb on terrestrial ecosystems near smelters, mines, and other industrial sources have been studied for several decades. Emissions of Pb from smelting and other industrial activities are accompanied by other trace metals (e.g., Zn, Cu, Cd) and SO_2 that may cause toxic effects independently or in concert with Pb. Those impacts include decreases in species diversity and changes in floral and faunal community composition. Ecosystem-level field studies are complicated by the confounding of Pb exposure with other factors such as the presence of trace metals and acidic deposition and the inherent variability in natural systems. In natural systems, Pb is often found co-existing with other stressors, and observed effects may be due to cumulative toxicity.

In laboratory studies and simulated ecosystems, where it is possible to isolate the effect of Pb, this metal has been shown to alter competitive behavior of species, predator-prey interactions and contaminant avoidance. These dynamics may change species abundance and community structure at higher levels of ecological organization. Uptake of Pb into aquatic and terrestrial organisms and subsequent effects on mortality, growth, physiological stress, blood, neurobehavioral and developmental and reproductive

endpoints at the organism level are expected to have ecosystem-level consequences, and thus provide consistency and plausibility for causality in ecosystem-level effects.

In the 1977 Pb AQCD the potential for Pb to interfere with ecosystem level processes was explored in a detailed review of a study on the effects of Pb on relationships between arthropods and leaf litter decomposition (U.S. EPA, 1977). Reduced arthropod density, biomass and richness were observed in the vicinity of a Pb smelting complex in Missouri. There were also several studies correlating feeding habits, habitat, and Pb concentrations in body tissues reported in the 1977 Pb AQCD, specifically in insects and small mammals indicating that species differences in Pb concentrations are determined in part by trophic position and habitat preference.

In the 1986 Pb AQCD it was reported that Pb at environmental concentrations occasionally found near roadsides and smelters (10,000 to 40,000 µg Pb/g dry weight [mg Pb/kg]) can eliminate populations of bacteria and fungi on leaf surfaces and in soil (U.S. EPA, 1986b). Some key populations of soil microorganisms and invertebrates die off at 1,000 mg Pb/kg soil interrupting the flow of energy through decomposition processes (U.S. EPA, 1986b) and altering community structure. At soil concentrations of 500 to 1,000 µg Pb/g (mg Pb/kg) or higher, populations of plants, microorganisms, and invertebrates may shift toward Pb-tolerant populations of the same or different species (U.S. EPA, 1986b).

The 2006 Pb AQCD reported that decreased species diversity, changes in floral and faunal community composition and decreased vigor of terrestrial vegetation were observed in ecosystems surrounding former smelters including the Anaconda smelter in southwestern Montana (U.S. EPA, 2006c). Several studies in the 2006 Pb AQCD documented reduced organic matter decomposition rates and decreased microbial biomass in areas heavily polluted by metals. Lower abundance and reduced biodiversity of soil invertebrate communities were observed in field surveys in proximity to Pb-point sources.

New evidence since the 2006 Pb AQCD supports previous findings of a link between high concentration of soil metals and substantial changes in soil microorganism community composition, as well as decreased abundance and diversity. In a naturally Pb-enriched forest in Norway, The number of fungal colony forming units was approximately 10 times lower in the highest Pb soil concentration (~4.5 mg Pb/g dry weight) than in control soils (Baath et al., 2005). The composition of the fungal community was drastically altered, with only one species common to both soils, and the number of species present was substantially lower.

The effect of Pb on microbial community function has been quantified previously using functional endpoints such as respiration rates, fatty acid production, and soil acid phosphatase and urease activities, which may provide a better estimate of ecological impacts than microbial diversity or abundance measurements. Studies available since the 2006 Pb AQCD provide further evidence of Pb effects on microbial processes. Pb contamination reduced phenol oxidase activity in several types of soils; concentrations between 5 and 50 nM Pb significantly decreased phenol oxidase activity in all soils tested, while 400 nM and greater completely arrested phenol oxidase activity in one soil tested (a high pH sandy loam) (Carine et al., 2009). Pb concentrations between 50 and 500 mg Pb/kg significantly reduced microbial abundance and diversity, and also resulted in lower soil phosphatase, urease, and dehydrogenase activities (Gao et al., 2010b). When the microbial properties of metal-contaminated urban soils were compared to those of rural soils, significant differences (Sudova and Vosatka, 2007) were detected in basal community respiration rates and microbial abundance (Yang et al., 2006). Gai et al. (2011) examined the microbial activity of three soils via microcalorimetric methods following Pb exposure. They noted an increase in activity immediately following Pb application (giving 10, 20, 40, 80, and 160 mg Pb/kg), and theorized that this was a result of rapid mortality of sensitive microbial species, followed by a concurrent proliferation of Pb-tolerant microorganisms. As Pb concentrations increased, however, the calculated microbial growth rate constant decreased, indicating a suppression of microbial activity (Gai et al., 2011). Akerblom et al. (2007) tested the effects of six metals (Cr, Zn, Mo, Ni, Cd, and Pb) individually. All tested metals had a similar effect on the species composition of the microbial community. Exposure to a high Pb concentration (52 mg Pb/kg) negatively affected respiration rates.

In addition to microbial communities, there is new evidence for effects of Pb on other terrestrial ecosystem components. Increased plant diversity was shown to ameliorate effects of Pb contamination on a microbial community (Yang et al., 2007). The presence of arbuscular mycorrhizal fungi may protect plants growing in Pb-contaminated soils (Bojarczuk and Kieliszewska-Rokicka, 2010; Sudova and Vosatka, 2007). Invertebrates affected by Pb in terrestrial systems may be altering community structure. New evidence since the 2006 Pb AQCD indicates that some species of worms avoid Pb-contaminated soils (Langdon et al., 2005). Reductions in microbial and detritivorous populations can affect the success of their predators (U.S. EPA, 2006c). Following a 28-day exposure to field-collected soils contaminated with metals (including Pb at 426 mg Pb/kg), both population growth and individual growth of the earthworm *L. rubellus* were diminished (Klok et al., 2006). The authors proposed that, although these reductions were unlikely to result in extirpation, avian predators such as the godwit (*Limosa limosa*) that feed heavily on earthworms may be affected by a reduction of available earthworm biomass.

Furthermore, the presence of earthworms increased Pb uptake by plants (Ruiz et al., 2011; Sizmur et al., 2011).

In terrestrial ecosystems, most studies show decreases in microorganism abundance, diversity, and function with increasing soil Pb concentrations in areas near point-sources. Specifically, shifts in nematode communities, bacterial species, and fungal diversity have been observed. Most evidence for Pb toxicity to terrestrial biota is from single-species assays in laboratory studies. Although the evidence is strong for effects of Pb on growth, reproduction and survival in certain species, considerable uncertainties exist in generalizing effects observed under small-scale, particular conditions up to predicted effects at the ecosystem level of biological organization. In many cases it is difficult to characterize the nature and magnitude of effects and to quantify relationships between ambient concentrations of Pb and ecosystem response due to existence of multiple stressors, variability in field conditions, and to differences in Pb bioavailability at that level of organization. However, the cumulative evidence for Pb effects at higher levels of ecological organization is sufficient to conclude that there is a likely causal relationship between Pb exposures and the alteration of species richness, species composition and biodiversity in terrestrial ecosystems.

7.4.2 Causal Determinations for Lead in Aquatic Systems

7.4.2.1 Physiological Stress-Aquatic Biota

Building on the body of evidence presented in the 2006 Pb AQCD (U.S. EPA, 2006c) recent studies provide consistent and coherent evidence of upregulation of antioxidant enzymes and increased lipid peroxidation associated with Pb exposure within one or two orders of magnitude above current or ambient conditions in many species of aquatic plants, invertebrates and vertebrates. A few studies provide evidence of effects at current concentrations of Pb measured in the environment. In plants, increases of antioxidant enzymes with Pb exposure occur in algae, aquatic mosses, and floating and rooted aquatic macrophytes. Most available evidence in aquatic plants for antioxidant responses to Pb are from laboratory studies conducted from 2 to 7 days and at concentrations higher than typically found in the environment. However, data from transplantation experiments from non-polluted to polluted sites indicate that elevated enzyme activities are associated with Pb levels measured in sediments. The macrophyte *Myriophyllum quitense* exhibited elevated antioxidant enzyme activity (glutathione-S-transferase, glutathione reductase, peroxidase) following transplantation in anthropogenically polluted areas containing

elevated Pb concentrations. These were correlated with sediment Pb concentrations in the range of 5 to 23 mg Pb/g dry weight (Nimptsch et al., 2005).

There is considerable evidence for antioxidant activity in response to Pb exposure in aquatic invertebrates, including gastropods, mussels, and crustaceans. Some of the recent evidence for invertebrate antioxidant response indicates effects at Pb levels detected in the environment. For example, SOD, catalase, and glutathione peroxidase activities were significantly reduced in the digestive gland of the marine bivalve *C. farreri* at 2 µg Pb/L (as measured in Bohai Bay, China) (Zhang et al., 2010c). Markers of oxidative damage are also observed in fish, amphibians and mammals in laboratory studies. Across all biota, there are differences in the induction of antioxidant enzymes that appear to be species-dependent.

Additional stress responses to Pb in a few aquatic invertebrates have been reported since the 2006 Pb AQCD, and included elevated heat shock proteins, osmotic stress, lowered metabolism and decreased glycogen levels associated with Pb exposure. Heat shock protein induction has been observed in zebra mussels exposed to 500 µg Pb/L for 10 weeks (Singer et al., 2005). Elevated expression of heat shock protein orthologs were reported for the first time in the hypothalamic and mesencephalic brain regions of Pb-treated fish (Giusi et al., 2008). Crayfish exposed for 14 days to 500 µg Pb/L exhibited a Pb-induced hypometabolism under conditions of environmental hypoxia in the presence of the metal (Morris et al., 2005). Glycogen levels in the freshwater snail *B. glabrata* were significantly decreased following 96-hour exposures at near environmentally relevant concentrations of Pb (50 µg/L and higher) (Ansaldo et al., 2006).

Evidence for stress responses observed in aquatic biota is supported by findings in terrestrial species (Section 7.4.1.1) as well as in humans and experimental animal studies of oxidative stress following impairment of normal metal ion functions (Section 5.2.4). Upregulation of antioxidant enzymes and increased lipid peroxidation are considered to be reliable biomarkers of stress, and provide evidence that Pb exposure induces a stress response in those organisms which may increase susceptibility to other stressors and reduce individual fitness. Evidence is sufficient to conclude that there is a causal relationship between Pb exposures and physiological stress in aquatic plants, invertebrates and vertebrates.

7.4.2.2 Hematological Effects-Aquatic Biota

Hematological responses are commonly reported effects of Pb exposure in aquatic invertebrates and vertebrates. Anemia was recognized as a symptom of chronic Pb poisoning in fish in the 1977 Pb AQCD and has been subsequently reported in various

species using common hematological endpoints (e.g., red blood cell counts, hematocrit, Hb concentrations) (Mager, 2012). In the 1986 Pb AQCD, hematological effects of Pb exposure to fish included a decrease in red blood cells and inhibition of ALAD (U.S. EPA, 1986b). In environmental assessments of metal-impacted habitats, ALAD is a recognized biomarker of Pb exposure (U.S. EPA, 2006c). ALAD activity is negatively correlated with total Pb concentration in bivalves, and lower ALAD activity has been correlated with elevated blood Pb levels in fish as well. Further evidence from the 2006 Pb AQCD and this review of Pb effects on ALAD enzymatic activity, including effects in bacteria, amphibians and additional field and laboratory studies on fish, confirms that the decreased activity in this enzyme is an indicator for Pb exposure across a wide range of taxa. The finding that the hematological system is a target for Pb in natural systems is also supported by some evidence of Pb-induced alterations of serum profiles and changes in white blood cell counts in fish (U.S. EPA, 2006c) and amphibians. This evidence is strongly coherent with evidence from terrestrial organisms (Section 7.4.1.2). It is also coherent with observations from human epidemiologic and animal toxicology studies (Section 5.7) where there is consistent evidence that exposure to Pb induces adverse effects on hematological endpoints, including altered heme synthesis mediated through decreased ALAD and ferrochelatase activities, decreased red blood cell survival and function, and increased red blood cell oxidative stress. Taken together, the overall weight of epidemiologic and toxicological evidence is sufficient to conclude that a causal relationship exists between exposure to Pb and hematological effects in humans (Section 5.7). Based on observations in both terrestrial and aquatic organisms and additionally supported by findings in terrestrial systems and by toxicological and epidemiologic evidence on human health effects, evidence is sufficient to conclude that there is a causal relationship between Pb exposures and hematological effects in invertebrates and vertebrates in aquatic ecosystems.

7.4.2.3 Neurobehavioral Effects-Aquatic Biota

Evidence from laboratory studies and limited data from field studies reviewed in this chapter and in previous Pb AQCDs have shown effects of Pb on neurological endpoints in aquatic animal taxa. These include changes in behaviors that may decrease the overall fitness of the organism such as avoidance responses, decreased ability of an organism to capture prey or escape predators, and alterations in feeding behaviors.

In the 1977 Pb AQCD behavioral impairment of a conditioned response (avoidance of a mild electric shock) in goldfish was observed as low as 70 µg Pb/L (Weir and Hine, 1970). Some organisms exhibit behavioral avoidance while others do not seem to detect the presence of Pb (U.S. EPA, 2006c). Evidence of alteration in behaviors at the level of

the organism is a potential endpoint at the ecological level when its effects on population or community are taken into consideration (U.S. EPA, 2003a).

In the 2006 Pb AQCD several studies were reviewed in which Pb was shown to affect predator-prey interactions, including alteration in prey size choice in juvenile fathead minnows following 2-week pre-exposure to 500 µg Pb/L (Weber, 1996). In limited studies available on worms, snails, tadpoles, hatchling turtles and fish there is evidence that Pb may affect the ability to escape or avoid predation. For example, in the tubificid worm *T. tubifex* the 96 hour EC_{50} for immobilization was 42 µg Pb/L (Khangarot, 1991).

New information since the 2006 Pb AQCD provides further evidence for Pb impacts on behaviors that may affect feeding and predator avoidance in freshwater environments. Prey capture ability was decreased in 10 day old fathead minnows born from adult fish exposed to 120 µg Pb/L for 300 days, then subsequently tested in a 21-day breeding assay (Mager et al., 2010). Zebrafish embryos exposed to low concentrations of Pb (10nM or 30 nM) until 24 hours post-fertilization and then subsequently tested as larvae or adult fish exhibited behavioral deficits in response to mechanosensory and visual stimuli (Rice et al., 2011). Startle response time in larvae measured as maximum head turn velocity and escape time decreased in a concentration-dependent pattern following a directional, mechanical stimulus (tapping). The pattern of escape swimming was altered in larvae of Pb-exposed embryos compared to non-exposed embryos. In adult fish hatched from Pb-exposed embryos (30 nM), visual response to a rotating black bar against a white background (ability to detect contrast) was significantly degraded.

In marine organisms there is evidence for neurobehavioral effects of Pb in a few species. In a study reviewed in the 2006 Pb AQCD, prey capture rate and predator avoidance was affected in mummichogs starting at 300 µg Pb/L (Weis and Weis, 1998). New studies on neurobehavioral endpoints in marine species support previous findings of decreased ability to escape predation associated with Pb exposure. In juvenile Catarina scallops exposed to Pb (40 µg/L to 400 µg/L) for 20 days, the average valve closing time increased from under one second in the control group to 3 to 12 seconds in juvenile scallops A decrease in valve closing speed in these bivalves may impact escape swimming behaviors important for predator avoidance (Sobrino-Figueroa and Caceres-Martinez, 2009). Behavioral effects in grunt fish *H. scudderi*, occupying the top level of a simulated marine food chain included lethargy and decreased food intake in a 42-day feeding study (Soto-Jiménez et al., 2011a). These fish were fed white shrimp exposed to Pb via brine shrimp that were initially fed microalgae cultured at 20 µg Pb/L. In the same study, surfacing, reduction of motility, and erratic swimming were observed in the white shrimp after 30 days of exposure to Pb via diet. The ornate wrasse, *T. pavo*, was exposed to sublethal (400 µg Pb/L) or a maximum acceptable toxicant concentration (1,600 µg

Pb/L) dissolved in seawater for one week to assess the effects of Pb on feeding and motor activities (Giusi et al., 2008). In the sublethal concentration group, hyperactivity was elevated 36% over controls. In the high concentration, a 70% increase in hyperactivity was observed and hyperventilation occurred in 56% of behavioral observations, however, no changes in feeding activity were noted between non-treated and treated fish.

Findings in laboratory animals and humans support the limited evidence for neurobehavioral effects of Pb in aquatic biota. In studies reviewed in Section 5.3, effects observed in laboratory animals following exposure to Pb include hyperactivity and mood disorders, visual and auditory sensory alterations, and changes in structure and function of neurons and supporting cells in the brain, including effects on the blood brain barrier. Mechanisms that include the displacement of physiological cations, oxidative stress and changes in neurotransmitters and receptors are also reviewed Section 5.3. Central nervous system effects in fish recognized in previous Pb AQCDs include effects on spinal neurons and brain receptors. New evidence from this review identifies the MAPKs ERK1/2 and $p38^{MAPK}$ as possible molecular targets for Pb neurotoxicity in catfish (Leal et al., 2006). Human epidemiologic evidence, based on several cohort and cross-sectional studies in diverse populations provides clear and consistent evidence of association between blood Pb concentrations and decrements in neurodevelopmental outcomes in young children (Section 5.3). In addition to the consistency of findings in children, the evidence is strengthened by the coherence of findings with toxicological studies and by coherence of association of blood Pb with a spectrum of behaviorally-related endpoints. The evidence presented in sections of this ISA dealing with human health is sufficient to conclude that there is a causal relationship between Pb exposure and neurobehavioral effects (Section 5.3). Evidence in terrestrial ecosystems is not as extensive, but it is highly coherent with findings in aquatic ecosystems. Data related to human health are also highly coherent with aquatic ecosystem data. Overall, the evidence from available studies on neurobehavioral effects of Pb in aquatic systems is limited, but sufficient to conclude that there is a likely causal relationship between Pb exposures and neurobehavioral effects in aquatic invertebrates and vertebrates.

7.4.2.4 Developmental and Reproductive Effects-Aquatic Biota

Evaluation of the findings in previous Pb AQCDs and new literature on Pb effects in aquatic fauna indicates that exposure to Pb is associated with reproductive effects at or near ambient concentrations of this metal in some species. Impaired fecundity at the organismal level can result in a decline in abundance and/or extirpation of populations, decreased taxa richness, and decreased relative or absolute abundance at the community level (Suter et al., 2005; U.S. EPA, 2003a). Various endpoints have been measured in

aquatic organisms to assess the effect of Pb on development, fecundity and hormone homeostasis. However, there are typically only limited studies available from different taxa.

There are no studies reviewed in the ISA or previous Pb AQCDs on development and reproductive effects of Pb in freshwater or saltwater aquatic algae or macrophytes.

Reproductive effects of Pb in freshwater aquatic invertebrates are well-characterized in previous Pb AQCDs and in the current ISA and have been observed at or near current ambient concentrations in some species. In the 1986 Pb AQCD reproductive effects were reported to begin at 19 µg Pb/L for the freshwater snail *Lymnaea palustris* and 27 µg Pb/L for Daphnia sp. (U.S. EPA, 1986b). In the 2006 Pb AQCD the number of neonates per surviving adult was significantly decreased in the amphipod *H. azteca* during chronic 42 day exposures to Pb (Besser et al., 2005). In the group exposed to Pb in water-only exposures, the LOEC for reproductive effects was 16 µg Pb/L while in amphipods receiving both water-borne and dietary Pb the LOEC for reproduction was 3.5 µg Pb/L. Reproductive output in chronic testing with the freshwater rotifer *B. calyciflorus* was measured as total number of individuals and intrinsic growth rate. The EC_{20} for number of rotifers was 125 µg Pb/L and the 48 hour EC_{20} for intrinsic rate of population increase was 307 µg Pb/L with an LOEC of 194 µg Pb/L (Grosell et al., 2006a). In a 7 day exposure of the cladoceran *C. dubia* to 50 to 500 µg Pb/L , increased DOC lead to an increase in mean EC_{50} for reproduction ranging from approximately 25 µg Pb/L to >500 µg Pb/L (Mager et al., 2011a).

Reproductive effects of Pb have also been reported in marine invertebrate species. In the 2006 Pb AQCD embryo development in two commercial bivalves *Ruditapes decussatus* and *M. galloprovincialis* was inhibited by Pb (Beiras and Albentosa, 2003). In *R. decussatus* an EC_{50} range of 156 to 312 µg Pb/L and LOEC of 156 µg Pb/L were observed for inhibition of embryonic development while in *M. galloprovincialis* the EC_{50} was 221 µg Pb/L and the LOEC was 50 µg Pb/L. Larvae of the mussel *M. edulis* were sensitive to Pb exposure with an EC_{50} of 476 µg Pb/L for abnormal development of embryos following 48 hour exposure to Pb during embryogenesis (Martin et al., 1981). In the marine polychaete *H. elegans* an EC_{50} of 261 µg Pb/L was observed for unhatched or abnormal larvae following 20 hour incubation with Pb (Gopalakrishnan et al., 2008). The 1 hour LC_{50} value for Pb toxicity to eggs in the same species was 692 µg Pb/L while the EC_{50} for the metal concentration causing 5% reduction in larval attachment was 100 µg Pb/L. The EC_{50} values for sperm and egg toxicity were 380 and 690 µg Pb/L, respectively. In a multigenerational study with the marine amphipod *E. laevis*, statistically significant delays in onset of reproduction (4 to 8 days), sexual maturation and first offspring were observed at concentrations of 188 µg Pb/g sediment and higher

(Ringenary et al., 2007). The authors indicate that this concentration is below the current sediment regulatory guideline for Pb (218 µg Pb/g sediment) (NOAA, 1999) and that reproductive effects are a more sensitive endpoint than lethality. The LOEC for embryogenesis in the marine bivalve *M. galloprovincialis* was 50 µg Pb/L with an EC_{50} for embryogenesis of 221 µg Pb/L (Beiras and Albentosa, 2003).

In freshwater aquatic vertebrates there is evidence for reproductive and developmental effects of Pb. Pb exposure in frogs has been demonstrated to delay metamorphosis, decrease larval size and produce skeletal malformations. For example, in northern leopard frog *R. pipiens* exposed to nominal concentrations of 100 µg Pb/L from embryonic stage to metamorphosis, maximum swimming speed was significantly slower than other treatment groups and 92% of tadpoles exposed to 100 µg Pb/L had lateral spinal curvature (compared with 6% in the control) (Chen et al., 2006b). Previous Pb AQCDs have reported developmental effects in fish, specifically spinal deformities in brook trout (*Salvelinus fontinalis*) exposed to 119 µg Pb/L for three generations (U.S. EPA, 1977), and in rainbow trout as low as 120 µg Pb/L (U.S. EPA, 1986b). Reproductive behaviors of fathead minnows including reduced time spent in nest preparation by males, increased interspawn periods and reduced oviposition by females was observed following a 4 week exposure to 500 µg Pb/L (Weber, 1993). In the 2006 Pb AQCD, decreased spermatocyte development in rainbow trout was observed at 10 µg Pb/L and, in fathead minnow testicular damage occurred at 500 µg Pb/L. In fish, there is new evidence of Pb in this ISA on alteration of steroid profiles and additional reproductive parameters. Reproduction in fathead minnows was affected in breeding exposures following 300 day chronic toxicity testing. However, reproductive performance was unaffected in zebrafish exposed to Pb-via consumption of contaminated prey. In one study from a saltwater fish, field collected smooth toadfish (*T. glaber*) from metal contaminated estuaries in Sydney, Australia had elevated Pb levels in gonad and decreased oocyte diameter and density.

Observations of Pb toxicity to reproductive and developmental endpoints in aquatic fauna are further supported by evidence terrestrial invertebrates and vertebrates (Section 7.4.1.4) and from laboratory animals (Section 5.8). Pb appears to affect multiple endpoints associated with reproduction and development in aquatic biota. A few sensitive species have been identified where effects are observed in laboratory studies at concentrations of Pb currently measured in the environment. Overall, there is a dearth of information on reproductive effects of Pb in natural environments, however, the weight of evidence is sufficient to conclude that there is a causal relationship between Pb exposures and developmental and reproductive effects in invertebrates and vertebrates.

In aquatic plants, the evidence is inadequate to conclude a causal relationship between Pb exposures and plant developmental and reproductive effects.

7.4.2.5 Growth Effects-Aquatic Biota

Alterations in the growth of an organism can impact population, community and ecosystem level variables. Growth is a commonly measured endpoint in aquatic plants. Evidence for Pb effects on growth in invertebrates has been observed most extensively in freshwater aquatic taxa, with inhibition in sensitive species occurring at or near the current range of Pb in surface waters. Growth effects observed in both invertebrates and vertebrates underscore the importance of lifestage to overall Pb sensitivity. In general, juvenile organisms are more sensitive than adults.

In the 2006 Pb AQCD, both freshwater algae and plants had EC_{50} values for growth in the range of 1,000 to >100,000 µg Pb/L with minimal inhibition of growth observed as low as 100 µg Pb/L (U.S. EPA, 2006c). The most sensitive aquatic macrophyte reported in the 2006 Pb AQCD was *A. pinnata* with an EC_{50} for relative growth rate of 1,100 µg Pb/L following a 4 day exposure to Pb (Gaur et al., 1994).

Growth effects of Pb on aquatic invertebrates are reviewed in the draft Ambient Aquatic Life Water Quality Criteria for Pb (U.S. EPA, 2008b) and the 2006 Pb AQCD. In the 2006 Pb AQCD, the LOEC for growth of amphipods *H. azteca* in 42-day chronic exposure to Pb was 16 µg Pb/L (Besser et al., 2005). Recent studies provide additional evidence for effects on growth of freshwater aquatic invertebrates at ≤ 10 µg Pb/L. Growth of juvenile freshwater snails *L. stagnalis* was inhibited below the lowest concentration tested resulting in an EC_{20} < 4 µg Pb/L (Grosell and Brix, 2009; Grosell et al., 2006a). In the same study, the NOEC was 12 µg Pb/L and the LOEC was 16 µg Pb/L. The authors indicated that the observed effect level for Pb was very close to the current U.S. EPA water quality criteria for Pb (3.3 µg Pb/L normalized to test water hardness) (Grosell and Brix, 2009). In the freshwater mussel, fatmucket (*L. siliquoidea*) juveniles were the most sensitive lifestage (Wang et al., 2010e). A chronic value of 10 µg Pb/L in a 28 day exposure of 2-month-old fatmucket juveniles was the lowest genus mean chronic value ever reported for Pb. The EC_{20} for reduced growth and emergence of the midge *C. dilutus* was 28 µg Pb/L, observed in a 55-day exposure, while the same species had a 96-hour LC_{50} of 3,323 µg Pb/L (Mebane et al., 2008) The EC_{10} for molting in the mayfly *B. tricaudatus* was 37 µg Pb/L (Mebane et al., 2008). These effects are occurring at or near the current range of Pb concentrations in surface waters (median 0.50 µg Pb/L, range 0.04 to 30 µg Pb/L) (U.S. EPA, 2006c).

Evidence for growth effects of Pb in aquatic vertebrates is limited to a few studies in amphibians and fish. In the 2006 Pb AQCD growth effects of Pb were reported in frogs at concentrations typically higher than currently found in the environment. A new study reviewed in this ISA supports findings of growth effects in frogs and suggests that these effects may be occurring at lower concentrations: the growth rate of tadpoles of the northern leopard frog exposed to 100 µg Pb/L from embryo to metamorphosis was slower than the growth rate of the controls (Chen et al., 2006b). In this study, Pb concentrations in the tissues of tadpoles were quantified and the authors reported that they were within the range of reported tissue concentrations reported in wild-caught populations.

Reports of Pb-associated growth effects in fish are inconsistent and are limited to freshwater species (Mager, 2012). In a review cited in the 2006 Pb AQCD general symptoms of Pb toxicity in fish include growth inhibition (Eisler, 2000) however, other studies with Pb show no growth effect (Mager, 2012). In the studies reviewed for the current ISA no growth effects were observed in fish exposed to Pb via dietary intake. Recent studies with fathead minnows showed significant increases in body length and body mass following chronic low Pb exposure, however, the authors noted that some effects were observed in tanks with high mortality early in the exposure (Mager and Grosell, 2011; Grosell et al., 2006b). Other studies with fathead minnows have shown growth reductions with Pb exposure, however, concentrations of observed effects typically exceeded the 96-hour LC_{50} value (Mager, 2012; Mager et al., 2010; Grosell et al., 2006b). Two 60-day early lifestage tests with rainbow trout showed differences in LOEC for reduced growth (Mebane et al., 2008). In the first test, a 69 day exposure, the LOECs for mortality and reduced growth were the same (54 µg Pb/L). In the second test, a 62 day exposure of Pb to rainbow trout, the LOEC for fish length was 18 µg Pb/L with an EC_{20} of >87 µg Pb/L .

Growth effects associated with exposure to Pb have also been reported in marine species. New studies in marine algae provide evidence for effects of Pb on growth within one to two orders of magnitude of measured levels of Pb in the environment. The lowest 72-hour EC_{50} for growth inhibition reported for marine algae was 105 µg Pb/L in Chaetoceros sp (Debelius et al., 2009). Growth of microalgae *T. suecica* exposed to environmentally relevant concentrations of Pb (20 µg Pb/L) was 40% lower than control cultures (Soto-Jiménez et al., 2011a). The microalgae was the base of a simulated marine food chain including primary, secondary and tertiary level consumers and effects on survival were observed at the higher trophic levels that originated from Pb exposure via consumption of the primary producer. Wang et al., (2009d) observed growth of embryos of the Asian Clam (*M. meretrix*) was significantly reduced by Pb with an EC_{50} of 197 µg Pb/L. In juvenile Catarina scallop, *A. ventricosus*, exposed to Pb for 30 days, the EC_{50} for growth was 4,210 µg Pb/L (Sobrino-Figueroa et al., 2007). Rate of growth of the deposit

feeding polychaete Capitella sp. decreased significantly with increasing concentrations of Pb associated with sediment from polluted estuaries (Horng et al., 2009).

Evidence of effects of Pb exposure on growth in terrestrial plants is highly coherent with evidence from aquatic plants. Evidence is sufficient to conclude that there **is a** causal relationship between Pb exposures and growth effects in aquatic plants and aquatic invertebrates. Evidence is inadequate for a causal relationship between Pb exposures and growth effects in aquatic vertebrates.

7.4.2.6 Survival-Aquatic Biota

The relationship between Pb exposure and survival has been well demonstrated in aquatic species as presented in Section 7.3.5 of this ISA and in the previous Pb AQCDs. Pb exposure can either result in direct lethality or produce sublethal effects that diminish survival probabilities. Survival is a biologically important response that may have a direct impact on population size. However, the concentration typically reported at which there is 50% mortality of test organisms (LC_{50}) is a poor measure for comparing environmental concentrations. LC_{50} is a relevant measure for acute toxicity whereas Pb effects on ecosystem receptors are likely characterized as a chronic, cumulative exposure rather than acute exposure. From the LC_{50} data on Pb in this review and previous Pb AQCDs, a wide range of sensitivity to Pb is evident across taxa and within genera. However, the LC_{50} is usually much higher than current environmental levels of Pb in the U.S, even though physiological dysfunction that adversely impacts the fitness of an organism often occurs at concentrations well below lethal ones. When available, LC_{10}, NOEC or LOEC are therefore reported.

There are no studies reported in the previous Pb AQCDs or the current ISA for aquatic plants that indicate phytotoxicity at current concentrations of Pb in freshwater or saltwater environments.

There is considerable data available on toxicity of Pb to aquatic invertebrates as reviewed in the previous Pb AQCDs and Ambient Water Quality Criteria for Lead (U.S. EPA, 1985). Table AX7-2.4.1 from the 2006 Pb AQCD summarizes LC_{50} data and other endpoints for freshwater and marine invertebrates (U.S. EPA, 2006c). Freshwater invertebrates are generally more sensitive to Pb exposure than other taxa, with survival impacted in a few species at concentrations occurring near point sources or at concentrations that approach ambient levels. These impacted species may include candidate or endangered species. For example, the freshwater mussel *L. rafinesqueana* (Neosho mucket), is a candidate for the endangered species list. The EC_{50} for foot

movement (a measure of viability) for newly transformed juveniles of this species was 188 µg Pb/L. (Wang et al., 2010e).

Freshwater biota that exhibit sensitivity to Pb in the range of Pb concentrations measured in U.S. waters (median 0.50 µg Pb/L, range 0.04 to 30 µg Pb/L (U.S. EPA, 2006c), include some species of gastropods, amphipods, cladocerans and rotifers although the toxicity of Pb is highly dependent upon water quality variables such as DOC, hardness and pH. In the 1986 Pb AQCD, increased mortality was observed in the freshwater gastropod *Lymnaea palutris* at Pb concentration as low as 19 µg Pb/L effectively reducing total biomass production (Borgmann et al., 1978). Toxicity testing with amphipods under various water conditions indicate these organisms are sensitive to Pb at <10 µg Pb/L (U.S. EPA, 2006c) and this ISA). A 7 day LC_{50} of 1 µg Pb/L was observed in soft water with the amphipod *H. azteca* (Borgmann et al., 2005). In this same species, the 96 hour LC_{50} for Pb at pH of 5 was 10 µg Pb/L (Mackie, 1989). In 42-day chronic exposures of *H. azteca* exposed to Pb via water and diet, the LC_{50} was 16 µg Pb/L (Besser et al., 2005). At higher pH and water hardness, amphipods are less sensitive to Pb (U.S. EPA, 2006c). In a series of 48 hour acute toxicity tests with the cladoceran *C. dubia* conducted in a variety of natural waters across North America, LC_{50} values ranged from 29 to 180 µg Pb/L and were most significantly influenced by DOC and water ionic strength (Esbaugh et al., 2011). In the 2006 Pb AQCD the range of 48 hour LC_{50} values for *C. dubia* were reported from 280 to >2,700 µg Pb/L when tested at varying pH levels (U.S. EPA, 2006c). In the rotifer genus *Lecane*, a 22-fold difference in LC_{50} values was observed in 48-hour exposure to Pb between *L. hamata*, *L. luna* and *L. quadridentata*. (Pérez-Legaspi and Rico-Martínez, 2001). *L. luna* was most sensitive to Pb toxicity with a 48-hour LC_{50} of 140 µg Pb/L. In neonate rotifers, *E. dilatata* the 48-hour LC_{50} was 35 µg Pb/L (Arias-Almeida and Rico-Martínez, 2011). Other freshwater invertebrates such as odonates may be tolerant of Pb concentrations that greatly exceed environmental levels. Some invertebrates are able to detoxify Pb such as through sequestration of Pb in the exoskeleton which is subsequently molted.

In aquatic vertebrates, there is considerable historic information on Pb toxicity to freshwater fish. Early observations from mining areas where Pb and other metals were present indicated local extinction of fish from streams (U.S. EPA, 1977). The lowest LC_{50} for fish reported in the 1977 Pb AQCD was 1,000 µg Pb/L in soft water for rainbow trout (*Salmo gairdneri*) following 96-hour exposure to Pb (U.S. EPA, 1977). More recently reviewed studies using fish have considered the role of water quality variables on Pb toxicity. Higher toxicity tends to occur in acidic waters where more free-Pb ion is available for uptake. The interactive effects of Pb concentration and water quality variables on toxicity may result in equivalent toxicity for a broad range of Pb concentrations. In a series of 96-hour acute toxicity tests with fathead minnow conducted

in a variety of natural waters across North America, LC_{50} values ranged from 41 to 3,598 µg Pb/L and no Pb toxicity occurred in three highly alkaline waters (Esbaugh et al., 2011). In the 2006 Pb AQCD, the 96-hr LC_{50} values in fathead minnow ranged from 810->5,400 µg Pb/L in varying pH and hardness (U.S. EPA, 2006c). Decreased survival is also a function of age of the fish. Thirty day LC_{50} values for larval fathead minnows ranged from 39 to 1,903 µg Pb/L in varying concentrations of DOC, $CaSO_4$ and pH (Grosell et al., 2006a). In a recent study of rainbow trout fry at 2 to 4 weeks post swim-up, the 96-hour LC_{50} was 120 µg Pb/L at a hardness of 29 mg/L as $CaCO_3$, a value much lower than in testing with older fish (Mebane et al., 2008).

Data on mortality of saltwater species associated with exposure to Pb is limited; however, in general, marine organisms are less sensitive to this metal than freshwater organisms and the highest toxicity is observed in juveniles. In the marine amphipod *Melita plumulosa*, juveniles were more sensitive to Pb than adults in 96 hour seawater-only exposures and 10 day sediment exposures (King et al., 2006). The 96-hour LC_{50} was 1,520 µg Pb/L for juveniles in comparison to adults (3,000 µg Pb/L). Ten-day exposures of juveniles in seawater resulted in an LC_{50} of 1,270 µg Pb/L, an NOEC of 190 µg Pb/L and a LOEC of 390 µg Pb/L compared to the adult values of 3,560 µg Pb/L. Effects of Pb on survival have been demonstrated though a simulated marine food chain in which the primary producer, the microalgae *T. suecica*, was exposed to 20 µg Pb/L and subsequently fed to brine shrimp *A. franciscana*, (mean Pb content 12 to 15 µg Pb/g) which were consumed by white-leg shrimp *L. vannamei*, itself consumed by grunt fish *H. scudderi* representing the top of the marine food chain (Soto-Jiménez et al., 2011a). Survival of brine shrimp was 25 to 35 % lower than the control and both white shrimp and grunt fish had significantly higher mortalities than controls. Data on Pb toxicity to marine fish is limited. Acute toxicity of Pb to plaice (*Pleuronectes platessa*) ranged from 50 µg Pb/L to 300,000 µg Pb/L depending on the form of Pb (Eisler, 2000). Evidence of effects of Pb on survival in aquatic animals is coherent with evidence in terrestrial ones.

The evidence is inadequate to conclude that there is a causal relationship between Pb exposures and survival in aquatic plants.

The evidence is sufficient to conclude that there is a causal relationship between Pb exposures and survival in aquatic invertebrates and vertebrates.

7.4.2.7 Community and Ecosystem Level Effects-Aquatic Biota

Most direct evidence of community- and ecosystem-level effects in aquatic systems is from near point sources where Pb concentrations are higher than typically observed environmental concentrations for this metal. Impacts of Pb on aquatic habitats that

receive runoff from point sources have been studied for several decades. For aquatic systems, the literature focuses on evaluating ecological stress from Pb originating from urban and mining effluents rather than atmospheric deposition. Ecosystem-level field studies are complicated by the confounding of Pb exposure with other factors such as the presence of trace metals and acidic deposition and by the variability inherent in natural systems. In natural systems, Pb is often found co-existing with other stressors, and observed effects may be due to cumulative toxicity.

In laboratory studies and simulated ecosystems, where it is possible to isolate the effect of Pb, this metal has been shown to alter competitive behavior of species, predator-prey interactions and contaminant avoidance. These dynamics may change species abundance and community structure at higher levels of ecological organization. Uptake of Pb into aquatic and terrestrial organisms and subsequent effects on mortality, growth, physiological stress, blood, neurobehavioral and developmental and reproductive endpoints at the organism level are expected to have ecosystem-level consequences, and thus provide consistency and plausibility for causality in ecosystem-level effects.

In aquatic ecosystems, numerous field studies reviewed in the 2006 Pb AQCD (summarized in Table AX7-2.5.2) and this ISA report reductions of species abundance, richness or diversity. This is particularly the case for benthic macroinvertebrate communities where sources of Pb were mining or urban effluents, and Pb coexisted with other metals. The results often indicate a correlation between the presence of one or more metals and the negative effects observed. For example, in the 2006 Pb AQCD, the Coeur d'Alene River watershed in Idaho, U.S. was used as a case study for Pb effects at the population and community level. Significant negative correlations were observed between Pb in water column and total taxa richness and Ephemeroptera, Plecoptera and Trichoptera (EPT) taxa richness in the river. In a simulated aquatic microcosm a reduction in abundance and richness of protozoan species was observed with increasing Pb concentration from 50 to 1,000 µg Pb/L (Fernandez-Leborans and Antonio-Garcia, 1988).

Since the 2006 Pb AQCD, there is further evidence for effects of Pb in sediment-associated communities and aquatic cyanobacteria communities. Exposure to three levels of sediment Pb contamination (322, 1,225, and 1,465 µg Pb/g dry weight) in a microcosm experiment significantly reduced nematode diversity and resulted in profound restructuring of the community structure (Mahmoudi et al., 2007). Sediment-bound Pb contamination appears to differentially affect members of the benthic invertebrate community, potentially altering ecosystems dynamics in small urban streams (Kominkova and Nabelkova, 2005). Although surface water Pb concentrations in monitored streams were determined to be very low, concentrations of the metal in

sediment were high enough to pose a risk to the benthic community (e.g., 34 to 101 mg Pb/kg). These risks were observed to vary with benthic invertebrate functional feeding group, with collector-gatherer species exhibiting larger body burdens of heavy metals than benthic predators and collector-filterers. Bacterial biomass and diversity of aquatic cyanobacteria communities was reduced in a microcosm following one week exposure to 25 mM Pb (Burnat et al., 2009). Pb exposure impacted individual cyanobacteria species differently, with *Microcoleus* sp. experiencing a greater decrease in abundance than *Halomicronema*-like cyanobacteria.

In a new study conducted since the 2006 Pb AQCD, changes to aquatic plant community composition have been observed in the presence of elevated surface water Pb concentrations at three lake sites impacted by mining effluents. The site with highest Pb concentration (103-118 µg Pb/L) had lowest number of aquatic plant species when compared to sites with lower Pb concentrations (78-92 µg Pb/L) (Mishra et al., 2008). Certain types of plants such as rooted and submerged aquatic plants may be more susceptible to aerially deposited Pb resulting in shifts in Pb community composition. High Pb sediment concentrations are linked to shifts in amphipod communities inhabiting plant structures.

Avoidance response to Pb exposure varies widely in different species and this could affect community composition and structure and species abundance. For example, frogs and toads lack avoidance response while snails and fish avoid higher concentrations of Pb (U.S. EPA, 2006c).

In the Annex to the 2006 Pb AQCD, the Coeur d'Alene River basin in Idaho was presented as a case study for a watershed impacted by Pb and other metals. A significant negative correlation was observed between Pb in water column (0.5 to 30 µg Pb/L) and total taxa richness, EPT taxa richness, and the number of metal-sensitive mayfly species (Maret et al., 2003). Additional lines of evidence including mine density, metal concentrations, and bioaccumulation in caddisfly tissue were included. Since the 2006 Pb AQCD, additional research at this site and model development has resulted in further characterization of the effects of Pb on waterfowl and other biota in this heavily contaminated ecosystem. Mean Pb concentrations in sediment range from 14 to 5,009 mg Pb/kg dry weight (Spears et al., 2007). Modeling of sediment and Pb levels in waterfowl predict a sediment Pb effects range of 147-944 mg Pb/kg dry weight and a mortality effects level of 1,652 mg/kg dry weight (Spears et al., 2007). In a 6-week feeding study with mallard (*Anas platyrhynchos*) ducklings, ingestion of Pb-contaminated sediments from the Coeur d' Alene basin was shown to result in decreased brain growth and altered brain chemistry (Douglas-Stroebel et al., 2004). These findings support previous observations of altered behavior and hematological, hepatotoxic, and histopathological

endpoints in waterfowl from Lake Coeur d'Alene that ingest Pb contaminated sediments and vegetation during feeding.

Fewer studies are available for community and ecosystem effects in saltwater systems. No studies on marine systems were reviewed in the 1977 Pb AQCD or the 1986 Pb AQCD. In a laboratory study with larval mummichogs reviewed in the 2006 Pb AQCD, feeding and predator avoidance behaviors were altered in this marine fish species following a 4 week exposure to Pb (300 to 1,000 µg Pb/L). Observations from field studies reviewed in the 2006 Pb AQCD included findings of a negative correlation between Pb and species richness and diversity indices of macroinvertebrates associated with estuary sediments and changes in species distribution and abundance in fish, crustaceans and macroinvertebrates correlated with Pb levels in marine sediments. In a recent study, significant differences in macroinvertebrate communities associated with seagrass beds were observed between sites with different sediment, biofilm, and leaf Pb concentrations (Marín-Guirao et al., 2005). Sediment Pb concentrations ranged from approximately 100 to 5,000 mg Pb/kg and corresponding biofilm concentrations were 500 to 1,600 mg Pb/kg, with leaf concentrations up to 300 mg Pb/kg. In a laboratory microcosm experiment conducted with estuarine sediments from South Africa, total meiofauna density decreased (range 3 to 5 taxa) after 32 days in Pb-treated (1,886 to 6,710 µg/Pb g sediment dry weight) sediments compared to 9 taxa in the control (3 µg/Pb g sediment dry weight) (Gyedu-Ababio and Baird, 2006).

Most evidence for Pb toxicity to biota is from single-species assays in laboratory studies. Although the evidence is strong for effects of Pb on growth, reproduction and survival in certain species, considerable uncertainties exist in generalizing effects observed under small-scale, particular conditions up to predicted effects at the ecosystem level of biological organization. In many cases it is difficult to characterize the nature and magnitude of effects and to quantify relationships between ambient concentrations of Pb and ecosystem response due to presence of multiple stressors, variability in field conditions and to differences in Pb bioavailability at that level of organization. Nevertheless, evidence of ecosystem effects in aquatic ecosystems is coherent with similar evidence in terrestrial ecosystems, and based on the cumulative evidence from laboratory studies and field data, there is a likely causal relationship between Pb exposures and the alteration of species richness, species composition and biodiversity in aquatic ecosystems.
