Mechanistic support for associations with higher hearing thresholds in children was provided by a few studies that found associations of blood Pb level with lower brainstem auditory evoked potentials in children. Brainstem auditory evoked potentials measure nerve electrical activity and are used to assess neurological auditory function. In prospective analyses of the Mexico City cohort (n = 100, 113), Rothenberg et al. (2000; 1994b) reported associations with prenatal and postnatal blood Pb levels. At age 5-7 years, the shape of the concentration-response relationship differed between prenatal maternal and postnatal (ages 1 and 4 years) blood Pb level. Higher blood Pb level at age 1 year and at age 4 years (mean reported for age 28 months: 10.8 µg/dL) was associated with lower interpeak intervals in auditory evoked potentials. Prenatal maternal blood Pb level showed a biphasic relationship, with lower evoked potentials found with blood Pb levels 1-8 µg/dL and higher evoked potentials found with blood Pb levels 8-30 µg/dL. Results were adjusted for age, sex, and head circumference. In this cohort, maternal first trimester blood Pb levels 10.5-32 µg/dL were associated with supernormal retinal ERG (Rothenberg et al., 2002b), the impact of which on visual impairment is not clear. Associations with lower auditory evoked potentials also were found in small studies (n = 13, 29) of children with higher concurrent blood Pb levels (i.e., range 6-84 µg/dL) than most of the current U.S. population (Holdstein et al., 1986; Robinson et al., 1985).

Recent cross-sectional studies aimed to identify the locus in the auditory system affected by Pb exposure in the examination of a population of children (n = 53, 117, ages 2-18 years) living in Pb glazing communities in Ecuador with higher blood Pb levels than those relevant to current U.S. children (means 33 and 37 µg/dL) (Buchanan et al., 2011; Counter et al., 2011). Concurrent blood Pb level was not correlated with the acoustic stapedius reflex (Counter et al., 2011) or distortion product otoacoustic emissions (Buchanan et al., 2011), indicating lack of effect on the auditory brainstem or inner ear, respectively. Other loci were not examined, and potential confounding was not considered.

5.3.7.2 Epidemiologic Studies of Sensory Organ Function in Adults

Studies of auditory function reviewed in the 2006 Pb AQCD consistently indicated associations between blood Pb levels and changes in auditory evoked brainstem potentials in occupationally-exposed adults but found less consistent associations with hearing thresholds (U.S. EPA, 2006b). A few recent studies found increases in hearing thresholds in Pb-exposed workers. A recent analysis of the NAS provided evidence in nonoccupationally-exposed men for associations of tibia Pb levels with hearing loss.

Among 448 men in the NAS, higher tibia Pb level (mean: 22.5 μg/g) at mean age 64.9 years, measured up to 20 years after initial hearing testing, was associated with a faster rate of increase in hearing threshold for frequencies of 1, 2, and 8 kHz and a pure tone average. Men were free of hearing loss at baseline and had hearing tested repeatedly (median 5 times per subject) over a median of 23 years (Park et al., 2010). Blood Pb was not examined. In cross-sectional analyses adjusted for age, race, education, body mass index, pack-years of cigarettes, diabetes, hypertension, occupational noise (based on a job-exposure estimate), and presence of a noise notch (indicative of noise-induced hearing loss), higher patella Pb level (mean 32.5 μg/g, measured within 5 years of hearing test) was associated with a higher hearing threshold for frequencies greater than 1 kHz. A 21 μg/g (interquartile range) increase in patella Pb level was associated with pure tone average hearing loss with an OR of 1.48 (95% CI: 1.14, 1.91) in adjusted analyses. Similar, but slightly weaker associations were found for tibia bone Pb levels. In the NAS, bone Pb levels were measured after the initial hearing measurement but reverse causation is unlikely since bone Pb is an indicator of cumulative Pb exposure, and tibia Pb has a half-life on the order of decades (Section 4.3). Bone Pb levels increase with age, and although age was included as a model covariate, residual confounding by age is possible.

Recent cross-sectional studies added evidence for associations between higher concurrent blood Pb levels and higher hearing thresholds in adults with occupational Pb exposures. A hospital-based case-control study examined workers from diverse occupations and examined potential confounding by other occupational exposures. Cases included workers referred for hearing testing (average hearing thresholds above 25 dB), and controls comprised workers with normal hearing thresholds who were having routine occupational health examinations (Chuang et al., 2007). Geometric mean blood Pb levels were 10.7 μg/dL for the 121 cases and 3.9 μg/dL for the 173 controls. In models that adjusted for age, smoking, alcohol consumption, years of noise exposure, as well as Mn, As, and Se levels in blood, higher blood Pb levels were associated with higher hearing threshold (0.5-6 kHz). The potential selection bias arising from the nonrandom population sample may limit implications of these findings. Other studies found associations of higher concurrent blood Pb level with increased hearing thresholds or

hearing loss in Pb-exposed workers (n = 183-259) but had limited or no consideration for potential confounding (Forst et al., 1997) and/or examined workers with mean blood Pb levels >50 µg/dL (Hwang et al., 2009; Wu et al., 2000).

5.3.7.3 Toxicological Studies of Sensory Organ Function

Effects on Auditory Function

The 2006 Pb AQCD (U.S. EPA, 2006b) described impaired auditory function in nonhuman primates exposed to lifetime Pb beginning in gestation or birth to ages 8-13 years (resulting in blood Pb levels 33-170 µg/dL during or just after Pb exposure) (Rice, 1997; Lilienthal and Winneke, 1996). Pb-related effects persisted after Pb exposure was terminated, and blood Pb levels had returned to baseline. Recent studies provided similar evidence with lower Pb exposures and blood Pb levels. These observations in animals are consistent with the epidemiologic associations described above (Sections 5.3.7.1 and 5.3.7.2) but were related to higher Pb exposures than those relevant for humans. Monkeys with lifetime Pb exposure from birth to age 13 years were found to have decrements in auditory function, as evidenced by elevated thresholds and increased latencies in brainstem auditory evoked potentials. Further, half of the pure tone detection thresholds were above the control range at certain frequencies (Rice, 1997). In addition to indicating hearing loss, brainstem auditory evoked potentials can indicate impaired synaptic maturation and incomplete neuron axon myelination leading to impaired neuronal conduction (Gozdzik-Zolnierkiewicz and Moszyński, 1969). Thus, the findings from Rice (1997) and those described in the preceding sections for children may indicate that Pb exposure impairs auditory nerve conduction. Studies in animals with blood Pb levels >300 µg/dL found that the cochlear nerve was especially sensitive to Pb exposure (Gozdzik-Zolnierkiewicz and Moszyński, 1969).

In a recent study, Laughlin et al. (2009) studied rhesus monkeys exposed to Pb acetate prenatally to birth or postnatally from birth through weaning at age 5.5 months (maternal drinking water, 3 months prior to mating until weaning, resulting in bone Pb levels at age 11 years of 7 and 13 µg/g for prenatal and postnatal groups, respectively, and blood Pb levels during Pb exposure of 35 and 46 µg/dL, respectively). Auditory threshold testing and threshold task testing was conducted at 13 years of age after blood Pb levels had returned to those found in controls. At birth, animals were cross fostered, creating a control group, a prenatal Pb group, and a postnatal Pb group; however, Pb-exposed animals were analyzed as a single group. Pb exposure induced small, statistically nonsignificant elevations in auditory thresholds in animals. Auditory threshold task-related behavioral testing was also impaired in Pb-exposed animals. This study has

multiple limitations that could have contributed to that lack of statistically significant aberrations, including limited power with the examination of 5 animals per group, the inability of some of the monkeys to engage or focus on the task at hand which resulted in fewer available measurements, differences between the sexes in inattention, and mixing of the postnatal Pb and prenatal Pb-exposed animals into one group.

Effects on Vision

The 1986 and 2006 Pb AQCDs (U.S. EPA, 2006b) detailed the effects of Pb exposure during perinatal development and adulthood on the visual system of animals, including reduced visual acuity and supporting mechanisms of action such as alterations in the retina (Fox et al., 1997; Fox and Sillman, 1979), CNS visual processing areas (Costa and Fox, 1983), and subcortical neurons involved in vision (Cline et al., 1996). For example, environmentally-relevant doses of Pb (10^{-3} µM) in tadpoles inhibited the growth of neurons in the subcortical retinotectal pathway, the main efferent from the retina (Cline et al., 1996). Pb-related aberrations in electrical responses in retinal cells, as measured by electroretinograms (ERGs), have been found in rodents, nonhuman primates, and children. Recent research expands upon the extant evidence by examining effects in animals with lower Pb exposures or blood Pb levels.

Extensive work in nonhuman primates with Pb exposure during development or over a lifetime (peak blood Pb levels 50-115 µg/dL) showed dysfunction in temporal visual function (responses to different frequencies of light flicker) under high luminance but no change in spatial function (Rice, 1998). A recent study found no effects of Pb exposure on spatial acuity as assessed with the modified Teller preferential looking paradigm (Laughlin et al., 2008) in rhesus monkeys exposed to Pb acetate postnatally (PND8-age 26 weeks via commercial milk formula, producing blood Pb levels of 35-40 µg/dL). In monkeys, effects on vision were tested with higher Pb exposures than those relevant to humans. Low-level developmental Pb exposure was found to result in sensorimotor deficits in adult zebrafish (Rice et al., 2011). Fish that were exposed as embryos (2 to 24 hours post-fertilization) to water containing 0.03 µM $PbCl_2$ had impaired response to visual stimulation (a rotating bar) under low light conditions. These zebrafish also failed to respond normally to mechanosensory stimulation (0.01 and 0.03 µM $PbCl_2$), showing a significantly impaired startle response.

Animal toxicological evidence also shows that the lifestage of exposure and the dose of Pb contribute to the complex and variable effects of Pb on the retina, as assessed by ERG (summarized in Table 5-13). The biological relevance of these variable findings is uncertain. Female rats exposed postnatally to 200 or 2,000 ppm Pb acetate exposure via dam drinking water from birth through lactation, resulting in blood Pb levels of 19 and

59 μg/dL at weaning, respectively, had subnormal scotopic ERGs (decreased A- and B-wave amplitudes) with decreased sensitivity and temporal resolution when assessed at 90 days of age (Fox et al., 1991). Similar results were obtained in multiple studies conducted in in vitro models (Otto and Fox, 1993; Fox and Farber, 1988; Fox and Chu, 1988). Monkeys exposed to relatively high levels of Pb continuously from the prenatal period to age 7 years (350 or 600 ppm Pb acetate, resulting in blood Pb levels of 40 and 50 μg/dL, respectively) had persistently increased maximal retinal ERG amplitude (B-wave only, supernormality) and increased mean ERG latency when assessed 2 years after Pb exposure was terminated when blood Pb levels were <10 μg/dL (Lilienthal et al., 1988).

Table 5-13 Summary of Pb-related effects observed on the visual system.

Study	Species	Sex	Pb Exposure Protocol/Dose	Maximal Blood Pb Level (µg/dL)	ERG Abnormality	Progenitor cell proliferation	Retinal Cellular Apoptosis	Retinal Dopamine Levels	Retinal Cell Layer Thickness
Fox et al. (2008)	Long-Evans Rat	F	Prenatal-PND10 DW						
			Low, 27 ppm	12	Supernormal	Yes	Not affected	Dose-dependent ↓	↑
			Moderate, 55 ppm	24	Supernormal	Yes	Not affected	Dose-dependent ↓	↑
			High, 109 ppm	46	Subnormal	No	Yes	Dose-dependent ↓	↓
Lilienthal et al. (1988)	Rhesus Monkey	M & F	Prenatal-lifetime, DW						
			350 ppm	~50	Supernormal	—	—	—	—

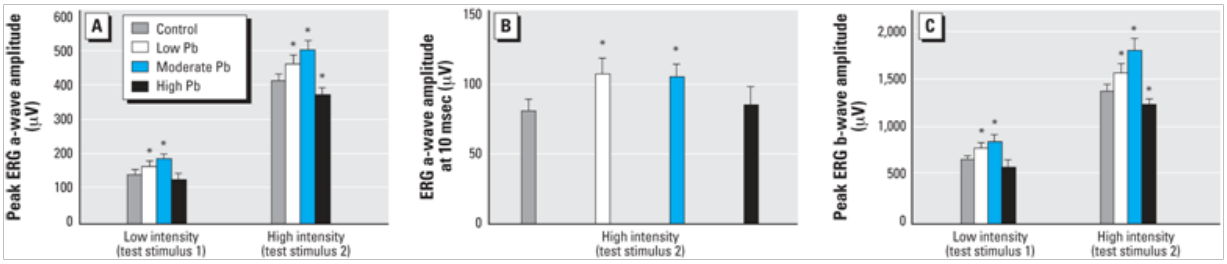
Pb exposure beginning in the gestational period (Pb acetate in drinking water from 2 weeks before mating to PND10) also induced supernormal ERGs in adult Long-Evans rats, but only with low (27 ppm) and moderate (55 ppm) doses that produced blood Pb levels 10-12 µg/dL and 21-24 µg/dL (Fox et al., 2008) (Figure 5-12 and Table 5-13). This exposure window represents the developmental period for the retina of the rat and is analogous to gestational human retinal development. Subnormal ERGs were induced by the high 109 ppm dose (Figure 5-12), which produced blood Pb levels 40-46 µg/dL. Results of this rodent study demonstrated persistent supernormal scotopic rod photoreceptor-mediated ERGs in animals with blood Pb levels relevant to humans. These findings were consistent with the associations observed between supernormal ERG and prenatal maternal blood Pb levels ≥ 10.5 µg/dL in male and female children (Rothenberg et al., 2002b). The functional relevance of findings is uncertain as supernormal scotopic ERGs may be recorded without other overt ophthamalogic changes and are rarely seen in the clinical setting (Terziivanov et al., 1982).

Animal studies indicate that the dose of Pb and the exposure lifestage not only differentially affect functional tests, i.e., ERG but also differentially affect retinal cell numbers and morphology. Concomitant with Pb-induced supernormal ERGs, Fox et al. (2008) found that 27 and 55 ppm gestational plus early postnatal Pb exposure increased neurogenesis of rod photoreceptors and rod bipolar cells without affecting apoptosis of Müller glial cells and increased the number of rods in central and peripheral retina (Table 5-13). Concomitant with subnormal ERGs, higher-level gestational plus early postnatal Pb exposure (109 ppm, blood Pb level 40-46 µg/dL) decreased the number of rods in the central and peripheral retina (Fox et al., 2008). Early postnatal (PND1-PND21) Pb exposure (200 or 2,000 ppm, producing blood Pb levels 19 and 59 µg/dL) induced scotopic ERG subnormality in adult rats, decreased the number of rods in the central and peripheral retina, and decreased the retinal Zn concentration (Fox et al., 1997) (Table 5-13). Similar observations were made in separate work in mice. Low and moderate doses of Pb from gestation to PND10 (27 or 55 ppm Pb acetate in dam drinking water, producing blood Pb levels of 12 and 25 µg/dL, respectively) induced greater and prolonged rod bipolar cell neurogenesis and greater thickness and cell number of the outer and inner neuroblastic layers of the retina (Giddabasappa et al., 2011). As in rats, at higher doses of Pb (109 ppm Pb acetate, resulting in blood Pb levels of 56 µg/dL), there was no increased rod neurogenesis in mice. Nitric oxide has been shown to regulate retinal progenitor cell proliferation in chick embryos (Magalhaes et al., 2006). Thus, these authors postulated that impaired NO production may contribute to aberrant retinal cell proliferation (Giddabasappa et al., 2011).



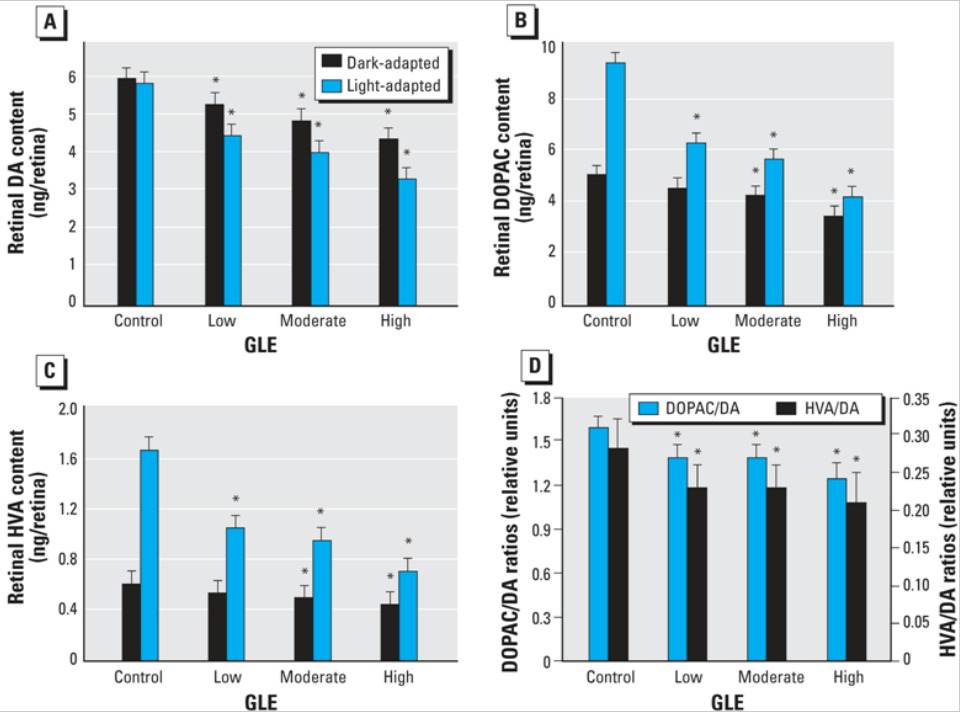
Note: *p <0.05. Low Pb = 27 ppm, blood Pb level 10-12 µg/dL, Moderate Pb = 55 ppm, blood Pb level 21-24 µg/dL, High Pb = 109 ppm, blood Pb level 40-46 µg/dL. Relative to controls (gray bars), low (white bars) or moderate (blue bars) Pb exposure from gestation through postnatal day 21 induced supernormal electroretinograms (ERGs) whereas high Pb exposure (black bars) induced subnormal ERGs.

Source: Fox et al. (2008)

Figure 5-12 Retinal a-wave and b-wave ERG amplitude in adult rats after prenatal plus early postnatal Pb exposure.

Mechanistic understanding of the effect of Pb on the visual system includes the capability of Pb to displace divalent cations, inhibit physiological enzymes, regulate cell proliferation and apoptosis, perturb normal neuroanatomical formation (cytoarchitecture in the brain), and affect neurotransmitters. The effects of Pb on the retina were shown to be mediated by its inhibition of cGMP phosphodiesterase (PDE) (Srivastava et al., 1995; Fox and Farber, 1988). Independent of Pb exposure, pharmacological inhibition of cGMP PDE has been linked with visual problems including alterations in scotopic ERGs (Laties and Zrenner, 2002). Postnatal Pb exposure of animals (peak blood Pb levels: 19, 59 µg/dL) or in vitro Pb exposure of rods isolated from these animals elevated cGMP which contributed to elevated rod calcium concentration (Fox and Katz, 1992) and subsequently induced apoptotic cell death in a concentration-dependent manner.

Pb has been shown to affect a plethora of neurotransmitters in the brain, and it has recently been shown to affect neurotransmitters in the retina. With the aforementioned gestational to PND10 exposure, Pb induced concentration-dependent decreases in adult rat retinal synthesis of dopamine, which has functions in retinal growth and development and signal transduction in rods and cones (Fox et al., 2008) (Figure 5-13). As discussed in the 2006 Pb AQCD (U.S. EPA, 2006b), other mode of action support for the effects of Pb on the visual system is provided by observations of Pb-induced decreased Na^+/K^+ATPase activity which have been reported in vitro and in vivo. Also, structural changes from chronic Pb exposure (birth to age 6 years) included cytoarchitectural changes in visual projection areas of the brain of monkeys; maximum blood Pb level in the low and high dose group reached 20 µg/dL and 220 µg/dL, respectively (Reuhl et al., 1989).



Note: *p <0.05. GLE = Gestational Pb exposure to postnatal day 10. Low Pb = 27 ppm, blood Pb levels 10-12 µg/dL, Moderate Pb = 52 ppm, blood Pb levels 21-24 µg/dL, High Pb = 109 ppm, blood Pb levels 40-46 µg/dL. A. DA = dopamine, B. DOPAC = dopamine metabolite, C. HVA = dopamine metabolite, D. DOPAC/DA = ratio of dopamine metabolite to dopamine. Pb exposure decreased dopamine, DOPAC, HVA, and DOPAC/DA in a concentration-dependent manner in light-adapted animals (blue bars). In dark adapted animals (black bars), Pb exposure decreased dopamine, DOPAC, and DOPAC/DA but not always in concentration-dependent manner.

5.3.7.4 Summary of Sensory Function

Children

Several studies indicated that higher blood Pb levels are associated with decrements in auditory function in children ages 3-19 years, as evidenced by increases in hearing thresholds. Results from the prospective Cincinnati cohort study (n = 215) provide key evidence for associations of neonatal, yearly age 1 to 4 year, and lifetime average blood Pb levels with increased hearing thresholds at age 57 months (Dietrich et al., 1992), and large (n = 3,000-4,000) cross-sectional analyses of children participating in NHANES and HHANES provide supporting evidence for concurrent blood Pb levels (Schwartz and Otto, 1991, 1987). The examination of multiple exposures and outcomes in NHANES and HHANES reduces the likelihood of participation conditional on Pb exposure and

hearing function. In the Cincinnati cohort, mean blood Pb levels were 4.8 µg/dL for neonatal and 17.4 µg/dL for lifetime average. In HHANES, the median concurrent blood Pb levels was ~8 µg/dL. Across studies, associations were found with adjustment for factors such as age, sex, ethnicity, family income, concurrent or past colds, antibiotic use, degree of urbanization, and Apgar score. Potential confounding by parental education, nutritional factors, environmental noise, and maternal smoking also was considered.

Mechanistic evidence was provided by observations of associations between blood Pb level with lower auditory evoked potentials in children, particularly associations found in the prospective analysis of children in Mexico City with prenatal, age 1 year, and age 4-year blood Pb levels (Rothenberg et al., 2000). Biological plausibility is provided by evidence in animals indicating increased thresholds and increased latencies in brainstem auditory evoked potentials in nonhumans primates with multi-year postnatal Pb exposure beginning at birth (Rice, 1997; Lilienthal and Winneke, 1996), although auditory assessment were made in adult animals ages 8-13 years. Pb exposure limited to the gestational period or to the postnatal period to age 5 months was found to have weaker effects (Laughlin et al., 2009). In animals, auditory effects were found with higher blood Pb levels (i.e., 33-170 µg/dL) than those relevant to humans; thus, it is difficult to ascertain support for observations in children.

Maternal first trimester blood Pb levels 10.5-32 µg/dL were associated with supernormal retinal ERGs in children in Mexico City at ages 5-7 years (Rothenberg et al., 2002b). The animal evidence showed ERGs in different directions depending on lifestage of Pb exposure and blood Pb level. Supernormal ERGs were found in adult rats with prenatal plus early postnatal (PND10) Pb exposure that produced blood Pb levels of 12 and 24 µg/dL (Fox et al., 2008). The implications of supernormal ERGs on visual impairment is not clear, and the biological relevance of the nonlinear concentration-response is not clear. For these reasons, the evidence for the effects of Pb on retinal ERGs was not a major consideration in drawing conclusions about the effects of Pb exposure on sensory function. In these animals, Pb exposure also increased rod cell neurogenesis and decreased dopamine. Toxicological studies demonstrated a range of other effects on the visual system including impaired visual function, and potential mechanisms such as alterations in morphology and cell architecture, signaling, enzyme inhibition, neurotransmitter levels, neuroanatomical development, cell proliferation, and retinal cell apoptosis.

Adults

In adults, increased hearing thresholds or hearing loss were associated with bone Pb levels in 448 NAS men who were unlikely to have had occupational Pb exposures (Park et al., 2010) and with concurrent blood Pb levels in adults with current occupational Pb exposure. In the NAS, the examination of multiple exposures and outcomes reduces the likelihood of participation conditional on Pb exposure and hearing function. Among NAS men, higher tibia Pb levels were associated with a faster rate of increase in hearing thresholds over a 23 year follow-up with adjustment for age, race, education, body mass index, pack-years of cigarettes, diabetes, hypertension, occupational noise, and presence of a noise notch. Tibia Pb levels were measured up to 20 years after initial hearing testing, and while Pb in tibia has a half-life on the order of decades, there is uncertainty regarding the temporal sequence with changes in hearing thresholds. Temporality also is difficult to establish in the cross-sectional occupational studies. A hospital-based case control study found an association between higher concurrent blood Pb levels and higher hearing thresholds among workers with relevant blood Pb levels (means 10.7 and 3.9 µg/dL in workers with and without hearing problems, respectively) (Chuang et al., 2007). Among other factors, results were adjusted for other occupational exposures. Biological plausibility is provided by evidence in animals with lifetime Pb exposure but with higher blood Pb levels (i.e., 33-107 µg/dL) than those relevant to humans. Adult monkeys were found to have supernormal ERGs with developmental or lifetime Pb exposure that produced blood Pb levels of 50 and 115 µg/dL (Rice, 1998); however, Pb-associated visual system effects in human adults are not well characterized.

5.3.8 Motor Function

Some studies in children have assessed fine motor function, i.e., response speed, dexterity, as part of a battery of neurodevelopmental testing, and most have found associations with blood Pb level. Fewer studies have examined gross motor function, i.e., postural balance, action tremor, agility, but also have found associations with blood Pb level in children. Poorer motor function also was found in Pb-exposed workers.

Key evidence from the prospective studies of the Cincinnati and Yugoslavia cohorts demonstrated associations of blood Pb levels with poorer motor function with either adjustment for or consideration for several potential confounding factors related to SES, parental caregiving quality and education, smoking exposure, birth outcomes, sex, and child health. In the Cincinnati cohort, higher earlier childhood average blood Pb levels (0-5 year average or 78 month, exact levels not reported) were associated with poorer fine (n = 195) (Ris et al., 2004) and gross motor function (n = 91) (Bhattacharya et al.,

2006) assessed in adolescence (ages 12, 15-17 years). In this cohort recruited from birth, follow-up participation was high and not conditional on blood Pb levels. The fine motor function results were adjusted for maternal IQ, SES, HOME score, and adolescent marijuana consumption. Collectively, these findings suggest the persistence of effects of earlier childhood Pb exposure to later childhood; however, later childhood or concurrent blood Pb levels were not examined. Assessments in Cincinnati cohort children at age 6 years indicated associations of concurrent (mean: 11.66 µg/dL), lifetime average (mean: 12.3 µg/dL), and neonatal (mean: 4.8 µg/dL) but not prenatal maternal (mean: 8.4 µg/dL) blood Pb levels with poorer upper limb dexterity, fine motor composite score (n = 245) (Dietrich et al., 1993a), and poorer postural balance (n = 202) (Bhattacharya et al., 1995). These results were adjusted for HOME score and race. Additional covariates included maternal IQ, SES, and sex for fine motor functions (Dietrich et al., 1993a) and height, BMI, birth weight, bilateral ear infection, and foot area for postural balance (Bhattacharya et al., 1995). Blood Pb levels were associated with fine and gross motor function in unadjusted and adjusted analyses, increasing confidence that confounding by the examined covariates did not unduly bias the observed associations. Prospective analysis of the Yugoslavian cohort indicated an association of lifetime average blood Pb level (exact levels not reported) with decrements in fine but not gross motor function at age 4.5 years in 283 children (Wasserman et al., 2000). Although only 50% of the cohort was examined, and participation was greater among children with lower SES and HOME score, participation was not conditional on higher blood Pb levels.

Supporting evidence was provided by most cross-sectional studies of motor function, which found that concurrent blood Pb level was associated with poorer fine motor function in children in Asia and Canada ages 3-16 years (n = 61-814) (Palaniappan et al., 2011; Min et al., 2007; Despres et al., 2005). In exception, Surkan et al. (2007) found that higher concurrent blood Pb level was associated with better fine motor function as indicated by faster finger tapping speed among 534 children in New England. This study examined lower blood Pb levels than other studies (mean: 2.2 µg/dL) but a similar age range (6-10 years) and set of potential confounding factors (age, sex, caregiver IQ, SES, race). Concurrent blood Pb level (mean: 5.0 µg/dL) was associated with greater sway oscillation, alternating arm movements, and action tremor in 110 Inuit children (ages 4-6 years) in Quebec, Canada (Despres et al., 2005) with consideration for potential confounding by factors such as HOME score, maternal education and several nutrient levels. The population of Inuit children was selected from subsistence fishing communities, who have higher exposure to Hg and polychlorinated biphenyls. Several indices of fine and gross motor function were associated with blood Pb level, with adjustment for these other exposures. Min et al. (2007) found impaired fine motor function in 61 children in Korea with a mean concurrent blood Pb level of 2.9 µg/dL; however, the results were not adjusted by SES-related variables.

An association of Pb exposure with poorer motor function in adults was found in Pb-exposed workers (Iwata et al., 2005), although implications are limited by the cross-sectional design, high concurrent blood Pb levels (mean: 40 µg/dL), and lack of consideration for potential confounding by other occupational exposures. Among 121 Pb smelter workers in Japan, higher blood Pb level was associated with greater sagittal sway with eyes open ($p < 0.05$) and eyes closed ($p < 0.01$) and transversal sway with eyes closed ($p < 0.05$) with adjustment for age, height, smoking status, and drinking status. The authors calculated a benchmark dose level (Budtz-Jorgensen et al., 2001; NRC, 2000) of 14.3 µg/dL from a linear concentration-response model. A supralinear concentration-response function was found to fit the data slightly better than was a linear function.

Pb exposure has shown mixed effects on endurance, balance, and coordination in animals as measured by rotarod performance and treadmill testing. Lower concentration gestational plus early postnatal (to PND10) Pb exposure (27 ppm, producing peak blood Pb level ≤ 10 µg/dL at PND0-PND10) resulted in significantly poorer rotarod performance (i.e., falling off more quickly) than did higher exposure (109 ppm, blood Pb level: 33-42 µg/dL) in male (but not female) adult mice, indicative of a nonlinear concentration-response relationship (Leasure et al., 2008). Other rotarod experiments examining various speeds of rotarod rotation and higher Pb exposures producing blood Pb levels >60 µg/dL, some administered by routes with uncertain relevance to humans, yielded mixed results (Kishi et al., 1983; Grant et al., 1980; Overmann, 1977). Herring gull chicks injected with a single i.p. bolus dose of Pb (100 mg/kg Pb acetate, a dose selected to represent exposure in the wild) had slower development of motor skills versus control birds, as assessed by the treadmill test (Burger and Gochfeld, 2005).

In summary, epidemiologic evidence demonstrates associations of higher blood Pb levels with poorer fine and gross motor function in children ages 3-17 years. Little evidence is available in adults. Prospective analyses of the Cincinnati and Yugoslavia cohorts (n = 91-283) that considered several potential confounding factors such as SES and child health found associations with earlier childhood blood Pb levels (i.e., age 78 month, 0-5 year average) in adolescents (Bhattacharya et al., 2006; Ris et al., 2004) and neonatal, lifetime average, and concurrent blood Pb levels in children ages 4-6 years (Wasserman et al., 2000; Bhattacharya et al., 1995; Dietrich et al., 1993a). In the Cincinnati cohort, neonatal blood Pb levels were lower than concurrent or lifetime average blood Pb levels at age 6 years (means 4.8, 11.7, 12 µg/dL, respectively). In cross-sectional studies that examined similar potential confounding factors, results were inconsistent in populations with lower blood Pb levels (means <5 µg/dL) (Surkan et al., 2007; Despres et al., 2005).

5.3.9 Seizures in Animals

Previous studies did not consistently show that Pb exposure induced seizures in animals. Pb-induced seizures were found in male Wistar rats exposed to Pb acetate postnatally (250-1,000 ppm in drinking water PND30-PND60, resulting in blood Pb levels of ~20-42 µg/dL), as indicated by a decrease in the elapsed time required to develop the first myoclonic jerk and tonic-clonic seizure (Arrieta et al., 2005). Also, the dose of the seizure-inducing agent pentylenetetrazol (PTZ) required to induce seizures significantly decreased in all Pb dose groups. Other studies showed no effect of Pb exposure on seizures (Schwark et al., 1985; Alfano and Petit, 1981). In a study of early postnatal Pb acetate exposure (2,000 ppm in drinking water PND1-PND25), Pb had variable effects on induction of seizures in Sprague Dawley rats examined at PND25 or PND50, depending on the convulsant-inducing agent administered (Chen and Chan, 2002). Chen and Chan (2002) hypothesized that the variable effects may be due to the selective effects on inhibitory and excitatory neurotransmission by age and blood Pb level, which were 47 µg/dL and 11 µg/dL at PND25 and PND50, respectively.

Recent investigation expanded on the work by Arrieta et al. (2005) by showing that Pb exposure may induce seizure activity in another rodent species, BALB/c mice. Adult (ages 2-3 months) male BALB/c mice were exposed to Pb acetate for 30 days via drinking water (range of blood Pb levels 50-400 ppm Pb groups: 6.4-18 µg/dL) (Mesdaghinia et al., 2010). Except for 50 ppm Pb exposure, all other Pb concentrations significantly reduced the thresholds of face and forelimb clonus, myoclonic twitch, running and bouncing clonus, and tonic hindlimb extension. In a study of adult male Wistar rats, Pb administration by bolus injection (200 mg/kg Pb acetate or 50 mg/kg Pb nitrate, single injection, 2 days, blood Pb levels >20 µg/dL) also induced epileptic form activity or seizures (Krishnamoorthy et al., 1993).

5.3.10 Neurodegenerative Diseases

5.3.10.1 Alzheimer's Disease

Higher bone Pb level in NAS men (Wang et al., 2007a; Weisskopf et al., 2004; Wright et al., 2003) but not blood Pb level in adults in Sweden (Nordberg et al., 2000) has been associated lower scores on the MMSE, which is widely used as a screening tool for dementia. Direct evidence regarding the effects of Pb exposure on Alzheimer's disease is limited to studies reviewed in the 2006 Pb AQCD (U.S. EPA, 2006b), which did not find higher occupational exposure to Pb (Graves et al., 1991) or Pb level in the brains (Haraguchi et al., 2001) in Alzheimer's disease cases than healthy controls. Overall, the latter studies have sufficient limitations (e.g., case-control design that may be subject to reverse causation, lack of blood or bone Pb measures, limited consideration for potential confounding) such that evidence is inconclusive regarding the effect of Pb exposure on Alzheimer's disease.

Despite inconclusive epidemiologic evidence, toxicological evidence indicates that Pb exposure in early life promotes Alzheimer's disease-like pathologies in the brains of aged adult animals. Alzheimer's disease is characterized by amyloid-beta peptide (Ab) plaques, hyper-phosphorylation of the tau protein, neuronal death and synaptic loss. In the last decade, the developmental origins of adult health and disease paradigm and the similar Barker hypothesis have indicated that early life exposures can produce aberrant effects in adults. Bolin et al. (2006) demonstrated the connection between developmental exposure to Pb in the rat and inflammation-associated DNA damage with neurodegenerative loss in the adult brain. Wu and colleagues (2008a) had similar findings in a study examining infantile Pb exposure of monkeys. These results suggest the need to directly examine the long-term effects of developmental exposure to toxicants rather than relying on adult exposure alone to predict potential health risks in adults (Dietert and Piepenbrink, 2006).

The fetal basis of amyloidogenesis has been examined extensively by the Zawia laboratory in both rodents and nonhuman primates. Mechanistically, Ab plaques originate from the cleavage of the amyloid precursor protein (APP). In male rodents exposed to Pb as infants (200 ppm Pb acetate PND1-PND20 in dam drinking water, resulting in pup PND20 blood Pb level of 46 µg/dL and cortex 0.41 µg/g wet weight of tissue) or as adults, infancy Pb exposure induced APP gene expression in the aged animal brains. A bimodal response was observed, with a significant increase in APP expression above that in control animals first manifesting in infancy and again in old age (82 weeks) (Basha et al., 2005). A concomitant bimodal response was observed in specificity protein 1 (Sp1), a

transcription factor involved in gene expression in the early development of an organism and known to be related to APP expression. Ab was also significantly elevated in the aged animals developmentally exposed to Pb. Adult-only (18-20 weeks) exposure to Pb did not alter APP or Sp1 expression or Ab production.

Consistent with findings in rodents, Wu et al. (2008a) found that Pb exposure in infancy (PND1-PND400, 1.5 mg/kg/day in infant formula) resulted in significantly higher gene expression of APP and Sp1 and significantly higher protein expression of APP and Ab in aged female monkey cortex tissue (23 year-old *Macaca fascicularis*) from a cohort of animals established in the 1980s by Rice (1992a, 1990). At PND400, the monkeys had blood Pb levels of 19-26 µg/dL. In old age when amyloid plaques had manifested, blood Pb levels and brain cortex Pb levels had returned to control levels. Together, the rodent and nonhuman primate evidence concurs, and indicates that developmental Pb exposure and not adult-only exposure induces elevations in neuronal Alzheimer's Disease-related plaque proteins in aged animals.

Mechanistic understanding of Ab production and elimination after Pb exposure was examined in human SH-SY5Y neuroblastoma cells exposed to Pb concentrations of 0, 5, 10, 20, and 50 µM for 48 hours. Pb was found to affect two separate pathways to increase Ab. Pb exposure induced both the overexpression of APP and repression of neprilysin, a rate-limiting enzyme involved in Ab metabolism or removal (Huang et al., 2011a). Further mechanistic understanding of how Ab peptide formation is affected by Pb exposure was provided by Behl et al. (2009). The choroid plexus is capable of removing beta-amyloid peptides from the brain extracellular matrix. Pb was shown to impair this function, possibly via the metalloendopeptidase, insulin-degrading enzyme (IDE), which metabolizes Ab (Behl et al., 2009). In another study, lactational Pb exposure of Long-Evans hooded rat pups induced perturbations in DNA binding of SP1 via its Zn finger protein motif (Basha et al., 2003). This effect of Pb was ameliorated by exogenous Zn supplementation.

An additional study with gestational plus lactational Pb exposure (1,000-10,000 ppm, dam drinking water, resultant offspring blood Pb levels: 40-100 µg/dL) showed that the rodent hippocampus as early as PND21 contained neurofibrillary changes, commonly used a marker for Alzheimer's disease. These changes manifested with hyper-phosphorylated Tau, which comprises neurofibrillary tangles, and increased tau and beta amyloid hippocampal protein levels (Li et al., 2010b).

In summary, recent studies showed that Pb exposure of rats and monkeys during infancy or during gestation/lactation induced significant increases in neuronal plaque associated proteins such as Ab-peptide, activation of Ab-supporting transcription factors, and hyperphosphorylation of tau, all of which are pathologies found in humans with

Alzheimer's disease. These pathologies were not found with adult-only Pb exposure of animals, further demonstrating that early life Pb is a critical window for Pb-induced Alzheimer's-like pathologies in animals. The few epidemiologic studies have not linked higher Pb exposure with Alzheimer's disease. These case-control studies lacked assessment of blood or bone Pb levels or consideration for potential confounding. The animal evidence indicates that epidemiologic studies assessing concurrent brain Pb levels or occupational Pb exposure may not have examined the etiologically relevant exposure period. However, the observations that were made in experimental animals with high Pb exposure and blood Pb levels (>40 µg/dL) may have uncertain relevance to humans. Further, animals were not behaviorally assessed for dementia.

5.3.10.2 Amyotrophic Lateral Sclerosis

The 2006 Pb AQCD (U.S. EPA, 2006b) reported mixed epidemiologic findings for an association between Pb and ALS based on case-control studies, several of which relied on indirect methods of assessing Pb exposure. Case-control studies that measured blood Pb levels produced contrasting results. A study of 16 ALS cases (mean blood Pb level: 12.7 µg/dL) and 39 controls (mean blood Pb level: 10.8 µg/dL) found a small difference in the mean concurrent blood Pb level (Vinceti et al., 1997). A larger study of 109 cases and 256 controls that examined concurrent blood and bone Pb levels in a New England-area population found higher odds of ALS among subjects with concurrent blood Pb levels ≥ 3 µg/dL (e.g., OR: 14.3 [95% CI: 3.0, 69.3] for n = 55 blood Pb levels 3-4 µg/dL compared with blood Pb levels <1-2 µg/dL) (Kamel et al., 2002). Odds of ALS were elevated in subjects in the highest two tertiles of patella and tibia Pb levels (≥ 10 µg/g patella Pb and ≥ 8 µg/g tibia Pb), but lacked precision. For example, compared with subjects with tibia Pb level <8 µg/g, the OR for tibia Pb levels 8-14 µg/g was 1.6 (95% CI: 0.5, 5.6). Results were adjusted for age, education, and hours/day inactive. Potential confounding by smoking was not considered. Also in this population, an estimate of cumulative Pb exposure based on occupational history was found to be associated with ALS (Kamel et al., 2002). The stronger findings for blood Pb level were surprising given that bone Pb level is a better biomarker of cumulative Pb exposure. One explanation for these findings is reverse causation. Blood was collected from people who already had ALS, and reduced physical activity among those with ALS could lead to more bone turnover and greater release of Pb from bones into circulation in ALS cases than controls.

Since the 2006 Pb AQCD, a few additional studies of ALS have been conducted with the same New England-area case-control group. Kamel et al. (2005) reported that the association between blood Pb level and ALS was not modified by the ALAD genotype, and Kamel et al. (2008) found that higher tibia and patella Pb levels were associated with

longer survival time among 100 of the original 110 ALS cases with adjustment for age, sex, and smoking. Results were not altered by the additional adjustment for education, BMI, or concurrent physical activity. Higher blood Pb levels were associated weakly with longer survival time. These paradoxical findings that point to a protective effect of Pb are not easily explainable but find coherence with results for Pb-induced increased survival time in an ALS mouse model (see below). On one hand, the cases with longer survival time may have higher bone Pb levels because they reflect a longer period of cumulative exposure. On the other hand, with longer survival time, there could be greater progression of disease and less mobility. Decreased mobility would tend to increase bone resorption, lower bone Pb levels, and increase blood Pb levels over time. The latter hypothesis is a less likely explanation for findings in this New England cohort because higher bone Pb levels were more strongly associated with longer survival time than was blood Pb level.

Another case-control study examined concurrent blood Pb levels and ALS among 184 cases (33 were either progressive muscular atrophy or primary lateral sclerosis, mean blood Pb level: 2.41 µg/dL) and 194 controls (mean blood Pb level: 1.76 µg/dL) (Fang et al., 2010). The cases were recruited from the National Registry of U.S. Veterans with ALS, and controls were recruited from among U.S. Veterans without ALS and frequency matched by age, gender, race, and past use of the Veterans Administration system for health care. A doubling of concurrent blood Pb level was associated with ALS with an OR of 2.6 (95% CI: 1.9, 3.7) with adjustment for age and a collagen protein as an indicator of bone formation. Associations did not differ substantially by indicators of bone turnover but were slightly higher among ALAD 1-1 carriers. The association with blood Pb level was similar in analyses that excluded the progressive muscular atrophy and primary lateral sclerosis cases. The similar results by degree of bone turnover suggest that reverse causation is not likely explaining the association between blood Pb level and ALS. However, as in other ALS case-control studies, the directionality of effects is difficult to establish. This study did not have measures of bone Pb to assess the association with biomarkers of longer-term Pb exposure.

Although epidemiologic studies have provided inconsistent evidence for associations of Pb biomarker levels with ALS in adults, toxicological studies have found that Pb exposure affects neurophysiologic changes associated with ALS. For example, chronic postnatal Pb exposure from weaning onward (200 ppm Pb acetate in drinking water, resultant blood Pb level: 27 µg/dL) reduced astrocyte reactivity and induced increased survival time in the superoxide dismutase transgenic (SOD1 Tg) mouse, which has SOD mutations found in humans with familial ALS (Barbeito et al., 2010). In this model, Pb exposure did not significantly increase the onset of the ALS disease. These findings provide coherence with the association observed between bone Pb level and longer survival time in patients diagnosed with ALS (Kamel et al., 2008).

Research outside of the Pb field has suggested different mechanisms for ALS initiation versus ALS progression, i.e., motor neuron function versus astrocyte and microglia function (Yamanaka et al., 2008; Boillee et al., 2006). Astrocyte vascular endothelial growth factor (VEGF) was examined for its involvement in the effects of Pb on increasing survival time in the ALS mouse model. Lower VEGF expression has been linked with risk of ALS in humans and ALS-like symptoms in animals. Baseline VEGF levels were elevated in astrocytes from the ventral spinal cord of untreated SOD1 Tg mice versus untreated nontransgenic mice. VEGF was not induced in the astrocytes of Pb-treated nontransgenic mice. In comparison, Pb-exposed SOD1 Tg mice, which had longer survival time, also had significant elevations in astrocyte VEGF (Barbeito et al., 2010). These findings for Pb-induced effects on astrocytes in a mouse model for ALS may provide a mechanistic explanation for Pb effects on survival time in ALS.

Others reported that VEGF administration to the SOD1 Tg mice significantly reduced glial reactivity, a marker or neuroinflammation (Zheng et al., 2007). Using a cell-based co-culture system of neurons and astrocytes isolated from Pb-exposed SOD1 Tg mice, Barbeito et al. (2010) found that an up-regulation of VEGF production by astrocytes was protective against motor neuron death in the SOD1 Tg mouse cells. Thus, in vivo and in vitro results indicate that chronic Pb exposure resulted in increased survival time in an ALS mouse model and was correlated with higher spinal cord VEGF levels, which made astrocytes less cytotoxic to surrounding motor neurons (Barbeito et al., 2010).

In summary, there is inconsistent evidence of association between indicators of Pb exposure (history of occupational exposure, Pb biomarker levels) and ALS prevalence and survival time in humans. Because of the potential for reverse causality and bias due to survival time in the case-control studies, and the lack of objective assessment of occupational exposure, firm conclusions are not warranted. While several studies have considered potential confounding by age, education, and physical activity, few have considered smoking. Toxicological evidence also points to Pb exposure increasing survival in a mouse model of ALS and has suggested explanations including Pb-induced increases in VEGF expression and subsequent reduction in glial activity and protection of motor neurons against inflammation.

5.3.10.3 Parkinson's Disease

Previous Pb AQCDs reviewed a few studies, some ecological (Rybicki et al., 1993; Aquilonius and Hartvig, 1986) and some case-control relying on questionnaire data or occupational history (Gulson et al., 1999; Gorell et al., 1997; Tanner et al., 1989) that indicated associations between exposure to heavy metals, particularly Pb, and risk of Parkinson's disease. The limited number of previous studies, weak study designs, and lack of examination of Pb biomarkers did not permit firm conclusions. Recent studies maintain several of these limitations but have indicated associations with bone Pb levels.

A recent large case-control study (330 cases, 308 controls) examined a population in the Boston, MA area with virtually no occupational exposures to Pb (Weisskopf et al., 2010). Subjects in the highest quartile of tibia Pb level (>16.0 μg/g) had higher odds of Parkinson's disease compared to those in the lowest quartile (≤ 5 μg/g) (OR: 1.91 [95% CI: 1.01, 3.60]) with adjustment for age, race, pack-years smoking, education, and recruitment site. Cases and controls were recruited from several different sources including movement disorder clinics and the NAS, which could have introduced biased participation by Pb exposure or reduced representativeness to the target population. In the NAS, cases were ascertained from self-report, which may introduce measurement error. However, when analyses were restricted to cases recruited from movement disorder clinics and their spouse, in-law, or friend as controls, the results were even stronger (OR: 3.21 [95% CI: 1.17, 8.83]). Although the use of spouse, in-law, and friend controls can introduce bias, this is expected to be toward the null as these groups are likely to share many exposures. Manganese (Mn) exposure has been associated with Parkinsonian symptoms and could potentially confound associations between Pb and Parkinson's disease. Weisskopf et al. (2010) did not adjust results for Mn exposure. However, unlike occupational exposure to Pb, general environment exposure to Pb is less likely to be correlated with environmental Mn exposure. Thus, it is less likely that the observed associations with Pb were confounded by co-occurring Mn exposure.

Coon et al. (2006) conducted a smaller case-control study of 121 Parkinson's disease patients and 414 controls frequency-matched by age, sex, and race, all receiving health care services from the Henry Ford Health System in Michigan. Subjects in the highest quartile of both tibia (OR: 1.62 [95% CI: 0.83, 3.17] for levels ≥ 15 μg/g) and calcaneus (OR: 1.50 [95% CI: 0.75, 3.00] for levels ≥ 25.29 μg/g) bone Pb levels had higher odds of Parkinson's disease compared to those in the lowest quartiles (0-5.91 μg/g for tibia and 0-11.70 μg/g for calcaneus). Subjects in the highest quartile of whole-body lifetime Pb level (≥ 80.81 μg/g, estimated using PBPK modeling) had the highest OR: 2.27 (95% CI: 1.13, 4.55) versus the lowest quartile, 0-40.04 μg/g. These results were adjusted for age, race, sex, pack-years smoking, regular coffee consumption, and regular alcohol use, but

Mn exposure was not considered. It was not clear what the extent of occupational exposure to Pb was among the participants; however, a previous Henry Ford Health System study had linked occupational Pb exposure to Parkinson's disease (Gorell et al., 1997). Thus, it is uncertain whether the observed associations were confounded by co-occurring Mn exposure.

In summary, a small number of recent case-control studies expand on previous evidence by finding associations of tibia and calcaneus bone Pb levels, biomarkers of cumulative Pb exposure, with Parkinson's disease in adults. The associations observed with biomarkers of cumulative Pb exposure increase confidence that associations are not explained by reverse causality. However, firm conclusions are not warranted. While associations were adjusted for potential confounding by age, sex, race, and education, Mn co-exposure was not considered.

5.3.10.4 Essential Tremor

The few available case-control studies of essential tremor have found associations with concurrent blood Pb levels. The 2006 Pb AQCD (U.S. EPA, 2006b) described case-control studies that found associations between concurrent blood Pb levels and essential tremor in New York City metropolitan area populations (Louis et al., 2005; Louis et al., 2003). In the larger study, mean (SD) blood Pb levels were 3.3 (2.4) µg/dL in the 100 essential tremor cases and 2.6 (1.6) µg/dL in the 143 controls (Louis et al., 2003). In the other study, mean (SD) blood Pb levels were 3.5 (2.2) µg/dL in the 61 essential tremor cases and 2.6 (1.5) µg/dL in the 101 controls (Louis et al., 2005). In Louis et al. (2005), the magnitude of association was larger among the 35 ALAD-2 carriers than among 129 adults with the ALAD-1 genotype. History of occupational Pb exposure was similarly rare in cases and controls (2%).

Recently, Dogu et al. (2007) reported on 105 essential tremor cases selected from a movement disorder clinic in Turkey and 105 controls (69 spouses and 36 other relatives) living in the same district. With adjustment for age, sex, education, smoking status, cigarette pack-years, and alcohol use, a 1 µg/dL higher blood Pb level (measured at the time of study recruitment) was associated with essential tremor with an OR of 4.19 (95% CI: 2.59, 6.78). This OR was much larger than that obtained in the New York area study (OR: 1.19 [95% CI: 1.03, 1.37]) (Louis et al., 2003). The magnitude of association in Dogu et al. (2007) is even more striking because so many of the controls were spouses who are expected to share many environmental exposures as cases. Most of the essential tremor cases were retired at the time of the study; however past occupational history was not examined.

In summary, a small body of studies indicates associations between blood Pb level measured at the time of the study and prevalence of essential tremor in adults. However, because of the case-control design, reverse causation cannot be excluded as a potential explanation for the observed associations since loss of physical activity and subsequent bone resorption may lead to an increase in blood Pb level. Further, the level, timing, frequency, and duration of Pb exposure associated with essential tremor are uncertain. History of occupational Pb exposure was not consistently examined, and potential confounding by Mn exposure was not examined.

5.3.10.5 Toxicological Studies of Cell Death Pathways

A common element of the neurodegenerative diseases described above is neuronal cell death. Studies reviewed in the 2006 Pb AQCD (U.S. EPA, 2006b) documented that Pb exposure induced cell death or apoptosis in various models including rat brain (Tavakoli-Nezhad et al., 2001), retinal rod cells (He et al., 2003; He et al., 2000), cerebellar neurons (Oberto et al., 1996), and PC12 cells (Sharifi and Mousavi, 2008). Recent studies produced similar findings, in most cases, in animals with higher blood Pb levels than those relevant to humans. Long-term (40 days) exposure to 500 ppm Pb in drinking water was found to increase pro-apoptotic Bax protein levels and the number of apoptotic cells in the hippocampus in young (exposure starting at 2-4 weeks of age) and adult (exposure starting at 12-14 weeks of age) male rats with blood Pb levels 98 µg/dL (Sharifi et al., 2010). Apoptosis was verified by light and electron microscopy. Another study followed the developmental profile of changes in various apoptotic factors in specific brain regions of animals exposed to 2,000 ppm Pb acetate during lactation (to PND20) via drinking water of dams (Chao et al., 2007). At the end of lactation, male offspring blood Pb level was 80 µg/dL. The data showed that hippocampal mRNA for various apoptotic factors including caspase-3, Bcl-x, and Brain-derived neurotrophic factor (BDNF) was significantly upregulated on PND12, PND15 and PND20. The cortex of these male pups showed upregulation of Bcl-x and BDNF on PND15 and PND20. The cerebellum did not have elevated apoptotic mRNA levels in this model. Thus, in this study, Pb-induced apoptosis varied by age and brain region in male offspring.

Pb exposure also has been shown to induce apoptosis of spinal cord cells during spinal cord development in chicks treated with 150 or 450 µg Pb acetate in ovo at embryonic day 3 or 5 and visualized six days later (Müller et al., 2012). TUNEL positive cells, indicating DNA fragmentation induced by apoptosis, were at significantly higher levels in Pb-exposed animals and were visualized in all layers of the developing spinal cords. Also, levels of glial fibrillary acidic protein (GFAP), a factor important in neuronal migration and cellular differentiation during nervous system development, was

significantly attenuated in spinal cords of Pb-exposed chicks. Liu et al. (2010b) examined apoptotic effects in 30 day-old male rats that were treated with Pb acetate once daily for 6 weeks via intragastric infusion. Four groups: control, low (2 mg/kg BW), medium (20 mg/kg BW), and high (200 mg/kg BW) had blood Pb levels of 1.0-7.5 μg/dL; 4.5-11 μg/dL; 9-42 μg/dL; and 48-73 μg/dL, respectively. Pb induced hippocampal neuronal apoptosis (TUNEL positive staining, statistically significant at all Pb doses) with hippocampal XIAP (significant at high dose only) and Smac (statistically nonsignificant trend) downregulation at the termination of the 6 week treatment. In another study, Pb exposure (500 ppm Pb acetate in drinking water for 8 weeks) of adult male rats induced regional-specific changes in brain apoptotic proteins poly(ADP-ribose) polymerase, Bcl-2, and caspase-3 with a greater effect observed in the hippocampus and cerebellum and a lesser effect observed in the brainstem and the frontal cortex (Kiran Kumar et al., 2009).

In summary, a small body of epidemiologic studies found Pb-associated increases in essential tremor and Parkinson's Disease in adults. However, limitations such as the potential for reverse causation to explain cross-sectional associations observed with blood Pb level, and the potential for confounding by Mn exposure preclude firm conclusions. However, toxicological evidence supports an effect of Pb on neurodegeneration by demonstrating that Pb exposure during various lifestages, early postnatal or adulthood, induces neuronal apoptosis in animals. Several of these observations were made with routes of Pb exposure (i.e., i.p.) that may not be relevant to those in humans.

5.3.11 Modes of Action for Pb Nervous System Effects

5.3.11.1 Effects on Brain Physiology and Activity

The 2006 Pb AQCD (U.S. EPA, 2006b) reviewed a small body of available epidemiologic studies demonstrating associations of Pb biomarkers with electrophysiologic and physical changes in the brains of young adults (Yuan et al., 2006; Cecil et al., 2005) and children (Meng et al., 2005; Trope et al., 2001) as assessed by magnetic resonance imaging (MRI) or spectroscopy (MRS). The implications of previous findings were limited by the small sample sizes (n = 12-45) and limited consideration for potential confounding. Recent studies examining MRI data were limited largely to the Cincinnati cohort as adults (ages 19-24 years). In addition to supporting associations of childhood blood Pb levels with physiological changes in the brain of adults, these recent analyses expanded on previous studies by including larger sample sizes, aiming to characterize important lifestages of Pb exposures, and evaluating potential links between

changes in brain activity and functional neurodevelopmental effects. While there are overall few studies in few populations, by showing physical and physiologic changes in areas of the brain associated with neurodevelopmental function, the evidence provides biological plausibility for the associations observed between Pb biomarker levels and cognitive function and behavior.

In prospective analyses of the Cincinnati cohort as adults (ages 20-23 years, n = 35, 42), Cecil et al. (2005) and Yuan et al. (2006) conducted functional MRI during a verb generation language task and found that higher age 3-78 month average blood Pb level (mean 14.2 µg/dL) was associated with decreased activation in the left frontal gyrus and left middle temporal gyrus, regions implicated in semantic language function. Yuan et al. (2006) considered birth weight, marijuana consumption, sex, SES, gestational age, and IQ as potential confounding factors. Whereas previous analyses of the Cincinnati cohort focused on activity in specific regions of the brain, Cecil et al. (2011) examined brain metabolites. Higher age 3-78 month average blood Pb levels (mean: 13.3 µg/dL) were associated with lower levels of N-acetylaspartate (NAA) and creatine (Cr) in the basal ganglia and lower levels of choline in white matter in 159 adults, ages 19-23 years. These results were adjusted for age and FSIQ; however, several other unspecified factors were considered. Lower levels of NAA, Cr, and choline are linked to decreased neuronal density and alteration in myelin. A recent prospective analysis of 31 men in the NAS cohort similarly reported an association between biomarkers of cumulative, long-term Pb exposure and changes in brain metabolites in older adults. Weisskopf et al. (2007b) found higher tibia and patella Pb levels to be associated with a higher myoinositol/Cr ratio in the hippocampus measured more than 10 years after bone Pb and adjusted for age. Myoinositol/Cr ratio may be indicative of glial activation and is a signal reportedly found in the early stages of HIV-related dementia and Alzheimer's disease.

Other studies in the Cincinnati cohort as young adults found that childhood average blood Pb levels were associated with altered brain architecture. Among 91 adults ages 20-26 years, Brubaker et al. (2009) found associations of age 3-78 month average blood Pb levels (mean: 13.3 µg/dL) with diffusion parameters that were indicative of less organization of fibers throughout white matter. Results were adjusted for maternal IQ, prenatal alcohol and tobacco exposure, and adult marijuana use. In regions of the corona radiata, higher blood Pb levels were associated with less myelination axonal integrity. In regions of the corpus callosum, higher blood Pb levels were associated with greater myelination and axonal integrity. The differential impact among neural elements may be related to the stage of myelination development present at various time periods.

Another study of 157 Cincinnati cohort adults ages 19-24 years provided evidence of region-specific reductions in gray matter volume in association with age 3-78 month

average blood Pb levels (mean: 13.3 µg/dL) with adjustment for sex (Cecil et al., 2008). The most affected regions included frontal gray matter, specifically the anterior cingulate cortex, and the ventrolateral prefrontal cortex (i.e., areas related to executive functions, mood regulation, and decision-making). Further, fine motor factor scores were positively correlated with gray matter volume in the cerebellar hemispheres; adding blood Pb level as a variable to the model attenuated this correlation. These findings suggested that changes observed with MRI may mediate the association between blood Pb levels and decrements in motor function. The functional relevance of these structural changes in the brain also is supported by observations from other studies that link changes in brain architecture and activity to changes in cognitive function (e.g., visuoconstruction, visual memory, eye-hand coordination) (Schwartz et al., 2007) and behavioral problems (impulsivity, aggression, violence) (Yang et al., 2005; Raine et al., 2000). In a subsequent comparison of blood Pb levels measured at various lifestages in 157 Cincinnati cohort adults ages 19-24 years, Brubaker et al. (2010) found that blood Pb levels at older ages (annual means from 3-6 years, means: 9.6-16.3 µg/dL) were associated with greater losses in gray matter volume than were age 3-78 month average or maximum blood Pb levels (mean: 23.1 µg/dL). Both Cecil et al. (2008) and Brubaker et al. (2010) found that Pb-associated reductions in gray matter were more pronounced in males than females in the Cincinnati cohort.

Studies of Pb-exposed workers (n = 15-532) also found associations of concurrent blood (means: 17-63.5 µg/dL) and tibia (mean 14.5 µg/dL) Pb levels with changes in brain structure and physiology, supporting the effects of chronic Pb exposure. Pb-associated changes included white matter lesions, smaller brain volumes, less total gray matter, and lower levels of brain metabolites such as NAA and Cr (Hsieh et al., 2009b; Jiang et al., 2008; Bleecker et al., 2007b; Stewart et al., 2006) with adjustment for similar factors as associations for cognitive function. Other occupational exposures were not examined. In a few of these occupational groups, Pb-associated brain changes were linked to poorer performance in cognitive function tests (Caffo et al., 2008; Bleecker et al., 2007b).

Higher concurrent blood Pb level also was associated with lower NAA/Cr ratio in small cross-sectional studies that included children (n = 6, 16, ages 4-21 years), although neither study considered potential confounding (Meng et al., 2005; Trope et al., 2001). All subjects had normal MRIs with no evidence of structural abnormalities. Thus, the biological relevance of the observed physiological changes is unclear. Additionally, the representativeness of findings is uncertain because results were based on comparisons of subjects with relatively high blood levels (23-65 µg/dL) to those with blood Pb levels <10 µg/dL.

In summary, results in a few populations indicate associations of childhood blood or adult tibia Pb levels with changes in brain structure and physiology in adults assessed by MRI or MRS. Associations were found in children, but implications are limited because of small samples sizes, lack of consideration of potential confounding, and high blood Pb levels of the children examined. Evidence from the prospective Cincinnati cohort studies improves characterization of the temporal sequence between Pb exposure and changes in brain structure and physiology. Several studies linked these changes to functional changes in cognitive performance or motor skills. Because of the small samples sizes of several studies and limited consideration for potential confounding, firm conclusion regarding the effects of Pb exposed on changes in brain structure and physiology is not warranted. However, the evidence provides biological plausibility for the associations observed between Pb biomarker levels and cognitive function and behavioral problems.

5.3.11.2 Oxidative Stress

Because the brain has the highest energy demand and metabolism of any organ, energy homeostasis is of utmost importance. Energy imbalance can increase the susceptibility of the highly energetic brain tissue to stressors and cell death. Pb has been shown to induce energy imbalance by inhibiting various enzymes involved in energy production or glucose metabolism including glyceraldehydes-3 phosphate dehydrogenase, hexokinase, pyruvate kinase, and succinate dehydrogenase (Verma et al., 2005; Yun and Hoyer, 2000; Regunathan and Sundaresan, 1984; Sterling et al., 1982). Mitochondria produce ATP or energy through oxidative phosphorylation. Aberrant mitochondrial function can decrease the energy pool and contribute to ROS formation via electron transport chain disruption. ATP depletion can also affect synaptic and extracellular neurotransmission. The mitochondrial Na^+/K^+ATPase is important in maintaining the inner mitochondrial membrane potential ΔΨm (delta psi[sub m]) and the functioning of the mitochondria.

Gestational Pb exposure was found to impair mitochondrial function and energy production in neuronal cells from mice and produce concomitant increases in mitochondrial and cellular ROS production. The effect of Pb exposure on these mitochondrial parameters were examined in the brains of mice after prenatal Pb exposure (1,000 ppm Pb acetate in dam drinking water, resulting in offspring blood Pb levels of 4 µg/dL and cerebella Pb levels of 7.2 µg/g dry weight) (Baranowska-Bosiacka et al., 2011b). Cerebellar granular cells were harvested from control and Pb-exposed animals at PND8. These neuronal cells were cultured for 5 days in vitro, at which point various mitochondrial parameters were measured. With Pb exposure, ROS were significantly increased in both the cortical granule cells and in the mitochondria. Intracellular ATP concentration and adenylate energy charge values were significantly decreased in cells of

Pb-exposed mice versus controls. Neuronal Na^+/K^+ATPase activity was significantly lower in cortical granule cells from Pb-exposed mice versus cells from controls. Mitochondrial mass was unaffected with Pb treatment, but mitochondrial membrane potential was significantly decreased with Pb exposure. Energy imbalances also were found in Wistar rats (PND15) of each sex injected daily for 2 weeks with Pb acetate (15mg/kg BW, i.p., resulting in a mean blood Pb level of 30 µg/dL; control blood Pb level 3 µg/dL) (Baranowska-Bosiacka et al., 2011a). ATP and ADP were significantly decreased in various brain regions with Pb exposure, with the cerebellum and hippocampus more strongly affected than the forebrain cortex. Also, expression of the pro-inflammatory P2XR receptor was enhanced in the glial fraction, indicating the astrocyte pool may be involved in the pathological changes found in Pb-exposed immature rat brains. Mitochondrial energy imbalances also were found in Pb-exposed crayfish that were placed under hypoxic conditions which induced a decrease in metabolism (Morris et al., 2005).

In rats, Pb exposure has been shown to induce oxidative stress, in some cases, with concomitant functional CNS changes. Exposure of adult male rats to 4,000 ppm Pb acetate in drinking water for 6 weeks increased brain levels of lipid peroxides (LPO) and lowered levels of antioxidants including nitric oxide (NO), total antioxidant capacity (TAC), glutathione (GSH), glutathione-S-transferase (GST), and superoxide dismutase (SOD). Whole blood Pb levels were positively correlated with brain tissue LPO levels and negatively correlated with NO levels. Evidence also indicated a role for oxidative stress in mediating the effects of Pb on cognition as evidenced by changes in synaptic plasticity (Hamed et al., 2010). These effects of Pb on oxidative stress parameters were attenuated with co-exposure to green tea extract (1.5%), which reduced brain (1.9 to 1.2 ppm) and blood Pb levels of rats (0.773 to 0.654 ppm). In a study of adult male Wistar albino rats, Pb acetate treatment by i.p. (20 mg/kg, 5 days) elevated lipid peroxidation, neuronal damage, and brain tissue DNA fragmentation and decreased antioxidant GSH levels and antioxidant enzyme activity, (Abdel Moneim et al., 2011a). These effects were attenuated with co-administration of the polyunsaturated fatty acid flaxseed oil (oral gavage 1,000mg/kg body weight for 5 days, 1 hour prior to Pb dosing). Flaxseed oil co-treatment also significantly attenuated the blood Pb level of Pb-exposed animals (~31 µg/dL the day after the last Pb injection to ~12 µg/dL) and control animals, indicating that flaxseed oil may alter Pb toxicokinetics in animals. Another study provided indirect evidence of Pb-induced oxidative stress with observations that Pb-induced (2,000 ppm Pb acetate in drinking water PND1-PND67) impairments in long-term potentiation (LTP), paired-pulse reactions, and input/output functions in the DG of male and female Wistar rats were significantly attenuated with treatment with the antioxidant quercetin (30 mg/kg BW, PND60-PND67) at PND67 (Hu et al., 2008a).

Quercetin-treated animals had significantly less hippocampal Pb than did the animals exposed only to Pb.

Oxidative stress may be involved in neurodegenerative pathologies including Alzheimer's disease. Hydrogen peroxide-induced oxidative stress has been shown to induce intracellular accumulation of Ab in human neuroblastoma cells (Misonou et al., 2000). Oxidative stress-induced DNA damage can be measured as the ratio of the adduct 8-hydroxy-2'-deoxyguanosine to 2-deoxyguanosine (8-oxo-dG/2-dG). 2-dG is a product of oxidative cleavage and is oxidized to form 8-oxo-dG. Pb-induced changes in the 8-oxo-dG to 2-dG ratio were examined recently as a mechanism underlying neurodegeneration. Similar to Ab levels, changes in the 8-oxo-dG to 2-dG ratio showed a biphasic relationship in the brains of rats exposed to 2,000 ppm Pb acetate via drinking water of dams from PND1-PND20 (blood Pb level 46 µg/dL) (Bolin et al., 2006). The 8-oxo-dG to 2-dG ratio decreased early in exposure (PND5) but increased at age 20 months. No increase was found in animals exposed to Pb from age 18 to 20 months (blood Pb level: 60 µg/dL). Activity of the base-excision DNA repair enzyme oxoguanine glycosylase was unaffected by Pb exposure. Similar findings were reported in a monkey study (Wu et al., 2008a). The ratio of 8-oxo-dG to 2-dG in the brains of aged monkeys (23 years) was significantly elevated above that in controls only with Pb exposure in infancy (PND1-PND400, infant formula, blood Pb levels: 19-26 µg/dL) but not as aged adults (Wu et al., 2008a). Thus, evidence in rats and monkeys suggests a possible role for oxidative stress in Pb-induced neurodegenerative effects and indicates that early life but not adult-only Pb exposure induces oxidative DNA damage and amyloidogenesis.

5.3.11.3 Nitrosative Signaling and Nitrosative Stress

The NO system is increasingly being recognized as a signaling system in addition to its more classical role as a marker of cellular stress. Pb exposures during the gestational-early postnatal period (GD6-PND21) (Chetty et al., 2001) and during the postnatal period only (Fan et al., 2009a) were found to reduce hippocampal levels of NO or neuronal NO synthase. In the hippocampus, NO mediates LTP, which is considered to be a major cellular mechanism underlying learning and memory. Thus, observations of Pb-induced changes in hippocampal NO may provide a mechanistic explanation for the effects of Pb on cognitive function decrements. Fan et al. (2009a) found reduced hippocampal NOS and NO in weanling male rats after either 4 or 8 weeks of Pb exposure resulting in blood Pb levels of 47 and 66 µg/dL, respectively. In the same study, dietary supplementation with taurine or glycine concomitant with 8 weeks of Pb exposure induced significant increases in hippocampal NOS, whereas Pb plus dietary supplementation with vitamin C, methionine, tyrosine, or vitamin B1 decreased hippocampal NOS. In this study,

co-exposure of specific nutrients also prevented Pb-induced impairments in learning as evidenced by lack of increased escape latency in the Morris water maze. Dietary supplementation with tyrosine, methionine, or ascorbic acid after 4 weeks of Pb exposure in weanling males (blood Pb levels upon cessation of exposure and after 4-week lag: 47.6 and 8.1 µg/dL, respectively) reversed Pb-induced decrements in NO/NOS. Zn supplementation given after Pb exposure had no effect on the NO system.

5.3.11.4 Synaptic Changes

Previous toxicological studies pointed to an effect of developmental Pb exposure on synapse development, which mechanistically may contribute to multiple Pb-related aberrant effects, including changes in LTP and facilitation. Facilitation of a neuronal terminal is defined as the increased capability to transmit an impulse down a nerve due to prior excitation of the nerve. Earlier work showed that developmental Pb exposure resulted in altered density of dendritic hippocampal spines (Király and Jones, 1982; Petit and Leboutillier, 1979), aberrant synapse elimination (Lohmann and Bonhoeffer, 2008), and abnormal long-term and short-term plasticity (MacDonald et al., 2006). In a recent study, Li et al. (2009c) focused on inflammatory endpoints and synaptic changes after gestational plus lactational Pb exposure (1,000-10,000 ppm Pb acetate via drinking water of dams, producing offspring blood Pb levels 40-100 µg/dL, respectively at PND21). Hippocampal TNF-α was significantly elevated with Pb exposure, and proteins that comprise the SNARE complex were all changed with Pb exposure. The SNARE complex of synaptic proteins includes SNAP-25, VAMP-2 and Syntaxin 1a and is essential in exocytotic neurotransmitter release at the synapse. Thus, Li et al. (2009c) found significant differences in hippocampal synaptic protein composition and increased pro-inflammatory cytokine levels in the brains of Pb-exposed offspring.

Recent research using the Drosophila larval neuromuscular junction model showed that compared with unexposed controls, Pb-exposed larvae had significant increases in intracellular calcium and significant delays in calcium decays back to baseline levels at the pre-synaptic neuronal bouton (as stimulated with multiple action potentials, also called AP trains). Pb-exposed larvae had reduced activity of the plasma membrane Ca^{2+}ATPase, which is responsible for extravasations of calcium from the synaptic terminal (He et al., 2009). Intracellular calcium in Pb-exposed larvae was no different from that in controls under resting conditions or in neurons with stimulation by a single action potential. Pb media concentrations in these experiments were 100 or 250 µM with the body burden of Pb from the lower dose calculated to be 13-48 µM per larvae. After stimulation of the axon, facilitation of the excitatory post-synaptic potential, which is dependent on residual terminal calcium, was significantly elevated in Pb-exposed larvae

versus control (He et al., 2009). The data from this synapse study demonstrate that developmental Pb exposure affected the plasma membrane Ca^{2+}ATPase, induced changes in the intracellular calcium levels during impulse activation, and produced changes in facilitation of the neuronal networks of Drosophila. Thus, the neuromuscular junction is a potential site of Pb interaction.

Neurotransmission is an energy-dependent process as indicated by the presence of calcium-dependent ATP releases at the synaptic cleft. At the synapse, ATP is metabolized by ectonucleotidases. Acute exposure (96 hours) of male and female zebrafish to Pb acetate (2 µg/dL) in their water induced significant decreases in ATP hydrolysis in brain tissue (Senger et al., 2006). This dose is deemed to be environmentally relevant. With chronic exposure (30 days), Pb acetate promoted the inhibition of ATP, ADP and AMP hydrolysis. These findings were consistent with findings in rodents (Baranowska-Bosiacka et al., 2011a). The authors hypothesized that at 30 days, this Pb-induced change in nucleotide hydrolysis was likely due to post-translational modification because expression of enzymes responsible for the hydrolysis, NTPDase1 and 5′-nucleotidase, were unchanged (Senger et al., 2006). Thus, Pb has been shown to affect nucleotidase activity in the CNS of zebrafish, possibly contributing to aberrant neurotransmission.

Another enzyme important in synaptic transmission at cholinergic junctions in the CNS and at neuromuscular junctions is acetylcholinesterase (AChE). After 24 hours of exposure to Pb acetate (2 µg/dL water), AChE activity was significantly inhibited in zebrafish brain tissue (Richetti et al., 2010). AChE activity returned to baseline by 96 hours and maintained baseline activity after 30 days of exposure. Thus, Pb was shown to affect synaptic homeostasis of AChE in the brains of zebrafish only transiently.

Pb has been shown to act as an antagonist of the NMDA receptor (NMDAR). The NMDAR is essential for proper presynaptic neuronal activity and function. Primary cultures of mouse hippocampal cells exposed to 10 or 100 µM Pb during the period of synaptogenesis had loss of two proteins necessary for presynaptic vesicular release, synaptophysin (Syn) and synaptobrevin (Syb) but no change in a similar protein synaptotagmin (Syt) (Neal et al., 2010a). This deficit was found in both GABAergic and glutamatergic neurons. Pb also induced an increase in the number of presynaptic contact sites. But, these sites may have been nonfunctional as they lacked the protein receptor complexes necessary for proper vesicular exocytosis. Another factor involved in maturation and signaling of presynaptic neurons is brain-derived neutrotrophic factor (BDNF), which is synthesized and released by postsynaptic neurons regulated by the NMDAR. In hippocampal cells, both pro-BDNF and BDNF release were significantly attenuated with Pb exposure (Neal et al., 2010a). Further, exogenous BDNF

administration rescued the aforementioned Pb-related effects on presynaptic proteins. Thus, this cell culture model showed that Pb-related presynaptic aberrations are controlled by NMDAR-dependent BDNF effects on synaptic transmission.

Glutamate is another neurotransmitter that is released from presynaptic neurons and via interactions with the NMDAR causes postsynaptic neuron depolarization. A recent study of Wistar albino rats exposed to Pb postnatally from birth to age 12 weeks (drinking water 3×10^4 µg/dL Pb acetate, resulting in blood Pb levels of 17 µg/dL at age 6 weeks) showed decreased learning ability, decreased hippocampal glutamate at 6, 8, 10 and 12 weeks of age, as well as significant decrements in the hippocampal glutamate synthesis-related enzymes aspartate aminotransferase and alanine aminotransferase (Niu et al., 2009).

5.3.11.5 Blood Brain Barrier

Two barrier systems exist in the body to separate the brain or the CNS from the blood. These two barriers are the blood brain barrier (BBB) and the blood cerebrospinal fluid barrier (BCB). The BBB, formed by tight junctions at endothelial capillaries forming the zonulae occludens (occludins, claudins, and cytoplasmic proteins), separates the brain from the blood and its oncotic and osmotic forces, allowing for selective transport of materials across this barrier.

Pb exposure during various developmental windows has been shown to increase the permeability of the BBB of animals (Dyatlov et al., 1998; Struzynska et al., 1997b; Moorhouse et al., 1988; Sundstrom et al., 1985). Possibly due the underdevelopment of the BBB early in life, prenatal and perinatal Pb exposure has been found to result in higher brain Pb accumulation than have similar exposures later in life (Moorhouse et al., 1988). The choroid plexus and cerebral endothelial cells that form the BBB and BCB tight junctions have been shown to accumulate Pb more than other cell types and regions of the CNS. Studies reviewed in earlier Pb AQCDs showed that the chemical form of Pb and its capability to interact with proteins and other blood components affects its capability to penetrate the BBB (U.S. EPA, 2006b). Pb also has been shown to compromise the BCB and decrease the cerebrospinal fluid level of transthyretin, which binds thyroid hormone in the cerebrospinal fluid. Low thyroid hormone levels in pregnant women have been linked with IQ deficits in their children (Lazarus, 2005).

Recent research with male weanling rats exposed to Pb acetate via drinking water showed leaky cerebral vasculature, an indication of a compromised BBB, as detected histologically with lanthanum nitrate staining of the brain parenchyma (Wang et al., 2007b). Cerebral vasculature leakiness was ameliorated or resembled that of controls

after iron supplementation. The cerebral vasculature leakiness may by explained by observations of significant Pb-induced decreases in the BBB tight junction protein occludin in the hippocampus, brain cortex, and cerebellum in these weanling animals. Occulin levels were rescued to control levels with iron supplementation. This loss of integrity at the junctional protein level was affirmed with additional experiments using the rat brain vascular endothelial cell line RBE4, in which 10 µM Pb acetate exposure for 2, 4, 8, 16 and 24 hours resulted in decreases in junctional proteins occludin and claudin 5 as well as scaffold proteins ZO1 and ZO2 (Balbuena et al., 2011). Because gene expression for these junctional and scaffold proteins did not show decrements, it was determined that these protein decrements were due to post-translational modifications.

Pb exposure also was found to contribute to leakiness of the BBB by decreasing the resistance across the junction (Balbuena et al., 2010). An in vitro co-culture system employing endothelial cells (RBE4 or bovine brain microvascular endothelial cells) and astrocytes (primary Sprague-Dawley neonatal pup astrocytes, GD21) served as the barrier between Pb-containing media and neurons. Pb acetate exposure (1 and 10 µM) for 14 hours significantly impaired transendothelial electrical resistance (TEER), a marker of BBB integrity, in a concentration-dependent manner.

Long-term Pb exposure of adult mice was found to increase regional edema and BBB permeability (López-Larrubia and Cauli, 2011). Adult male rats exposed to Pb acetate in drinking water for 4 or 12 weeks (50 or 500 ppm, resulting in blood Pb levels of 12 and 55 µg/dL, respectively) were assessed by diffusion weighted imaging for changes in apparent diffusion coefficent (ADC), a measure of tissue water diffusivity that changes under pathological conditions like cerebral edema. With 12 weeks of exposure, 50 ppm Pb increased the ADC values in the cerebellum and mesencephalic reticular formation, and 500 ppm Pb exposure significantly increased ADC in the corpus callosum and caudate putamen. With 4 weeks of exposure, 500 ppm Pb significantly increased the water ADC in the hippocampus, mesencephalic reticular formation, and cerebellum but not in other brain areas. The brain areas with elevated ADC also showed increased BBB permeability as measured with evans blue dye.

5.3.11.6 Cell Adhesion Molecules

Classic cell adhesion molecules including neural cell adhesion molecule (NCAM) and the cadherins are junctional or cell surface proteins that are critical for cell recognition and adhesion. While direct effects of Pb on cell adhesion molecules have not been described, the calcium-dependency of these molecules suggests that interaction from competing cations like Pb can potentially contribute to nervous system barrier function disruption, neurite outgrowth, synaptic plasticity, learning and memory (Prozialeck et al., 2002).

5.3.11.7 Effects on Glial Cells

Astroglia and oligodendroglia are supporting cells in the nervous system that maintain the extracellular space in the brain and provide structural support to neurons, deliver nutrients to neurons, and promote myelination. Glial cells provide immune surveillance in the brain and contribute to inflammation-mediated pathologies. In Wistar rats, Pb treatment (15 mg/kg of Pb acetate, i.p.) during early postnatal maturation was observed to produce chronic glial activation with inflammation and neurodegeneration (Strużyńska et al., 2007). Among the cytokines detected in the brains of these Pb-treated rats were IL-1β, TNF-α and IL-6. Glial cells have been shown to serve as Pb sinks in the developing and mature brain by sequestering Pb (Tiffany-Castiglioni et al., 1989). This glial sequestration of Pb was accompanied by a decrease in brain glutamine concentrations at doses of 0.25 ± 1.0 μM Pb acetate and a reduction in glutamine synthetase activity in the astroglia; astroglia take up released glutamate and convert it to glutamine. Pb has been shown to induce hypomyelination and demyelination (Coria et al., 1984) mediated through the oligodendrocytes with younger animals found to be more susceptible to the effects of Pb (Tiffany-Castiglioni et al., 1989). Pb accumulation in young glial cells may contribute to a lifelong exposure of neurons to Pb as Pb is released from the sink over time. Thus, Pb accumulation in glial cells can contribute to continual damage of surrounding neurons (Holtzman et al., 1987).

Glial transmitters

Evidence indicates that glial transmission is affected with Pb exposure and that the NMDAR may be involved in this aberrant glial transmission. To determine the contribution of the gliotransmitter serine to Pb-mediated changes in LTP, Sun et al. (2007) exposed rats to Pb acetate from gestation through lactation to PND28 via maternal drinking water and collected hippocampal sections. CA1 section LTPs were examined using in vitro patch clamp monitoring. Chronic Pb exposure impaired the magnitude of

hippocampal LTPs, but the magnitude of long-term depression was restored with supplementation with D-serine (Sun et al., 2007), which is known to be regulated by the NMDAR (Bear and Malenka, 1994). The use of 7-chlorokynurenic acid, an antagonist of the glycine binding site of the NMDAR, which also is the binding site of D-serine, effectively abolished the rescue of LTP by D-serine. NMDAR-independent LTP hippocampal neurotransmission was inhibited in slices of Pb-exposed mossy-CA3 synapses and was not rescued by exogenous D-serine supplementation.

5.3.11.8 Neurotransmitters

Pb has been shown to compete with calcium for common binding sites and second messenger activation. When Pb activates a calcium-dependent system in the nervous system, it can contribute to aberrant neurotransmitter regulation and release because this system intimately relies on calcium signaling for its homeostasis. Pb also has been shown to interfere with other physiological divalent cations. Pb-related alterations in neurotransmission are discussed in further detail below.

Monoamine Neurotransmitters and Stress

The monoamine neurotransmitters include dopamine (DA), serotonin (5HT), and norepinephrine (NE). Combined exposures of maternal stress and Pb exposure can synergistically enhance neurobehavioral impairments in offspring of exposed animals and can sometimes potentiate an effect that would otherwise be sub-threshold. Virgolini et al. (2008a) found enhanced DA and NE release in male rats and enhanced NE release in female rats after developmental Pb exposure (50 or 150 ppm via drinking water, 2 months prior to mating through lactation, resulting in blood Pb levels of 11 µg/dL and 35 µg/dL, respectively) and combined maternal and offspring stress. In most cases, stress potentiated the effects of Pb exposure on offspring NE and DA concentrations. Regional 5HT levels were unaffected in offspring with Pb exposure alone. Pb (50 and 150 ppm) combined with stress (maternal and/or offspring stress) significantly potentiated 5HT levels in the frontal cortex in females and in the nucleus accumbens (NAC) and striatum in male offspring. The concentration of 5-Hydroxyindoleacetic acid (5HIAA), the main metabolite of 5HT, was significantly increased in the striatum of male offspring with 150 ppm Pb exposure alone. With 50 ppm Pb, stress potentiated striatal and frontal cortex 5HIAA in males. Potentiation of 5HIAA levels in females was significant in the NAC with 50 ppm Pb exposure; stress alone also significantly increased 5HIAA levels in the NAC of females with no Pb exposure. Pb-induced changes in brain neurochemistry with

or without concomitant stress exposure are complex with differences varying by brain region, neurotransmitter type, and sex of the animal.

Monoamine Neurotransmitters and Auditory Function

Earlier work showed that perinatal Pb exposure of rats induced increased tyrosine hydroxylase, increased DA, and increased cerebral cortex catecholamine neurotransmission (Devi et al., 2005; Leret et al., 2002; Bielarczyk et al., 1996). Earlier publications detailing important time windows, durations, and doses of Pb exposure indicated varying effects on monoamine neurotransmitters. In recent work, these neurotransmitters, among others, have been implicated in Pb effects on auditory function in various integration centers of the brainstem including the lateral superior olive (LSO) and the superior olivary complex (SOC). Among various functions, the SOC is vital for sound detection in noisy settings. A recent study in mice found significant decreases in immunostaining of LSO and SOC brainstem sections for monoamine vesicular transporter VMAT2, 5HT, and dopamine beta-hydroxylase (DbH, a marker for NE) after gestational-lactational Pb exposure (10 or 100 µM Pb acetate from the formation of breeding pairs to PND21). This exposure period corresponds to the period of auditory development in the mouse. Statistically significant decreases in VMAT2 and DbH were found in mice with blood Pb levels of 8.0 and 42.2 µg/dL; however, decrements in 5HT were statistically significant only in mice with 8.0 µg/dL blood Pb level. Immunostaining for tyrosine hydroxylase and transporters including VGLUT1, VGAT, VAChAT indicated that they were unaffected by developmental Pb exposure. These data provide evidence that specific regions of the brainstem involved in auditory integration are affected by developmental Pb exposure via effects on monoamine neurotransmitters (Fortune and Lurie, 2009). The Pb-induced effects on the monoamine system of the auditory portion of the brainstem provide possible mechanistic explanation for the epidemiologic and toxicological evidence for Pb-associated decrements in auditory processing (Section 5.3.7).

Dopamine

The 2006 Pb AQCD (U.S. EPA, 2006b) detailed evidence for Pb-related decreased dopaminergic cell activity in the substantia nigra and ventral segmental areas. Earlier studies with postnatal or adult Pb exposure reported changes in DA metabolism, as indicated by changes in DA and DOPAC, a DA metabolite. Expanding upon these findings, a recent study measured DA and DOPAC in various brain regions of year-old male C57BL/6 mice to examine if gestational plus lactational Pb exposure affected DA metabolism (Leasure et al., 2008). Exposure of males to 27 and 109 ppm Pb acetate

induced significant elevations in DOPAC concentration and the DOPAC to DA ratio in the forebrain. In the forebrain, DA was significantly decreased with the lower dose and significantly elevated with the higher dose compared to controls. In the striatum, DOPAC was significantly elevated with both doses, but DA concentration was only significantly elevated with the higher dose. The striatum ratio of DOPAC to DA was not significantly different from that in controls. These recent data expand upon the monoamine literature base which indicates that Pb exposure of rats during the gestational/lactational, lactational, or postweaning period producing blood Pb levels 9-34 µg/dL induces increased sensitivity of the dopamine receptors (D2 and D3) (Gedeon et al., 2001; Cory-Slechta et al., 1992), produces higher DA levels (Devi et al., 2005; Leret et al., 2002), and enhances catecholamine neurotransmission in the cerebral cortex, cerebellum, and hippocampus (Devi et al., 2005).

The interaction of DA and the NO system in the striatum was studied after prenatal Pb exposure (Nowak et al., 2008). Blood Pb levels were not reported in this study, but similarly treated Wistar rat pups had blood Pb levels at parturition in range of 50-100 µg/dL (Grant et al., 1980). 7-nitroinidazole (7-NI), a selective inhibitor of nNOS, enhanced amphetamine-evoked DA release in the rat striatum (Nowak et al., 2008). Prenatal Pb exposure attenuated the facilitatory effect of 7-NI on DA release in the striatum. This interaction was ROS-independent; using spin trap measurements, investigators found no significant concentration changes in hydroxyl radical with Pb exposure (Nowak et al., 2008). Thus, the neuronal NO system appears to be involved in specific aspects of Pb-related dopaminergic changes.

In various animal models, the loss of retinal DA, dopamine turnover (DOPAC:DA ratio), or Zn was associated with abnormal rod-mediated scotopic ERGs. These effects may explain observations of Pb-associated subnormal or supernormal retinal ERGs observed in animals and children (Rothenberg et al., 2002b; Lilienthal et al., 1994; Lilienthal et al., 1988; Alexander and Fishman, 1984) (Sections 5.3.7.1 and 5.3.7.3), although the biological relevance of the variable effects of Pb exposure on subnormal versus supernormal ERGs is not clear.

NMDA Receptors

The glutamate receptor, NMDAR, has been shown to contribute to synaptic plasticity, and Pb exposure at different developmental stages has been shown to contribute to aberrations in LTP or long term depression (LTD) in the hippocampus via reduced NMDA current, among other mechanisms (Liu et al., 2004). The 2006 Pb AQCD (U.S. EPA, 2006b) indicated that Pb attenuated the stimulation of glutamate release, which in turn, affected LTP. Further, the effects of Pb exposure on decreasing the magnitude of

LTP and increasing the threshold of the LTP in the hippocampus were found to be biphasic or nonlinear. NMDAR subtypes have been shown to be significantly decreased with developmental Pb exposure (Guilarte and McGlothan, 1998). Recent evidence indicated Pb-related decreases in the gene expression and protein level of NMDAR subunits NR1, NR2A, and NR2B in weanling male rats exposed to 4×10^4 µg/dL Pb acetate in drinking water for 8 weeks. Several of these responses were attenuated with methionine-choline co-exposure (Fan et al., 2010). Other recent mechanistic studies found that pretreatment of primary fetal brain neuronal rat cultures with glutamic acid, a NMDAR agonist, reversed Pb-induced reductions in NMDAR subunits (Xu and Rajanna, 2006) whereas pretreatment with the NMDA antagonist MK-801 exacerbated Pb-induced NMDAR deficits (Xu and Rajanna, 2006). Further strengthening the link among Pb exposure, NMDAR function, and learning, Guilarte et al. (2003) demonstrated that rats exposed to 1,500 ppm Pb during gestation and lactation then reared in isolation, had reduced expression of hippocampal NMDA receptor subunit 1, reduced induction of BDNF mRNA, and learning impairment. These effects were attenuated in Pb-exposed rats reared in an enriched environment with toys.

Other Glutamate Receptors

The metabotropic glutamate receptor (mGluR) is another well-recognized target of Pb toxicity. In vitro (GD18 fetal rat cultures, 0.01, 100, 1 µM Pb chloride in culture media) and in vivo studies (gestational and lactational Pb acetate exposure; 500, 2,000, 5,000 ppm in dam drinking water, with respective weanling blood Pb levels of 18, 57, 186 µg/dL) showed that Pb exposure induced mGluR5 mRNA and protein decrements in a concentration-dependent manner (Xu et al., 2009c). Recent evidence indicates a role for mGluR5 in synaptic plasticity, LTP, and LTD; thus, the Pb-related attenuation of mGlu5 expression may represent a mechanism by which Pb impairs learning and memory.

5.3.11.9 Neurogenesis

Studies continue to show that Pb exposure decreases neurogenesis (i.e., proliferation of neuronal cells) in the hippocampus, which is important in LTP, spatial learning, neuronal outgrowth, and possibly mood disorders such as schizophrenia. Coherence for these findings is provided by evidence for Pb-induced decreases in NMDAR, which mediates the integration of new neurons into existing neuronal pathways in the adult hippocampal DG. Earlier work by Schneider et al. (2005) showed that postnatal Pb exposure (PND25 to PND50 or PND55, 1,500 ppm Pb acetate in chow, resulting in blood Pb level of

20 µg/dL) of male Lewis rats induced significant decrements in BrdU incorporation (an indicator of DNA replication) at PND50-PND55.

Recent publications affirm this previous finding with different sex of animals, dosing and exposure time windows. Postnatal Pb exposure of Wistar rat pups from PND1-PND30 (2,000 ppm Pb acetate, resulting in blood Pb levels of 34 and 6.5 µg/dL at PND21 and PND80, respectively) induced a statistically significant decrement in the number of new cells (BrdU positive cells) in the DG at PND80 (Fox et al., 2010) (Figure 5-14). In another study, lifetime Pb exposure beginning in gestation (1,500 ppm Pb acetate in chow from 10 days before mating to PND50 or PND78, resulting in blood Pb levels 26 µg/dL) of female Long-Evans rats induced significant decrements in hippocampal granule cell neurogenesis in adult rats (Verina et al., 2007). Also, Pb-exposed animals had significant decreases in brain volume in the stratum oriens (SO) region of the hippocampus, specifically in the mossy fiber terminals of the SO. Pb-exposed animals also showed a significant decrease in the length-density of immature or newly-formed neuron in the outer portion of the DG. These findings show that Pb exposure at doses relevant to humans induced significant decreases in adult hippocampus granule cell neurogenesis and morphology, potentially providing mechanistic explanations for Pb-induced neuronal aberrations and downstream effects such as learning and memory. Exposure of zebrafish embryos to Pb (50–700 µM Pb acetate in embryo medium from 0 to 6 days post hatch) caused significant apoptosis of brain cells (increased TUNEL positive brain cells) and decreased brain levels of some (gfap and huC) but not all (crestin and neurogenin1) genes involved in neurogenesis (Dou and Zhang, 2011).

Note: Light micrograph pictures of Brd-U positive cells (proliferating cells undergoing DNA replication), black dots, in control (A) and Pb-exposed rats (B). Counts of Brd-U positive cells (C) and Volume of hippocampus dentate gyrus (D) in control (white bars) and Pb-exposed animals (black bars). *p <0.05 vs. control. Rats were exposed to 2,000 ppm Pb acetate from postnatal day 1-30 (blood Pb levels 34 µg/dL) and were examined at postnatal day 80.

Figure 5-14 Neurogenesis (production of new cells) in the rat hippocampal dentate gyrus after early postnatal Pb exposure.

5.3.11.10 Neurite Outgrowth

As described in the 2006 Pb AQCD (U.S. EPA, 2006b), Pb was shown to decrease neurite outgrowth in vitro and mediate such effects via protein kinase mediated pathways (MAPK/ERK); earlier work had documented decreased primary DA neuron outgrowth with 0.001 µM Pb exposure (Lidsky and Schneider, 2004). A recent study showed that gestational exposure of female Wistar rats to 500-4,000 µM Pb chloride (resulting in offspring blood Pb levels up to 12 µg/dL) significantly decreased offspring hippocampal neurite outgrowth and reduced the expression of hippocampal polysialylated neural cell adhesion molecule (PSA-NCAM), NCAM, and sialytransferase (Hu et al., 2008b). PSA-NCAM is transiently expressed in newly formed neurons during the period of neurite outgrowth from embryogenesis until the early postnatal period and is down-regulated in the brains of adults except in areas known to exhibit synaptic plasticity (Seki and Arai, 1993). NCAM is important for memory formation, plasticity and synapse formation, and its suppression by early-life Pb exposure may represent a mechanism mediating Pb-associated impairments in cognitive function.

5.3.11.11 Epigenetics

Many investigators are beginning to show that environmental chemical exposures and air pollution exposure are associated with epigenetic changes in humans (Baccarelli and Bollati, 2009; Pavanello et al., 2009; Tarantini et al., 2009; Bollati et al., 2007). Epigenetic changes involve changes in DNA expression without changes in the DNA sequence, and these changes may be heritable. Epigenetic changes include histone modification, DNA methylation, miRNA changes, or pathways that affect these processes. Differential epigenetic modification has the potential to contribute to disease by silencing or activating genes in an aberrant manner. For example, a recent study identified differential methylation of a specific locus in monozygotic twins discordant for schizophrenia (Dempster et al., 2011); Pb was not examined in this study.

DNA methyltransferases catalyze the transfer of a methyl group to DNA and are important in epigenetics (i.e., silencing of genes like tumor suppressors) and imprinting. DNA methyltransferase activity was significantly decreased in cortical neurons from aged monkeys at ages 20-23 years after infancy exposure (PND1-PND400, blood Pb level 19-26 µg/dL) and fetal mouse brain cells exposed to Pb in culture (0.1 µM Pb) (Wu et al., 2008b). Changes in DNA methyltransferases (Dnmt1, Dnmt3a) were noted in control monkey brains as they aged and these changes were exacerbated by early postnatal Pb exposure (Bihaqi et al., 2011). Another enzyme involved in DNA methylation, methyl CpG binding protein 2 MECP2, showed a similar trend as the Dnmts. Profiles of the histone modifying gene H34mc2 increased with age in control animals. This age-related increase was significantly attenuated in Pb-exposed animals. The cerebral cortex tissue used in this experiment was obtained from female primates who had received 1.5 mg/kg Pb acetate via diet per day from birth until 400 days of age (resulting in blood Pb levels 19-26 µg/dL at age 400 days) (Rice, 1990). Methyltransferases catalyze biological methylation reactions using cofactor S-adenosyl methionine (SAM) as the methyl donor. In rats, SAM exposure after gestational-lactational Pb exposure (1,500 ppm Pb acetate via drinking water of dams followed by 20-22 days of daily 20 mg/kg BW SAM exposure of offspring) improved hippocampal LTP and Morris water maze performance at PND44-PND54 (Cao et al., 2008). Thus, the improved cognition and synaptic plasticity observed with co-exposure to Pb and the methyl donor SAM suggest that methylation reactions may be involved in Pb-associated effects on cognition.

5.3.11.12 Cholesterol and Lipid Homeostasis

Various pathological conditions are associated with elevated plasma free fatty acids or elevated cholesterol. Adult male rats exposed to Pb acetate (200, 300, or 400 ppm) in their drinking water for 12 weeks had increased cholesterogenesis and phospholipidosis in brain tissue (Ademuyiwa et al., 2009). Pb-induced changes in brain cholesterol showed an inverse U concentration-response relationship, with the largest increase in brain cholesterol observed with 200 ppm Pb followed by 300 ppm Pb. Animals exposed to 400 ppm Pb did not have significant changes in brain cholesterol. In a separate study, Pb treatment (single dose 100 µmol/kg, i.v.) was shown to depress the activity of cholesterol-7-a-hydroxylase, an enzyme involved in biosynthesis of bile acid, which mediates elimination of cholesterol from the body (Kojima et al., 2005). In Ademuyiwa et al. (2009), Pb exposure significantly increased brain triglycerides by 83% at 300 ppm and by 108% at 400 ppm. At 200 ppm, Pb exposure induced a statistically nonsignificant decrease in brain triglycerides. Pb exposure across all three dose groups induced significantly increased brain phospholipids. Interestingly, plasma free fatty acids were significantly elevated in a concentration-dependent manner; plasma triglycerides and cholesterol were unaffected by Pb exposure. The molar ratio of brain cholesterol to phospholipids, an indicator of membrane fluidity, was significantly increased at 200 and 300 ppm Pb exposure, indicating increased membrane fluidity. Brain Pb in all dose groups was below the limit of detection (0.1 ppm). Blood Pb levels at 0, 200, 300, and 400 ppm were 7, 41, 61, and 39 µg/dL, respectively, higher than those relevant to humans. In summary, a recent study found that adult 12-week Pb exposure significantly increased brain cholesterol, triglycerides, and phospholipids as well as significantly increased plasma free fatty acids in rats. These effects were sometimes more prominent at the lower 200 ppm Pb dose. The impacts of these Pb-related changes in phospholipidosis and cholesterogenesis in the brain on downstream nervous system effects are not well characterized.

5.3.12 Lifestage of Pb Exposure and Neurodevelopmental Deficits

Environmental exposures during critical lifestages can affect key physiological systems that orchestrate plasticity (Feinberg, 2007). Exposures during the prenatal and/or early postnatal period may be especially detrimental for neurodevelopmental effects because of active neuronal growth and/or synaptogenesis/pruning structure that occur during these periods (Rice and Barone, 2000; Landrigan et al., 1999). However, brain development has been shown to continue throughout adolescence. MRI studies in children and adults ages 3-30 years have shown that total cerebral volume peaks at age 10.5 and 14.5 years in females and males, respectively (Giedd et al., 2009; Lenroot and Giedd, 2006). The

volume of the cerebellum was found to peak two years later. Lateral ventricular volume and white and gray matter volume also were found to increase throughout adolescence. Gray matter volume peaked 1 to 3 years earlier in females than males. These observations that brain development is active throughout childhood and in adolescence indicate the potential for neurodevelopment to be altered later in childhood.

Epidemiologic studies consistently show that blood Pb levels measured during various lifestages and time periods, including the prenatal period, early childhood, later childhood, and averaged over multiple years, are associated with cognitive function decrements and increases in behavioral problems. These observations of Pb-associated elevated risk of neurodevelopmental deficits in children are well supported by findings in animals that prenatal and/or postweaning Pb exposure alters brain development via changes in synaptic architecture (Section 5.3.11.4) and neuronal outgrowth (Section 5.3.11.10) and leads to impairments in memory and learning (Section 5.3.2.3) and increases in impulsivity (Section 5.3.3.1). In monkeys, Pb exposures during multiple lifestages and time periods, including lifetime, lactational, or postlactation to adulthood, resulted in impaired cognitive function, although not on all tests (Rice, 1992b, 1990; Rice and Karpinski, 1988). On one test of executive function in the same monkeys at ages 5-6 years, impairments were found with lifetime Pb exposure starting from birth or starting after weaning but not infancy-only exposure (Rice and Gilbert, 1990b). The latter observations indicate that gestational or early infancy Pb exposures are not necessary to induce cognitive function decrements in juvenile animals.

Unlike other organ systems, the unidirectional nature of CNS development limits the capability of the developing brain to compensate for cell loss, and environmentally-induced cell death can result in a permanent reduction in cell numbers (Bayer, 1989). Hence, when normal development is altered, the early effects have the potential to persist into adult life even in the absence of concurrent exposure, magnifying the potential public health impact. Some epidemiologic evidence indicates associations of earlier childhood blood or tooth Pb levels with cognitive function decrements, increases in inattention, and increases in misconduct in adolescents or adults (Mazumdar et al., 2011; Fergusson et al., 2008; Wright et al., 2008; Ris et al., 2004; Bellinger et al., 1994a; Stiles and Bellinger, 1993). These epidemiologic studies did not examine adult blood Pb levels, thus the relative influence of adult Pb exposure cannot be ascertained. In the Boston cohort, stronger associations observed for age 2 year blood Pb level than concurrent blood Pb level with FSIQ decrements at ages 57 months and 10 years indicated an effect of earlier rather than later childhood Pb exposures (Bellinger et al., 1992; 1991). The persistence of effects of early exposures is supported by findings of impaired learning in adults monkeys that had juvenile Pb exposure (Rice, 1992b, 1990). A few available recent toxicological studies also found that infancy Pb exposure but not adult-only Pb exposure

led to neurodegenerative amyloid plaque formation in the brains of aged rodents and monkeys (Section 5.3.10.1).

With repeated assessments of children prenatally to later childhood and early adulthood, the prospective cohort studies have provided data to compare the neurodevelopmental effects associated with blood Pb levels measured at different lifestages and time periods. In the collective body of evidence, cognitive function decrements in children have been associated with prenatal, early childhood, childhood average, and concurrent blood Pb levels, without clear indication of a single critical lifestage or duration of Pb exposure related to risk of neurodevelopmental effects in children. In prospective studies, the identification of critical developmental periods with regard to risk of neurodevelopmental decrements from Pb exposure has been complicated by the high degree of correlation of the blood Pb levels of children over time and the confounding of age and peak blood Pb levels (Lanphear et al., 2005; Dietrich et al., 1993a; Needleman et al., 1990).

As described in detail in the 2006 Pb AQCD (U.S. EPA, 2006b), several studies with varying lengths of follow-up demonstrated associations of prenatal blood Pb levels (maternal and umbilical cord) with decrements in cognitive function throughout childhood and into early adulthood (Section 5.3.2). These findings are consistent with the observations of active CNS development occurring during prenatal development as described above. Substantial fetal Pb exposure may occur from mobilization of maternal skeletal Pb stores, which may be related to past maternal Pb exposures (Gulson et al., 2003; Hu and Hernandez-Avila, 2002). Pb can cross the placenta to affect the developing fetal nervous system (Rabinowitz, 1988). Among 94-211 mother-child pairs in Albany, NY, maternal-cord blood Pb level correlations of 0.53-0.81 were reported, depending on the stage of pregnancy, indicating the influence of maternal blood Pb levels on newborn blood Pb levels (Schell et al., 2003). Depending on the magnitude of child exposure, the contribution of maternal blood Pb levels on child blood Pb levels may wane early, and by age 9 months, child blood Pb levels may be influenced mainly by child Pb exposures (Section 4.4.1). Thus, associations of neurodevelopmental outcomes assessed after infancy with postnatal blood Pb levels may reflect effects of postnatal Pb exposures.

In most studies of very young children, ages <2 years, decrements in MDI score were associated with higher prenatal (maternal or cord) and concurrent blood Pb levels (Table 5-14). Among studies that examined blood Pb levels at multiple time periods, several found larger blood Pb-associated decrements in MDI for prenatal blood Pb than concurrent blood Pb (Hu et al., 2006; Gomaa et al., 2002; Bellinger et al., 1987; Dietrich et al., 1986). In the Yugoslavia cohort, per log increase in blood Pb level, the MDI decrement at age 2 years was larger for concurrent blood Pb than for prenatal cord blood Pb (Wasserman et al., 1992). Concurrent blood Pb levels were higher than prenatal cord

blood Pb levels. The collective evidence indicates that both prenatal and postnatal child Pb exposures may contribute to neurodevelopmental effects in children from infancy to age 2 years, with some indication that prenatal Pb exposure has a stronger effect.

Table 5-14 Associations of cognitive function with blood Pb levels measured at various lifestages and time periods in prospective studies.

Study[a]	Study Population and Methodological Details (Within studies, effect estimates are presented in order of lifestage or time period of blood Pb measurement, with largest effect estimate in bold)	Blood Pb Levels (µg/dL)	Outcome	Effect Estimate (95% CI)[b]
Cognitive Assessment at Age 2 Years and Younger				
Bellinger et al. (1987)	249 children followed from birth (1979-1981) to age 3 yr, Boston area, MA Moderate participation rate, high follow-up retention. Participants had higher cord blood Pb levels, higher SES, maternal IQ, HOME score. Regression model adjusted for the maternal age, race, IQ, education, years cigarette smoking,3rd trimester alcoholic drinks/ week, study period mean SES, HOME, child sex, birth weight, gestational age, birth order.	Prenatal (cord) Mean (SD): 6.6 (3.2)	Overall Bayley MDI among Ages 6, 12, 18, and 24 mo	vs. prenatal blood Pb level <3 µg/dL: **Prenatal 6-7 µg/dL: -3.8 (-6.3, -1.3)** **Prenatal ≥ 10 µg/dL: -4.8 (-7.3, -2.3)** Concurrent reported to not to be associated with overall MDI, no quantitative data reported.
Dietrich et al. (1986)	280 children followed prenatally to age 6 mo, Cincinnati, OH No information on participation rate. Log linear regression model adjusted for birth weight, gestation, sex. Also considered potential confounding by SES, HOME score, prenatal smoking and alcohol use, maternal Fe binding.	Prenatal (maternal) Mean (SD): 8.0 (3.8) Concurrent Mean (SD): 4.5 (2.9)	Bayley MDI Age 6 mo	**Prenatal: -0.6 (-1.1, -0.09)** Concurrent: -0.23 (-0.58, 0.12)
Hu et al. (2006)	146 children born 1997-1999 followed prenatally to age 2 yr, Mexico City, Mexico Moderate follow-up participation. Eligible similar to non-eligible. Log linear regression model adjusted for sex, maternal age, current weight, height-for-age Z score, maternal IQ, concurrent blood Pb (in models examining blood Pb at other lifestages). Considered potential confounding by other unspecified factors.	Prenatal (maternal 1st trimester): Mean(range): 7.1 (1.5-43.6) Prenatal avg: NR Earlier childhood at 12 mo: Mean (SD): 5.2 (3.4) Concurrent Mean (SD): 4.8 (3.7)	Bayley MDI Age 24 mo	Per log increase in blood Pb: **Prenatal 1st trimester: -4.1 (-8.1, -0.17)** Prenatal avg: -3.5 (-7.7, 0.63) Age 12 month: -2.4 (-6.2, 1.49) Concurrent: -1.0 (-3.9, 1.9)

MDI = Mental Development Index, FSIQ = full-scale IQ, NR = Not reported

[a]Results are presented first for MDI in children up to age 3 years, then for FSIQ in school-aged children. Within studies, effect estimates are presented in order of increase lifestage or time period of blood Pb measurement, with the largest effect estimate in bold.

[b]Effect estimates are standardized to a 1 µg/dL increase in blood Pb level in analyses of blood Pb as a linear continuous variable.

[c]Effect estimates represent comparisons between children in different categories of blood Pb level, with children in the lower blood Pb category serving as the reference group.

[d]Sufficient data were not provided in order to calculate 95% CI.

Prenatal and early postnatal (age 6 month) blood Pb levels also were associated with cognitive function in children examined at school-age (ages 4-17 years) (Table 5-14). However, most of these studies also found cognitive function decrements in association with postnatal blood Pb levels, and results did not identify an individual postnatal time period of blood Pb measurement associated with cognitive function decrements. Increases in concurrent blood Pb levels were associated with larger decrements in FSIQ in the Cincinnati and Yugoslavia cohorts at ages 3-6.5 years than were prenatal blood Pb levels (Wasserman et al., 1994; Dietrich et al., 1993b). In the Cincinnati cohort as adolescents ages 15-17 years, increases in both prenatal and higher earlier childhood (age 6.5 years) were associated with decrements in a learning/memory composite score (Ris et al., 2004). In the Boston and Port Pirie cohorts, increases in age 2 year blood Pb levels were associated with larger FSIQ decrements at ages 7 and 10 years, respectively, than were concurrent or lifetime average blood Pb levels (Baghurst et al., 1992; Bellinger et al., 1992). However, in the Port Pirie cohort, an association also was found lifetime (to age 7 years) average blood Pb level. Among children ages 6-10 years in Mexico City, per unit increase, prenatal blood Pb levels were associated with larger FSIQ decrements than individual blood Pb levels between ages 1-5 or the age 6-10 year average (Schnaas et al., 2006). In contrast, results from the Rochester cohort indicated that increases in lifetime average and concurrent blood Pb level were associated with larger FSIQ decrements at ages 5 years than were increases in peak blood Pb level (Canfield et al., 2003a). Collectively, the epidemiologic findings indicate that blood Pb levels measured at various postnatal time periods, earlier childhood, childhood average, later childhood, and concurrent blood Pb levels are associated with decrements in cognitive function when assessed in school-aged children.

Consistent with individual studies, analyses combining studies pointed to associations of FSIQ in school-aged children with blood Pb levels measured at various lifestages and time periods. The analysis pooling data from seven prospective studies found that increases in infancy average (age 6-24 months), peak, concurrent, and lifetime average peak blood Pb levels were associated with decreases in FSIQ in children ages 4.8-10 years (Table 5-14). Investigators reported that the model with concurrent blood Pb level explained the largest proportion of variance in FSIQ (R^2) (Lanphear et al., 2005). In a meta-analysis of results from five cohort studies (Pocock et al., 1994), a larger decrease in FSIQ was estimated for an increase in peak (around age 2 years) blood Pb level than for blood Pb level measured around birth or after age 2 years. Deciduous tooth Pb levels have been associated with decrements in cognitive function and increases in attention-related behavioral problems in children and young adults (Table 5-8, Table 5-9, and Table 5-11). These results indicate cumulative Pb exposure over several years may contribute to neurodevelopmental effects in children. In school-aged children, concurrent blood Pb levels reflect past Pb exposures that are mobilized from bone remodeling to

blood and recent exposures. Thus, associations with concurrent blood Pb levels also may reflect an effect of cumulative past and more recent Pb exposures.

Studies conducted in the Cincinnati cohort examined diverse neurodevelopmental effects and found that prenatal and neonatal blood Pb levels were associated with impaired auditory processing in children ages 5 years and increases in parental ratings of delinquent behavior in adolescents ages 15-17 years (Dietrich et al., 2001; Dietrich et al., 1992) but not cognitive function or motor function decrements in children at age 6 years (Bhattacharya et al., 2006; Bhattacharya et al., 1995; Dietrich et al., 1993b; Dietrich et al., 1993a). These findings suggest that the critical lifestage of Pb exposure may vary among nervous system effects.

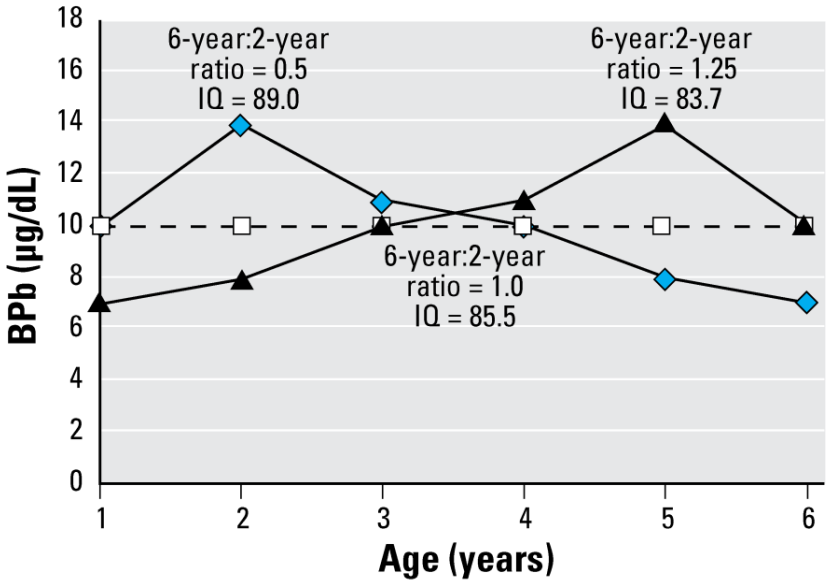
Some studies have aimed to improve the characterization of important lifestages and time periods of Pb exposure by examining children in whom blood Pb levels are not strongly correlated over time (i.e., children whose blood Pb level ranking changed over time) (Hornung et al., 2009; Schnaas et al., 2006; Chen et al., 2005; Tong et al., 1998; Bellinger et al., 1990). Collectively, most results indicated FSIQ decrements in association with concurrent blood Pb levels but did not conclusively demonstrate stronger findings for early or concurrent blood Pb levels (Table 5-15).

Table 5-15 Comparisons of blood Pb-FSIQ associations in groups of children with different temporal trends in blood Pb levels.

Study	Study Population and Methodological Details	Blood Pb Levels (µg/dL)	Outcome	Effect Estimate(95% CI)
Hornung et al. (2009)	397 children followed from birth (1979-1984) to age 6 yr, Rochester, NY and Cincinnati, OH. High follow-up participation. No selective attrition. Linear regression model adjusted for city, HOME score, birth weight, maternal IQ, maternal education.	Geometric mean (5th-95th): Earlier childhood age 2 yr: 8.9 (3.0-23.8) Concurrent: 6.0 (1.9-17.9)	FSIQ Wechsler Intelligence Scale for Children-Revised (WISC-R) Age 6 yr	Difference in FSIQ at age 6 yr with an age 6:2 yr blood Pb level ratio = 0.5 as the reference Ratio age 6:2 yr blood Pb level = 2.0 -7.0 (-10, -4.0)
Bellinger et al. (1990)	170 children followed prenatally to age 57 mo, Boston area, MA High follow-up participation. No report on characteristics of subjects followed. Log linear regression adjusted for HOME score, SES, maternal IQ, maternal age, sex, ethnicity	High prenatal (cord) >10 Low concurrent: <3 Medium concurrent: 3-10 High concurrent >10	Change in McCarthy General Cognitive Index (GCI) z-score Between ages 24 and 57 mo	High prenatal/Low concurrent 0.42 (-0.15, 0.99) High prenatal/Medium concurrent 0.15 (-0.14, 0.44) High prenatal/High concurrent -0.15 (-0.56, 0.26)
Tong et al. (1998)	375 children followed from birth (1979-1982) to age 11-13 yr, Port Pirie, Australia Moderate follow-up participation. Participants had lower early blood Pb-cognitive function association. Log linear regression model adjusted for sex, birth weight, birth rank, feeding style, breastfeeding duration, maternal IQ, maternal age, SES, HOME score, parental smoking, parents living together. ANOVA to assess association of change in IQ with change in blood Pb across time intervals	Means Earlier childhood age 2 yr: 21.2 Age 11-13 yr: 7.9	Change in cognitive function z-scores between ages 2 and 11 yr Bayley MDI, age 2 yr McCarthy GCI, age 4 yr WISC-R, ages 7, and 11-13 yr	<10.2 µg/dL decline: 0.03 (-0.15, 0.21) 10.2-16.2 µg/dL decline: 0.04 (-0.15, 0.23) >16.2 µg/dL decline: -0.01 (-0.20, 0.18)
Chen et al. (2005)	780 children participating in the TLC trial from age 12-33 mo to age 7 yr, Baltimore, MD; Cincinnati, OH; Newark, NJ; Mostly African-American. 50% given chelation at ages 12-33 mo, blood Pb levels 20-44 µg/dL. No information on participation rate. Regression-based path analysis adjusted for city, race, sex, language, parental education and employment, single parent, age at blood Pb measurement, caregiver IQ. Considered potential confounding by chelation but not parental caregiving quality.	Mean (SD): Age 2 yr: 26.2 (5.1) Age 5 yr: 12.0 (5.2) Age 7 yr: 8.0 (4.0) Low age 2 yr: <24.9 Low age 7 yr: <6.2	WISC-III at age 7 yr	Difference in FSIQ vs. Low age 2, Low age 7 as the reference Low age 2, High age 7: -0.27 (-0.48, -0.05) High age 2, Low age 7: 0 (-0.21, 0.20) High age 2, High age 7: -0.28 (-0.47, -0.10)

Schnaas et al. (2006) followed children in Mexico City prenatally to age 10 years and found maternal blood Pb levels at 28-36 weeks of pregnancy to be weakly correlated with repeated measures of blood Pb between ages 1 and 10 years (Pearson $r \leq 0.23$). In models analyzing different lifestages of blood Pb level individually and in a mixed effects model that included prenatal and multiple postnatal blood Pb measures, maternal 28-36 week blood Pb level was associated with a larger decrement in FSIQ (Table 5-15). In the model with multiple lifestages of blood Pb level, analysis of variance inflation factors indicated a lack of collinearity among the serial blood Pb measures.

Pooling the Cincinnati and Rochester cohorts (n = 397), Hornung et al. (2009) created a new indicator of Pb exposure: the ratio of blood Pb level at 6 years of age to that at 2 years of age. As illustrated in Figure 5-15, the three groups of children representing the three temporal trends in blood Pb levels: no change ages 2-6 years (ratio = 1), higher blood Pb at age 6 years than 2 years (ratio = 1.25), higher blood Pb levels at age 2 years than 6 years (ratio = 0.5), have similar areas under the curve, indicating that cumulative blood Pb levels were similar in the three groups. Thus, differences in FSIQ are more likely to be attributable to differences in temporal trends. The lowest FSIQ at age 6 years was found in children with an age 6:age 2 year blood Pb ratio 1.25, i.e., children who had an increase in blood Pb level from 2 to 6 years of age (Figure 5-15 and Table 5-15).



Note: In combined Cincinnati and Rochester cohorts, FSIQ was compared among three different patterns of blood Pb level changes over time: peak at 2 years and age 6:2 year ratio = 0.5 (blue diamonds), peak at 5 years and age 6:2 year ratio = 1.25 (black triangles), and constant blood Pb level and age 6:2 year ratio = 1 (white squares). All three patterns have a similar cumulative blood Pb level (10 µg/dL) as indicated the areas under the curve. Children whose blood Pb levels peaked at age 5 years had the lowest FSIQ at age 6 years.

Source: Hornung et al. (2009)

Figure 5-15 Estimated FSIQ for three patterns of temporal trends in blood Pb level from ages 2 to 6 years in the Rochester and Cincinnati cohorts.

In the Boston cohort with comparable blood Pb levels to those in the Rochester cohort, Bellinger et al. (1990) found that at age 57 months, FSIQ, as assessed by McCarthy GCI, was similar between children in the high (≥ 10 µg/dL) and low (<3 µg/dL) prenatal cord blood Pb groups. Additionally, children with high prenatal and high concurrent blood Pb level (≥ 10 µg/dL) had a decrease (-0.15 standard deviation [95% CI: -0.46, 0.26]) in FSIQ from age 24 to 57 months. In contrast, children with high prenatal blood Pb but low concurrent blood Pb level (<3 µg/dL) had an increase (0.42 standard deviation [95% CI: -0.15, 0.99]) in FSIQ from age 24 to 57 months (Table 5-15). These findings indicated that by age 5 years, children with higher prenatal blood Pb levels appeared to recover the Pb-associated decrements in cognitive function unless concurrent blood Pb levels remained high. The investigators also demonstrated that optimal sociodemographic characteristics (e.g., higher HOME score, SES, maternal IQ and age, female) also protected against decrements in cognitive function associated with higher postnatal blood Pb levels. Collectively, these results suggest that cognitive development is not fixed early in childhood and can be affected negatively or positively by postnatal influences.

Chen et al. (2005) also found a stronger influence of higher concurrent blood Pb levels on FSIQ at age 7 years among children participating in a multi-city chelation trial. Children with higher concurrent blood Pb levels (≥ median 7.2 µg/dL) had lower IQ at age 7 years, regardless of whether blood Pb level at age 2 years was low or high (less than or greater than the median of 24.9 µg/dL, respectively). Blood Pb levels at ages 2 and 7 years were weakly correlated (r = 0.27). Because these children had been treated with chelators due to high blood Pb levels (20-44 µg/dL) at ages 12 to 33 months, the findings may have limited generalizability to the general population of children currently living in the U.S.

In contrast with the aforementioned studies, Tong et al. (1998) found that higher early-life blood Pb level was associated with a larger decrease in FSIQ than was concurrent blood Pb level in the Port Pire, Australia cohort at age 11-13 years (Table 5-15). This conclusion was based on the analysis of groups of children with different degrees of decline in blood Pb levels between ages 2 and 11-13 years. Although the mean blood Pb level in the study population declined overall from 21.2 µg/dL at age 2 years to 7.9 µg/dL at age 11-13 years, the magnitude of decline varied among children. The change in FSIQ between ages 2 and 11-13 years did not significantly differ between children with the largest decline (>16 µg/dL) in blood Pb level and children with the smaller decline (<10 µg/dL) (Table 5-15). These findings indicated an influence of higher blood Pb levels early in life despite declines in blood Pb with age and a persistence of Pb effects. The results do not preclude an independent association with concurrent blood Pb level.

A common limitation of studies that examined different temporal trends in blood Pb levels is the higher blood Pb levels of the study populations compared to those currently measured in most U.S. children. Additionally, in several study populations, children experienced large changes in blood Pb levels over time, for example, 50% decline or 25% increase in four years in Hornung et al. (2009). It is unclear whether these findings would apply to children currently in the U.S. within the same age range who would be expected to have smaller changes in blood Pb levels over time.

To conclude, the collective body of epidemiologic evidence does not strongly identify an individual critical lifestage or duration of Pb exposure with regard to neurodevelopmental effects in children. Cognitive function decrements and behavioral problems have been associated with prenatal, early childhood, lifetime average, and concurrent blood Pb levels as well as with childhood tooth Pb levels. The identification of critical lifestages of Pb exposure is complicated further by the fact that blood Pb levels in older children, although affected by recent exposure, are also influenced by Pb stored in bone due to rapid growth-related bone turnover in children relative to adults. Thus, associations of neurodevelopmental effects with concurrent blood Pb level in children may reflect the effects of past and/or recent Pb exposures (Section 4.3.5.1). Evidence indicates that

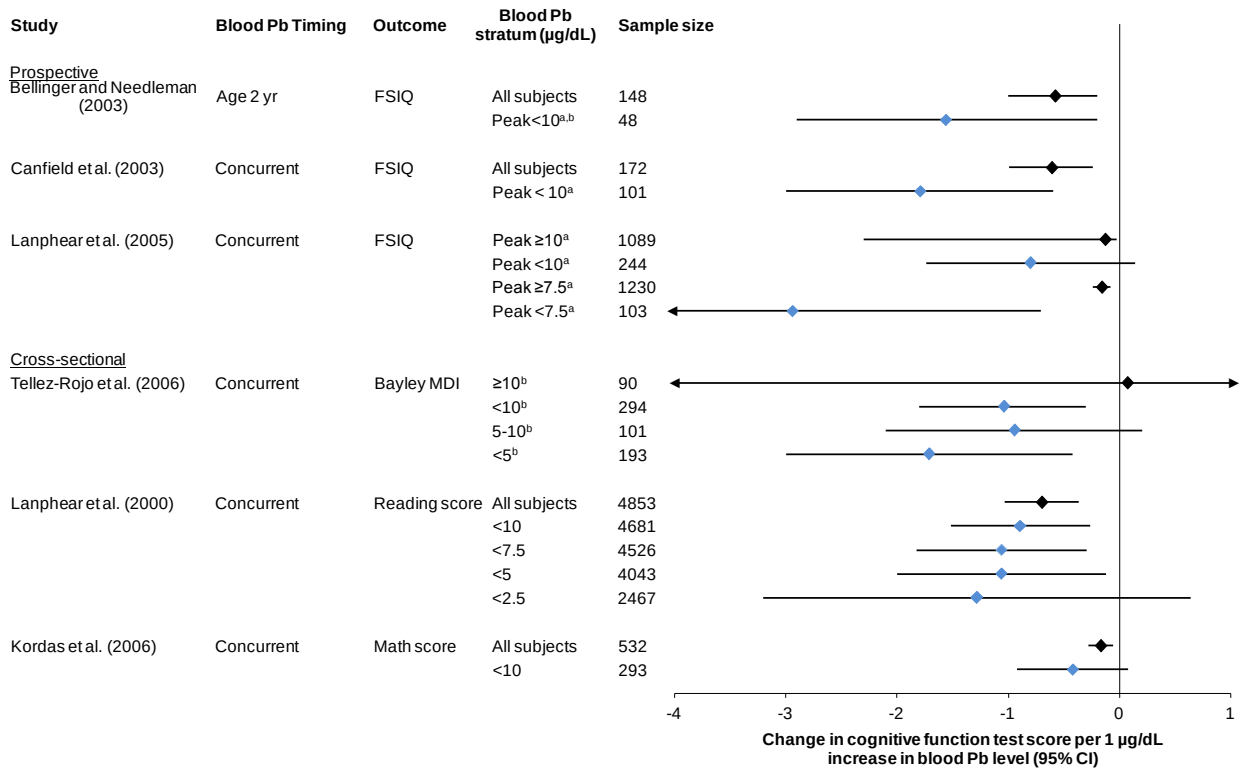
prenatal blood Pb levels are associated with mental development in very young children <age 2 years. However, increases in postnatal (earlier childhood, lifetime average, concurrent) blood Pb levels generally are associated with larger cognitive function decrements than are increases in prenatal blood Pb levels in older children and adolescents (Table 5-14). These results suggest that per unit increase, postnatal Pb exposures that are reflected in concurrent or cumulative blood Pb levels or tooth Pb levels may have a larger magnitude of effect on cognitive function decrements as children age. These findings are consistent with the understanding that the nervous system continues to develop throughout childhood. The epidemiologic evidence for associations of neurodevelopmental effects with multiple lifestages of Pb exposure, including more recent exposures, is supported by evidence in monkeys for Pb exposures during multiple lifestages, including infancy only, lifetime starting from birth, or lifetime starting after weaning, inducing impairments in cognitive function when assessed between ages 6 and 10 years (Rice, 1992b, 1990; Rice and Gilbert, 1990b).

5.3.13 Examination of the Pb Concentration-Response Relationship

With successive Pb AQCD and supplements, epidemiologic and toxicological studies find that progressively lower blood Pb levels are associated with cognitive and behavioral impairments. For example, among children, such effects were observed in association with blood Pb levels in the range of 10-15 µg/dL in the 1986 Addendum (U.S. EPA, 1986c) and 1990 Supplement (U.S. EPA, 1990a), and 10 µg/dL and lower in the 2006 Pb AQCD (U.S. EPA, 2006b). Further, in the 2006 Pb AQCD, several individual studies and pooled or meta-analyses estimated a supralinear concentration-response relationship in children, i.e., greater decrements in cognitive function per unit increase in blood Pb level among children in lower strata of blood Pb levels compared with children in higher strata of blood Pb level (Figure 5-16 and Table 5-16). Some toxicological evidence also indicates nonlinear concentration-response relationships for various endpoints, including those related to learning impairments. Some toxicological evidence points to larger absolute effects in lower Pb exposure groups (relative to control groups) than in the higher exposure groups. However, these toxicological findings of U- or inverted U-shaped relationships are distinct from epidemiologic findings of supralinear relationships in that some toxicological relationships do not indicate Pb-induced impairments at higher exposure concentrations.

Several prospective epidemiologic studies found supralinear concentration-response relationships for concurrent, earlier childhood, and lifetime average blood Pb levels and FSIQ in children ages 2-10 years. Most studies used a blood Pb level of 10 µg/dL to define lower and higher strata and reported mean blood Pb levels in the lower strata of

3-5 µg/dL (Bellinger, 2008; Canfield, 2008; Hornung, 2008; Téllez-Rojo, 2008). Except for the pooled analysis, the lower strata of blood Pb levels comprised >30% of the study population, indicating that the blood Pb-FSIQ relationships calculated for the lower strata likely are not outliers or unrepresentative of the overall study population. Studies in the Boston and Rochester cohorts each examined different ages of blood Pb and FSIQ but lower blood Pb levels compared to other studies (means ~6 µg/dL), and found nonlinear blood Pb-FSIQ concentration-response relationships with respect to children whose peak blood Pb levels did not exceed 10 µg/dL (Bellinger and Needleman, 2003; Canfield et al., 2003a; Bellinger et al., 1992). Pooled analyses of seven prospective studies, involving a wider range of blood Pb levels, 5th-95th percentiles 2.4-33.1 µg/dL, found that nonlinear models (e.g., log-linear, piecewise linear) fit the relationship between blood Pb level and FSIQ better than a linear model did (Lanphear et al., 2005; Rothenberg and Rothenberg, 2005).



Note: Results are presented first for prospective studies then for cross-sectional studies. FSIQ = full-scale IQ, MDI = mental development index. Effect estimates (concentration-response) are presented for a 1 µg/dL increase in blood Pb level. Black symbols represent effect estimates among all subjects or subjects in the higher blood Pb stratum. Blue symbols represent effect estimates in lower blood Pb strata. [a]Strata were defined by the peak blood Pb level measured in child at any point during follow up. [b]95% CI estimated from reported p-value.

Figure 5-16 Comparison of associations between blood Pb level and cognitive function among various blood Pb strata.

Table 5-16 Additional characteristics and quantitative results for studies presented in Figure 5-16.

Study	Study Population and Methodological Details	Blood Pb Timing and Levels (µg/dL)	Outcome	Blood Pb stratum (µg/dL)	Effect Estimate (95% CI)[a]
Bellinger et al. (1992) Bellinger and Needleman (2003) Bellinger (2008)	148 children followed from birth (1979-1981) to age 10 yr, Boston area, MA. **Prospective**. Recruitment at birth hospital. Participation by 59% of original cohort but 88% of eligible. Participants had higher SES. Linear regression model adjusted for HOME score (age 10 and 5), child stress events, race, maternal IQ, SES, sex, birth order, marital status, # residence changes before age 5 yr.	Earlier childhood (age 2 yr) Mean (SD) All subjects: 6.5 (4.9) Peak <10: 3.8 (range: 1-9.3)	FSIQ WISC-R Age 10 yr	All 148 subjects 48 subjects peak <10	-0.58 (-1.0, -0.2)[b] -1.56 (-2.9, -0.2)[b]

FSIQ = Full-scale IQ, WISC-R = Wechsler Intelligence Scale for Children-Revised, WPPSI-R = Wechsler Preschool and Primary Scale of Intelligence-Revised, MDI = Mental Developmental Index, NR = Not reported, WRAT = Wide Range Achievement Test.

[a]Effect estimates are derived from linear models and are presented for a 1 µg/dL increase in blood Pb level.

[b]95% CIs calculated from reported p-value.

[c]Results not included in Figure 5-16 because nonparametric analysis did not produce 95% CIs for various strata of blood Pb levels.

A few cross-sectional studies demonstrated larger Pb-associated decreases in cognitive function with concurrent blood Pb levels <5 µg/dL. Tellez-Rojo et al. (2006) estimated a larger decrement in age 2 year Bayley MDI per unit increase in blood Pb level for children with concurrent blood Pb levels <5 µg/dL compared with children with blood Pb levels 5-10 µg/dL, and >10 µg/dL (Figure 5-16 and Table 5-16). However, it is not clear what the implications of age 2 year MDI results may be on cognitive function at later ages. Among children ages 5-16 years participating in NHANES 1989-1994, Lanphear et al. (2000) found larger decrements in reading and math skills and memory per unit increase in blood Pb level in children with concurrent blood Pb levels <2.5 µg/dL than

children with levels <5 µg/dL, <7.5 µg/dL, <10 µg/dL, and all subjects. However, higher Pb exposures earlier in childhood may have contributed to associations.

Several (Min et al., 2009; Jusko et al., 2008; Schnaas et al., 2006) but not all (Palaniappan et al., 2011) recent studies found a nonlinear blood Pb-cognitive function relationship in nonparametric regression analyses using splines or lowess with smoothing parameters that did not produce quantitative results for each blood Pb group. Similar to the pooled analyses of the seven prospective cohorts, these relationship were evaluated for a wide range of blood Pb levels. In the Rochester and Mexico City cohorts, the blood Pb-FSIQ relationship was more negative for children with lower blood Pb levels, specifically for peak blood Pb levels <10 µg/dL (range: 2.1-45.7 µg/dL) in the Rochester cohort at age 6 years and (Jusko et al., 2008) and for prenatal maternal week 28-36 blood Pb levels <6µg/dL (5th-95th percentile 2.5-24.6 µg/dL) in the Mexico City cohort at ages 6-10 years (Schnaas et al., 2006). In a formal test of nonlinearity, Schnaas et al. (2006) found the nonlinear blood Pb term to fit the data better than a linear term. Among 267 children ages 4 years (blood Pb range: 1.3-23.8 µg/dL) who had high prenatal alcohol and drug exposure, Min et al. (2009) reported a p-value of 0.19 for a restricted cubic spline term for blood Pb level and described the covariate-adjusted concurrent blood Pb level-FSIQ curve to be more negative at blood Pb levels <7 µg/dL. Among 814 children in India ages 3-7 years, Palaniappan et al. (2011) mostly found linear associations between concurrent blood Pb level (range: 2.6-40.5 µg/dL) and indices of cognitive function. The exception was visual-motor skills, for which a greater blood Pb-associated decline was found with blood Pb levels >30 µg/dL. The linearity versus nonlinearity of the blood Pb-FSIQ concentration-response relationship within a lower, more narrow range of blood Pb levels has not been examined in detail.

Few studies of adults have examined whether the relationship between blood or bone Pb level and cognitive function is described better with a linear or nonlinear function. In analyses of adults in NHANES, only log-linear models were used to fit the data (Krieg et al., 2010; Krieg and Butler, 2009; Krieg et al., 2009). Nonlinearity in the BMS and NAS cohorts was examined with the use of quadratic terms, penalized splines, or visual inspection of bivariate plots (Bandeen-Roche et al., 2009; Weisskopf et al., 2007b; Shih et al., 2006). There was some evidence for nonlinearity in prospective analyses of the NAS cohort (Figure 5-8 and Figure 5-9), but not all results indicated greater declines in cognitive function per unit increase in bone Pb level in the lower bone Pb groups. Wang et al. (2007a) found that among NAS men with an HFE variant, there was a larger decline in MMSE score per unit increase in tibia Pb level at higher tibia Pb levels, 20-25 µg/g (Figure 5-9). In the BMS cohort, linear relationships were indicated for various tests of cognitive function by a statistically nonsignificant quadratic term (Shih et al., 2006) or spline (Bandeen-Roche et al., 2009) for tibia Pb level.

Although not specific to Pb exposure, attenuation of concentration-response relationships at higher exposure or dose levels has been reported in the occupational literature, and explanations have included greater exposure measurement error and saturation of biological mechanisms at higher levels and larger proportions of at-risk populations at lower exposure levels (Stayner et al., 2003). Hypotheses for nonlinearity in the relationship between Pb and cognitive function have included a lower incremental effect of Pb due to covarying risk factors such as low SES, poor caregiving environment, higher exposure to other environmental factors (Schwartz, 1994), different mechanisms operating at different exposure levels, and confounding by omitted or misspecified variables. The contribution of these factors to the supralinear relationship between blood Pb levels and cognitive function in children has not been examined in many epidemiologic studies to date. Several studies found that risk factors such as SES, parental education, and parental caregiving quality explain a greater proportion of variance in cognitive function than does blood Pb level (Wasserman et al., 1997; Greene et al., 1992). Recently, among 57,678 fourth grade children across North Carolina, Miranda et al. (2009) found that lower parental education and enrollment in a free/reduced fee lunch program accounted for larger decrements in EOG scores than did blood Pb level across the various quantiles of EOG score distribution (Figure 5-7).

Few studies have examined effect modification of the blood Pb level-cognitive function relationship by covarying risk factors such as sociodemographic factors, and the limited evidence is inconclusive. None of these studies examined effect modification within specific strata of blood Pb levels. In the Boston cohort at age 57 months, a greater Pb-associated FSIQ decrement was reported in the group that was female and had higher HOME score, SES, and maternal IQ (Bellinger et al., 1990). However, the Boston cohort overall had higher SES and parental education, and the group that included higher SES may not be comparable to other cohorts. In the Port Pirie, Australia cohort, larger blood Pb-associated FSIQ decrements were found in groups with lower SES (Tong et al., 2000) but not lower HOME score (McMichael et al., 1992). Overall, evidence does not clearly indicate whether the blood Pb-IQ relationship is modified by factors such as SES or other sociodemographic characteristics or whether these differences can explain the observed nonlinear concentration-response relationship.

Results from the pooled analysis by Rothenberg and Rothenberg (2005) do not indicate that residual confounding by covariates explains the nonlinear blood Pb-FSIQ relationship. Modeling maternal IQ, HOME score, and maternal education as spline functions (df = 2) did not significantly improve model fit either with a linear blood Pb term or log blood Pb term, which indicated that the improved model fit with log-specification of blood Pb level was not influenced by the modeling of covariates as linear or nonlinear functions.

Bowers and Beck (2006) postulated that a supralinear concentration-response function necessarily will be found in a model with a log-normally distributed independent variable and a normally distributed outcome variable. However, as discussed in the 2006 Pb AQCD, this modeling strategy was not employed in the epidemiologic analyses showing a supralinear concentration-response function. FSIQ scores generally were not forced into a normal distribution. Normalized FSIQ scores were not the basis for individual findings from four of the seven studies included in the pooled analysis by Lanphear et al. (2005) or the results pooling the seven cohorts (Hornung et al., 2006). Further, a log-linear model (a linear relationship between IQ and the log of blood Pb) provided a better fit of the pooled data.

Results from prospective analyses in the Boston and Rochester cohorts for associations between blood Pb level as a continuous variable and FSIQ in groups of children in the lower segment of the population blood Pb distribution have not identified a threshold in the range of blood Pb levels examined. In the Boston cohort, higher age 2 year blood Pb levels were associated with lower FSIQ at age 10 years in children with blood Pb levels 1-9.3 µg/dL whose peak blood Pb levels never exceeded 10 µg/dL (Bellinger, 2008; Bellinger and Needleman, 2003). Schwartz (1994) explicitly assessed evidence for a threshold in the Boston cohort data by regressing FSIQ and blood Pb level on age, race, maternal IQ, SES, and HOME score and fitting a nonparametric smoothed curve to the residuals of each regression model (variation in FSIQ or blood Pb level not explained by covariates). A 7-point decrease in FSIQ was found over the range of blood Pb residuals below 0 (corresponding to the mean blood Pb level of 6.5 µg/dL), indicating an association between blood Pb level and FSIQ down to a blood Pb level of 1 µg/dL. In the Rochester cohort, higher peak blood Pb levels were associated with lower FSIQ at ages 3 and 5 years in children with peak blood Pb levels < 10 µg/dL (Canfield et al., 2003a). A threshold also was not identified for the association between concurrent blood Pb level and MDI score at age 2 years among children in Mexico City with blood Pb levels in the range of 0.8-9.8 µg/dL (Téllez-Rojo, 2008; Téllez-Rojo et al., 2006).

In conjunction with downward trends in population blood Pb distributions (Figure 4-16), more sensitive quantification methods have improved the detection limits for blood Pb measurements (e.g., in NHANES, from 0.6 µg/dL in 1999-2002 to 0.025 µg/dL in 2003-2004). Consequently, the examination of groups of children (ages 8-11 years) with lower blood Pb levels, overall range <1 to 16 µg/dL, has indicated Pb-associated cognitive function decrements or increases in attention-related behavioral problems, at lower blood Pb levels (Cho et al., 2010; Kim et al., 2009b; Miranda et al., 2009; 2007a). In the studies examining concurrent blood Pb levels, the potential contribution of higher past Pb exposures obscures assessment of a threshold. However, Miranda et al. (2009) examined blood Pb levels measured between ages 6 and 36 months during 1995-1999

and found lower 9th grade EOG scores in 57,678 children in North Carolina with early childhood blood Pb levels of 2 µg/dL compared with children with blood Pb levels of 1 µg/dL. Other studies did not identify a threshold for Pb-associated cognitive function decrements in children using nonparametric regression analyses, but results have weaker implications because the blood Pb levels in the examined populations of children were higher than those in the current U.S. population (e.g., minimum 2.1, 5th percentiles 2.5 and 4.0 µg/dL) (Jusko et al., 2008; Schnaas et al., 2006; Lanphear et al., 2005).

Analyses of blood Pb level as a categorical variable did not clearly address the identification of a threshold for the blood Pb-cognitive function relationship; however, such analyses are not as sensitive as those of blood Pb level as a continuous variable. In the analysis of large numbers (>600) of children participating in NHANES with blood Pb levels <1 µg/dL, Braun et al. (2008; 2006) found higher odds of parental reports of conduct disorder and ADHD among children ages 4-15 years with concurrent blood Pb levels ~1.0 µg/dL compared with children with blood Pb levels <0.8 µg/dL. However, higher past Pb exposures may have contributed to associations found with concurrent blood Pb levels because of the older age of some subjects and the birth of study adolescents in the 1970s during the use of leaded gasoline. Other analyses of blood Pb level categories indicated that cognitive function decrements were limited to children ages 7-8 years with age 30-month blood Pb levels >10 µg/dL (Chandramouli et al., 2009) or children ages 6-10 years with concurrent blood Pb levels 5-10 µg/dL (Surkan et al., 2007).

Some toxicological studies found nonlinear relationships between Pb exposure and effects related to impaired learning and memory in animals. These results are distinct from epidemiologic results as toxicological studies often show that lower and higher Pb exposures have effects in opposite directions (U- or inverse U-shaped curves). Results summarized across multiple studies in multiple species demonstrated that lower Pb exposures increased FI response rates relative to controls, and higher Pb exposures decreased FI response rates (Cory-Slechta, 1994). Increased FI response rates indicate impaired learning by reflecting the impaired ability of animals to respond according to a fixed schedule of reinforcement (Section 5.3.3.1). Consistent with previous findings, Rossi-George et al. (2011) found that 50 ppm gestational plus lactational Pb exposure when combined with stress increased FI responses of 2-month old rats whereas 150 ppm Pb exposure with stress did not affect FI responses. Nonlinear effects of Pb on learning are less consistently observed with longer duration exposures (e.g., 8-11 months) (Rossi-George et al., 2011; Cory-Slechta, 1990). These nonlinear effects of Pb on impaired learning were supported by evidence in animals indicating that lower and higher Pb exposures differentially activate underlying mechanisms. Gilbert et al. (1999) found reduced LTP in adult rats exposed to 1,000 and 5,000 ppm but not 10,000 ppm Pb acetate

in drinking water (from GD16). LTP is one indication of synaptic plasticity (Section 5.3.11.4), which is considered to contribute to learning and memory. Learning and memory have also been affected by glutaminergic neurotransmission via its NMDA receptor (Section 5.3.11.8), and reduced glutamate release in the hippocampus was found in adult rats exposed to Pb acetate from GD15-GD16 with blood Pb levels 27-40 µg/dL but not with blood Pb levels of 62-117 µg/dL (Lasley and Gilbert, 2002).

Dopaminergic neurotransmission is involved in many CNS processes including cognition, behavior, and motor function. The shape of the Pb-DA concentration-response relationship varied among toxicological studies. Some studies found that lower Pb exposures (~50 ppm) did not affect or increased DA activity relative to controls and higher Pb exposure (109-250 ppm) (Leasure et al., 2008; Virgolini et al., 2005; Lewis and Pitts, 2004). Others found higher Pb exposures (109 or 150 ppm) to increase or impair DA activity (Leasure et al., 2008; Virgolini et al., 2005). These differential responses of DA may be related to the diverse CNS effects of DA in different regions of the brain. For example, the increased forebrain dopamine turnover with 27 ppm gestational/lactational Pb acetate exposure was accompanied by less spontaneous activity in male mice compared with male mice exposed to 109 ppm Pb (Leasure et al., 2008).

In vitro results indicated differential effects on calcineurin enzyme activity, with inhibited activity resulting from higher Pb exposure (>2×10^{-4} µM) and stimulated activity from lower Pb exposure (Kern and Audesirk, 2000). While calcineurin activity has been found to modulate learning, LTP, and behavior in animals, studies have found lower calcineurin activity to be associated with both impaired and improved effects related to learning (Zeng et al., 2001). Thus, it is uncertain whether altered calcineurin activity contributes to the nonlinear relationships observed between Pb exposure and impaired learning in animals. At lower concentrations, Pb may displace calcium at its binding sites on calmodulin and by acting as a calmodulin agonist at the catalytic A subunit of calcineurin and stimulate calcineurin activity. At higher Pb exposure, Pb may bind directly to a separate calcium-binding B subunit, override the calmodulin-dependent effect and turn off the activity of calcineurin. Lasley and Gilbert (2002) found that 2,000 ppm but not 5,000 or 10,000 ppm Pb acetate exposure of rats (in drinking water starting at GD15-GD16) inhibited glutamate release by acting as a calcium mimetic.

Some toxicological studies have found nonlinear relationships for non-cognitive outcomes in animals. U-shaped Pb concentration-response relationships were found for spontaneous motor activity level and latency to fall from rotarod (Leasure et al., 2008). Inverted U-shaped relationships were found for hippocampal neurogenesis (Fox et al., 2008; Gilbert et al., 2005). Evidence also points to differences in hormone production by Pb exposure concentration. In male mice with long-term Pb exposure (PND21-9 months

of age), basal corticosterone levels were significantly lower with 50 ppm Pb than with 150 ppm Pb or controls (Cory-Slechta et al., 2010). Visual system effects in animals also have shown to be affected differentially by lower versus higher Pb exposure (GD1-PND10, pup blood Pb levels 12, 24, and 46 µg/dL). Inverted U-shaped concentration-response curves were observed for rod photoreceptor numbers or neurogenesis (Giddabasappa et al., 2011) and retinal thickness (Fox et al., 2010). These dichotomous histological findings may give insight to the complex Pb-associated changes in ERG wave amplitudes that vary by exposure window and dose (Section 5.3.7.3).

To conclude, several studies found a supralinear blood Pb-cognitive function concentration-response relationship in children but not adults based on comparisons of effect estimates in lower and higher strata of blood Pb level and nonparametric regression. Explanations for this supralinear relationship have not been well characterized by epidemiologic studies. Evidence from the prospective studies in the Boston and Rochester cohorts has not identified a threshold for Pb-associated cognitive function decrements in the range of blood Pb levels examined. Increases in childhood blood Pb levels in the range of <1.0-9.8 µg/dL (means: 2.9 and 3.8 µg/dL) were associated with cognitive function decrements at ages 3 to 10 years in children whose peak blood Pb levels did not exceed 10 µg/dL (Bellinger, 2008; Canfield, 2008; Bellinger and Needleman, 2003; Canfield et al., 2003a). Further, a recent study found an association between higher ages 6-36 month blood Pb levels (1995-1999) and lower 4th grade EOG scores in 57,678 children in North Carolina with blood Pb levels 1-16 µg/dL (Miranda et al., 2009). Concurrent blood Pb levels in the range of 0.8-9.8 µg/dL were associated with MDI decrements in children age 2 years in Mexico City (Téllez-Rojo, 2008; Téllez-Rojo et al., 2006). The lack of a reference population with blood Pb levels reflecting pre-industrial Pb exposures limits the ability to identify a threshold. Analysis of ancient bones in pre-industrialized societies suggests that "background" blood Pb levels in preindustrial humans was approximately 0.016 µg/dL (Flegal and Smith, 1992), approximately 65-fold lower than that of the current U.S. population and lower than the levels at which neurodevelopmental effects have been examined. Thus, the current evidence does not preclude the possibility of a threshold for neurodevelopmental effects in children existing with lower blood levels than those currently examined. While distinct from supralinear relationships observed in epidemiologic studies, toxicological studies showed that lower Pb exposures (e.g., 50 ppm in drinking water) induced learning and memory impairments in animals compared to control exposures or higher Pb exposures (e.g., 150 ppm). Additional toxicological evidence suggests that differentially activated mechanisms at lower and higher Pb exposures and reduced LTP and hippocampal glutamate release with lower Pb exposures may provide explanation for impaired learning observed with lower Pb exposures in animals.

5.3.14 Confounding in Epidemiologic Studies of Nervous System Effects

In addition to Pb exposure, many factors influence cognitive function and behavior in children, including parental IQ and education, SES of the family, quality of the caregiving environment, and other environmental exposures (Wasserman and Factor-Litvak, 2001). These other risk factors often are correlated with blood, tooth, and bone Pb levels, thus, a major challenge to observational studies examining associations of Pb biomarker levels with cognitive function and behaviors in children has been the assessment and control for potential confounding factors. By definition, a confounder is associated with both the independent variable and the outcome and consequently has the potential to bias the association between the independent variable of interest and the outcome. Most epidemiologic studies of Pb biomarkers in children have examined potential confounding by parental IQ and SES-related variables such as parental education, household income, and the Hollingshead Four-Factor Index of Social Position, which incorporates education and income of both parents. Fewer but still several studies have examined confounding by quality of the caregiving environment (i.e., HOME score), birth weight, and smoking exposure. A relatively smaller number of studies have considered nutritional status, other environmental exposures, parental substance abuse, or parental psychopathology. Studies have varied with respect to the number of potential confounding factors examined, with some studies considering multiple SES-related variables and other studies focusing on a smaller set. The extent of confounding by a particular factor likely varies across studies, depending on the population examined. Thus, the impact of adjustment for specific covariates on the Pb effect estimate also likely varies across studies.

Various methods have been used to control for potential confounding, including examining a population relatively homogeneous in SES, examining populations in which factors are not correlated, conducting multivariate regression, characterizing the change in the blood Pb level effect estimate with adjustment for a covariate, and examining associations in different strata of a covariate. The evidence derived from each of these control strategies is discussed below. No single method is without limitation and adjustment for SES is difficult as it is highly correlated with Pb exposure and there is no single measure that represents SES. Residual confounding also is likely by factors not considered. The combination of evidence from prospective studies that considered several well-characterized potential confounding factors plus evidence that Pb exposure induces impairments in cognitive function in animals, in particular, visual-spatial memory and executive function, which are also found to be affected in children, increase confidence that the associations observed between blood Pb and tooth Pb levels and cognitive function in children represent a relationship with Pb exposure.

In the Boston prospective study, potential confounding by SES was controlled for by study design and statistical adjustment for SES. The study subjects were from middle- to upper-middle-class families, a majority with married, college-educated parents. Hence, the potential for confounding by SES in this study was considerably less compared to other studies examining similar outcomes. In this cohort, higher prenatal and concurrent blood Pb levels were associated with FSIQ decrements at age 57 months, and higher age 2 year blood Pb levels were associated decrements in FSIQ and executive function at age 10 years (Stiles and Bellinger, 1993; Bellinger et al., 1992; Bellinger et al., 1990). In contrast, blood Pb levels were weakly associated with cognitive function decrements in the Sydney, Australia cohort of middle-SES children (i.e., 20% mothers with greater than high school education) (Cooney et al., 1991). However, a relationship between Pb exposure and cognitive function decrements is supported by a similar magnitude of blood Pb-associated FSIQ decrement found in the Boston and low-SES Rochester cohort (majority of mothers with less than college education and annual income <$15,000), with adjustment for similar covariates (Figure 5-2 and Table 5-3) (Canfield et al., 2003a). For some outcomes, larger effects were estimated in the Boston cohort than in other cohorts.

Blood Pb levels also were associated with cognitive function decrements in populations in which blood Pb levels were not correlated with SES-related factors (Factor-Litvak et al., 1999; Bellinger et al., 1987). In the Yugoslavia cohort, blood Pb levels at age 4 years were higher in groups with higher maternal education, maternal IQ, and HOME score in one city near Pb sources and were lower in the distant city. Among all children, higher blood Pb level was associated with lower FSIQ and learning and memory scores and with higher ratings of internalizing behaviors (Factor-Litvak et al., 1999). In the Boston cohort, parental education, social class, and HOME score were similar among low (<3 µg/dL), medium (6-7 µg/dL), and high (≥ 10 µg/dL) cord blood Pb level groups. Further, adjusting for these and other demographic variables, Bellinger et al. (1987) found that children in the high cord blood Pb group had a 4.8-point lower Bayley MDI score at age 2 years than did children in the low cord blood Pb group.

The primary method used by epidemiologic studies to control for potential confounding, in particular recent studies of children with blood Pb levels more similar to current U.S. levels, has been multivariate regression. Some studies modeled a set of covariates based on a priori evidence, whereas others selected specific covariates based on their association with the outcome in a model with all potential covariates and/or a greater than 10% change in the blood Pb level effect estimate. Studies also varied in the number of potential confounding factors included in models. Some included multiple SES-related variables, whereas others analyzed one or two factors. Regardless of the method used to select model covariates or the number of covariates included, studies consistently found associations of higher blood Pb level with cognitive function decrements and behavioral

problems. The evidence suggests that confounding by particular factors may vary across populations and increases confidence that the associations observed with neurodevelopmental effects in children represent a relationship with Pb exposure

The consistency of association across populations with different SES and co-exposures and across studies examining different covariates was reinforced in pooled and meta-analyses (Marcus et al., 2010; Lanphear et al., 2005; Schwartz, 1994). Pooling data from seven international prospective cohorts, Lanphear et al. (2005) found similar FSIQ decrements per log increase in blood Pb level (-2.6 to +8.6% difference) by excluding one study at a time. These results indicated a relatively robust pooled estimate despite between-study differences in population characteristics, including SES. In a meta-analysis, Schwartz (1994) found a relatively narrow range of blood Pb-FSIQ effect estimates among studies despite large between-study differences in the correlation between blood Pb level and SES. A wider range of effect estimates would be expected if omitted SES factors confounded the association. A recent meta-analysis of the association between blood Pb level and conduct problems in earlier and recent studies of children (Marcus et al., 2010) found that adjustment for SES and HOME score did little to attenuate the association.

Among the several studies that provided both unadjusted and adjusted effect estimates, most indicated that blood Pb level was a statistically significant predictor of cognitive function (e.g., FSIQ, executive function, learning, memory) in children ages 5-10 years before and after adjusting for potential confounders. Although most effect estimates changed by 20-50% in multivariate models, they remained within the 95% CI of the unadjusted estimate (Min et al., 2009; Kordas et al., 2006; Schnaas et al., 2006; Canfield et al., 2003a; Dietrich et al., 1993a; Bellinger et al., 1992). Such observations were made in previous analyses of the Boston and Rochester cohort with mean blood Pb levels 6.5 and 5.8 µg/dL, respectively, with adjustment for SES, maternal IQ and education, and HOME score (Canfield et al., 2003a; Bellinger et al., 1992). These analyses also adjusted for or considered potential confounding by nutritional factors. Recent studies of children of a similar age range and mean blood Pb levels also found statistically significant associations (as indicated by correlation and/or regression coefficients) between blood Pb level and cognitive function before and after adjustment for similar covariates; however, these populations had high prevalence of prenatal alcohol or drug use which may limit the representativeness of their results (Min et al., 2009; Chiodo et al., 2007).

Blood Pb level also was a statistically significant predictor of cognitive function after adjustment for covariates such as maternal education and IQ, SES, and HOME score in with children with higher mean blood Pb levels, 8-14 µg/dL (Kordas et al., 2006; Schnaas et al., 2006; Tong and Lu, 2001; Dietrich et al., 1993b). Exceptions include multiple

analyses of the Cleveland cohort, in which blood Pb level was estimated to have a weak and imprecise or null effect after adjustment for potential confounding factors (Greene et al., 1992; Ernhart et al., 1989; Ernhart et al., 1988). Analyses of the Cleveland cohort considered similar potential confounding factors as other studies, with the exception of Greene et al. (1992) who also adjusted for pica and home conditions. However, these latter variables each accounted for only a small partial correlation with FSIQ. HOME score was the major factor accounting for the attenuation of the effect of Pb in the Cleveland cohort. An analysis of the Yugoslavia cohort, which adjusted for most of the same covariates as several of the Cleveland analyses reported larger magnitude blood Pb-cognitive function associations in covariate-adjusted models (Factor-Litvak et al., 1999). The collective findings in children indicate potential confounding by the SES-related and demographic factors examined in the literature base but also demonstrate that blood Pb level is an independent predictor of cognitive function decrements in children with adjustment for these factors.

A challenge to separating the effects of Pb exposure from those related to SES and parental caregiving quality is their frequently high correlation with blood Pb levels. In such cases, it is difficult to know how much variation in the outcome to attribute to each of the risk factors (Needleman and Bellinger, 2001). For example, due to the high correlation between blood Pb level and SES, a model that includes SES may underestimate the Pb effect because some of the variance in outcome due to Pb is mistakenly attributed to the variance due to SES. This misattribution may be exacerbated when multiple correlated variables are included in the same model (i.e., overcontrol). The relationships observed for Pb biomarker levels with SES and parental caregiving quality may indicate that they are proxies or determinants of Pb exposure rather than a confounder of the association of interest. Lower SES in urban children is closely linked to residence in older, poorer condition housing that, in turn, may increase exposure of children to environmental Pb and risk of cognitive deficits (Clark et al., 1985). In such cases where Pb exposure is a mediator of the SES effect, statistical adjustment for SES will result in overcontrol of the Pb effect (Bellinger, 2004a). This type of overcontrol could explain results from the New Zealand cohort, which were adjusted for residence in older wooden housing, which is associated with higher exposure to Pb paint and accumulated dust and soil and higher child tooth Pb levels (Fergusson et al., 1988a, b). However, even in models with older wooden housing, Pb remained a statistically significant predictor of poorer reading skills and teacher ratings of school performance. SES has been shown to be an effect modifier of the Pb-child cognitive function relationship. Larger blood Pb-associated decreases in cognitive function were found with lower SES in some studies (Ris et al., 2004; Tong et al., 2000; Bellinger et al., 1990) and higher SES in a meta-analysis (Schwartz, 1994). In cases of effect modification, potential confounding by SES is less likely.

In summary, the collective epidemiologic evidence consistently demonstrates associations of higher blood and tooth Pb levels with cognitive function decrements and behavioral problems in children. These associations have been observed in diverse populations in the U.S., Mexico, Europe, Asia, and Australia. Associations have been observed across studies that use different methods to control for confounding and adjust for different potential confounding factors but commonly, maternal IQ and education, SES, and HOME score. Several studies have found associations with additional adjustment for smoking exposure, child birth outcomes, and nutritional factors. No single method to control for potential confounding is without limitation, and there is potential for residual confounding by unmeasured factors. However, the consistency of findings among different populations and study methods with consideration of several well-characterized potential confounding factors as described above increases confidence that the associations observed between blood Pb level and neurodevelopmental effects in children represent a relationship with Pb exposure. Biological plausibility is provided by the coherence with extensive evidence in animals with Pb exposures that produce blood Pb levels relevant to humans and that is not subject to confounding by factors such as social class and correlated environmental factors. Further, Pb exposure has been shown to induce impairments in visual-spatial memory, rule learning and reversal, and response inhibition, which also have been associated with blood or tooth Pb levels in children. Additional support for the epidemiologic evidence is provided by extensive toxicological evidence describing modes of action for Pb-induced cognition and behavioral problems, including changes in neurogenesis, synaptic pruning, and neurotransmitter function in the hippocampus, prefrontal cortex, and nucleus accumbens of the brain (Section 5.3.11).

5.3.15 Public Health Significance of Associations between Pb Biomarkers and Neurodevelopmental Effects

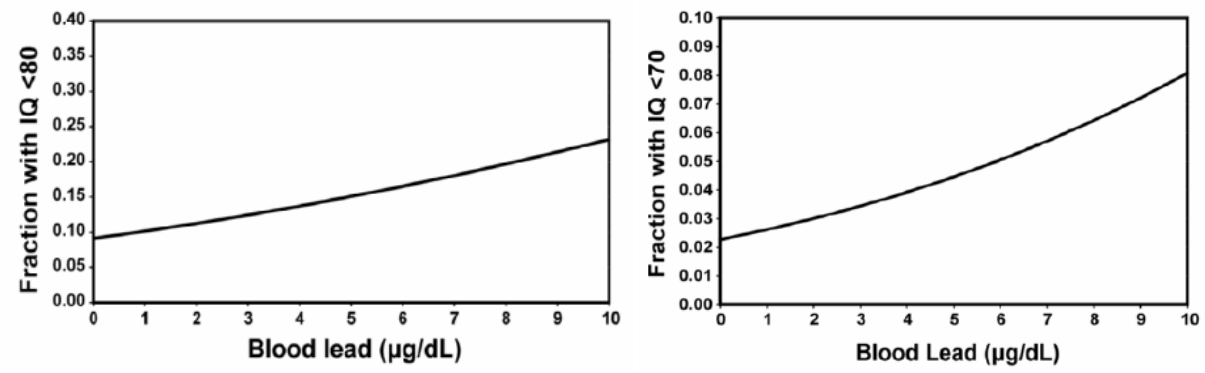
As described in Section 5.3.2.1, most studies found that a 1 µg/dL increase in blood Pb level was associated with decrements in FSIQ in school-aged children in the range of <1 to 2 points, depending on the model and blood Pb level range examined (Figure 5-2 and Table 5-3). Similarly, a 1 µg/dL increase in blood Pb level typically was associated with lower scores on tests of executive function (Table 5-8) and academic performance (Table 5-9), and higher ratings of behavioral problems (Figure 5-10, Table 5-11, Table 5-12) on the order of less than 1 standard deviation. Such findings prompt consideration of the public significance of blood Pb level-associated effects on cognitive function and behavioral problems in children, specifically, whether the magnitudes of change have consequences on the health and life-success of individuals. According to the WHO, "Health is a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity" (WHO, 1948). By this definition, even decrements in

health status that are not severe enough to meet diagnostic criteria might be undesirable if they reflect a decrement in the well being of an individual. Deficits in health indices or life-success may not be observable except at the population level. The American Thoracic Society discussed the need to consider the prevalence of exposures in the population and exposure to other risk factors in evaluating whether shifts in the population-level risk are adverse (ATS, 2000). Neurodevelopmental deficits measured in childhood may set affected children on trajectories more prone toward lower educational attainment and financial well-being. Thus, early deficits in children may have lifetime consequences. There also may be groups in the population at increased risk of neurodevelopmental deficits from Pb exposure. For example, some evidence points to larger blood Pb-associated decrements in cognitive function in children with lower SES (Ris et al., 2004; Tong et al., 2000; Bellinger et al., 1990), whereas a meta-analysis found a larger effect estimate for studies with higher SES (Schwartz, 1994).

It has been argued that blood Pb-associated decrements in IQ points less than 3 or 4 points are meaningless given that such changes are within the standard error of a single test (i.e., the statistic that defines the range within which the true value of an individual is likely to lie) (Kaufman, 2001). However, this argument incorrectly assumes that conclusions drawn from individual-level data apply to populations. Evidence does not indicate that the standard error is nonrandom, i.e., biased in one direction. Hence, there is no reason to expect that children with higher blood Pb levels systematically test lower than their true IQ value and that children with lower blood Pb levels test higher than their true IQ value. Thus, in a population of children, on a given assessment, some children will test lower than their true value and others will test higher than their true value. In such cases, between-group differences will be measureable on a population basis. Error in the measurement of IQ in an individual will contribute nondifferential error on a population-level and bias the association to the null.

The issue of individual-level versus population-level risk also pertains to the relevance of the magnitude of decrease in cognitive function or increase in behavioral problems per unit increase in blood Pb level. Although fractional changes in IQ, memory, or attention-related behavioral problems may not be consequential for an individual, they may be consequential on a population level, especially in the two tails of the distribution (Bellinger, 2007, 2004b). For example, interventions that shift the population mean, in a beneficial direction, by an amount that is without clinical consequence for an individual have been shown to produce substantial decreases in the percentage of individuals with values that are clinically significant (Bellinger, 2007, 2004b). In statistical exercises not specific to Pb or analysis of data collected from individuals, Weiss (1990, 1988) predicted that a downward shift of five points in mean IQ, if the amount of dispersion in the distribution remained the same, should be accompanied by a doubling of the numbers

of individuals with scores two or more standard deviations below the mean. With a reduction in population mean IQ from 100 to 95, the percentage of individuals predicted to score above 130 (two standard deviations above the mean) decreases from 2.3% to 0.99%. Weiss (1988) stated that the implication of such a loss transcends the current circumscribed definitions of risk. In addition to implications on the loss of intellectual ability, the loss of a few IQ points potentially could result in the loss of academic opportunities in children. For example, schools or programs for the gifted have used IQ cut-offs (e.g., score of 130) to screen or accept applicants. In another hypothetical analysis presented in the 2006 Pb AQCD (U.S. EPA, 2006b), based on a blood Pb-IQ effect estimate of -0.9 points/µg/dL (the median for blood Pb levels <10 µg/dL), the fraction of the population with an IQ <80 was estimated to more than double from 9% with a blood Pb level of 0 µg/dL to 23% with a blood Pb level of 10 µg/dL (Figure 5-17). The proportion with an IQ <70, which often requires community support to live (WHO, 1992), is predicted to increase from a little over 2% with a blood Pb level of 0 µg/dL to about 8% with a blood Pb level of 10 µg/dL [(Figure 5-17) and (U.S. EPA, 2006b)]. These theoretical exercises estimate that for an individual in the low range of the IQ distribution, a Pb-associated decline of a few points might be sufficient to drop that individual into the range associated with increase risk of educational, vocational, and social failure.



Note: The results presented in the figure are based on a theoretical analysis of changes in population IQ using a concentration-response estimate of -0.9 IQ points/µg/dL, which was the median estimate from studies reviewed in the 2006 Pb AQCD for blood Pb levels <10 µg/dL .

Source: 2006 Pb AQCD (U.S. EPA, 2006b).

Figure 5-17 Hypothetical effect of increasing blood Pb level on the proportion of the population with IQ <70 and <80 points.

The hypothetical predictions presented in Weiss (1990, 1988) and the 2006 Pb AQCD (U.S. EPA, 2006b) have been supported by findings from analyses using data from studies of blood Pb levels and FSIQ decrements in children. Among children in 1st and 2nd grades from towns around Boston, Needleman et al. (1982) found that a 4-point downward shift in the study population mean IQ estimated for tooth Pb levels >24 ppm was associated with a 3-fold increase in the percentage of children with an IQ of <80 and a decrease in the percentage achieving an IQ >125 from 5% to 0%.

The aforementioned hypothetical analyses and those using data collected from individuals that estimate Pb-associated changes in the population IQ distribution assume that the magnitude of change is equal across segments of the IQ distribution. Few studies of Pb and cognitive function have examined whether the effect of Pb varies across the distribution of cognitive function. However, in a recent study of fourth graders across the entire state of North Carolina, Miranda et al. (2009) found that higher blood Pb level measured once in each child between age 9 months and 3 years was associated with larger decreases in fourth grade EOG scores in the lower segment of the EOG distribution. An increase in blood Pb level from 1 to 10 µg/dL was estimated to decrease EOG score by 0.8 points in the 95th percentile of EOG scores but by 2.3 points in the 5th percentile of EOG score (Figure 5-7). These findings by Miranda et al. (2009) based analysis of a large database representative of fourth graders in North Carolina indicate that a shift in the population mean from increased Pb exposure may increase the proportions of children at the lower end of the cognitive function over that estimated by theoretical analyses.

In summary, the public health significance of evidence demonstrating associations between increases in blood Pb levels and decrements in IQ of children in the range of a few points is supported by hypothetical predictions that a shift in the population mean increases the proportion of individuals in the lower range of cognitive function and decreases proportion of individual in the upper range of cognitive function. These changes in the population distribution also were found in children in 1st and 2nd grade in Massachusetts in whom higher tooth Pb level was associated with decrements in IQ (Needleman et al., 1982). Further support for the public health significance is provided by findings that the blood Pb-associated decrement in cognitive function may be larger in children in the lower range of cognitive function (Miranda et al., 2009) and in specific groups within the populations such as those with lower SES (Ris et al., 2004; Tong et al., 2000; Bellinger et al., 1990). On a population-level, small Pb-associated decreases in cognitive function could increase the number of individuals at increased risk of educational, vocational, and social failure and decrease the number of individuals with opportunities for academic and later-life success.

5.3.16 Summary and Causal Determination

The collective body of epidemiologic and toxicological evidence integrated across that reviewed in the 2006 Pb AQCD (U.S. EPA, 2006b) and recent studies indicates relationships between Pb exposure and a range of nervous system effects. In children, effects on cognitive function include FSIQ, learning, memory, executive function, and academic performance. Outcomes evaluated related to attention-related behavioral problems include inattention, impulsivity, hyperactivity, and ADHD. Effects on conduct problems in children comprise aggression, delinquency, and criminal offenses. Effects on internalizing behaviors include withdrawn behavior, depression-like symptoms, fearfulness, and anxiety. Other nervous system effects evaluated in children are sensory function and motor function. Relationships for Pb exposure with cognitive function and sensory function also were evaluated in adults. Other nervous system effects in adults examined in relation to Pb exposure include psychopathological effects such as depression-like symptoms, anxiety, and panic disorder. Additionally, effects on neurodegenerative diseases include Alzheimer's disease, ALS, Parkinson's disease, and essential tremor. The subsequent sections describe the evaluation of evidence for each of these outcome groups with respect to causal relationships with Pb exposure using the framework described in Table II of the Preamble. The application of the key supporting evidence to the causal framework is summarized in Table 5-17.

5.3.16.1 Evidence for Cognitive Function in Children

A causal relationship between Pb exposure and cognitive function decrements in children is supported by evidence from prospective studies in diverse populations consistently demonstrating associations of higher blood and tooth Pb levels with lower FSIQ and performance on tests of executive function and academic performance in children ages 4-17 years (Section 5.3.2), coherence with evidence in animals for impairments in learning, memory, and executive function with relevant Pb exposures, and evidence describing modes of action (Table 5-17).

Clear support for Pb-associated cognitive function decrements in children, as described in the 2006 Pb AQCD (U.S. EPA, 2006b), was provided by prospective epidemiologic studies indicating associations of higher earlier childhood, concurrent, and childhood average blood and tooth Pb levels with lower FSIQ in children ages 4-17 years (Table 5-17 and Section 5.3.2.1). Across studies, FSIQ was measured with similar instruments (i.e., WISC-R, WISC-III, WPPSI, Stanford-Binet) scored on a similar scale with similar measurement error. Associations were found in most of the prospective studies, conducted in the U.S., Mexico, Europe, and Australia in representative populations, most

of which had moderate to high follow-up participation without indication of selective participation among children with higher blood Pb levels and lower cognitive function (Table 5-3). The prospective studies found associations of blood or tooth Pb levels measured earlier in life (i.e., prenatal cord or maternal, age 2 year, age 6 year) and averaged over multiple years with FSIQ decrements later in childhood (i.e., ages 4-17 years), better establishing the temporal sequence between Pb exposure and decrements in cognitive function compared with cross-sectional analyses. Another strength of the evidence from prospective studies was the consideration for several potential confounding factors. As indicated in Table 5-3, results from most cohort studies were adjusted for maternal IQ and education, child sex and birth weight, SES, and HOME score. Although not considered as frequently, some studies also found associations with adjustment for parental smoking and nutritional factors. The consistency and reproducibility of the blood Pb-FSIQ association in children were substantiated in a pooled analysis of seven prospective studies by Lanphear et al. (2005) as well as multiple meta-analyses that combined results across various prospective and cross-sectional studies (Pocock et al., 1994; Schwartz, 1994; Needleman and Gatsonis, 1990), with Schwartz (1994) demonstrating the robustness of evidence to potential publication bias.

Among individual studies, a wide range of blood Pb-FSIQ effect estimates was obtained, which is not unexpected given the wide range of blood Pb levels examined and modeling methods used (i.e., linear, log-linear). The pooled analysis of seven prospective cohorts demonstrated precision of effect estimates by applying a uniform method across populations (Lanphear et al., 2005). A narrow range of estimates was obtained by excluding one study at a time, -2.4 to -2.9 points per log increase in concurrent blood Pb level. Results from several individual studies indicated a supralinear concentration-response relationship which estimated a greater decrement in cognitive function per unit increase in blood Pb level among children in lower strata of blood Pb levels than children in higher strata of blood Pb levels (Figure 5-16 and Table 5-16). Among the largest effect estimates were found in the Boston and Rochester cohorts (Canfield et al., 2003a; Bellinger et al., 1992), which had relatively smaller sample sizes but considered several potential confounding factors as listed above and in Table 5-3, examined lower blood Pb levels than did other prospective studies, and examined cohorts of different SES. Thus, their results may be more generalizable. In the Boston cohort, a 1µg/dL increase in age 2 year blood Pb level was associated with a -1.6 (95% CI: -2.9, -0.2) point change in FSIQ at age 10 years in 48 children with blood Pb levels 1-9.3 µg/dL whose peak blood Pb levels never exceeded 10 µg/dL (Bellinger, 2008; Bellinger and Needleman, 2003). In the Rochester cohort, a 1 µg/dL increase in concurrent blood Pb level was associated a -1.8 (95% CI: -3.0, -0.60) change in FSIQ at age 5 years in 101 children with concurrent blood Pb levels 0.5-8.4 µg/dL, and peak blood Pb levels <10 µg/dL (Canfield, 2008; Canfield et al., 2003a). In the pooled analysis, a 1 µg/dL increase in concurrent blood Pb

level was associated a -2.9 (95% CI: -5.2, -0.71) change in FSIQ at ages 4.8-10 years in 103 children with concurrent blood Pb levels 0.9-8.4 µg/dL and peak blood Pb levels <7.5 µg/dL (Hornung, 2008; Lanphear et al., 2005). These observations do not provide evidence for a threshold in the ranges of blood Pb level examined. Null or weak associations were limited to a few cohorts, namely, the Cleveland and Sydney cohorts (Greene et al., 1992; Cooney et al., 1991; 1989a, b; Ernhart et al., 1988). The Cleveland and Sydney studies were not outliers with respect to population mean blood Pb levels or the specific confounding factors considered (Table 5-3), and the Cleveland cohort had high prevalence of maternal prenatal substance abuse which may limit the representativeness of results.

Other previous studies estimated smaller magnitude of effects for the blood Pb-FSIQ association with either linear or log-linear models but examined higher blood Pb levels (means: 8-16 µg/dL) without analysis of the concentration response at the lower range of the study population blood Pb distribution (Table 5-3). Recent cross-sectional studies supported associations between higher concurrent blood Pb levels and decrements in FSIQ. Among studies that examined populations with mean blood Pb levels <5 µg/dL, some lacked representative populations due to high prevalence of prenatal alcohol and/or drug exposure (Chiodo et al., 2007) or had limited consideration for potential confounding (Zailina et al., 2008). Kim et al. (2009b) estimated similar effects as the Boston and Rochester studies although the log-linear model makes comparisons difficult. Among children ages 8-11 years in Korea with mean blood Pb level 1.73 µg/dL, a 1 µg/dL increase in concurrent blood Pb level was associated with a 3.2-point decrease (95% CI: -6.1, -0.23) in FSIQ among children ages 8-11 years in Korea with blood Mn levels >1.4 µg/dL in the 10th-90th percentile interval of blood Pb level (0.9-2.8 µg/dL). In this study, the potential influence of higher past Pb exposures cannot be excluded. Among children ages 6-10 years in New England with a mean concurrent blood Pb level 2.2 µg/dL, lower FSIQ was found in the group with blood Pb levels 5-10 µg/dL (Surkan et al., 2007). While results from these studies were adjusted for SES and parental IQ or education, parental caregiving quality was not examined.

A causal relationship between Pb exposure and cognitive function decrements in children also is supported by previous prospective studies (several of which contributed to the FSIQ evidence) that found associations of blood or tooth Pb level with decrements in executive function and academic performance in children ages 4-18 years (Sections 5.3.2.4, 5.3.2.5, and Table 5-17). The bodies of evidence for executive function, and academic performance are smaller than that for FSIQ but consistently indicate associations with blood or tooth Pb level. Associations with performance on tests of learning and memory were less consistently found across populations (Section 5.3.2.3). In most studies, previous and recent, multiple testing was common; however, the

consistent pattern of association observed across the ages of blood Pb level and/or cognitive test examined increases confidence that the evidence is not unduly biased by an increased probability of associations found by chance alone. While recent studies of executive function and academic performance adjusted for SES and parental education and/or IQ, few examined potential confounding by parental caregiving quality.

Adding to the evidence for Pb-associated cognitive function decrements in children were recent prospective studies that indicated associations between higher earlier childhood blood Pb level and poorer academic performance in school-aged children (Chandramouli et al., 2009; Miranda et al., 2009). Among 57,678 children in North Carolina, lower fourth grade EOG scores were found in children with age 3-36 month blood Pb levels 2 µg/dL compared with children with blood Pb levels 1 µg/dL, with adjustment for parental education and enrollment in a free lunch program as an indicator of SES (Miranda et al., 2009). In addition to finding associations with lower early childhood blood Pb levels, this study indicated a greater incremental association of blood Pb level with decrement in EOG score among children in the lower end of the EOG distribution. Chandramouli et al. (2009) found decrements in school achievement tests in 488 children ages 7-8 years in U.K. in children with age 30 month blood Pb levels >5 µg/dL. These results were adjusted for several potential confounding factors, including SES, parental education, SES, home facilities score, and family adversity. Recent cross-sectional studies conducted in the U.S. (Krieg et al., 2010; Surkan et al., 2007) found associations of concurrent blood Pb level with decrements in executive function and academic performance in children, including the large analysis of >700 children ages 12-16 years participating in NHANES (Krieg et al., 2010). Cho et al. (2010) did not find an association between concurrent blood Pb level and executive function among children in Korea ages 8-11 years with a mean blood Pb level 1.9 µg/dL.

Several studies found associations of higher prenatal, earlier infancy, and concurrent blood Pb levels with lower Bayley MDI scores in children ages 2 and 3 years (Table 5-4). Similar to studies of FSIQ, Tellez-Rojo et al. (2006) estimated a larger decrement in age 2 year MDI per unit increase in concurrent blood Pb level for children in Mexico City with blood Pb levels <5 µg/dL compared with children with blood Pb levels 5-10 µg/dL, and >10 µg/dL (Figure 5-16 and Table 5-16). MDI is a well-standardized measure of current infant mental development. However, the test of MDI is not an intelligence test, and MDI scores, particularly before ages 2-3 years, are not necessarily correlated with later measurements of FSIQ in children with normal development.

A causal relationship between Pb exposure and cognitive function decrements in children is further supported by consistent observations in animals of decrements in learning, memory, and executive function with relevant dietary Pb exposures. In particular,

coherence was found between evidence in children and animals of Pb-associated decrements in visual-spatial memory, working memory (Section 5.3.2.3) and rule learning and reversal (Section 5.3.2.4). Previous studies in monkeys demonstrated impairments in learning, memory, and executive function with dietary Pb exposures during infancy only, lifetime after infancy, and lifetime from birth that produced blood Pb levels of 19 and 26 µg/dL (Rice, 1992b, 1990; Rice and Karpinski, 1988).

Several recent toxicological studies added to the evidence for impaired learning and memory in animals with lower blood Pb levels, 8-17 µg/dL after gestational-lactational, lactational, or lifetime (with and without gestational) Pb exposure (Cory-Slechta et al., 2010; Niu et al., 2009; Virgolini et al., 2008a; Stangle et al., 2007). Together, the prospective epidemiologic and toxicological studies provide evidence for the temporal sequence between Pb exposure and decrements in cognitive function. Additional biological plausibility for Pb-associated cognitive function decrements was provided by toxicological evidence for the effects of Pb on modes of action for cognitive function (Section 5.3.11). Pb has been shown to increase the permeability of the blood-brain barrier and deposit in the target CNS. Pb has been shown to impair neurogenesis, synaptic architecture, and neurite outgrowth. The high activity of these processes during fetal and infant development provides biological plausibility for the effects of childhood Pb exposure on decrements in cognitive function. Cognitive function is mediated by the cortical and subcortical structures of the brain that integrate function in the hippocampus, prefrontal cortex, and nucleus accumbens using dopamine and glutamate as primary neurotransmitters. Experimental studies have shown that Pb induces changes in dopamine and glutamate release in these regions and decreases the magnitude of LTP, which is a major cellular mechanism underlying synaptic plasticity and learning and memory.

With regard to critical lifestages of Pb exposure, toxicological evidence clearly demonstrates impaired learning and memory in animals exposed to Pb gestationally with or without lactational exposure that produced blood Pb levels 8-17 µg/dL. This evidence is well supported by knowledge that processes such as neurogenesis, synaptogenesis, and synaptic pruning are very active during this developmental period. However, evidence in monkeys also indicates impaired cognitive function at ages 5-8 years with Pb exposure starting after weaning (Rice, 1992b; Rice and Gilbert, 1990a; Rice, 1990; Rice and Gilbert, 1990b). Epidemiologic studies also found cognitive function decrements associated with blood Pb levels measured during various lifestages and time periods. Distinguishing among the effects of Pb exposures at different time periods is difficult in epidemiologic studies due to the high correlations commonly found among blood Pb levels within children over time. Among studies of young children ages 6 months to 3 years, several found larger magnitudes of associations of MDI with prenatal maternal or cord blood Pb than with postnatal child blood Pb (Hu et al., 2006; Bellinger et al., 1987;

Dietrich et al., 1987a; Vimpani et al., 1985). However, in older children, ages 4-17 years, in whom cognitive function is more stable and reliably measured, larger decrements in cognitive function were found in association with postnatal blood Pb levels, i.e., concurrent, earlier childhood, and cumulative average blood Pb levels as well with tooth Pb levels. There was no clear indication of an individual critical lifestage, timing, or duration of Pb exposure associated with cognitive function decrements in children. Because of the contribution of bone Pb levels to concurrent blood Pb levels in children, associations with concurrent blood Pb levels may reflect an effect of past and/or recent Pb exposures.

The consideration for potential confounding varied among studies. Most studies adjusted for SES-related variables such as the Hollingshead Index, household income, and/or parental education. Several, in particular the prospective studies, additionally adjusted for parental cognitive function and caregiving quality commonly evaluated as HOME score. A few studies considered nutritional factors. Few recent studies considered potential confounding by parental caregiving quality. The adjustment for SES is difficult as it is highly correlated with Pb exposure and there is no single measure that represents SES. Residual confounding also is possible by factors not considered. The combination of evidence from prospective studies that considered several well-characterized potential confounding factors plus evidence that Pb exposure induces impairments in cognitive function in animals, in particular, for similar constructs as those associated with blood Pb levels in children, increase confidence that the associations observed between blood Pb levels and cognitive function in children represent a relationship with Pb exposure.

In conclusion, multiple prospective studies conducted in diverse populations consistently demonstrate associations of higher blood and tooth Pb levels with lower FSIQ, executive function, and academic performance and achievement. Most studies examined representative populations and had moderate to high follow-up participation without indication of selective participation among children with higher blood Pb levels and lower cognitive function. Associations between blood Pb level and cognitive function decrements were found with adjustment for several potential confounding factors, most commonly, SES, parental IQ, parental education, and parental caregiving quality. In children ages 4-11 years, associations were found with prenatal, early childhood, childhood average, and concurrent blood Pb levels in populations with mean blood Pb levels in the range 2-8 μg/dL. Neither epidemiologic nor toxicological evidence has identified an individual critical lifestage or duration of Pb exposure within childhood that is associated with cognitive function decrements. Several epidemiologic studies found a supralinear concentration-response relationship. Examination of children with blood Pb levels in the range <1 to 10 μg/dL, with consideration of early or peak childhood blood Pb levels, has not identified a threshold for cognitive function decrements in the range of

blood Pb levels examined. Evidence in children was clearly supported by observations of Pb-induced impairments in learning, memory, and executive function in juvenile animals. Several studies in animals indicated learning impairments with prenatal, lactational, and lifetime (with or without prenatal) Pb exposures that resulted in blood Pb levels of 8-26 µg/dL. The mode of action for Pb-associated cognitive function decrements is supported by observations of Pb-induced impairments in neurogenesis, synaptogenesis and synaptic pruning, LTP, and neurotransmitter function in the hippocampus, prefrontal cortex, and nucleus accumbens. The associations consistently found for FSIQ and other measures of cognitive function in prospective studies of children with adjustment for SES, parental education, and caregiving quality and the biological plausibility provided by evidence in animals for impairments in learning, memory, and executive function with relevant Pb exposures and evidence describing modes of action is sufficient to conclude that there is a causal relationship between Pb exposure and decrements in cognitive function in children.

5.3.16.2 Evidence for Attention-related Behavioral Problems in Children

A causal relationship between Pb exposure and attention-related behavioral problems in children is supported by evidence from prospective studies in diverse populations for associations of blood or tooth Pb levels with inattention, impulsivity, and hyperactivity, coherence with evidence in animals with relevant Pb exposures, and evidence describing modes of action (Table 5-17). Although attention-related behavioral problems have been examined less extensively than cognitive function, several epidemiologic and toxicological studies have found associations with Pb. Prospective studies provided key evidence for associations of childhood blood and tooth Pb levels with increases in inattention, impulsivity, and hyperactivity in children ages 6-17 years and young adults ages 19-24 years. These associations were found in populations in the U.S., U.K., Australia, and New Zealand (Table 5-17). Most studies had population-based recruitment from prenatal clinics, hospitals at birth, or schools and had moderate to high participation. A few prospective studies had increased loss-to-follow-up in certain groups, for example, lower SES, earlier FSIQ, or HOME score. This potential selection bias may have reduced the generalizability of findings to the original study population, but there was not a strong indication that participation was biased to those with higher blood Pb levels and greater behavioral problems. The most compelling evidence was that for inattention, impulsivity, and hyperactivity assessed with neuropsychological testing or rated by parents or teachers with widely-used structured questionnaires. A few studies found associations between blood Pb level and diagnosis of ADHD but in studies that did not consider potential confounding by parental caregiving quality.

Key evidence provided by prospective studies supported associations of blood and tooth Pb levels with inattention and impulsivity as assessed using neuropsychological tests or parent or teacher ratings (Section 5.3.3.1). Thus, the collective evidence does not appear to be unduly influenced by biased reporting of such behaviors by parents of children with higher blood Pb levels. Most studies that examined inattention with the continuous performance test found associations with blood Pb level (Figure 5-10 and Table 5-11), including previous prospective studies that indicated associations of higher prenatal or earlier childhood blood Pb levels or tooth (from ages 5-8 years) Pb levels with increases in commission and omission errors or reaction time in adolescents ages 15-17 years in Cincinnati (Ris et al., 2004) and young adults 19-24 years in Chelsea/Sommerville, MA (Bellinger et al., 1994a). Results from prospective studies also indicated associations with parental and teacher ratings of inattention and impulsivity in children ages 8-13 years in Australia, New Zealand, and Boston, MA (Burns et al., 1999; Fergusson et al., 1993; Leviton et al., 1993). The mean blood Pb levels (prenatal cord, early childhood, lifetime average) of populations examined in the prospective studies were in the range of 7-14 µg/dL. The prospective findings better established the temporal sequence between Pb exposure and inattention than did cross-sectional studies. Although the specific factors varied by study, prospective studies of inattention and impulsivity considered several potential confounding factors, including SES, parental IQ, maternal education, HOME score, self drug use, prenatal drug and alcohol exposure, and birth outcomes. Evidence did not strongly indicate associations between concurrent blood Pb levels and ratings of inattention in younger children ages 4-5 years in Rochester and Yugoslavia (Canfield et al., 2003b; Wasserman et al., 2001). These groups of younger children had lower blood Pb levels, mean 6.5 µg/dL; however, inattention may be less reliably rated in younger children.

Consistent with previous prospective studies, recent cross-sectional studies found associations of higher concurrent blood Pb level with increases in inattention as measured by CPT, impulsivity using the stop task, and higher ratings of inattention and impulsivity in children ages 8 to 12 years with mean concurrent blood Pb levels of 1 to 4 µg/dL (Cho et al., 2010; Nicolescu et al., 2010; Nigg et al., 2008). However, the contribution of higher Pb exposures earlier in childhood cannot be excluded. Further, while these recent studies considered potential confounding by parental education, they had less consistent consideration for other SES-related factors or parental caregiving quality than did prospective studies. Some considered parental history of psychopathology; however, its relationship with parental caregiving quality is not well characterized (Cho et al., 2010; Nicolescu et al., 2010). Chiodo et al. (2007; 2004) found associations between concurrent blood Pb level and increases in inattention as measured by the CPT and by independent examiner ratings. Mean blood Pb levels were ~5 µg/dL, and results were adjusted for SES, parental education, and HOME score. However, the study population lacked

representativeness because of the high prevalence of prenatal alcohol and drug use. Recent cross-sectional studies that included younger children (ages 3-5 years) also found associations between concurrent blood Pb level and higher inattention as rated by teachers or study examiners (Plusquellec et al., 2010; Roy et al., 2009a); however, ratings in young children may be less reliably measured.

A causal relationship between Pb exposure and attention-related behavioral problems also is supported by a recent prospective study that found higher teacher ratings of hyperactivity among children ages 7-8 years in the U.K. with age 30 month blood Pb levels >10 µg/dL (Chandramouli et al., 2009). Previous findings were limited to cross-sectional and case-control studies (Section 5.3.3.2). A strength of the recent prospective study was the adjustment for several potential confounding factors, including maternal education and smoking, SES, home facilities score, and family adversity index. Among the recent cross-sectional studies, associations were found with consideration for potential confounding by SES and maternal education; however, parental caregiving quality was examined infrequently. Recent cross-sectional studies also found associations of concurrent blood Pb level with higher parental ratings of a composite index of ADHD-related behaviors, including the large U.S. representative analysis of 2,588 children participating in NHANES which used DSM-IV criteria (Froehlich et al., 2009). With the exception of findings from the Rochester cohort (Canfield et al., 2003b), studies generally found associations between blood Pb level and attention-related behavioral problems with adjustment for child IQ or other measure of cognitive function (Cho et al., 2010; Chandramouli et al., 2009; Nigg et al., 2008; Silva et al., 1988). These findings add support for higher Pb exposures having effects on attention-related behavioral problems, independent of effects on cognitive function.

In the few available studies, concurrent blood Pb levels were associated with ADHD prevalence in children (Section 5.3.3.4). Because of the cross-sectional or case-control design of studies and lack of consideration for potential confounding by parental caregiving quality or attention-related problems, the ADHD evidence is not a major consideration in drawing conclusions about the relationship between Pb exposure and attention-related behavioral problems.

Further support for a causal relationship between Pb exposure and attention-related behavioral problems is provided by observations of impulsivity in animals in tests of response inhibition (e.g., discrimination reversal learning, FR/waiting for reward) with relevant dietary Pb exposures. In particular, coherence is found with observations in children of associations between blood Pb levels and performance on the stop signal task, which also measures response inhibition. Impulsivity in rodents and monkeys was found with gestational and lactational dietary Pb exposures that resulted in blood Pb levels of 10

to 31 µg/dL (Table 5-17 and Section 5.3.3.1). In animals, the effects of Pb exposure on sustained attention were inconsistent as assessed with a signal-detection test with distracting stimuli. In monkeys ages 9-10 years, lifetime dietary Pb exposure from birth producing blood Pb levels 15 and 25 µg/dL induced distractibility as assessed by poorer performance on discrimination reversal tasks with distracting stimuli (Gilbert and Rice, 1987). Relevant dietary Pb exposures (i.e., producing blood Pb level of 10 µg/dL) also were found to increased activity in male (not female) mice with but only with amphetamine co-treatment (Leasure et al., 2008); thus, the findings may not be directly comparable to observations of Pb-associated increases in hyperactivity in children.

Additional support for a causal relationship between Pb exposure and attention-related behavioral problems is provided by evidence describing modes of action. Attention-related behavioral problems have been linked with changes in the prefrontal cerebral cortex, cerebellum, and hippocampus, and Pb exposure has been found to affect development and neuronal processes in these regions. For example, Pb has been found to affect dopaminergic neurons of the frontal cortex and striatum of the brain by altering dopamine release and receptor density. Other lines of evidence supporting the mode of action for the effects of Pb exposure on attention-related behavioral problems include Pb-induced changes in neurogenesis, synapse formation, and synaptic plasticity.

In conclusion, although examined less extensively than cognitive function, several prospective studies demonstrate associations of earlier childhood (e.g., age 6 years) and lifetime average blood Pb levels or tooth (from ages 5-8 years) Pb levels with inattention, impulsivity, and hyperactivity in children 7-17 years and young adults ages 19-24 years as assessed using objective neuropsychological tests and rated by parents and teachers. Most of these prospective studies examined representative populations without indication of participation conditional on blood Pb levels and behavioral problems. The results from prospective studies were adjusted for potential confounding by SES and parental caregiving quality, with a few studies also considering substance abuse and nutritional status. Blood Pb-associated increases in attention-related behavioral problems were found in populations with earlier childhood (age 6 years) or lifetime average (to age 11-13 years) mean blood Pb levels of 7 and 14 µg/dL and groups with earlier childhood (age 30 months) blood Pb levels >10 µg/dL. Several cross-sectional studies found associations between concurrent blood Pb level (means 1-4 µg/dL) and attention-related behavioral problems in children ages 8-12 years but had less consistent adjustment for SES and parental caregiving quality. Biological plausibility for observations in children is provided by several findings in animals for increases in impulsivity or impaired response inhibition with relevant prenatal, lactational, and lifetime Pb exposures that resulted in blood Pb levels of 10 to 31 µg/dL. The mode of action for Pb-associated attention-related behavioral problems is supported by observations of Pb-induced impairments in

neurogenesis, synaptic pruning, and dopamine transmission in the prefrontal cerebral cortex, cerebellum, and hippocampus. The consistency of epidemiologic evidence, particularly for inattention, impulsivity, and hyperactivity in prospective studies, and the biological plausibility provided by evidence for Pb-induced impulsivity in animals and for underlying modes of action is sufficient to conclude that there is a causal relationship between Pb exposure and attention-related behavioral problems in children.

5.3.16.3 Evidence for Conduct Problems in Children and Young Adults

Epidemiologic evidence indicates that a causal relationship is likely to exist between Pb exposure and misconduct in children and young adults. Key evidence is provided by recent prospective studies finding associations of higher earlier childhood blood and tooth (from ages 6-8 years) Pb levels with criminal offenses in young adults in Cincinnati and Christchurch, New Zealand, ages 19-24 years, as assessed through government records (Fergusson et al., 2008; Wright et al., 2008). In the Cincinnati cohort, a 1 µg/dL increase in age 6 year blood Pb level (mean 6.8 µg/dL) was associated with an increased risk of criminal arrests at age 19-24 years with an RR of 1.05 (95% CI: 1.01, 1.09). Additional support was provided by most previous and recent prospective studies that found associations of blood or tooth Pb levels with higher parent and teacher ratings of delinquent behavior, aggression, antisocial activities, and destructive behavior in children ages 8-17 years from diverse locations and SES (i.e., U.K., Cincinnati, Port Pirie, Australia) (Table 5-12 and Table 5-17). Associations were found with lifetime average blood Pb levels in boys ages 11-13 years in Port Pirie, Australia with a mean blood Pb level 14 µg/dL (Burns et al., 1999) and with age 30 month blood Pb levels >10 µg/dL in children ages 7-8 years in the U.K. (Chandramouli et al., 2009). The moderate to high follow-up participation and associations found with parent and teacher ratings of conduct problems do not provide strong evidence for biased participation or reporting of conduct problems for children with higher blood Pb levels. Studies of criminal offenses and ratings of conduct problems found associations with adjustment for several potential confounding factors such as SES, smoking, drug, and alcohol exposure, and parental caregiving quality.

Supporting evidence was provided by the large cross-sectional analysis of 2,867 adolescents ages 8-15 years participating in NHANES, which found that compared with children with concurrent blood Pb levels <0.8 µg/dL, children with concurrent blood Pb levels 0.8-1.0 µg/dL had higher odds of conduct disorder as assessed by parents with adjustment for age, sex, race, poverty to income ratio, and smoking exposure (Braun et al., 2008). Parental caregiving quality was not examined. These associations observed in adolescents with relatively low concurrent blood Pb levels could have been influenced by

higher past Pb exposures. Further supporting the consistency of association between blood Pb levels and conduct problems in children, a recent meta-analysis found that evidence was robust to heterogeneity in study design, definition and assessment method of conduct problems, potential confounding variables examined, and range of blood Pb levels (Marcus et al., 2010). Evidence of Pb-induced aggression in animals was inconsistent, with increases in aggression found in some studies of adult animals with gestational plus lifetime Pb exposure but not juvenile animals.

Associations of conduct problems in children and young adults with earlier childhood, earlier childhood average, and lifetime average blood Pb levels, tooth Pb levels, and bone Pb levels point to the effects of early childhood or cumulative Pb exposures. Most prospective studies did not analyze Pb biomarker levels at multiple lifestages or time periods and thus did not provide information on potential associations with more recent blood Pb measurements or differences in association among Pb biomarkers at various time periods. With respect to blood Pb levels, an association with criminal offenses was found in young adults ages 19-24 years with a mean age 6 year blood Pb level of 6.8 µg/dL, and associations with ratings of conduct problems were found in children ages 7-8 years with age 30 month blood Pb levels >10 µg/dL and boys ages 11-13 years with a mean lifetime average blood Pb level of ~14 µg/dL (Table 5-17).

In conclusion, the few prospective studies consistently indicate that earlier childhood (age 30 months) or lifetime average (to age 11-13 years) blood Pb levels or tooth (from ages 6-8 years) Pb levels are associated with criminal offenses in young adults ages 19-24 years and with higher parent and teacher ratings of conduct problems in children ages 7-17 years. These associations were found without indication of strong selection bias and with adjustment for SES, parental education and IQ, parental caregiving quality, family functioning, smoking, and substance abuse. Supporting evidence is provided by cross-sectional evidence of children participating in NHANES and a meta-analysis of prospective and cross-sectional studies. Evidence for Pb-induced aggression in animals is mixed. The consistent epidemiologic evidence from prospective and cross-sectional studies for criminal offenses and ratings of misconduct but lack of clear evidence for aggression in animals is sufficient to conclude that a causal relationship is likely to exist between Pb exposure and conduct problems in children and young adults.

5.3.16.4 Evidence for Internalizing Behaviors in Children

Epidemiologic and toxicological evidence indicates that a causal relationship is likely to exist between Pb exposures in children and internalizing behaviors, including withdrawn behavior, fearfulness, and symptoms of depression and anxiety. Internalizing behaviors

have been examined to a lesser extent than cognitive function and attention-related behaviors. However, supporting evidence is provided by a few previous prospective studies that found associations of higher lifetime average blood or tooth Pb levels with higher parent and teacher ratings of withdrawn behavior or symptoms of depression in school-aged children, 8-13 years (Burns et al., 1999; Bellinger et al., 1994b) (Table 5-17). These prospective studies followed children from birth and had moderate follow-up participation to later childhood. Participation was not conditional on early childhood blood Pb levels, and associations were found with both parent and teacher ratings of internalizing behaviors, reducing the likelihood of undue influence by biased participation and ratings of internalizing behaviors by parents of children with higher Pb exposures. Internalizing behaviors were assessed with widely-used structured questionnaires such as the Child Behavior Checklist but not assessed as clinically-diagnosed conditions such as depression.

The analysis of the Port Pirie, Australia cohort had the most extensive consideration of potential confounding. Among only the 163 girls, ages 11-13 years, Burns et al. (1999) found that 1 µg/dL increase in lifetime average blood Pb level was associated with an increased odds of an anxious/depressed parental rating above the median of 1.04 (95% CI: 1.0, 1.09) with the adjustment for several SES-related variables and factors related to parental caregiving including HOME score, family functioning score, and current maternal psychopathology. In a Boston-area cohort, Pb level in deciduous teeth collected around age 6 years was associated with a higher teacher rating of a composite of anxious and social withdrawn behaviors in children ages 8 years with adjustment for receiving public assistance at birth and maternal education but not parental caregiving quality (Bellinger et al., 1994b). In the Yugoslavia cohort, higher lifetime average blood Pb levels were associated with higher maternal ratings of anxious-depressed and withdrawn behaviors in 191 children ages 4-5 years with a mean blood Pb level ~8 µg/dL, with stronger associations found with delinquent behaviors (Wasserman et al., 2001). Behavior ratings may be less reliable in these younger children. With respect to critical lifestages and durations of Pb exposure, evidence from prospective studies for associations with tooth Pb levels and lifetime average blood Pb levels indicates an effect of cumulative childhood exposure on increasing internalizing behaviors in children.

Cross-sectional studies, including several recent studies, indicated associations between concurrent blood Pb levels and internalizing behaviors in children ages 3-16 years, but most did not consider potential confounding by parental caregiving quality (Section 5.3.5.1). Previously, Chiodo et al. (2004) found that among children age 7 years in Detroit, MI (mean blood Pb level: 5 µg/dL), HOME score, SES, maternal education, and prenatal alcohol and drug exposure did not influence associations between blood Pb level and internalizing behaviors; however, the population lacks representativeness

because of the high prevalence of prenatal alcohol or drug exposure (Table 5-17). A recent study reported a lack of association between concurrent blood Pb level and internalizing behaviors in Inuit children age 5 years in Quebec, Canada with a mean blood Pb level of ~5 µg/dL with consideration of potential confounding by HOME score, caregiver education and IQ, blood Hg levels, and prenatal smoking and alcohol exposure (Plusquellec et al., 2010).

Supporting evidence for a relationship between Pb exposure and internalizing behaviors is provided by the coherence of epidemiologic findings in children with evidence in rodents that dietary prenatal plus lactational or lactational only Pb exposure resulted in depression-like and loss of motivation behavior in rodents, in some cases with blood Pb levels relevant to humans (13-17 µg/dL) (Beaudin et al., 2007; Dyatlov and Lawrence, 2002). Other studies found Pb-induced increases in emotionality, depression, and tactile defensiveness in animals with blood Pb levels >30 µg/dL after gestational and/or lactational Pb exposure (Section 5.3.5.2). Biological plausibility for Pb-associated increases in internalizing behaviors also is provided by evidence that describes mode of action, including Pb-induced changes in the HPA axis (Section 5.3.2.3) and dopaminergic and GABAergic systems (Sections 5.2.2.2, 5.3.11.4, and 5.3.11.8), which are found to affect mood and emotional state.

In conclusion, prospective studies in a few populations demonstrate associations of higher lifetime average blood (mean: ~14 µg/dL) or childhood tooth (from ages 6-8 years) Pb levels with higher parent and teacher ratings of internalizing behaviors such as depression, anxiety, and withdrawn behavior in children ages 8-13 years. The lack of selective participation by blood Pb level and associations found with parental and teacher ratings do not provide strong indication of biased reporting of behaviors for children with higher blood Pb levels. While results were adjusted for maternal education and SES-related variables, consideration for potential confounding by parental caregiving quality was inconsistent. The biological plausibility for the effects of Pb on internalizing behaviors is provided by consistent findings in animals with dietary prenatal plus lactational or lactational only Pb exposure, with some evidence at blood Pb levels relevant to humans. Additional toxicological evidence supports modes of action, including Pb-induced changes in the HPA axis and dopaminergic and GABAergic systems. The evidence from prospective studies in a few populations and the supporting toxicological evidence with some uncertainty related to potential confounding by parental caregiving quality in studies of children is sufficient to conclude that a causal relationship is likely to exist between Pb exposure and internalizing behaviors in children.

5.3.16.5 Evidence for Sensory Function in Children

A causal relationship is likely to exist between Pb exposure and sensory function decrements in children based on evidence from a previous prospective study indicating associations of increased hearing thresholds with early childhood and lifetime average blood Pb levels in 215 children age 5 years (Dietrich et al., 1992) and previous large (n = >3,000) cross-sectional NHANES and HHANES studies for concurrent blood Pb levels in children ages 4-19 years (Schwartz and Otto, 1991, 1987). The high follow-up participation from birth in the Cincinnati cohort and the examination of multiple exposures and outcomes in NHANES and HHANES reduce the likelihood of biased participation by children with high blood Pb levels.

The epidemiologic evidence in children is strengthened by the consideration for several potential confounding factors. In the Cincinnati cohort at age 5 years, higher prenatal maternal, neonatal (10 day, mean 4.8 µg/dL), and lifetime average (mean: 17.4 µg/dL) blood Pb levels were associated with higher hearing thresholds with adjustment for SES, HOME score, several birth outcomes, and maternal alcohol consumption and consideration for factors such as maternal smoking and child health (Dietrich et al., 1992). In NHANES and HHANES, higher concurrent blood Pb levels (median: 8 µg/dL) were associated with increased hearing thresholds with adjustment for age, sex, race, family income, parental education, and nutritional factors (Schwartz and Otto, 1991, 1987).

Additional support for a relationship between Pb exposure and sensory function decrements in children is provided by evidence supporting modes of action. A previous prospective study in children in Mexico City (n = 100, 113) found associations of prenatal maternal (1-8 µg/dL) and age 1 and 4 year blood Pb levels (age 2 year mean: 10.8 µg/dL) with lower auditory evoked potentials (Rothenberg et al., 2000). Increased thresholds and increased latencies in brainstem auditory evoked potentials were also found in nonhuman primates ages 8-13 years with long-term (multiple years) postnatal Pb exposure beginning at birth (Rice, 1997; Lilienthal and Winneke, 1996). Pb exposure from gestation through age 5 months was found to have weaker effects (Laughlin et al., 2009). In animals, auditory effects were examined with higher Pb exposures than those relevant to the current U.S. general population (i.e., resultant blood Pb levels 33-170 µg/dL); thus, it is difficult to assess coherence with observations in children.

Toxicological studies demonstrated a range of effects on the visual system including impaired visual function, and potential mechanisms such as alterations in morphology and cell architecture, signaling, enzyme inhibition, neurotransmitter levels, neuroanatomical development, cell proliferation, and retinal cell apoptosis. An epidemiologic study in children (Rothenberg et al., 2002b) and toxicological studies in

rats found Pb-associated supernormal retinal ERGs (Fox et al., 2008). Animal studies also showed subnormal ERGs depending on lifestage of Pb exposure and blood Pb level. Because the implications of supernormal ERGs on vision are not clear, the retinal ERG findings are not a major consideration in drawing conclusions about Pb exposure and sensory function decrements in children.

In conclusion, evidence from a prospective study and cross-sectional studies in a few populations indicates associations of higher blood Pb level with increases in hearing thresholds and decreases in auditory evoked potentials with adjustment for potential confounding by SES in most studies and by child health and nutritional factors in some studies. The high participation rates, particularly in the prospective study with follow-up from birth, reduce the likelihood of biased participation by children with higher blood Pb levels. Across studies, associations were found with blood Pb levels measured at various time periods, including prenatal maternal, neonatal (10 day, mean 4.8 µg/dL), lifetime average (to age 5 years, mean 17.4 µg/dL), and concurrent (ages 4-19 years) blood Pb levels (median 8 µg/dL). Findings in monkeys ages 8-13 years indicate increases hearing thresholds and latencies for auditory evoked potentials with lifetime postnatal dietary Pb exposure, albeit with higher blood Pb levels (i.e., 33-107 µg/dL) than those relevant to humans. The evidence in children, particularly that from a prospective study, but uncertainties related to effects on auditory function in animals with relevant Pb exposures, is sufficient to conclude that a causal relationship is likely to exist between Pb exposure and decrements in sensory function in children.

5.3.16.6 Evidence for Motor Function in Children

A causal relationship is likely to exist between Pb exposure and motor function decrements in children based on evidence from previous prospective epidemiologic studies and supporting toxicological evidence. In the Cincinnati cohort, higher neonatal, concurrent, and lifetime average blood Pb levels were associated with poorer fine and gross motor function in 245 children ages 6 years (Dietrich et al., 1993a), and higher age 0-5 year average and 78 month blood Pb levels were associated with poorer fine motor function in 195 children ages 15-17 years (Ris et al., 2004). In the Yugoslavian cohort, higher lifetime average blood Pb level was associated with decrements in fine but not gross motor function at age 4.5 years in 283 children (Wasserman et al., 2000). These studies had high follow-up participation from birth or infancy reducing the likelihood of biased participation by children with higher blood Pb levels. Motor function was assessed using varied but widely-used, structured tests. The evidence from the Cincinnati and Yugoslavia cohorts is substantiated by the consideration of several potential confounding factors such as SES, parental caregiving quality, child health, and in adolescents,

marijuana use (Ris et al., 2004). In the prospective studies, mean concurrent and childhood average blood Pb levels mostly ranged from 11 to 28 µg/dL, higher than those in most of the current U.S. population. Recent cross-sectional studies examining lower concurrent blood Pb levels, means 2-5 µg/dL, produced contrasting associations (Surkan et al., 2007; Despres et al., 2005). An association between concurrent blood Pb level and poorer motor function was found with adjustment for several potential confounding factors including SES, parental caregiving quality, and blood levels of Hg and polychlorinated biphenyls in 110 Inuit children living in subsistence fishing communities (Despres et al., 2005). Higher blood Pb level was associated with improved motor function in a more representative population of 534 children ages 6-10 years in New England (Surkan et al., 2007).

Epidemiologic evidence is supported by observations of poorer performance on the rotarod balance test in male (not female) mice with relevant blood Pb levels, i.e., 10 µg/dL after dietary Pb exposure from gestation to PND10 (Leasure et al., 2008). Other toxicological studies produced mixed results for effects on endurance, balance, and coordination (Section 5.3.8) but are less relevant to humans because of the higher concentrations of Pb exposure examined, i.e., those producing blood Pb levels >30 µg/dL.

In conclusion, evidence from prospective and cross-sectional studies in a few populations indicates associations of decrements in fine and gross motor function with higher blood Pb levels measured earlier in childhood (ages 0-5 year average, age 78 months) in children ages 15-17 years or lifetime average blood Pb levels in children ages 4.5 years with adjustment for several potential confounding factors, including SES, parental caregiving quality, and child health. The prospective studies had high follow-up participation from birth or early infancy, reducing the likelihood of biased participation by children with higher blood Pb levels. The biological plausibility for associations observed in children is provided by a study that found poorer balance in male mice with relevant gestational to early postnatal (PND10) Pb exposures. The evidence in children, particularly from a few prospective studies, and the coherence with limited available findings in mice is sufficient to conclude that a causal relationship is likely to exist between Pb exposure and decrements in motor function in children.

5.3.16.7 Evidence for Cognitive Function in Adults

Epidemiologic and toxicological evidence indicates that a causal relationship is likely to exist between Pb exposure and cognitive function decrements in adults based primarily on recent prospective and cross-sectional studies that indicate associations with bone Pb

level (Table 5-17). Key evidence for bone Pb levels comprised prospective analyses of the BMS and NAS, with support provided by the cross-sectional Nurses' Health Study. The multiple risk factors and health outcomes examined in these studies reduces the likelihood of biased participation and/or follow-up by adults with higher Pb exposure and lower cognitive function. While the NAS and Nurses' Health Study examined primarily white men and white women, respectively, the BMS examined a more ethnically diverse population of men and women, increasing the generalizability of findings. There was variability in associations across the various domains of cognitive function tested within studies; however, bone Pb levels were associated with decrements in most neuropsychological tests performed. In many studies, bone Pb levels were associated with poorer executive function, visuospatial skills, learning, and memory.

Recent evidence from prospective analyses of the NAS and BMS cohorts expanded upon previous cross-sectional evidence by improving characterization of the temporal sequence between Pb exposure and cognitive function declines in adults (n = 405-943, mean ages 60 and 69 years) by demonstrating that higher tibia (means 19, 20 µg/g) or patella (mean 25 µg/g) bone Pb levels measured at baseline were associated with subsequent declines in cognitive function over 2- to 4-year periods (Bandeen-Roche et al., 2009; Weisskopf et al., 2007b). The specific potential confounding factors considered differed between studies; both studies adjusted for age and education. Additional adjustment was made for income in the BMS and current alcohol use and current smoking in the NAS.

Evidence from most cross-sectional analyses supported associations between higher bone Pb level and decrements in cognitive function in adults. A strength of cross-sectional studies overall was the adjustment for the same potential confounding factors described above and also dietary factors, physical activity, medication use, and comorbid conditions (Rajan et al., 2008; Weuve et al., 2006). Cross-sectional studies generally demonstrated larger decrements in cognitive function in adults in association with tibia or patella Pb levels than with concurrent blood Pb levels. Results from the NAS and Nurses' Health Study did not clearly indicate a difference in association with cognitive performance between tibia and patella Pb levels (Weuve et al., 2009; Weisskopf et al., 2007b). In NHANES analyses, higher concurrent blood Pb levels were associated with lower cognitive function in particular age and genetic variant subgroups but not consistently across the various cognitive tests conducted (Krieg et al., 2010; Krieg and Butler, 2009; Krieg et al., 2009). NHANES did not have bone Pb measures for comparison.

Because bone Pb is a major contributor to blood Pb levels, blood Pb level also can reflect longer term exposures, including higher past exposures, especially in adults without occupational exposures. Thus, in the NHANES results, it is difficult to characterize the

relative contributions of recent and past Pb exposures to the associations observed between concurrent blood Pb level and cognitive function. The discrepant findings for blood and bone Pb levels indicate that cumulative Pb exposure that likely included higher past exposures may be a better predictor of cognitive function in adults than is concurrent blood Pb level.

Additional support for the effects of cumulative or past Pb exposure is provided by analyses of a few child cohorts as adults, which indicate that childhood tooth (from ages 5-8 years) and blood (e.g., age 10 years) Pb levels are associated with decrements in cognitive function in adults ages 19-30 years (Mazumdar et al., 2011; Bellinger et al., 1994a). An uncertainty in the evidence for bone Pb levels is potential residual confounding by age. Increasing age is highly correlated with increasing bone Pb level (Section 4.3.5.2), and distinguishing Pb-related declines in cognitive function from age-related declines with model adjustment is difficult. One explanation for the more variable findings in adults than in children may be that cognitive reserve may compensate for the effects of Pb exposure on learning new information. Compensatory mechanisms may be overwhelmed with age and with higher long-term or cumulative Pb exposure represented by higher bone Pb levels.

Higher blood and bone Pb levels were associated with cognitive function decrements in adults with current or former occupational Pb exposures. Some studies examined current workers with blood Pb level means 26 or 31 μg/dL (Table 5-17). Among adults with current occupational Pb exposures, both concurrent and cumulative exposures may affect cognitive function. Several of these studies considered potential confounding by a similar set of factors as did studies of adults without occupational Pb exposures but did not examine other occupational exposures. In the prospective study of adults with former occupational Pb exposure, peak tibia Pb levels were associated more strongly with cognitive performance than were concurrent blood Pb levels (Khalil et al., 2009a). Thus, in the absence of higher current Pb exposures, cumulative Pb exposures may have a greater effect on cognitive function in adults.

Additional support for a relationship between Pb exposure and cognitive function decrements in adults is provided by the coherence with evidence in adult animals that lifetime Pb exposure of animals starting from gestation, birth, or after weaning induces learning impairments (Table 5-17 and Section 5.3.2.3). Biological plausibility also is provided by evidence describing the effects of Pb on modes of action underlying cognitive function. Cognitive function is mediated by actions of the neurotransmitters dopamine and glutamate in the hippocampus, prefrontal cortex, and nucleus accumbens. Experimental studies have shown that Pb induces changes in neurotransmitter release in these regions. Studies also have shown Pb-induced decreases in the magnitude of LTP.

In conclusion, in adults without occupational exposure, recent prospective studies in the NAS and BMS cohorts indicate associations of higher baseline tibia (means 19, 20 µg/g) or patella (mean 25 µg/g) Pb levels with declines in cognitive function in adults (>age 50 years) over 2- to 4-year periods. While the specific covariates differed between studies, these tibia Pb-associated cognitive function decrements were found with adjustment for potential confounding factors such as age, education, SES, current alcohol use, and current smoking. Supporting evidence is provided by cross-sectional analyses of the NAS, BMS, and the Nurses' Health Study, which found stronger associations with bone Pb level than concurrent blood Pb level. Cross-sectional studies also considered more potential confounding factors, including dietary factors, physical activity, medication use, and comorbid conditions. The multiple exposures and health outcomes examined in many studies reduces the likelihood of biased participation by adults with higher Pb exposure and lower cognitive function. The collective evidence indicates associations in cohorts of white men and women and a cohort of more ethnically diverse men and women. The specific timing, frequency, duration, and magnitude of Pb exposures contributing to the associations observed with bone Pb levels are uncertain. Also uncertain is the potential for residual confounding by age. The effects of recent Pb exposures on cognitive function decrements were indicated in Pb-exposed workers by associations found with blood Pb levels, although these studies did not consider potential confounding by other workplace exposures. The biological plausibility for the effects of Pb exposure on cognitive function decrements in adults is provided by findings that lifetime Pb exposures from gestation, birth, or after weaning induce learning impairments in adult animals and by evidence for the effects of Pb altering neurotransmitter function in hippocampus, prefrontal cortex, and nucleus accumbens. The associations between bone Pb level and cognitive function decrements consistently found in the few prospective and cross-sectional studies of adults without occupational Pb exposure, the coherence with animal findings, and toxicological evidence supporting modes of action but uncertainties related to potential residual confounding by age in epidemiologic studies are sufficient to conclude that a causal relationship is likely to exist between long-term cumulative Pb exposure and cognitive function decrements in adults.

5.3.16.8 Evidence for Psychopathological Effects in Adults

Evidence indicates that a causal relationship is likely to exist between Pb exposure and psychopathological effects in adults, based on the cross-sectional associations found between concurrent blood Pb level (Bouchard et al., 2009) or bone Pb level (Rajan et al., 2008) and self-reported depression, anxiety, and panic disorder in adults participating in NHANES and NAS, respectively and supporting toxicological evidence. Higher prenatal

blood δ-ALA level was associated with schizophrenia in adults in California (Opler et al., 2008; 2004), but because of the lack of assessment of blood or bone Pb levels, results were not a major consideration in conclusions. In both NHANES and NAS, the high participation rates and examination of multiple exposures and outcomes reduces the likelihood that findings are influenced by biased participation or reporting of symptoms by subjects with higher Pb exposures. Depression and anxiety were assessed with widely-used structured questionnaires such as the Profile of Mood States, but there is uncertainty regarding the effects of Pb exposure on clinically-diagnosed conditions.

Epidemiologic evidence for associations between blood or bone Pb level and psychopathological effects is strengthened by the consideration of several potential confounding factors. Among adults ages 20-39 years participating in NHANES, 369 adults with concurrent blood Pb level ≥ 2.11 µg/dL had the highest OR for self-reported major depressive disorder (OR: 2.32 [95% CI: 1.13, 4.75]) and panic disorder (OR: 4.94 [95% CI: 1.32, 18.48]) compared with the 449 adults with blood Pb levels <0.7 µg/dL with adjustment for age, sex, race, education, and poverty to income ratio (Bouchard et al., 2009). Among 526 NAS men ages 48-70 years, a 27 µg/g increase in tibia Pb level was associated with a combined index of self-reported anxiety, depression, and phobic anxiety with an OR of 2.08 (95% CI: 1.06, 4.07) with adjustment for age, grams/day alcohol ingested, education, and employment status (Rhodes et al., 2003). Because of the cross-sectional design of studies, the temporal sequence between Pb exposure and psychopathological symptoms in adults is uncertain. This uncertainty is somewhat reduced with results for tibia Pb, since it is an indicator of cumulative Pb exposure. For results with blood and bone Pb level, there is uncertainty regarding the critical level, timing, frequency, and duration of Pb exposure associated with psychopathological effects.

The epidemiologic evidence for Pb-associated psychopathological effects is supported by the coherence with findings in rodents that dietary prenatal/lactational or lactational Pb exposure resulted in depression-like and loss of motivation behavior in rodents, with some evidence at blood Pb levels relevant to humans (13-17 µg/dL) (Beaudin et al., 2007; Dyatlov and Lawrence, 2002). Other studies found Pb-induced increases in depression-like behavior in animals with higher blood Pb levels (Section 5.3.5.2). Further support for Pb-associated increases in psychopathological effects in adults is provided by evidence that describes modes of action, including Pb-induced changes in the HPA axis (Section 5.3.2.3) and dopaminergic and GABAergic systems (Sections 5.2.2.2 and 5.3.11.8), which are found to affect mood and emotional state.

In conclusion, cross-sectional studies in a few populations demonstrate associations of higher concurrent blood or tibia Pb levels with self-reports of depression and anxiety in

adults. The examination of multiple exposures and outcomes in the available studies does not provide strong indication of biased reporting of psychopathological effects by adults with higher Pb exposures. In adults, Pb-associated increases in depression and anxiety were found with adjustment for age, SES, and in the NAS, daily alcohol intake. The biological plausibility for epidemiologic evidence is provided by observations of depression-like behavior in animals with dietary prenatal/lactational or lactational Pb exposure, with some evidence at blood Pb levels relevant to humans and by toxicological evidence supporting modes of action, including Pb-induced changes in the HPA axis and dopaminergic and GABAergic systems. The associations of blood and bone Pb level with self-reported psychopathological effects found in the few studies of adults without occupational Pb exposure, the biological plausibility provided by the coherence of findings in animals and underlying modes of action, but uncertainties related to residual confounding of bone Pb results by age in epidemiologic studies are sufficient to conclude that a causal relationship is likely to exist between Pb exposure and psychopathological effects in adults.

5.3.16.9 Evidence for Sensory Function Decrements in Adults

The small body of epidemiologic and toxicological evidence is suggestive of a causal relationship between Pb exposure and sensory function decrements in adults. Key evidence in humans is provided by the recent analysis of NAS males in which a 15 µg/g higher tibia Pb level at mean age 64.9 years was associated with a 0.05 dB/year (95% CI: 0.017, 0.083) increase in hearing threshold for a pure tone average frequency (Park et al., 2010). Results were adjusted for baseline age, race, education, occupational noise, BMI, pack-years smoking, noise notch, diabetes, and hypertension. Although the generalizability of results in this primarily white population of men is limited, high follow-up participation and the examination of multiple exposures and outcomes in this cohort reduces the likelihood that findings are biased by selective participation of men with higher Pb exposures. Bone Pb levels were measured up to 20 years after the initial hearing measurement; however, tibia Pb level is considered an indicator of cumulative Pb exposure since the half-life of Pb in bone is on the order of decades (Section 4.3). Bone Pb levels increase with age, and although age was included as a model covariate, residual confounding by age is possible. Supporting evidence was provided by a recent case-control study of adults attending a hospital for occupational health exams. Despite limitations of a nonrandom population and uncertain comparability of controls, the examination of multiple metals reduces the likelihood of biased participation by higher Pb exposure. Higher concurrent blood Pb level was associated with hearing loss with

adjustment for several factors (Table 5-17) including blood levels of Mn, As, and Se (Chuang et al., 2007).

These epidemiologic findings are supported by the coherence of findings for Pb-induced increases in hearing thresholds in animals, albeit at higher blood Pb levels than those relevant for humans. Monkeys that were exposed to Pb in drinking water from gestation through testing at age 13 years and had blood Pb levels 33-107 µg/dL were found to have elevated thresholds and increased latencies in brainstem auditory evoked potentials (Rice, 1997; Lilienthal and Winneke, 1996). A recent study found lack of persistence of effects in monkeys tested at age 13 years that had shorter duration exposure, gestation through age 5.5 months (Laughlin et al., 2009).

In conclusion, the evidence provided by the analysis of NAS men for associations of higher tibia Pb level with a greater rate of elevations in hearing threshold over 20 years and the biological plausibility provided by the evidence for Pb-induced decreases in auditory evoked potentials in animals but at higher blood Pb levels than those relevant to humans, is suggestive of a causal relationship between Pb exposure and sensory function decrements in adults.

5.3.16.10 Evidence for Neurodegenerative Diseases in Adults

Epidemiologic and toxicological studies have found associations between indicators of Pb exposure and neurodegenerative diseases such as Parkinson's disease and essential tremor, but evidence is inconclusive for Alzheimer's disease and ALS. Despite the evidence for some neurodegenerative diseases, because of limitations as described below, the evidence is inadequate to determine that there is a causal relationship between Pb exposure and neurodegenerative diseases.

The few case-control studies of essential tremor found higher concurrent blood Pb levels in cases than controls (Section 5.3.10.4). A common limitation of these studies was the potential for reverse causation. Reduced physical activity among cases could result in greater bone turnover and greater release of Pb from bones into blood in cases than controls. Some case-control studies found adults with Parkinson's disease to have higher bone Pb levels, which are not likely to increase with decreases in physical activity (Weisskopf et al., 2010; Coon et al., 2006). While some of these studies of Parkinson's disease and essential tremor considered potential confounding by factors such as age, sex, race, education, and alcohol consumption, they did not consider Mn co-exposure. Epidemiologic findings for Parkinson's disease are supported by limited available mode of action evidence for Pb-induced decreased dopaminergic cell activity in the substantia nigra, which contributes to the primary symptoms of Parkinson's disease.

The few case-control studies of Alzheimer's disease did not find higher prevalence of occupational Pb exposure or higher brain Pb levels in cases but did not measure Pb in blood or bone (Section 5.3.10.1). Toxicological studies indicated that infancy exposure during lactation but not adult-only Pb exposures of monkeys and rats induced pathologies that underlie Alzheimer's disease, including the formation of amyloid plaques and neurofibrillary tangles in the brains of aged animals (Section 5.3.10.1). While these results suggest the need to consider early-life Pb exposure in epidemiologic studies, some indicate that effects may be attributable to the high Pb exposure concentrations tested, i.e., producing blood Pb levels >40 µg/dL in rats (Li et al., 2010; Basha et al., 2005). Studies of ALS have not consistently found higher blood Pb levels among ALS cases and controls (Section 5.3.10.2), and a recent study found that higher tibia and patella Pb levels were associated with longer survival time among ALS cases (Kamel et al., 2008).

In conclusion, while evidence is inconclusive for ALS and Alzheimer's disease, a few case-control studies each found higher blood Pb levels in adults with essential tremor and higher bone Pb levels in adults with Parkinson's disease. Because of the inconclusive evidence for some diseases and limitations such as reverse causation for essential tremor and the lack of consideration for potential confounding by Mn exposure for both essential tremor and Parkinson's disease, the evidence is inadequate to determine that there is a causal relationship between Pb exposure and neurodegenerative diseases.

Table 5-17 Summary of Evidence Supporting Nervous System Causal Determinations.

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	References[b]	Pb Biomarker Levels Associated with Effects[c]
Cognitive Function Decrements in Children - Causal			
Consistent associations from multiple, high quality epidemiologic studies with relevant blood Pb levels	Evidence from prospective studies for decrements in FSIQ in association with prenatal, earlier childhood, peak, concurrent, lifetime average blood Pb levels and tooth Pb levels in children ages 4-17 yr in multiple U.S. locations, Mexico, Europe, Australia	Canfield et al. (2003a), Bellinger et al. (1992), Jusko et al. (2008), Dietrich et al. (1993b), Schnaas et al. (2006), Wasserman et al. (1997), Tong et al. (1996) Section 5.3.2.1	Blood Pb (various lifestages and time periods): means 3-14 µg/dL
	Most studies adjust for confounding by SES, maternal IQ and education, HOME score. Several adjust for birth weight, smoking. A few, nutritional factors.		
	Pooled analysis of seven cohorts indicates precise effect estimates, -2.36 to -2.94 FSIQ points per log increase in blood Pb level, excluding one study at a time	Lanphear et al. (2005)	
	Meta-analyses demonstrate the consistency of association	Pocock et al. (1994), Schwartz (1994)	
	Evidence from prospective studies for lower scores on tests of executive function and academic performance in association with earlier childhood or lifetime average blood Pb levels or tooth Pb levels in children ages 5-18 yr in multiple U.S. locations, U.K, New Zealand. Associations less consistent for learning and memory.	Bellinger et al. (1991), Canfield et al. (2004), Ris et al. (2004), Stiles and Bellinger (1993), Miranda et al. (2009; 2007a), Fergusson et al. (1997, 1993), Leviton et al. (1993), Chandramouli et al. (2009) Sections 5.3.2.3, 5.3.2.4, 5.3.2.5	Blood Pb (various lifestages and time periods): Means 4.8-8 µg/dL, Groups with early childhood blood Pb >2 and >5 µg/dL Tooth Pb (ages 6-8 yr): means 3.3, 6.2 µg/g
	Supporting evidence from cross-sectional studies of children ages 3-16 yr, but most did not consider potential confounding by parental caregiving quality. Includes large NHANES III analysis.	Surkan et al. (2007), Kim et al. (2009b), Roy et al. (2011), Lanphear et al. (2000), Froehlich et al. (2007)	Concurrent blood Pb : Means 1.7-11.4 µg/dL, Groups with blood Pb >10 µg/dL
	Studies had population-based recruitment, most with moderate to high follow-up participation not conditional on blood or tooth Pb level.	Table 5-3, Table 5-5; Table 5-8, Table 5-9	
	Outcomes assessed using widely-used, structured questionnaires.		
	Several studies indicate supralinear C-R relationship, with larger decrements in cognitive function per unit increase in blood Pb at lower blood Pb levels in children ages 5-10 yr	Canfield et al. (2003a), Bellinger et al. (1992), Jusko et al. (2008), Kordas et al. (2006), Lanphear et al. (2005)	Groups with peak blood Pb <10 µg/dL: concurrent mean 3.3 µg/dL, age 2 year mean 3.8 µg/dL

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	References[b]	Pb Biomarker Levels Associated with Effects[c]
Epidemiologic evidence supported by consistent toxicological results with relevant exposures	Impaired learning in juvenile and adult animals as indicated by performance in Y maze, Operant Schedules of Reinforcement with relevant dietary Pb exposure. Impaired learning, memory, executive function in juvenile and adult animals as indicated by poorer performance on spatial delayed alternation and discrimination reversal learning tasks with dietary Pb exposures.	Stangle et al. (2007), Niu et al. (2009), Cory-Slechta et al. (2010), Virgolini et al. (2008a), Altmann et al. (1993), Section 5.3.2.3 Gilbert and Rice (1987), Rice and Gilbert (1990b), Rice (1992b), Rice and Gilbert (1990a), Rice and Karpinski (1988), Sections 5.3.2.3 and 5.3.2.4	Blood Pb (after prenatal/ lactation, lactation only, postlactation, prenatal/lifetime Pb exposure): 8-31 µg/dL Blood Pb (after lifetime Pb exposure after lactation): 15-26 µg/dL
Evidence clearly describes mode of action			
Impaired neuron development	Decreased neurogenesis in hippocampus DG, which is involved in LTP and learning, with lactational, postlactational (25 days), lifetime from gestation dietary Pb exposures. Decreased NMDAR, which is involved in integration of new neurons into existing neuronal pathways with postlactational (8 weeks) and lifetime from gestation dietary Pb exposures. Decreased neurite outgrowth in animals with gestational Pb exposure	Section 5.3.11.9 and 5.3.11.10	
Synaptic changes	Decreased synaptic development with gestational-lactational dietary Pb exposures. Changes in synaptic protein composition with gestational-lactational Pb exposure. Decreased ATP, AchE, which mediate neurotransmission with gestational Pb exposure	Section 5.3.11.4	
LTP	Decreased magnitude, increased threshold of LTP with gestational-lactational Pb exposure.	Section 5.3.11.8	
Neurotransmitter changes	Decreased dopamine in substantia nigra with gestational-lactational dietary Pb exposure. Increased sensitivity of dopamine receptor with gestational-lactational, lactational, or postlactational Pb exposure. Increased catecholamine transmission in cerebral cortex, cerebellum, hippocampus with gestational-lactational Pb exposure. Decreased glutamate and expression of glutamate receptor, NMDAR in vitro and in rats with gestational-lactational Pb exposure.	Section 5.3.11.8	

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	References[b]	Pb Biomarker Levels Associated with Effects[c]
Attention-related Behavioral Problems in Children (e.g., inattention, impulsivity, hyperactivity, ADHD) **– Causal**			
Consistent associations from multiple, high quality epidemiologic studies with relevant blood Pb levels	Evidence from prospective studies for inattention, impulsivity, and hyperactivity in association with prenatal (maternal or cord), earlier childhood, and lifetime avg blood Pb and tooth Pb levels in children ages 7-17 yr and young adults 19-24 yr in U.S., U.K., Australia, New Zealand. Most studies adjusted for SES, maternal education, and parental caregiving quality. Some also considered parental IQ, smoking, birth outcomes. A few considered substance abuse, nutritional factors. Studies had population-based recruitment with moderate to high follow-up participation not conditional on blood or tooth Pb level. Associations found with neuropsychological tests (CPT) and teacher and parent ratings using widely-used, structured questionnaires.	Ris et al. (2004), Fergusson et al. (1993), Bellinger et al. (1994a), Chandramouli et al. (2009), Leviton et al. (1993) Burns et al. (1999) with the most extensive consideration for potential confounding Sections 5.3.3.1, 5.3.3.2, 5.3.3.3	Blood Pb: means 6.8 µg/dL (prenatal cord), 14 µg/dL (lifetime avg to age 11-13 yr), Group with age 30 mo >10 µg/dL Tooth Pb (age 5-8 yr) means: 3.3, 6.2, 14 µg/g
	Associations with inattention ratings inconsistent in prospective studies examining children with lower blood Pb levels, but children were younger, <5 yr	Wasserman et al. (2001), Canfield et al. (2003b) Section 5.3.3.1	Concurrent blood Pb means 6.5 µg/dL
	Supporting evidence from cross-sectional studies for associations of concurrent blood Pb level with inattention, impulsivity, and hyperactivity, and total ADHD rating in children ages 8-15 yr. Cross-sectional studies had less extensive consideration for potential confounding, particularly parental caregiving quality.	Cho et al. (2010), Nicolescu et al. (2010), Froehlich et al. (2009), Silva et al. (1988) Sections 5.3.3.1, 5.3.3.2, 5.3.3.3	Concurrent Blood Pb means 1.9-11.1 µg/dL
Epidemiologic evidence supported by toxicological results with relevant exposures	Impulsivity indicated by premature responses, increased perseveration, decreased pause time between events on tests of response inhibition in rodents and monkeys with relevant dietary postnatal Pb exposures.	Stangle et al. (2007), Brockel and Cory-Slechta (1998), Rice (1985), Brockel et al. (1999b) Section 5.3.3.1	Blood Pb: 15, 25 µg/dL in monkeys after infancy only exposure, 11, 29 µg/dL in rats after 40-day postweaning exposure, 10, 26 µg/dL after 3, 7 mo postweaning exposure
	Increased distractibility found in adult monkeys with relevant lifetime dietary Pb exposure as assessed by poorer performance on discrimination reversal learning tests with distracting stimuli.	Gilbert and Rice (1987) Section 5.3.3.1	Blood Pb after lifetime (after birth) exposure: 15, 25 µg/dL
	Relevant postnatal dietary Pb exposure not found consistently to affect sustained attention in rats as assessed using signal detection test with distracting stimuli.	Brockel and Cory-Slechta (1999a), Stangle et al. (2007) Section 5.3.3.1	Blood Pb: 16, 28 µg/dL after 34-day postweaning exposure, 13, 31 µg/dL after lactational exposure.

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	References[b]	Pb Biomarker Levels Associated with Effects[c]
Evidence clearly describes mode of action	Same as above for cognitive function in children		
Internalizing Behaviors in Children (e.g., withdrawn behavior, symptoms of depression, anxiety, fearfulness) **– Likely Causal**			
Associations found in high-quality epidemiologic studies with relevant exposures	Evidence from prospective studies for higher ratings of internalizing behaviors in children ages 8-13 yr in Boston and Port Pirie cohorts in association with tooth or lifetime average blood Pb levels. Results adjusted for SES, birth outcomes, parental education. Port Pirie also adjusted for HOME, current maternal psychopathological symptoms.	Burns et al. (1999), Bellinger et al. (1994b) Section 5.3.5.1	Blood Pb lifetime (to age 11-13 yr) average mean: ~14 µg/dL Tooth Pb (age 6 yr) mean: 3.4 µg/g
	Associations also found in children age 4-5 yr in Yugoslavia in association with lifetime average blood Pb level; stronger association found for delinquent behavior. Results adjusted for similar covariates as above plus maternal history of smoking, residence type. Studies had population-based recruitment with moderate follow-up participation. Participation not conditional on tooth/blood Pb levels and behavior. Associations found with teacher and parent ratings on widely used, structured questionnaires.	Wasserman et al. (2001)	Blood Pb lifetime (to age 4-5 yr) average mean: 9.6 µg/dL
	Cross-sectional studies found associations with concurrent blood Pb level but had limited consideration for potential confounding and/or nonrepresentative populations (e.g., prenatal drug exposure).	Section 5.3.5.1	
Epidemiologic evidence supported by toxicological evidence with relevant exposures	Postnatal dietary Pb exposure increased emotionality, loss of motivation in response to reward omission in juvenile female rats Postnatal dietary Pb exposure increased sickness behavior due to bacteria infection in juvenile mice. No specific mode of action examined with Pb exposure	Stangle et al. (2007), Beaudin et al. (2007) Dyatlov and Lawrence (2002) Section 5.3.5.2	Blood Pb at PND45 after PND1-PND30 exposure: 13, 31 µg/dL Blood Pb at PND22 after PND1-PND22 exposure: 17 µg/dL

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	References[b]	Pb Biomarker Levels Associated with Effects[c]
Conduct Problems in Children and Young Adults (e.g., criminal offenses, delinquent behavior, aggression, antisocial behavior) **– Likely Causal**			
Consistent results from high-quality epidemiologic studies with relevant blood or tooth Pb levels	Evidence from prospective studies for criminal offenses in young adults ages 19-24 yr in Cincinnati and New Zealand in association with earlier childhood blood or tooth Pb levels.	Wright et al. (2008), Fergusson et al. (2008), Section 5.3.4.1	Age 6 yr blood Pb mean 6.8 µg/dL Tooth Pb (age 6-8 yr) mean: 6.2 µg/g
	Evidence from prospective studies for higher parent and teacher ratings of aggression, antisocial behavior, delinquent behavior in children ages 8-17 yr in U.S., U.K., Australia in association with earlier childhood or lifetime average blood Pb and tooth Pb levels.	Dietrich et al. (2001), Burns et al. (1999), Chandramouli et al. (2009), Bellinger et al. (1994b), Section 5.3.4.1	Blood Pb: lifetime (to age 11-13 yr) avg mean: 14 µg/dL, age 30 month group with blood Pb >10 µg/dL Tooth Pb (age 6 yr) mean 3.4 µg/g
	Associations also found in children age 4-5 yr in Yugoslavia in association with lifetime average blood Pb level; stronger association found for delinquent behavior. Studies had moderate to high follow-up participation, not conditional on blood Pb level. Most studies considered potential confounding by SES, parental education and IQ, other SES factors, parental caregiving/functioning, smoking, substance abuse.	Wasserman et al. (2001),	Mean lifetime (to age 4-5 yr) average: 9.6 µg/dL
	Supporting evidence for parental report of conduct disorder in association with concurrent blood Pb in cross-sectional study of children ages 8-15 yr participating in NHNANES. Examination of multiple exposures and outcomes reduces likelihood of selection bias.	Braun et al. (2008) Section 5.3.4.1	Groups with concurrent blood Pb >0.8 µg/dL.
	Consistency supported by meta-analysis indicating similar effect estimates by study design, potential confounding factors considered Teacher and parental ratings derived from widely-used, structured questionnaires.	Marcus et al. (2010) Section 5.3.4.1	Blood Pb range of study means (concurrent or lifetime avg): 1.0-26 µg/dL
Inconsistent evidence in animals for aggression at relevant exposures	Aggression observed in adult hamsters with gestational-lifetime dietary Pb exposure. Other evidence in adult animals with similar duration exposure inconsistent. Aggression generally not found in juvenile animals with lactational Pb exposure. No specific mode of action examined with Pb exposure	Delville (1999) Section 5.3.4.2	Blood Pb after gestational-lifetime exposure: 10-15 µg/dL

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	References[b]	Pb Biomarker Levels Associated with Effects[c]
Sensory Function Decrements in Children – Likely Causal			
Consistent findings from high-quality epidemiologic studies with relevant blood Pb levels	Prospective study indicated associations of prenatal (maternal), neonatal, yearly age 1 to 5 yr, lifetime avg blood Pb levels with poorer auditory processing in children at age 5 yr in Cincinnati. Information was not provided on participation rates. Results were adjusted for SES, HOME, birth weight, gestational age, obstetrical complication, maternal smoking. Several other factors considered.	Dietrich et al. (1992) Section 5.3.7.1	Blood Pb means: neonatal (10 day) 4.8 µg/dL, yearly age 1 to 5 year 10.6-17.2 µg/dL, lifetime (to age 5 yr) avg NR
	Supporting evidence from cross-sectional studies for increased hearing thresholds in children ages 4-19 yr participating in NHANES and HHANES in association with higher concurrent blood Pb levels. Examination of multiple exposures and outcomes in NHANES and HHANES reduces likelihood of selection bias. Studies considered potential confounding by age, sex, race, income, parental education, nutritional factors.	Schwartz and Otto (1991, 1987) Section 5.3.7.1	Concurrent blood Pb median in HHANES: 8 µg/dL, NHANES: NR
Limited toxicological results at relevant exposures	Increased hearing thresholds in monkeys age 13 years with lifetime dietary Pb exposure.	Rice (1997), Section 5.3.7.3	Blood Pb after lifetime (from birth) exposure: 33-170 µg/dL
	Supernormal or subnormal retinal ERGs in rats depending on timing and dose of Pb exposure. Uncertain biological relevance.	Fox et al. (1997), Section 5.3.7.3	Blood Pb: 12, 24 µg/dL with gestational-lactational exposure, 19 µg/dL with lactational exposure
Evidence describes mode of action	Decreased auditory evoked potentials with lifetime Pb exposure of monkeys ages 13 years. Rod cell proliferation, retinal cell apoptosis, dopamine changes	Section 5.3.7.3	

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	References[b]	Pb Biomarker Levels Associated with Effects[c]
Motor Function Decrements in Children – Likely Causal			
Consistent findings from high-quality epidemiologic studies with relevant blood Pb levels	Evidence from prospective studies for fine and gross motor function decrements in children ages 4.5-17 yr in Cincinnati, Yugoslavia in association with neonatal, earlier childhood, concurrent, lifetime avg blood Pb levels. High follow-up participation, no selective attrition in Cincinnati cohort, higher loss-to-follow-up in Yugoslavia cohort with lower maternal IQ, HOME. Both studies adjusted for maternal IQ, parental education, SES, HOME score	Ris et al. (2004), Dietrich et al. (1993a), Bhattacharya et al. (2006), Wasserman et al. (2000) Section 5.3.8	Cincinnati: blood Pb means: neonatal 4.8 µg/dL, age 6 yr 11.6 µg/dL, lifetime (to age 15-17 yr) avg 12.3 µg/dL Yugoslavia: NR
	Supporting evidence from cross-sectional studies in children ages 3-7 yr in India, Canada. In Inuit Canadian children, potential confounding factors varied by outcome but included HOME, maternal education, weight, prenatal alcohol exposure, Hg, polychlorinated biphenyls.	Despres et al. (2005), Palaniappan et al. (2011) Section 5.3.8	Concurrent blood Pb means: 4.1 µg/dL Canada, 11.5 µg/dL India
	No decrease in motor function found in children ages 6-10 yr in New England with lower concurrent blood Pb levels with adjustment for age, race, sex, caregiver education, SES. Studies used various, widely-used tests to assess outcomes.	Surkan et al. (2007)	Concurrent blood Pb mean: 2.2 µg/dL
Limited toxicological evidence at relevant exposures	Poorer balance (fell off rotarod more quickly) in adult mice with gestational-lactation dietary Pb exposure	Leasure et al. (2008) Section 5.3.8	Peak blood Pb after gestational -lactational exposure ~10 µg/dL
	Inconsistent results with higher postnatal exposures	Section 5.3.8	Blood Pb after 3-7 week postnatal Pb exposure >60 µg/dL

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	References[b]	Pb Biomarker Levels Associated with Effects[c]
Cognitive Function Decrements in Adults – Likely Causal			
Consistent results from high-quality epidemiologic studies with relevant bone Pb levels	Prospective analyses in NAS cohort of white men and BMS cohort of men and women of diverse ethnicities found cognitive function decrements over 2 to 4 years in association with bone Pb levels. Baseline participation rates differed but high follow-up participation, not conditional on bone Pb levels. Different potential confounding factors considered. Adjustment for age and education in both cohorts, SES in BMS, smoking and alcohol use in NAS.	Weisskopf et al. (2007b), Bandeen-Roche et al. (2009) Table 5-10 and Section 5.3.2.7	Baseline tibia Pb means: 18.8, 20 µg/g, patella mean 25 µg/g
	Supporting cross-sectional evidence from NAS, BMS, and also women in Nurses' Health Study with adjustment for additional potential confounding factors, including dietary factors, medications, physical activity, comorbid conditions.	Nurses Healthy Study: Weuve et al. (2009) Section 5.3.2.7 Table 5-10	Concurrent tibia Pb Mean: 10.5 µg/g
	Associations with blood Pb level found in men and women participating in NHANES in certain genetic variant groups with adjustment for age, sex, education, income, race/ethnicity, alcohol use, computer/video game familiarity.	Krieg et al. (2009), Krieg et al. (2010), Krieg and Butler (2009) Section 5.3.2.7	Concurrent blood Pb means: 3-4 µg/dL
	Several studies found associations with blood Pb levels and bone Pb levels in former and current Pb-exposed workers. Most studies adjusted for age and education. Some also adjusted for depression and/or alcohol use, but none considered other occupational exposures. Outcomes assessed using various but widely used, structured instruments. Uncertainty regarding potential residual confounding of bone Pb results by age.	Khalil et al. (2009a), Dorsey et al. (2006), Bleecker et al. (2007a), Stewart et al. (2002) Section 5.3.2.7	Concurrent blood Pb: 12 (former workers)-31 µg/dL. Peak tibia Pb: mean 26.2 µg/g, median 57 µg/g.
Epidemiologic evidence supported by consistent toxicological results with relevant exposures	Impaired learning, memory, and executive function in adult monkeys with lifetime dietary Pb exposures after weaning. Impaired learning in animals with lifetime dietary Pb exposures starting in gestation.	Rice (1992b), Rice and Gilbert (1990a), Rice (1990) Section 5.3.2.3 See above for cognitive function in children.	Blood Pb after post-weaning exposure to age 7-10 yr means 19, 26 µg/dL
Evidence clearly describes mode of action	Same as above for cognitive function in children		

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	References[b]	Pb Biomarker Levels Associated with Effects[c]
Psychopathological Effects in Adults (e.g., self ratings of depression, anxiety, panic disorder) **– Likely Causal**			
Consistent findings from high-quality epidemiologic studies with relevant blood and bone Pb levels	A few cross-sectional studies indicate associations of higher concurrent blood or tibia Pb level with increased reporting of depression, anxiety, panic disorder in adults without occupational Pb exposures. Studies examine multiple exposures and outcomes.	Bouchard et al. (2009), Rhodes et al. (2003), Rajan et al. (2008) Section 5.3.6.1	
	Association with blood Pb level among 1,987 adults participating in NHANES; adjustment for age, sex, race, education, poverty to income ratio.	Bouchard et al. (2009) Section 5.3.6.1	Group with concurrent blood Pb >2.11 µg/dL
	Associations with blood and bone Pb level among NAS men (mostly white) with high follow-up participation and adjustment for education, age, employment, pack-years smoking, alcohol use.	Rhodes et al. (2003), Rajan et al. (2007) Section 5.3.6.1	Concurrent blood Pb mean: 6.3 µg/dL, concurrent tibia Pb mean: 21.9 µg/g
	Higher ratings of disorders also in Pb-exposed workers with higher blood Pb levels. Studies used widely used, structured instruments to assess outcomes but not diagnosed conditions.	Section 5.3.6.1	Concurrent or peak blood Pb: means 31-79 µg/dL
Supporting toxicological evidence at relevant Pb exposures	Same as above for internalizing behaviors in children		
Sensory Function Decrements in Adults – Suggestive			
Limited but high-quality epidemiologic evidence with relevant bone or blood Pb levels	Prospective study indicates associations between tibia Pb level and faster rate of increase in hearing threshold over 23 yr, among NAS male adults. Population comprises only males, primarily white, but study examines multiple exposures and outcomes and has high follow-up participation. Results adjusted for age, race, education, BMI, pack-years smoking, diabetes, hypertension, occupational noise.	Park et al. (2010) Section 5.3.7.2	Tibia Pb mean: 22.5 µg/g, measured near end of follow-up
	Supporting evidence from case-control study finding higher blood Pb levels in workers from various occupations with hearing loss with adjustment for age, smoking, alcohol consumption, years of noise exposure, blood Mn, As, Se	Chuang et al. (2007) Section 5.3.7.2	Concurrent blood Pb mean in cases: 10.7 µg/dL
Supporting toxicological evidence with relevant exposures	Same as above for sensory function decrements in children, including mode of action		

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	References[b]	Pb Biomarker Levels Associated with Effects[c]
Neurodegenerative Diseases (e.g., Alzheimer's disease, ALS, Parkinson's disease, Essential tremor) **– Inadequate**			
The available evidence is not sufficiently informative	The few available case-control studies found higher blood or bone Pb levels and history of occupational exposure in cases with Parkinson's disease and essential tremor. For ALS, association also found with increased survival time.	Parkinson's disease: Gorell et al. (1997), Gulson et al. (1999), Tanner et al. (1989), Weisskopf et al. (2010), Coon et al. (2006) Section 5.3.10.3	Parkinson's disease: groups with tibia Pb levels >15 µg/g
	Studies subject to selection and recall bias and reverse causation (blood Pb) that could produce artifactual associations.	Essential tremor: Louis et al. (2005; 2003), Dogu et al. (2007) Section 5.3.10.4	Essential tremor: concurrent blood Pb means 3-4 µg/dL
	Some studies consider potential confounding by age, smoking, education, BMI, and activity levels, occupational studies did not consider Mn co-exposures.	ALS: Kamel et al. (2002), Kamel et al. (2005), Vinceti et al. (1997), Fang et al. (2010) Section 5.3.10.2	ALS: groups with blood Pb >3 µg/dL, groups with tibia Pb >8 µg/g
	Case-control studies did not show associations between occupational history of Pb exposure or brain Pb levels and Alzheimer's disease.	Graves et al. (1991), Hariguchi et al. (2001), Section 5.3.10.1	
Some evidence describes mode of action	Amyloid plaques found in brains of adult monkeys and rodents with infancy-only lactational Pb exposures.	Section 5.3.10.1	
	In monkeys (ages 20-23 yr), no effect with adult-only Pb exposure	Wu et al. (2008a)	Blood Pb with lactational exposure: 19-26 µg/dL
	In rodents, adult blood Pb levels at testing had returned to baseline.	Basha et al. (2005)	Blood Pb with lactational exposure: 46 µg/dL
	Increases in neuronal cell apoptosis found in vitro with Pb exposure	Section 5.3.10.5	

[a]Described in detail in Table II of the Preamble.

[b]Describes the key evidence and references contributing most heavily to causal determination. References to earlier sections indicate where full body of evidence is described.

[c]Describes the blood Pb levels in children with which the evidence is substantiated and blood Pb levels in animals most relevant to humans.

5.4 Cardiovascular Effects

5.4.1 Introduction

The 2006 Pb AQCD (U.S. EPA, 2006b) concluded that both epidemiologic and animal toxicological studies support the relationship between increased Pb exposure and increased cardiovascular effects, in particular, increased blood pressure (BP) and increased incidence of arterial hypertension. Although fewer in number, epidemiologic studies demonstrated associations of blood and bone Pb levels with other cardiovascular diseases (CVDs) in adults, such as ischemic heart disease, cerebrovascular disease, peripheral vascular disease, and CVD-related mortality. As the cardiovascular and renal systems are intimately linked, cardiovascular effects can arise secondarily to Pb-induced renal injury (Section 5.5). Toxicological studies also provided compelling evidence supporting the biological plausibility for Pb-associated cardiovascular effects by characterizing a number of the underlying mechanisms by which Pb exposure can lead to human cardiovascular health effects. Such studies demonstrated that the Pb content in heart tissue of animals reflects the increases in blood Pb levels (Lal et al., 1991), indicating that the cardiovascular morbidity associated with blood Pb levels may represent the effects of the bioavailable Pb in the target tissue. The strongest evidence supported the role of oxidative stress in the pathogenesis of Pb-induced hypertension. Additionally, several toxicological studies characterized other pathways or cellular, molecular, and tissue events promoting the Pb-induced increase in BP. These mechanisms included inflammation, adrenergic and sympathetic activation, renin-angiotensin-aldosterone system (RAAS) activation, vasomodulator imbalance, and vascular cell dysfunction.

With regard to the concentration-response relationship, a meta-analysis of human studies found that each doubling of blood Pb level (between 1 and >40 μg/dL measured concurrently in most studies) was associated with a 1 mmHg increase in systolic BP and a 0.6 mmHg increase in diastolic BP (Nawrot et al., 2002). On a population-wide basis, the estimated effect size could translate into a clinically significant increase in the segment of the population with the highest BP. In a moderately-sized population, a relatively small effect size thus has important health consequences for the risk of sequelae of increased BP, such as stroke, myocardial infarction, and sudden death. It was also noted that most of the reviewed studies examining bone Pb levels, biomarkers of cumulative Pb exposure, also showed increased BP (Cheng et al., 2001; Hu et al., 1996a) or increased hypertension with increasing bone Pb level (Lee et al., 2001a). Across studies, over a range of bone Pb concentrations (<1.0 to 96 μg/g), every 10 μg/g increase in bone Pb was associated with increased odds ratios of hypertension between 1.28 and

1.86. Studies observed an average increase in systolic BP of ~0.75 mmHg for every 10 µg/g increase in bone Pb concentration over a range of <1 to 52 µg/g.

With regard to etiologically-relevant timing of Pb exposure, toxicological evidence demonstrated increases in BP after long-term (>4 weeks) Pb exposure. In epidemiologic studies, cardiovascular outcomes were most often examined in cross-sectional studies with one or a limited number of Pb biomarker measurements, so uncertainty exists as to the specific Pb exposure level, timing, frequency, and duration that contributed to the observed associations. While associations of adult bone Pb (particularly tibia Pb) with health outcomes in adults are indicative of effects related to past or cumulative exposures, interpretation of similar associations involving adult blood Pb levels, especially those measured concurrently with outcomes, is complicated by the higher past exposures generally observed in U.S. adults populations. Detailed interpretation of Pb in blood and bone are provided in Sections 4.3 and 4.7.3. Briefly, higher past Pb exposures in adults increased their bone Pb stores which contribute to current blood Pb levels through the normal process of bone remodeling, as well as periods of increased bone remodeling and loss (e.g., osteoporosis and pregnancy). Due to the long latency period for the development of increased BP and CVD, associations of cardiovascular effects with low concurrent blood Pb levels (e.g., population means 1.6-4 µg/dL) in adults may be influenced by higher past Pb exposures (Section 4.4.1).

Past air Pb concentration and blood Pb data provide context for the cardiovascular studies. Section 3.2 notes that the peak U.S. use of Pb anti-knock additives in automobile gasoline occurred between 1968 and 1972 and was finally banned from use in 1996. Section 3.5 shows that air Pb measured at trends monitors across the U.S. decreased from 1.3 µg/m^3 in 1980 to 0.14 µg/m^3 in 2010. Many of the monitors reporting to the trends network were more recently influenced only by Pb sources; the mean 2010 3-month rolling average for non-source monitors was an order of magnitude lower than the 2010 trends site average. Collective review of blood Pb studies from the late 1960s and 1970s, including NHANES II (1976-1980) suggest that blood Pb levels ranged from roughly 10 to 30 µg/dL (Pirkle et al., 1994; Billick et al., 1979; Tepper and Levin, 1975; Fine et al., 1972).

This section reviews the published studies pertaining to the cardiovascular effects of Pb exposure in humans, experimental animals, isolated vascular tissues, and cultured vascular cells. With the large and strong existing body of evidence serving as the foundation, emphasis was placed on studies published since the 2006 Pb AQCD. Epidemiologic and toxicological studies continued to augment the evidence for increases in BP and hypertension development associated with long-term Pb exposure and expanded the evidence for the biological pathways of these effects. Epidemiologic studies strengthened the evidence for associations between Pb biomarkers and cardiovascular effects after adjusting for potential confounding factors such as age, SES, diet, alcohol use, BMI, comorbidities, and smoking. Emphasis was placed on studies that had extensive consideration for confounding and prospective study designs. The epidemiologic evidence was substantiated with results from several available prospective studies demonstrating the directionality of effects by indicating associations between Pb biomarkers and the subsequent incidence of cardiovascular health effects.

5.4.2 Blood Pressure and Hypertension

5.4.2.1 Epidemiology

The most commonly used indicator of cardiovascular morbidity was increased BP and its derived index, hypertension. Hypertension in these studies was defined as diastolic and/or systolic BP above certain cut-points or use of anti-hypertensive medicines. The BP cut-points were established by reference to informed medical opinion, but BP cut-points defining hypertension have been lowered over time, as medical knowledge has improved. Consequently, different studies using "hypertension" as a cardiovascular outcome may have assigned different cut-points, depending on the year and location of the study and the individual investigator. All of the recent studies in the current review used the same criteria for hypertension (e.g., systolic BP at or above 140, diastolic BP at or above 90, or use of anti-hypertensive medications). Studies in the medical literature show that elevated BP is associated with increased risk of CVD including coronary disease, stroke, peripheral artery disease, and cardiac failure. Coronary disease (i.e., myocardial infarction, angina pectoris, and sudden death) is the most lethal sequelae of hypertension (Ingelsson et al., 2008; Chobanian et al., 2003; Pastor-Barriuso et al., 2003; Prospective Studies Collaboration, 2002; Kannel, 2000a, b; Neaton et al., 1995).

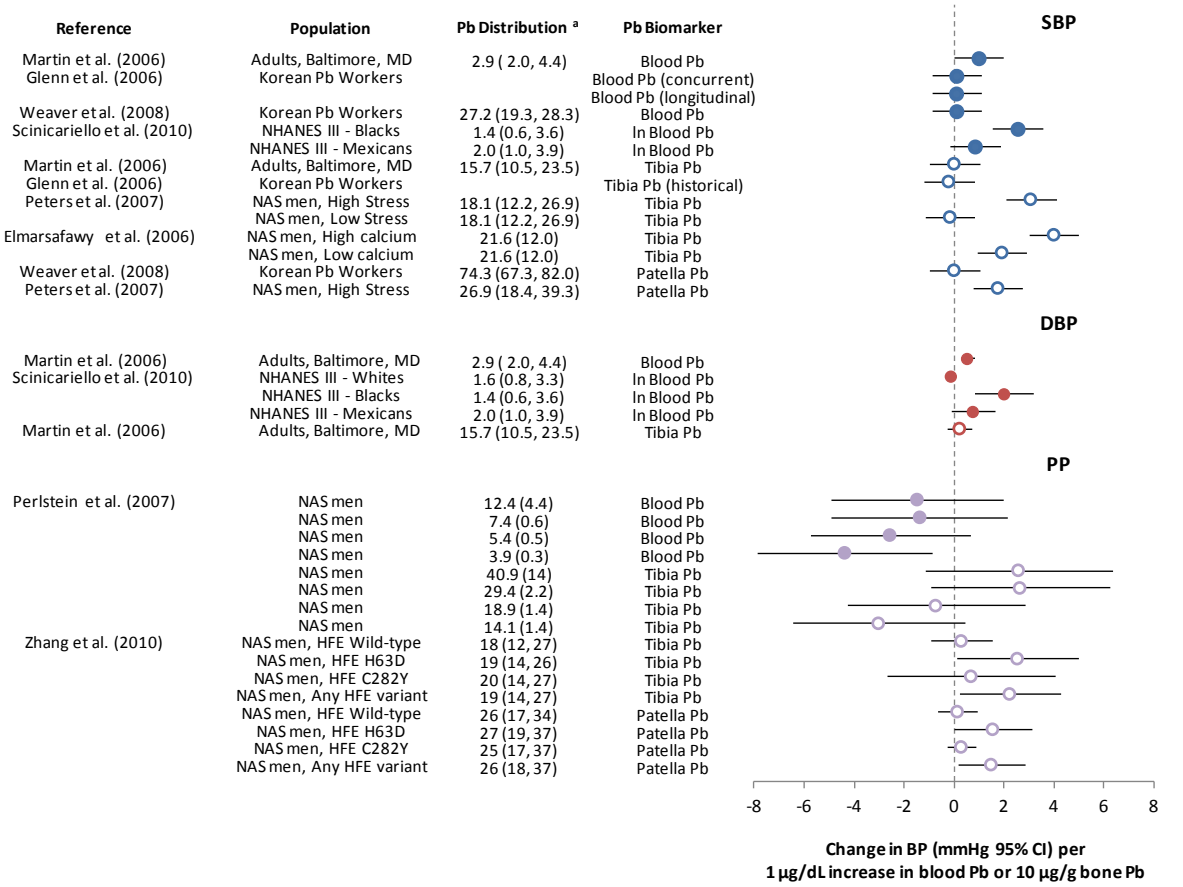
Earlier, U.S. EPA (1990a) reviewed the then available studies examining Pb exposure and BP and hypertension outcomes which included evaluation of several studies conducting analysis of the data in NHANES II (1976-80). They noted that across a range

of 7 to 34 µg/dL, no evident threshold was found below which blood Pb was not significantly related to blood pressure. U.S. EPA (1990a) concluded that a small but positive association exists between blood Pb levels and increases in blood pressure. Quantitatively, the relationship appears to hold across a wide range of blood Pb values and, furthermore, an estimated mean increase of about 1.5-3.0 mmHg in systolic blood pressure appears to occur for every doubling of blood Pb concentration in adult males and something less than 1.0-2.0 mmHg for adult females. U.S. EPA (1990a) further concluded that the plausibility of these relationships observed in epidemiologic studies of human populations being of a causal nature is supported by controlled experimental animal studies demonstrating increased blood pressure clearly attributable to Pb. Subsequently, the 2006 Pb AQCD (U.S. EPA, 2006b) reviewed the literature examining Pb exposure and effects of BP and hypertension, published after the 1990 document as discussed in Section 5.4.1.

Several recent general population and occupational cohort and cross-sectional studies strengthened the evidence for associations of blood and bone Pb levels with measures of BP (Figure 5-18 and Table 5-18) and with the prevalence and incidence of hypertension (Figure 5-19 and Table 5-19). Further, recent studies expanded evidence, finding differences in association among racial/ethnic groups, perceived stress, diet, and genetic variants, and thus, identified populations potentially at increased risk of Pb-associated cardiovascular effects.

In a cross-sectional analysis, Martin et al. (2006) examined the associations of concurrent blood and tibia Pb levels with BP and hypertension in a large, community-based study of older adults (n = 964, age ranging from 50 to 70 years) in Baltimore, MD. Although cross-sectional in design, a key strength of this study was the extensive consideration of potential confounding variables. Four models evaluated associations for BP and hypertension. The base model included age, sex, BMI, sodium intake, potassium intake, total cholesterol, time of day, testing technician, and hypertensive medication use. Other models added SES, race/ethnicity, or both as covariates. Blood Pb but not tibia Pb level was a strong predictor of BP in all models; a 1 µg/dL increase in concurrent blood Pb level was associated with an approximately 1 mmHg increase in systolic BP and an approximately 0.5 mmHg increase in diastolic BP. Tibia Pb but not blood Pb was associated with hypertension in logistic regression models. The authors applied propensity analysis to their models to better account for the effect of other risk factors for hypertension such as race/ethnicity, age, and SES that were strongly associated with tibia Pb level. The propensity score analysis and model adjustment did not substantially change the numerical findings and conclusions (e.g., tibia Pb and hypertension were positively associated independently of race/ethnicity and SES), indicating that neither SES nor race/ethnicity confounded the association between tibia Pb level and

hypertension. No evidence for effect modification by race/ethnicity was found either. Martin et al. (2006) concluded that Pb in blood has a short term effect on BP and that Pb contributes to hypertension risk as a function of cumulative, chronic exposure (as represented as bone Pb in this population). While different aspects of Pb exposure may contribute differentially to increases in BP and hypertension, it is important to note that concurrent blood Pb levels in adults also reflect cumulative Pb exposure. Thus, its association with BP may not reflect a short term effect but may also reflect an effect of cumulative Pb exposure.



[a]Pb distributions present the median (IQR), which were estimated from the mean and SD assuming a normal distribution.

[b]Effect estimates were standardized to 1 µg/dL blood Pb or 10 µg/g bone Pb.

Note: In general, results are categorized by specific BP parameter, then by Pb biomarker. For categories with multiple studies, the order of the studies follows the order of discussion in the text. Results display associations (95% CI) of a 1 µg/dL increase in blood Pb level (closed circles) or 10 µg/g increase in bone Pb (open circles) with systolic BP (SBP; blue), diastolic BP (DBP; red), and pulse pressure (PP; purple) in adults.

Figure 5-18 Associations of blood and bone Pb levels with systolic BP, diastolic BP, and pulse pressure in adults.

Table 5-18 Additional characteristics and quantitative data for associations of blood and bone Pb with BP measures for studies presented in Figure 5-18.

Study	Study Population / Methodology	Parameter	Pb Data	Statistical Analysis	Effect Estimate β (95% CI)

[a]Not included in Figure 5-19 because OR data were not reported.

In an occupational cohort in South Korea, Glenn et al. (2006) simultaneously modeled multiple Pb dose measures of individuals collected repeatedly over four years of follow up. Thus, through the assessment of cross-sectional and longitudinal relationships with BP, this study provided key insight on potentially important time periods of Pb exposure and also informed the directionality of association. The initial blood Pb level was used as a baseline covariate and the difference in blood Pb level between visits was computed for each subsequent visit. The bone Pb measures (tibia Pb at visits 1 and 2, patella Pb at visit 3) were used to indicate historical exposure and cumulative dose. Four models were specified: Model 1 was conceptualized to reflect short-term changes in BP associated with recent dose; Model 2 to reflect longer-term changes associated with cumulative dose controlling for the association of baseline BP with recent dose; Model 3 to reflect longer-term changes associated with cumulative dose controlling for cross-sectional influence of cumulative dose on baseline BP; and Model 4 to reflect both short-term change with recent dose and longer-term change with cumulative dose. Concurrent blood Pb and increases in blood Pb between visits were associated with increases in systolic BP in Model 1 (short-term dose) and Model 4 (short- and longer-term dose). No association was observed between BP and tibia Pb at baseline while higher tibia Pb was associated with a decrease in systolic BP in each of the models.

Glenn et al. (2006) was strengthened by the analysis of associations between changes in blood Pb and changes in BP over time within individual subjects. These results indicate that circulating Pb (e.g., blood Pb) may act continuously on systolic BP and reduction in blood Pb may contribute to reductions in BP, while cumulative Pb exposure (represented

by bone Pb in this study) may contribute to hypertension incidence by different mechanisms over longer time periods and in older subjects. This analysis in relatively young subjects (mean [SD] age at baseline 41.4 [9.5] years) with a low prevalence of hypertension suggests that at least one of the biological pathways that influences how systolic BP responds to Pb operates over a relatively rapid timeframe. This may reflect an immediate response to Pb at a biochemical site of action as a consequence of the biologically available Pb circulating in blood. A persistent effect of cumulative doses over a lifetime may occur via other mechanisms. Bone Pb level may exert influence on blood Pb levels and consequently on BP in an aging population with prolonged Pb exposure. Thus, the findings contribute important information regarding the various short and long-term exposure relationships with increases in BP and hypertension. It is important to acknowledge the uncertainty regarding the applicability of these findings regarding short-term and long-term effects in Pb workers with relatively high current Pb exposures contributing to blood Pb levels (mean blood Pb levels over time: 20-37 µg/dL) to adults in the U.S. general population whose concurrent blood Pb levels are influenced more by Pb mobilized from bone stores. Further, for bone Pb analysis, the potential for bone Pb BP and hypertension findings in older populations to be impacted by residual confounding by age may be a factor to consider since exposure studies of older cohorts (NAS/ mean age >60 years; (Wilker et al., 2011; Kim et al., 1997)) indicate that bone Pb is correlated with age.

In a separate cross-sectional analysis of the same occupationally exposed group in year three of follow-up, Weaver et al. (2008) examined associations of concurrent patella Pb and blood Pb level with systolic BP, diastolic BP, and hypertension and effect modification by ALAD and vitamin D receptor (VDR) polymorphisms. None of the Pb biomarkers were associated with diastolic BP. Patella Pb alone was not significantly associated with systolic BP. However, blood Pb, either alone or with patella Pb, was significantly associated with higher systolic BP. The patella Pb-age and blood Pb-age interactions were not statistically significant. There were no significant associations of blood Pb or patella Pb with hypertension status or effect modification by age or sex. Further, interactions between polymorphisms of the VDR and of ALAD with blood Pb and patella Pb on systolic BP were not statistically significant. Mean blood Pb level was high (30.9 µg/dL) compared to non-occupational groups.

Weaver et al. (2010) provided the results of further analysis of this Korean worker cohort, with a focus on determining the functional form of the concentration-response relationships. In a log linear model, the coefficient indicated that every doubling of blood Pb level was associated with a systolic BP increase of 1.76 mmHg. The J test, a statistical test for determining which, if either, of two functional forms of the same variable provides a superior fit to data in non-nested models (Davidson and MacKinnon, 1981),

returned a p-value of 0.013 in favor of the natural log blood Pb level over the linear blood Pb level specification. This analysis indicates that the systolic BP increase in this cohort is better described as a logarithmic function of blood Pb level within the range of the study than by a linear function.

Several analyses in the NAS cohort of predominantly white older men in the greater Boston area found associations of blood and bone Pb level with BP and hypertension, and they indicated effect modification by calcium intake, perceived stress, and HFE gene variants. In a cross-sectional analysis, Perlstein et al. (2007) found a statistically significant association between blood Pb and diastolic BP in adjusted models. The subjects in this study had at least one bone Pb measurement during the years 1991-1997 and were not on antihypertensive medication at the time of the measurement. While tibia Pb was not significantly associated with BP, it was associated with pulse pressure (PP). Men with tibia Pb above the median (19 µg/g) had a higher mean PP (4.2 mmHg [95% CI: 1.9, 6.5]) compared to men with tibia Pb below the median. The trend toward increasing PP with increasing quintile of tibia Pb was statistically significant although none of the confidence intervals for PP referenced to the lowest quintile of tibia Pb (<7.4 µg/g) excluded the null value.

Peters et al. (2007) examined cross-sectionally the modification of the associations of tibia and patella Pb with BP and hypertension by self-reported stress (assessed by questionnaire) in NAS men. High stress also has been linked with higher BP, potentially via activation of sympathetic pathways, ROS, and the HPA axis. Among all subjects, higher bone Pb level was associated (statistically nonsignificant) with greater odds of hypertension status and higher systolic BP. As indicated in Figure 5-20, the association between systolic BP and tibia Pb differed between those with high and low self-reported stress (β for tibia Pb x stress interaction = 3.77 [95% CI: 0.46, 7.09]) per SD increase in tibia Pb. Stress also was found to modify the patella Pb-BP association (β for patella Pb x stress interaction = 2.60 [95% CI: -0.95, 6.15] per SD increase in patella Pb). Neither bone, self-reported stress, nor their interaction was associated significantly with diastolic BP. Peters et al. (2007) also used Cox proportional hazards models to assess the interaction of stress and bone Pb level in the development of hypertension among those free of hypertension at baseline. The results of this analysis showed that increasing tibia and patella Pb were associated with greater risk of developing hypertension among those with high stress compared to those with lower perceived stress (RR of developing hypertension among those with high stress: 2.66 [95% CI: 1.43, 4.95] per SD increase in tibia Pb and 2.64 [95% CI: 1.42, 4.92] per SD increase in patella Pb). These results provide evidence supporting adults with higher stress as a population at increased risk of Pb-associated cardiovascular effects. Earlier, Cheng et al. (2001) examined the NAS cohort in 474 subjects without hypertension (mean [SD] blood Pb level: 5.87 [4.01]) at

baseline measurement and analyzed linear models with patella Pb and reported that only patella Pb level was associated with a significant increase in the rate ratio for hypertension using a Cox's proportional hazards model.

Figure 5-20 The relationship between tibia Pb and estimated systolic BP (SBP) for those with high self-reported stress versus those with low self-reported stress.

Elmarsafawy et al. (2006) examined the modification of the relationship between Pb and hypertension by dietary calcium, with 467 subjects from the NAS. Responses on a semi-quantitative dietary frequency questionnaire with one-year recall were used to estimate calcium intake. Effect modification by calcium intake (dichotomized at 800 mg/day) was examined using interaction terms in logistic regression models and by conducting analyses stratified on the calcium variable. Increasing bone and blood Pb increased the odds of hypertension, particularly among subjects with low dietary calcium.

Zhang et al. (2010a) examined the effect of polymorphisms of the hemochromatosis gene (HFE) on the relationship of bone Pb with PP in NAS men. HFE polymorphisms promote Fe absorption and have been shown to modify the impact of adult cardiac function. Subjects had up to three PP measurements during the 10 year study period. The overall results demonstrated a strong relationship between bone Pb and PP in this study, similar to an earlier cross-sectional PP study of many of the same subjects (Perlstein et al., 2007). Zhang et al. (2010a) extended these findings by demonstrating larger increases in PP per

unit increase in tibia and patella Pb level among those with the H63D variant compared to those with the wild-type or the C282Y variant.

A small number of cross-sectional studies examined and found that blood Pb level was associated with hypertension in pregnancy. Yazbeck et al. (2009) examined a community-based group of pregnant women in France and unlike most other studies, adjusted for potential confounding by blood concentrations of Cd, Mn, and Se. Pregnancy induced hypertension (PIH) was defined as systolic BP >140 mmHg and/or diastolic BP >90 mmHg during at least two clinic visits after week 22 of gestation. Patients with pre-existing chronic hypertension were excluded. The mean (SD) blood Pb levels measured during pregnancy were 2.2 (1.4 µg/dL) in PIH cases and 1.9 (1.2) µg/dL in normotensive women. An association between blood Pb and PIH was observed (OR 3.29 [95% CI: 1.11, 9.74] per unit increase in log-transformed blood Pb level). Cd and Se concentrations were comparable between PIH and no PIH groups. Adjustment for the metals slightly attenuated but did not eliminate the association between blood Pb levels and the risk of PIH. Investigators observed no significant interactions among blood Pb level, any of the other elements, and maternal characteristics in predicting the risk of PIH. Interaction between blood Se and Pb concentrations was not significant, and the putative protection effects of Se through antioxidative properties were not found in this study.

Wells et al. (2011b) measured the relationship of cord blood Pb with BP in 285 women at admission to the Johns Hopkins Hospital in Baltimore, MD, during labor and delivery. Women with cord blood Pb levels in the highest quartile for the study group (>0.96 µg/dL) had significantly higher systolic and diastolic BP (upon admission and for maximum BP) compared to women in the first quartile (<0.46 µg/dL). The level of uncertainty at these levels of exposure is difficult to estimate. The authors used Benchmark Dose Software V2.1, developed by the EPA, to estimate the blood Pb level (benchmark dose or BMD) and the associated lower confidence limit (BMDL) that was associated with one standard deviation (SD) increase in BP. In this study group, one SD is approximately equivalent to a 10% increase above the mean for the first quartile blood Pb reference group. The BMD approach was used only as a means of quantifying the relationship of blood Pb with BP in this population. This analysis indicated that the 95% lower bound confidence limit on the maternal blood Pb level (estimated from cord blood Pb levels) that was associated with a 1 SD increase in all blood pressure outcomes was about 1.4 µg/dL. These reported results are similar to those reported in the 2006 Pb AQCD as well as those found 25 years ago but with blood Pb levels an order of magnitude lower in the more recent study. However, uncertainty exists as to the specific Pb exposure level, timing, frequency, and duration that contributed to the observed associations.

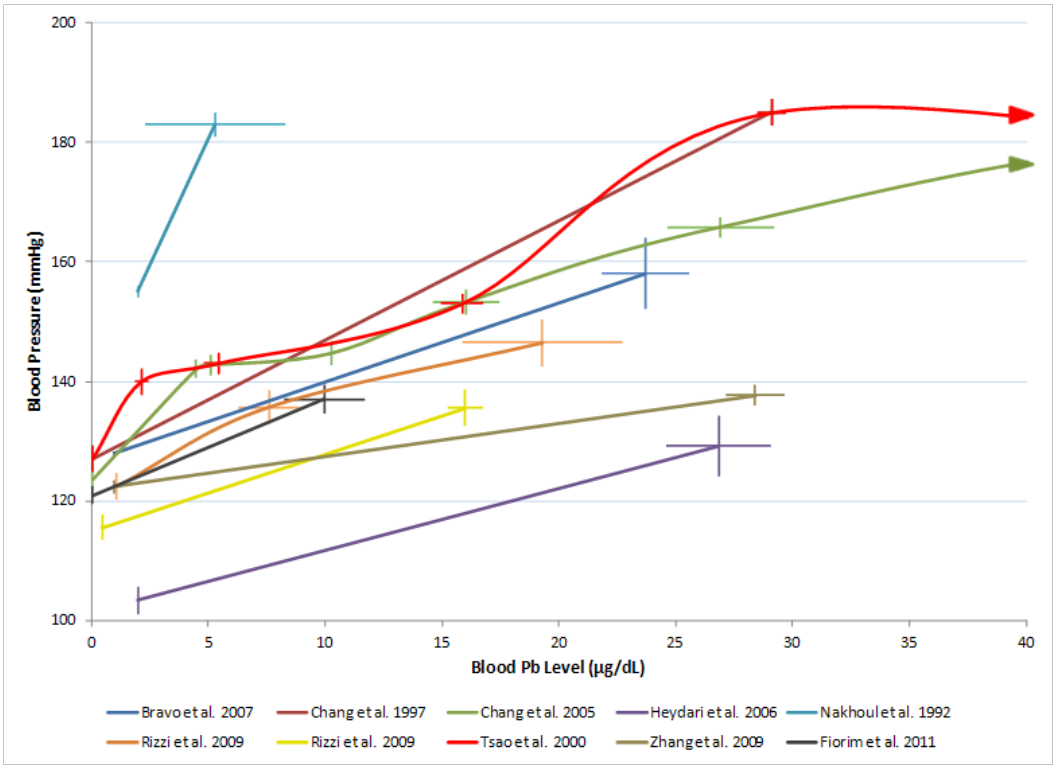
Recent analyses using NHANES data continued to indicate associations of Pb biomarkers with BP and hypertension. Muntner et al. (2005) previously used the NHANES 1999-2002 data to indicate that concurrent blood Pb levels were associated with hypertension, peripheral artery disease (PAD), and chronic kidney disease. The PAD results are discussed later in Section 5.4.3.5, and chronic kidney disease results are discussed in Section 5.5.2. Blood Pb increased regularly with age (geometric means [95% CIs]: 1.28 µg/dL [1.23, 1.33] in the 18-39 age group to 2.32 µg/dL [2.20, 2.44] in the 75 and older age group). Associations were observed between concurrent blood Pb level and hypertension across race/ethnicity groups with significant trends observed for non-Hispanic blacks and Mexican Americans.

In the NHANES III 1988-1994 population, Scinicariello et al. (2010) found a gene-environment interaction between blood Pb level and ALAD genotype (the genotypes have different affinities for Pb) in relation to systolic BP and diastolic BP in a cross-sectional analysis. These interactions varied across race/ethnicity strata. The strongest associations were observed among non-Hispanic blacks (Figure 5-18, Table 5-18). A statistically significant interaction was observed between concurrent blood Pb level and ALAD1-2/2-2b among non-Hispanic whites and non-Hispanic blacks. Scinicariello et al. (2010) also found an interaction between ALAD genotype and blood Pb level in the association with hypertension. Statistically significant associations between concurrent blood Pb level and hypertension were observed among non-Hispanic blacks and nonsignificant increases were observed among non-Hispanic whites and Mexican Americans (with the exception of Mexican Americans in the second quartile of blood Pb level) (Figure 5-19, Table 5-19). In addition, non-Hispanic white ALAD2 carriers in the highest blood Pb level quartile 3.8-52.9 µg/dL) had a significantly higher association with hypertension compared with ALAD1 homozygous individuals in the highest quartile of blood Pb. In the same NHANES population, Park et al. (2009c) predicted bone Pb levels using a model developed with NAS data. Concurrent blood Pb was associated with hypertension overall in the NHANES population, with larger associations observed among black men and women as well as older adults (Figure 5-19, Table 5-19). Associations also were observed with estimated bone Pb.

5.4.2.2 Toxicology

Studies on the effect of Pb (as blood Pb level) on systolic BP in unanesthetized adult rats consistently reported an increase in BP with increasing blood Pb level as shown in Figure 5-21 (results summarized in Table 5-20). An array of studies has provided evidence that long-term Pb exposure (>4 weeks), resulting in blood Pb levels relevant to humans, i.e., below 10 µg/dL can result in the onset of hypertension (after a latency period) in

experimental animals that persists long after the cessation of Pb exposure (U.S. EPA, 2006b). Tsao et al. (2000) presented evidence for increased systolic and diastolic BP in rats with blood Pb levels similar to the current U.S. population (mean [SD]: 2.15 [0.92] µg/dL blood Pb; 140 [7] mmHg systolic BP, 98 [7] mmHg diastolic BP) compared to untreated controls (mean [SD]: 0.05 [0.05] µg/dL blood Pb; 127 [7] mmHg systolic BP, 88 [7] mmHg diastolic BP). As this was the lowest Pb level tested, no evidence of a threshold was evident. Further, a test for linear trend revealed a statistically significant, positive trend for increasing BP with increasing blood Pb levels up to 56 µg/dL (e.g., mean [SD]: 5.47 [2.1] µg/dL blood Pb; 143 [6] mmHg systolic BP, 97 [8] mmHg diastolic BP), with the effect leveling off at higher blood Pb levels.



Note: Crosses represent standard error for blood Pb and BP measurements. If no crossbar is present, error results were not reported. Arrows represent higher doses tested.

[c]Difference in systolic BP (SBP) between group means not within one exposure group.

Experimental animal studies continued to provide evidence that long-term Pb exposure results in sustained arterial hypertension after a latency period. Systolic BP increased in rats after exposure to 90-10,000 ppm Pb (as Pb acetate in drinking water) for various time periods that resulted in blood Pb levels between 19.3-240 µg/dL (Mohammad et al., 2010; Zhang et al., 2009a; Badavi et al., 2008; Grizzo and Cordellini, 2008; Reza et al., 2008; Bravo et al., 2007; Vargas-Robles et al., 2007; Heydari et al., 2006; Bagchi and Preuss, 2005). Past studies have shown statistically significant elevations in BP in rats with lower blood Pb levels. For example, long-term Pb exposure to spontaneously hypertensive rats (resulting in mean [SEM] blood Pb level: 5.3 [3] µg/dL) led to increased BP (Nakhoul et al., 1992). Consistent with measurements of systolic BP by tail-cuff plethysmography, Pb exposure (100 ppm for 14 weeks; mean blood Pb level: 24 µg/dL) also caused an increase in intra-aortic mean arterial pressure (Bravo et al., 2007). In a study that tested low levels of Pb exposure (30 ppm; mean blood Pb level: 7.6 µg/dL), a statistically significant increase in systolic BP was not observed despite

elevated blood Pb level after 8 weeks of treatment. Nonetheless, there was a trend of higher BP with higher blood Pb levels (Rizzi et al., 2009).

Studies found that Pb-induced increases in BP persisted long after cessation of Pb exposure. Bagchi and Preuss (2005) found that elevated systolic BP was maintained for 210 days after cessation of Pb exposure (10,000 ppm Pb acetate in water, 40 days, monitored for one year). However, chelation therapy using $Na_2CaEDTA$ returned systolic BP to levels comparable to those in rats not treated with Pb (Bagchi and Preuss, 2005). Chang et al. (2005) reported a partial reversibility of effect after cessation of Pb exposure, where Pb-induced elevated BP decreased but did not return to control levels 7 months post Pb exposure. After Pb exposure was removed, blood, heart, aorta, and kidney Pb levels decreased quickly within the first three months (Chang et al., 2005). Pb-induced elevated systolic BP persisted for one month following Pb exposure cessation, followed by obvious decreases in BP until 4 months after Pb exposure cessation. Between 4 and 7 months after Pb exposure cessation, the still-elevated BP did not decrease further, thus never returning to control BP levels. Decreases in BP were strongly correlated with decreases in blood Pb level after exposure cessation.

The aforementioned studies all assessed the relationship between long-term exposure (>4 weeks) of rats to Pb and measures of BP. However, recent research also investigated BP elevation occurring after short-term treatment with Pb (<4 weeks). Studies found increased systolic BP after 7 days of Pb treatment (daily injections resulting in mean [SEM] blood Pb levels of 9.98 [1.7] µg/dL) (Fiorim et al., 2011) and after 2 weeks of Pb exposure (100 ppm via drinking water) (Sharifi et al., 2004). A study utilizing intra-arterial pressure measurements found that a single high-dose Pb injection in rats (resulting in mean [SEM] blood Pb levels of 37 [1.7] µg/dL) increased systolic arterial pressure after only 60 minutes (Simões et al., 2011). The injection of Pb into the rat may not allow for extrapolation of these results to humans since this is not a comparable Pb exposure method. These studies suggest that there is the potential for increase in BP following short-term Pb treatment. It is possible that the increases in BP following short- and long-term Pb exposures are occurring through separate mechanisms; however, studies using both short- and longer-term Pb exposure have correlated increased BP with an activation of the renin-angiotensin system (i.e., increase in angiotensin converting enzyme (ACE) activity) (Section 5.4.2.3). Several of these aforementioned studies used the injection route of Pb administration, and the relevance of these bolus doses over short periods of time to human routes of short-term exposure is uncertain. However, it is important to acknowledge that the results were similar to those from the study that examined short-term exposure to Pb via drinking water,

5.4.2.3 Hypertension Modes of Action

The 2006 Pb AQCD (U.S. EPA, 2006b) examined a number of mechanisms leading to Pb-induced hypertension, including oxidative stress, hormonal and blood pressure regulatory system dysfunction, vasomodulation, and cellular alterations. As described below, recent studies in experimental animals and cells further supported roles for these potential mechanisms in mediating hypertension from Pb exposure.

Oxidative Stress Response - Reactive Oxygen Species and Nitric Oxide

Several studies discussed in the 2006 Pb AQCD demonstrated a role for oxidative stress in the pathogenesis of Pb-induced hypertension, mediated by the inactivation of nitric oxide (NO) and downregulation of soluble guanylate cyclase (sGC) (Dursun et al., 2005; Attri et al., 2003; Gonick et al., 1997; Vaziri et al., 1997; Khalil-Manesh et al., 1994; Khalil-Manesh et al., 1993b). Pb-induced reduction of biologically active NO was found not to be due to a reduction in NO-production capacity (Vaziri and Ding, 2001; Vaziri et al., 1999a); instead it was found to result from inactivation and sequestration of NO by ROS (Malvezzi et al., 2001; Vaziri et al., 1999b). Oxidative stress from Pb exposure in animals may be due to upregulation of NAD(P)H oxidase (Ni et al., 2004; Vaziri et al., 2003), induction of Fenton and Haber-Weiss reactions (Ding et al., 2001; Ding et al., 2000), and failure of the antioxidant enzymes, CAT and GPx, to compensate for the increased ROS (Farmand et al., 2005; Vaziri et al., 2003). Many biological actions of NO, such as vasorelaxation, are mediated by cGMP, which is produced by sGC from the substrate GTP. Oxidative stress also has been found to play a role in Pb-induced downregulation of sGC (Farmand et al., 2005; Courtois et al., 2003; Marques et al., 2001). Thus, the reduction of the vasodilator NO from inactivation and sequestration by Pb-induced ROS leads to increased vasoconstriction and BP.

Pb-induced oxidative stress also has been found to induce renal tubulointerstitial inflammation which plays a crucial role in models of hypertension (Rodriguez-Iturbe et al., 2005; Rodriguez-Iturbe et al., 2004). Tubulointerstitial inflammation from treatment with Pb has been coupled with activation of the redox sensitive NF-κB (Ramesh et al., 2001). Pb-induced hypertension, inflammation, and NF-κB activation can be ameliorated by antioxidant therapy (Rodriguez-Iturbe et al., 2004). There is mixed evidence to suggest that Pb-induced hypertension may also be promoted by activation of PKC leading to enhanced vascular contractility (Valencia et al., 2001; Watts et al., 1995).

Recent studies continued to provide evidence for the role of ROS and NO metabolism in Pb-induced hypertension and vascular disease. Increased systolic BP after Pb exposure was accompanied by increased superoxide (O_2^-) and O_2^- positive cells (Bravo et al., 2007;

Vargas-Robles et al., 2007), elevated urinary malondialdehyde (MDA, a measure of lipid peroxidation) (Bravo et al., 2007), and increased 3-nitrotyrosine (Vargas-Robles et al., 2007). Inhibition of NAD(P)H oxidase, an enzyme that generates O_2^- and hydrogen peroxide, was able to block Pb-induced (1 ppm) aortic contraction to 5-hydroxytryptamine (5-HT) (Zhang et al., 2005). Increases in systolic BP, intra-aortic mean arterial pressure, and MDA after Pb exposure (100 ppm; mean blood Pb level: 23.7 µg/dL) were also prevented by treatment with the immunosuppressant, mycophenolate mofetil (MMF) (mean blood Pb level in MMF-treated animals: 27 µg/dL) (Bravo et al., 2007). MMF has been shown to inhibit endothelial NAD(P)H oxidase, which could explain how it decreases Pb-induced increases in oxidative stress and BP. MMF was not found to alter blood Pb levels of animals. Red grape seed extract and ascorbic acid supplementation were also able to protect rats from Pb-induced (100 ppm) increased BP and heart rate, perhaps through the antioxidant properties of the extract (Badavi et al., 2008) and vitamin C (Mohammad et al., 2010). Red grape seed extract did not alter the accumulation of Pb in blood, indicating that its protective effect was not mediated through altered Pb toxicokinetics; however, internal doses of Pb were not measured in the vitamin C study to clarify the mechanism of action of vitamin C. Another study found that the antioxidant, anti-inflammatory chemical, curcumin, as well as physical exercise training reversed Pb-induced increases in serum creatinine kinase-MB (CK-MB), low density lipoprotein (LDL), heart high-sensitivity C-reactive protein (hs-CRP), and MDA. Pb-induced decreases in serum total antioxidant capacity, high density lipoprotein (HDL), and heart glutathione peroxidase (GPx) were also reversed by curcumin and exercise. However, internal doses of Pb were not measured to clarify the mechanism of action in this study (Roshan et al., 2011).

Exposure to Pb can also affect the activity and levels of antioxidant enzymes. Male (♂) and female (♀) rats exposed to Pb for 18 weeks (100-1,000 ppm) had altered responses in antioxidant enzymes in heart tissue (Sobekova et al., 2009; Alghazal et al., 2008a). Pb exposure in female rats increased the activity of cardiac SOD, GST, GR, and GPx (>100 ppm) and increased cardiac thiobarbituric acid reactive substances (TBARS, a measure of lipid peroxidation) (1,000 ppm). Pb exposure in male rats did not affect the activity of SOD or production of TBARS, however decreased the activity of GST and GR (>100 ppm). Male and female rats also accumulated different amounts of Pb in the cardiac tissue after similar Pb exposure (♂ 100 ppm: 205% of control, 1,000 ppm: 379%; ♀ 100 ppm: 246%, 1,000 ppm: 775%), which could explain the sex differences observed in antioxidant enzyme responses.

Oxidative stress can trigger a cascade of events that promote cellular stress, renal inflammation, and hypertension. As was shown previously (Rodriguez-Iturbe et al., 2005), Pb exposure can increase renal NF-κB, which was associated with

tubulointerstitial damage and infiltration of lymphocytes and macrophages (Bravo et al., 2007). These events could also be ablated by MMF treatment, likely due to its anti-inflammatory and antioxidant properties. Pb also was found to induce inflammation in human endothelial cells as a model for vessel intima hyperplasia (Zeller et al., 2010). The pro-inflammatory cytokine, interleukin (IL)-8 protein and mRNA were increased, concentration- and time-dependently, after in vitro Pb exposure (5-50 µM). Enhanced IL-8 production was mediated through activation of the transcription factor Nrf2 (but not NF-κB, hypoxia inducible factor-1, or aryl hydrocarbon receptor), as shown through increased nuclear translocation and Nrf2 cellular knockdown experiments. Additionally, measures of endothelial stress, NQO1 and HO-1 protein, were induced by Pb exposure (Zeller et al., 2010). Pb treatment (20 ppm, i.p., 3 days/week, 8 weeks) increased the inflammatory markers hs-CRP and CK-MB in rat hearts (Roshan et al., 2011).

Oxidative stress affects vascular reactivity and tone through inactivation and sequestration of NO, causing a reduction in biologically active NO. Recent studies affirmed past conclusions on the interplay of ROS and NO metabolism in the cardiovascular effects of Pb. Elevated systolic BP and altered vasorelaxation after Pb exposure was accompanied by a decrease in total nitrates and nitrites (NO_X) (Mohammad et al., 2010; Zhang et al., 2007a; Heydari et al., 2006). Serum NO_X levels in Pb-treated rats remained depressed for 8 weeks and then reversed after 12 weeks, despite continued elevation in systolic BP (Heydari et al., 2006). This return of serum NO_X levels to levels similar in controls could be a result of compensatory increases in endothelial NOS (eNOS) attempting to replenish an over-sequestered NO supply. With this in mind, studies showed increased eNOS protein expression after long-term Pb exposure in kidney (Zhang et al., 2007a) and isolated cultured aorta (Vargas-Robles et al., 2007). No change in inducible NOS was observed in isolated cultured aorta after 1 ppm Pb exposure (Zhang et al., 2007a). In contrast to long-term exposure, Pb treatment over a short time period (daily injections resulting in mean [SEM] blood Pb levels of 9.98 [1.7] µg/dL) was found to increase iNOS and phosphorylated eNOS protein (Fiorim et al., 2011) which may cause an increase in NO production and a short-term increase in NO bioavailability. This increase in NO bioavailability early after Pb exposure could be the immediate compensatory mechanism against the elevation in BP.

NO, also known as endothelium-derived relaxing factor, is a potent endogenous vasodilator. Toxicological studies continued to investigate the effects of Pb on NO-dependent vascular reactivity by using NO stimulating vasodilators, such as acetylcholine (ACh) and sodium nitroprusside (SNP), and NO inhibiting vasoconstrictors, such as L-NAME. Studies provided mixed evidence; however, results suggested that Pb disrupts the vasorelaxant response to NO in the aorta due to damage to the endothelium. Pb exposure (1 ppm and 100 µM, 1 hour) decreased ACh-induced

vasorelaxation, which triggers the release of NO from the endothelial cell, in isolated rat tail artery, suggesting damage to the endothelium (Silveira et al., 2010; Zhang et al., 2007a). In aortic rings of perinatally exposed rats (1,000 ppm through pregnancy and lactation, mean blood Pb level: 58.7 µg/dL), blocking NOS with L-NAME abolished the relaxant response evoked by ACh (Grizzo and Cordellini, 2008). However, there was no change observed in the relaxation response to ACh by Pb alone (Fiorim et al., 2011; Rizzi et al., 2009; Grizzo and Cordellini, 2008). Conversely, Skoczynska and Stojek (2005) found that Pb exposure (50 ppm; blood Pb level 11.2 µg/dL) enhanced NO-mediated vasodilation by ACh in rat mesenteric arteries, and NOS inhibition enhanced the ACh relaxant response. A number of studies found that Pb exposure did not affect smooth muscle integrity since SNP-induced vasorelaxation, which is endothelium independent, was unchanged (Fiorim et al., 2011; Silveira et al., 2010; Rizzi et al., 2009; Grizzo and Cordellini, 2008).

NO also was found to play a role in the interaction between Pb and the vasoconstrictor response. Blocking NOS with L-NAME or inhibiting iNOS specifically, which decreases NO production, increased the contraction of aortic rings in response to the vasoconstrictor phenylephrine (PHE), and Pb exposure potentiated this response (Fiorim et al., 2011). Also, L-NAME increased the Pb pressor response to PHE after perinatal Pb exposure (1,000 ppm through pregnancy and lactation, blood Pb level 58.7 µg/dL) (Grizzo and Cordellini, 2008). Conversely, in rat renal interlobar arteries, Pb exposure blunted the increase in renal angiotensin II (AngII)-mediated contraction from NOS inhibition by L-NAME (Vargas-Robles et al., 2007). Treatment with the SOD mimetic tempol, which would increase NO bioavailability, decreased, but did not eliminate, the Pb pressor response (Silveira et al., 2010).

In summary, recent studies continued to provide evidence for the role of ROS in Pb-induced hypertension and vascular disease by indicating Pb-induced increases in ROS and modulation of cardiovascular responses by antioxidant substances. Additionally, recent studies continued to show that Pb-induced hypertension and vascular responses are mediated primarily via inactivation of NO not via inhibition of NO production.

Vascular Reactivity

Alteration of the adrenergic system from Pb exposure, which can increase peripheral vascular resistance, and thereby arterial pressure, may be one mediator of Pb-induced hypertension. Pb exposure in animals can increase stimulation of the sympathetic nervous system (SNS), as shown by increased plasma levels of norepinephrine (NE) and other catecholamines (Carmignani et al., 2000; Chang et al., 1997) and decreased β adrenergic receptor density and β agonist-stimulated cAMP production in the aorta and heart (Tsao

et al., 2000; Chang et al., 1997). These stimulatory effects on the SNS paralleled the effects of Pb on BP, cardiac contractility, and carotid blood flow. Pb-induced elevations in arterial pressure and heart rate were abrogated by ganglionic blockade (Simões et al., 2011; Lai et al., 2002). Arterial pressure and heart rate gradually decreased 7 months after Pb exposure cessation as did the Pb-induced SNS alterations (Chang et al., 2005).

Increases in BP can be caused by activation of the SNS, which can lead to vascular narrowing, in turn, resulting in increased total peripheral resistance. In this neural mechanism, activation of the SNS leads to vasoconstriction, whereas inhibition leads to vasodilation. It has been suggested that Pb leads to increased vascular reactivity to catecholamines (i.e., epinephrine, NE, and dopamine), hormones of the SNS. Indeed, the isolated mesenteric vessel bed from Pb-treated rats (50 ppm with blood Pb level: 11.2 µg/dL, but not 100 ppm with blood Pb level: 17.3 µg/dL) exhibited increased reactivity to NE (Skoczynska and Stojek, 2005). However, in another study, 100 ppm Pb did not affect the NE-induced contractile response after 10 months of exposure (Zhang et al., 2009a), suggesting a small range of Pb doses affects pressor response to NE. Catecholamines act primarily through the adrenergic and dopaminergic receptors. Antagonists of α1-adrenergic, α2-adrenergic, β-adrenergic, and dopamine D1 receptors were found to abolish Pb-induced aortic contraction (Fazli-Tabaei et al., 2006; Heydari et al., 2006). However, the α1-adrenergic receptor agonist, PHE, induced aortic contractions and these were enhanced by treatment with Pb (100 ppm; blood Pb level: 26.8 µg/dL), indicating a specific role for the α1-adrenergic receptor (Silveira et al., 2010; Grizzo and Cordellini, 2008; Heydari et al., 2006). Removal of the endothelium blunted the PHE-induced contraction. Conversely, short-term Pb treatment (7 days, i.p.) decreased the contractile response induced by PHE in rat aortas resulting in a decreased vascular reactivity (Fiorim et al., 2011). This decrease may be playing a compensatory role in attempting to correct the Pb-induced BP elevation. Additionally, Pb blunted the isoproterenol-induced relaxation, supporting a role for the β-adrenoceptors (Vassallo et al., 2008; Heydari et al., 2006).

Recently, there was mixed evidence for Pb disrupting vascular reactivity to other pressor agents. Pb (1 ppm) treatment of isolated rat thoracic aorta increased 5-HT induced contraction, which was endothelium dependent, but not due to 5-HT2B receptor expression (Zhang et al., 2005). Follow-up of this study in whole animals found, on the contrary, that Pb (100 ppm; blood Pb level: 28.4 µg/dL) decreased the maximum contractile response to 5-HT, but did not affect 5-HT plasma levels or 5-HT2B receptor expression (Zhang et al., 2009a). In addition, Pb exposure (100 ppm, 12 weeks) increased the renal vascular response to AngII in isolated perfused kidneys from Pb-exposed rats (Vargas-Robles et al., 2007).

Studies continued to investigate the effects of Pb on NO-dependent vascular reactivity by using NO stimulating vasodilators, such as ACh and SNP, and NO inhibiting vasoconstrictors, such as L-NAME. These studies were discussed in the preceding subsection (*Oxidative Stress Response*).

Renin-Angiotensin-Aldosterone and Kininergic Systems

The adrenergic system also affects the renin-angiotensin-aldosterone system (RAAS), which is responsible for fluid homeostasis and BP regulation, and has been shown to be affected by Pb exposure. A meta-analysis found that Pb exposure (resulting in blood Pb levels: 30-40 µg/dL) increased plasma renin activity and renal tissue renin in young but not old rats (Vander, 1988). Exposure of experimental animals to Pb also induced increases in plasma, aorta, heart, and kidney angiotensin converting enzyme (ACE) activity; plasma kininase II, kininase I, and kallikrein activities; and renal AngII positive cells (Rodriguez-Iturbe et al., 2005; Sharifi et al., 2004; Carmignani et al., 1999). ACE activity declined over time while arterial pressure stayed elevated, suggesting that the RAAS may be involved in the induction, but not the maintenance of Pb-induced hypertension in rats.

Recent studies continued to implicate the RAAS in the development of Pb-induced hypertension, especially during early exposure in young animals. AngII, a main player in the RAAS, induces arteriolar vasoconstriction leading to increased BP. Pb exposure increased the vascular reactivity to AngII (Vargas-Robles et al., 2007). Acute (60 minutes) or short-term (7 days) treatment of rats to Pb increased the plasma ACE activity (Fiorim et al., 2011; Simões et al., 2011), and Fiorim et al. (2011) additionally found this increase to be correlated with the Pb-induced increase in systolic BP. However, at these short time points there were no changes in the AngII receptors 1 or 2 protein levels or expression. Treatment with the AngII receptor (AT_1R) blocker, Losartan, or the ACE inhibitor, Enalapril, blocked the Pb-induced systolic BP increase (Simões et al., 2011) and decreased the PHE-induced vasoconstrictor response in Pb-treated aortas (Fiorim et al., 2011). Similarly, treatment with Losartan resulted in a greater decrease in systolic BP in highly Pb-exposed rats (10,000 ppm Pb, 40 days; blood Pb level >240 µg/dL after exposure, 12-13 µg/dL after chelation after 1 year) compared to control rats that continued into later periods of follow-up (day 283) (Bagchi and Preuss, 2005). Increased systolic BP after early exposure to Pb corresponded with increased water intake, urine output, potassium excretion, and decreased urinary sodium and urine osmolality. These functional changes in renal behavior are consistent with the actions of a stimulated RAAS. Lower level Pb (100 ppm, 14 weeks; range of blood Pb levels: 23.7-27 µg/dL) exposure increased renal cortical AngII content and the number of tubulointerstitial AngII-positive cells (Bravo et al., 2007). This heightened intrarenal

angiotensin corresponded with sodium retention and increased systolic BP and was ablated by the anti-inflammatory antioxidant, MMF. Sodium reabsorption is important for the maintenance of BP, and Na^+ transporters play a key role in this process. In other studies, Pb exposure increased activity and levels of the α-1 subunit protein of Na^+/K^+ATPase, which plays a major role in Na^+ reabsorption and is regulated by the RAAS (Fiorim et al., 2011; Simões et al., 2011). These studies point to the activation of the RAAS in the course of Pb-induced hypertension, particularly in the early stages of elevated BP.

Vasomodulators

The balance between production of vasodilators and vasoconstrictors is important in the regulation of BP and cardiovascular function. The 2006 Pb AQCD reported that Pb did not affect all vasomodulators in the same way. Urinary excretion of the vasoconstrictor, thromboxane (TXB_2), and the vasodilatory prostaglandin, 6-keto-PGF1α, was unchanged in rats with Pb-induced hypertension (Gonick et al., 1998). However, in vitro Pb exposure promoted the release of the prostaglandin precursor, arachidonic acid, in vascular smooth muscle cells (VSMCs) via activation of phospholipase A_2 (Dorman and Freeman, 2002). Plasma concentration and urinary excretion of the vasoconstrictive peptide, endothelin (ET) 3 was increased after low (100 ppm), but not high-level (5,000 ppm) Pb exposure in rats (Gonick et al., 1997; Khalil-Manesh et al., 1994; Khalil-Manesh et al., 1993b). Antagonism of the ET receptor A blunted the downregulation of sGC and cGMP production by Pb in isolated rat artery segments, suggesting that some of the hypertensive effects of Pb exposure may be mediated through ET (Courtois et al., 2003). Additionally, Pb-exposed animals exhibited fluid retention and a concentration-dependent decline in the vasodilator, atrial natriuretic factor (ANF) (Giridhar and Isom, 1990). Results from these studies suggest that Pb may interfere with the balance between vasodilators and vasoconstrictors that contribute to the complex hormonal regulation of vascular contraction and BP.

The imbalance in vasomodulators is one explanation for the concentration-dependent vasoconstriction observed in some animals after Pb exposure (Valencia et al., 2001; Watts et al., 1995; Piccinini et al., 1977). However, vasoconstriction after Pb exposure was not reported in all studies (Shelkovnikov and Gonick, 2001) and is likely varied depending on the type of vessel used, the Pb concentration employed, and the animal species being studied. Studies have reported Pb-induced attenuation of ACh- and NO-mediated vasodilation (Marques et al., 2001; Oishi et al., 1996) in some, but not all vascular tissues and in some, but not all studies (Purdy et al., 1997). These effects have been variably attributed to Pb-mediated activation of PKC and direct action on the

VSMCs through the Ca^{2+} mimetic properties of Pb among other possibilities (Valencia et al., 2001; Watts et al., 1995; Piccinini et al., 1977).

A recent study investigated the role of the endothelial-derived vasoconstrictor, ET-1, in Pb-induced hypertension. ET-1 from the endothelium acts on the ET_A-type receptors located on the vascular smooth muscle layer and may be involved in vascular reactivity by NO and COX derivatives. Pb exposure (1 ppm, 24 hours) to rat aortic segments decreased expression of sGC-β1 subunit, an enzyme involved in NO-induced vasodilation, and increased expression of COX-2 in an endothelium-dependent manner (Molero et al., 2006). Even though Pb treatment did not alter ET-1 or ET_A-type receptor protein expression in this system, blocking the ET_A-type receptors partially reversed Pb-induced changes in sGC and COX-2 in vascular tissue. These results suggest that the endothelium and ET-1 may contribute to Pb-induced hypertension through activation of ET_A-type receptors that alter expression of COX-2 and sGC-β1 subunit, which affects NO signaling.

COX-2 blockade has been shown to prevent Pb-induced downregulation of sGC expression (Courtois et al., 2003). Inhibition of COX-2 also decreased the Pb-induced pressor response to ACh (Grizzo and Cordellini, 2008) and PHE (Silveira et al., 2010) in experimental animals. These results suggest that Pb-induced vascular reactivity may depend on the participation of a COX-derived vasoconstrictor, such as prostaglandins, prostacyclins, or thromboxanes.

In summary, recent studies continued to show that Pb exposure affects vasomodulatory pathways that are important for the maintenance of vascular tone; however, results indicated that not all vascular cell types are similarly affected by Pb exposure. Further, effects appeared to vary according to the concentration of Pb exposure. Pb exposure has been shown to interrupt baseline or endogenous NO-mediated vasodilation of vessels via alterations in PKC, sGC, VSMC, endothelial cells, NADPH oxidase, and Ca^{2+} levels. Recent studies indicated that Pb exposure may affect vascular reactivity by increasing COX-2 and COX-2-dependent vasoconstrictors. Also, the vasoconstrictor endothelin may contribute to Pb-induced vasomodulation via similar pathways as NO including effects on sGC and COX-2.

5.4.2.4 Summary of Blood Pressure and Hypertension

The 2006 Pb AQCD (U.S. EPA, 2006b) reported a clear association between higher blood Pb levels and higher BP. The effect was modest, but robust, as determined by a meta-analysis (Nawrot et al., 2002) of over 30 cross-sectional and prospective studies comprising over 58,000 adults (Figure 5-22). In the meta-analysis, each doubling of

concurrent blood Pb was associated with a 1 mmHg increase in systolic BP and a 0.6 mmHg increase in diastolic BP. Recent epidemiologic studies supported this association at lower concurrent blood Pb levels (in populations with mean blood Pb levels <2 µg/dL) and added to the evidence base regarding populations potentially at increased risk (i.e., high stress, genetic variants) and regarding associations of bone Pb levels with BP and hypertension in populations with mean bone Pb levels less than 20 µg/g. As these studies were mostly cross-sectional in design and were conducted in adults whose concurrent blood Pb levels are influenced both by current Pb exposures and past Pb exposures mobilized from bone, uncertainty exists over the Pb exposure conditions that contributed to the associations observed between concurrent blood Pb level with increased BP and hypertension (Sections 4.3 and 4.7.3). However, U.S. EPA (1990a) reviewed studies available prior to 1990, a period when Pb exposures from air were probably at the highest level, that examined Pb exposure and BP outcomes which included evaluation of several studies of the population represented in NHANES II (1976-80). They noted that across a range of 7 to 34 µg/dL, no evident threshold was found below which the blood Pb level was not significantly related to BP. U.S. EPA (1990a) concluded that a small but positive association exists between blood Pb levels and increases in BP.

A recent prospective study in Pb workers found independent associations of both baseline blood Pb level and subsequent changes in blood Pb over follow-up with changes in BP over follow-up and bone Pb level with hypertension (Glenn et al., 2006). Although these Pb workers had higher current Pb exposure compared with nonoccupationally-exposed adults, the results indicated that different mechanisms may mediate shorter-term Pb-associated increases in BP and longer-term Pb-associated development of hypertension.

Key evidence was further provided by a recent cross-sectional study in an ethnically diverse community-based cohort of women and men aged 50-70 years of age that found associations of both blood and tibia Pb levels with BP with extensive consideration of potential confounding factors (Martin et al., 2006). Additionally, a recent epidemiologic study provided evidence for associations in an adult cohort between blood Pb level and BP and hypertension with relatively low blood Pb levels; a positive relationship was found in the NHANES adult data (1999-2002) with a geometric mean blood Pb level of 1.64 µg/dL (Muntner et al., 2005). However, as noted above, in adults, uncertainty exists regarding the magnitude, timing, frequency, and duration of Pb exposure that contribute to the associations observed with concurrent blood Pb levels.

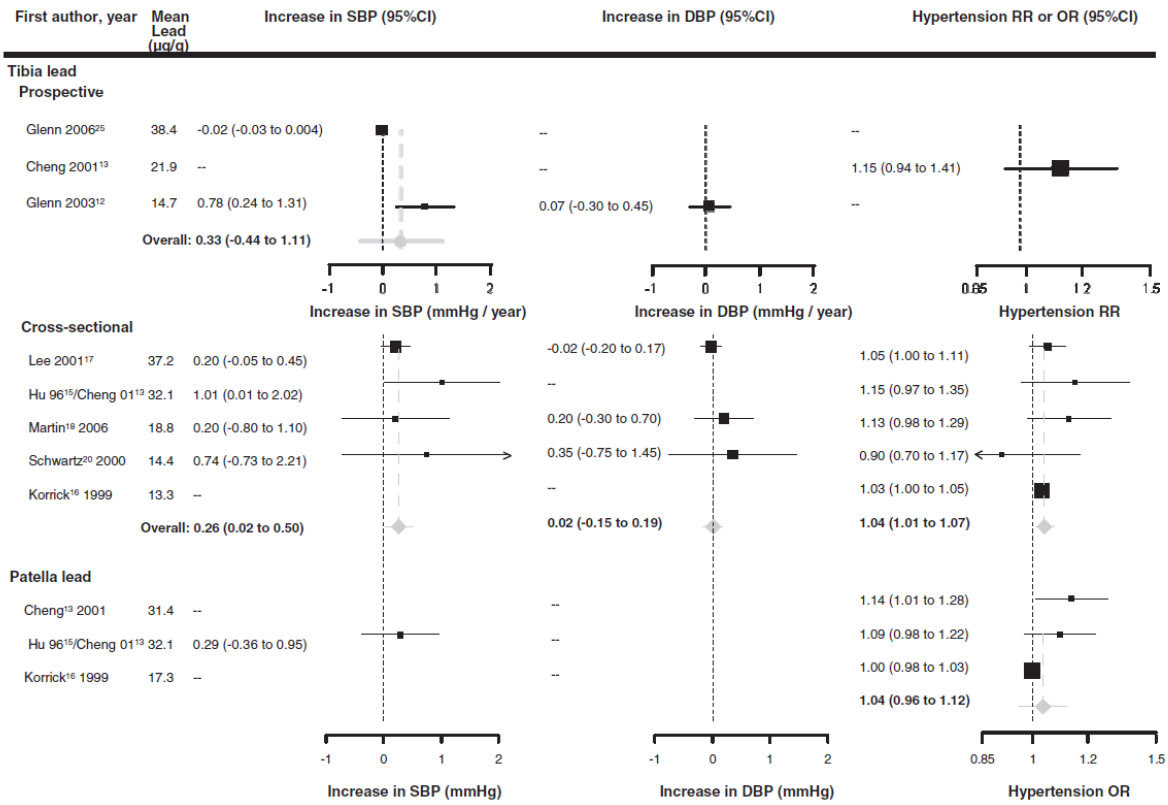
Note: Individual study results are presented in each row. The rightmost columns indicate the sex of subjects and study sample size. Circles represent individual groups and squares represent the combined association sizes. Open circles denote a nonsignificant association size that was assumed to be zero.

Figure 5-22 Meta-analysis of change in systolic BP (SBP), in mmHg with 95% CI, associated with a doubling in the blood Pb concentration.

In concordance with epidemiologic evidence, collectively, the animal toxicological studies providing blood Pb level and BP measurements reported higher BP with higher blood Pb levels in adult rodents (Figure 5-21). While the contribution of low concurrent blood Pb levels to the findings is difficult to ascertain in adult humans, animal toxicological studies provide support for low blood Pb level effects with increases in BP observed in groups of animals with long-term dietary Pb exposure resulting in blood Pb levels as low as 2 µg/dL (Rizzi et al., 2009; Tsao et al., 2000; Nakhoul et al., 1992). However, the majority of animal toxicological studies showing Pb-induced hypertension

were conducted at higher Pb exposure levels that result in blood Pb levels >10 µg/dL. In addition, recent animal evidence suggests the potential for increased BP following short-term (4 weeks) Pb treatment that included injected bolus doses that may have uncertain relevance to human routes of Pb exposure (Fiorim et al., 2011; Simões et al., 2011; Sharifi et al., 2004). A recent study also demonstrated partial reversibility (not to levels in controls) of Pb-induced elevations in BP following Pb exposure cessation or chelation (Chang et al., 2005).

Epidemiologic studies continued to investigate the relationship between bone Pb and BP. A recently published meta-analysis (Figure 5-23) (Navas-Acien et al., 2008) included several studies (three prospective, five cross-sectional) that individually showed that bone Pb level was associated with systolic BP but not diastolic BP. In the cross-sectional studies, a pooled estimate indicated an increase in systolic BP of 0.26 mmHg (95% CI: 0.02, 0.50) per 10 µg/g tibia Pb. In the longitudinal studies, a 0.33 mmHg (95% CI: -0.44, 1.11) increase was estimated per 10 µg/g bone Pb. Most studies also reported associations of bone Pb with hypertension. Pooled odds ratios for hypertension of 1.04 (95% CI: 1.01, 1.07) per 10 µg/g increase in tibia Pb and 1.04 (95% CI: 0.96, 1.12) per 10 µg/g increase in patella Pb were reported.



In the Normative Aging Study, Hu et al. (1996a) reported the cross-sectional association between bone Pb levels and the prevalence of hypertension and Cheng et al. (2001) reported the cross-sectional association between bone Pb levels and systolic BP in study participants free of hypertension at baseline.

Note: The studies are ordered by increasing mean bone Pb levels. The area of each square is proportional to the inverse of the variance of the estimated change or log relative risk. Horizontal lines represent 95% confidence intervals. Diamonds represent summary estimates from inverse-variance weighted random effects models. Because of the small number of studies, summary estimates are presented primarily for descriptive purposes. RR indicates risk ratio.

Figure 5-23 Meta-analysis of an increase in systolic BP (SBP) and diastolic BP (DBP) and relative risk of hypertension per 10 µg/g increase in bone Pb levels.

A few recent epidemiologic studies also emphasized the potential interaction between measures of long-term Pb exposure, i.e., bone Pb levels, and factors such as chronic stress and HFE genetic variants to moderate or modify the relationship of BP and hypertension with Pb. For example, among NAS men, tibia Pb level was associated with a larger risk of developing hypertension in an originally nonhypertensive group among men with higher self-reported stress (Peters et al., 2007).

In addition to stress, recent epidemiologic studies investigated effect modification by race/ethnicity and genetic variants. In the NHANES 1988-1994 population of adults, the association of concurrent blood Pb with systolic BP was higher among Mexican Americans. In the same NHANES population, the association between blood Pb level and

hypertension was higher among non-Hispanic Blacks with the ALAD2 allele (see Figure 5-18 and Figure 5-19 for results) (Scinicariello et al., 2010). Additionally, the association between blood Pb and PP was larger among NAS men with the HFE H63D variant (Figure 5-18) (Zhang et al., 2010a). PP represents a good predictor of cardiovascular morbidity and mortality and an indicator of arterial stiffness. The aforementioned genes are related to iron metabolism and have been linked with differences in Pb distribution in blood and bone. Park et al. (2009b) provided further evidence of variants in iron metabolism genes impacting the association of bone Pb levels with QT interval changes (see Table 5-21 for results).

Animal toxicological evidence continued to build on the evidence characterizing the mechanisms leading to these Pb-induced cardiovascular alterations. Biological plausibility for the consistent associations observed between blood and bone Pb and cardiovascular effects is provided by enhanced understanding of Pb-induced oxidative stress including NO inactivation, endothelial dysfunction leading to altered vascular reactivity, activation of the RAAS, and vasomodulator imbalance.

5.4.3 Vascular Effects and Cardiotoxicity

Not only has Pb been shown to increase BP and alter vascular reactivity, but Pb can alter cardiac function, initiate atherosclerosis, and increase cardiovascular mortality. Past toxicological studies have reported that Pb can increase atheromatous plaque formation in pigeons, increase arterial pressure, decrease heart rate and blood flow, and alter cardiac energy metabolism and conduction (Prentice and Kopp, 1985; Revis et al., 1981). A limited number of available epidemiologic studies discussed in the 2006 Pb AQCD (U.S. EPA, 2006b) provided evidence of associations of blood Pb level with ischemic heart disease (IHD) and peripheral artery disease (PAD).

5.4.3.1 Effects on Vascular Cell Types

The endothelial layer is an important constituent of the blood vessel wall, which regulates macromolecular permeability, VSMC tone, tissue perfusion, and blood fluidity. Damage to the endothelium is an initiating step in development of atherosclerosis, thrombosis, and tissue injury. Given that epidemiologic and toxicological evidence suggests that long-term Pb exposure is associated with a number of these conditions, numerous toxicological studies have investigated and found an effect of Pb on endothelial dysfunction. A recent occupational study found that endothelial function assessed by

flow-mediated dilatation was impaired in highly Pb-exposed workers (mean blood Pb levels: 24.1 in workers versus 7.8 µg/dL in unexposed controls) (Poręba et al., 2010).

The endothelial layer makes up only a small part of the vascular anatomy; the majority of the vessel wall is composed of VSMCs, which work in concert with the endothelial cells (EC) in contraction and relaxation of the vessel, local BP regulation, and atherosclerotic plaque development. Since Pb has been shown repeatedly to result in hypertension and vascular disease in experimental animals, studies continued to investigate and find an effect of Pb on VSMCs.

In in vitro assays, Pb (50 µM, 2 weeks) stimulated VSMC invasiveness in isolated human arteries leading to the invasion of medial VSMC into the vessel intima and development of intimal hyperplasia, a key step in atherosclerotic progression (Zeller et al., 2010). In addition, treatment with Pb (50 µM, 12 hours) promoted VSMC elastin expression and increased arterial extracellular matrix in isolated human arteries. VSMC invasiveness was also increased in culture by treatment with supernatant of Pb-treated human EC (50 µM), suggesting that Pb-exposed ECs secrete an activating compound. This compound was confirmed to be IL-8. Pb exposure (5-50 µM) was able to, in a concentration-dependent manner, increase IL-8 synthesis and secretion in human umbilical vein EC cultures through activation of the transcription factor Nrf2. Neutralization of IL-8 could block VSMC invasion and arterial intima thickening (Zeller et al., 2010). This study provides evidence that Pb exposure stimulates ECs to secrete IL-8 in an Nrf2-dependent manner which stimulates VSMC invasion from the vessel media to intima leading to a vascular thickening and possibly atherogenesis.

A number of CVDs, including atherosclerosis, are characterized by increased inflammatory processes. Numerous studies have shown that Pb exposure is associated with an inflammatory environment in vascular tissues of humans and animals as indicated by higher levels of inflammatory mediators like prostaglandin E_2 (PGE_2). Human aortic VSMCs treated with Pb (1 µM, 1-12 hours) exhibited increased secretion of PGE_2 time-dependently through enhanced gene transcription (Chang et al., 2011). This was preceded by a Pb-induced increase in the gene expression of cytosolic phospholipase A_2 ($cPLA_2$) and COX-2, two rate limiting enzymes in the regulation of prostaglandins. The induction of these enzymes was mediated by activation of ERK1/2, MEK1, and MEK2. Further investigation of the entrance of Pb into the cell revealed that inhibition of the store-operated calcium channels (SOC) could only partially suppress $cPLA_2$ and COX activation by Pb; however inhibition of epidermal growth factor receptor (EGFR) attenuated Pb-induced PGE_2 secretion and activation of $cPLA_2$ and COX. A follow-up to this study found that Pb treatment (1µM) of a human epithelial cell line increased COX-2 gene expression, promoter activity, and protein (Chou et al., 2011). Inhibition of NF-κB

decreased the Pb-induced COX-2 activation; whereas EGFR inhibition blocked COX-2 upregulation and NF-κB nuclear translocation. Overall these results suggest that Pb can induce pro-inflammatory events in VSMC in the form of increased PGE_2 secretion and expression of $cPLA_2$ and COX-2 through activation of EGFR via ERK1/2 and NF-κB pathways.

Damage to the endothelium is a hallmark event in the development of atherosclerosis. Past studies have shown that Pb exposure results in de-endothelialization, impaired proliferation, and inhibition of endothelium repair processes after injury (Fujiwara et al., 1997; Ueda et al., 1997; Kaji et al., 1995; Kishimoto et al., 1995). However, Pb exposure was not found to lead to nonspecific cytotoxicity at low exposure levels (2-25 µM) as shown by the lack of release of lactate dehydrogenase (LDH) from Pb-treated bovine aortic EC (Shinkai et al., 2010). Instead, Pb induced specific apoptosis (caspase3/7 activation) through endoplasmic reticulum (ER) stress that was protected against by the ER chaperones glucose-regulated protein 78 (GRP78) and glucose-regulated protein 94 (GRP94). GRP78 and GRP94 play key roles in the adaptive unfolded protein response that serves as a marker of and acts to alleviate ER stress. Exposure of ECs to Pb induced *GRP78* and *GRP94* gene (2-25 µM) and protein (GRP78 [5-25 µM] and GRP94 [10-25 µM]) expression through activation of the IRE1-JNK-AP-1 pathways (Shinkai et al., 2010). This finding suggests that the functional damage in ECs caused by Pb exposure may be partly attributed to induction of ER stress.

5.4.3.2 Cholesterol

As blood cholesterol rises so does the risk of coronary heart disease. Previous occupational studies (Ademuyiwa et al., 2005a; Bener et al., 2001b; Kristal-Boneh et al., 1999) examining higher than current adult blood Pb levels (>40 µg/dL) reported higher total cholesterol levels related to Pb exposure, but mixed results for HDL, LDL, and triglycerides. More recently, Poreba et al. (2010), in an occupational study, reported no significant differences in parameters of lipid metabolism between Pb exposed workers (mean blood Pb level: 25 µg/dL) and unexposed individuals. Conversely, Kamal et al. (2011) reported that occupational Pb exposure (mean blood Pb level: >40 µg/dL) was associated with higher levels of triglycerides, total cholesterol, and LDL, and decreased HDL-C. Other Pb studies adjusted models for total cholesterol to control for this coronary heart disease risk factor. Higher mean total cholesterol with higher blood Pb levels has been reported in a NHANES study (Menke et al., 2006). In developing models to predict bone Pb levels, Park et al. (2009c) noted in a NAS study that total and HDL cholesterol were selected as 2 of 18 predictors for the bone Pb level model. Their findings suggested that higher Pb exposure in nonoccupationally-exposed men may be associated with

higher total and HDL cholesterols. In support of epidemiologic evidence, a recent toxicological study reported increased LDL and decreased HDL in rats treated with Pb (20 ppm, i.p., 3 days/week, 8 weeks) (Roshan et al., 2011). The major risk factor that lipids represent for heart disease make relating lipid levels to Pb exposures an interesting but challenging hypothesis to test.

5.4.3.3 Atherosclerosis

A small number of toxicological and cross-sectional epidemiologic studies provide evidence for increased atherosclerosis and intimal medial thickening (IMT) due to Pb exposure. The association of stroke subtypes and severity of cerebral atherosclerosis was examined in relation to a single concurrent blood Pb level and total 72-hour urinary Pb level (body Pb store-EDTA mobilization test) in a cross-sectional study of 153 patients (mean age 63.7 years) receiving digital subtraction angiography in Chang Gung Memorial Hospital in Taiwan from 2002 to 2005 (Lee et al., 2009). In an analysis adjusted for age, sex, hypertension, diabetes, triglyceride, uric acid, smoking, and alcohol consumption, a 1 µg increase in urine Pb was associated with ≥ 50% stenosis in the intracranial carotid system with an OR of 1.02 (95% CI: 1.00, 1.03). Urine Pb was not associated with greater stenosis in the extracranial or vertebrobasilar systems. Blood Pb level was not associated with greater stenosis in any region. As the development of atherosclerosis is a lifelong process, body Pb stores, analyzed by total 72-hour urine Pb amount, may more strongly be associated with atherosclerosis than are single blood Pb measurements.

A recent study correlated greater carotid artery IMT with higher concurrent serum Pb levels (mean [SD] 0.41 [0.38] µg/dL) in hemodialysis patients (Ari et al., 2011). A few available recent occupational studies also presented evidence for increased measures of atherosclerosis in highly Pb-exposed adult populations with mean blood Pb levels around 25 µg/dL. Poręba et al. (2011a) reported increased local arterial stiffness and more frequent left ventricular diastolic dysfunction in Pb-exposed workers with hypertension compared to nonexposed controls with hypertension. Occupational exposure to Pb (mean blood Pb levels: 24 µg/dL in workers, 8.3 µg/dL in nonexposed group) was also associated with greater IMT and atherosclerotic plaque presentation, analyzed by Doppler ultrasound (Poreba et al., 2011).

Zeller et al. (2010) examined human radial and internal mammary arteries exposed to Pb in culture and reported a concentration-dependent increase in arterial intimal thickness (statistically nonsignificant at 5 µM Pb, significant at 50 µM Pb, 2 week treatment) and intimal extracellular matrix accumulation (50 µM). Also, Pb promoted EC proliferation

(5 and 50 µM, 72 hours) and VSMC elastin expression (50 µM, 12 hours), as discussed above (Section 5.4.3.1) (Zeller et al., 2010). Another study showed that Pb exposure (100 ppm in drinking water for 10 months; mean blood Pb level 28.4 µg/dL) of rats also increased the aortic media thickness, media-lumen ratio, and medial collagen content (Zhang et al., 2009a). These morphological changes to the vessel due to Pb exposure indicate initiation of arteriosclerosis and could be the cause of decreased contractile response of the vessel due to altered visco-dynamic vessel properties. Alternatively, these vascular changes could be an effect of Pb-induced hypertension.

5.4.3.4 Heart Rate Variability

HRV and BP are regulated, in part, by the sympathetic and parasympathetic nervous systems. Changes in either may increase the risk of cardiovascular events. HRV is defined as the oscillation in the interval between consecutive heart beats and between consecutive instantaneous heart rates. Decreases in HRV have been associated with cardiovascular mortality/morbidity in older adults and those with significant heart disease [(1996), Task Force of the European Society of Cardiology and the North American Society of Pacing and Electrophysiology]. In addition, decreased HRV may precede some clinically important arrhythmias, such as atrial fibrillation, as well as sudden cardiac death, in high risk populations (Chen and Tan, 2007; Sandercock and Brodie, 2006).

Pb has been shown not only to affect vascular contractility in animals, but also is associated with cardiac contractility. The 2006 Pb AQCD (U.S. EPA, 2006b) described one study that investigated Pb-induced alterations in HRV (Cheng et al., 1998). Cheng et al. (1998) found increasing duration of corrected QT interval (QTc) with increasing bone Pb levels in men <65 years, but not in men ≥ 65 years. Eum et al. (2011) and Park et al. (2009b) followed up this previous NAS cohort (Cheng et al., 1998) (details found in Table 5-21). Eum et al. (2011) prospectively examined the association between blood and bone Pb levels and the development of electrocardiographic (ECG) conduction abnormalities among 600 men who were free of ECG abnormalities at the baseline assessment. A second ECG was obtained for 496 men 8.1 (SD: 3.1) years later on average. Baseline Pb concentrations in blood (mean [SD]: 5.8 [3.6] µg/dL), patella bone (mean [SD]: 30.3 [17.7] µg/g), and tibia bone (mean [SD]: 21.6 [12.0] µg/g) were similar to those found in other samples from the general U.S. adult population and much lower than those reported in occupationally exposed groups. Higher tibia Pb was associated with increases in QTc interval and QRSc duration. Compared with those in the lowest tertile of baseline tibia Pb (<16 µg/g), participants in the highest tertile (>23 µg/g) had a 7.94 msec (95% CI: 1.42, 14.45) greater increase in QTc interval and a 5.94 msec (95%

CI: 1.66, 10.22) greater increase in QRSc duration over 8 years after adjusting for covariates: age, education, smoking, BMI, albumin-adjusted serum calcium, and diabetes status at baseline, and years between ECG tests and QT-prolongation drugs at the time of ECG measurement. There were no statistically significant associations with patella or blood Pb levels. These associations with tibia bone Pb levels were observed in men with relatively low blood and bone Pb concentrations who were free of cardiac conduction abnormalities at baseline and were examined prospectively. Thus, they indicate that long-term cumulative Pb exposure may increase the risk of developing cardiac abnormalities. Uncertainty exists as to the specific Pb exposure level, timing, frequency, and duration contributing these associations observed for tibia Pb levels. A recent occupational study reported lower HRV and abnormal parameters of heart rate turbulence in Pb-exposed workers (mean blood Pb levels: ~25 µg/dL) compared to control subjects (Poręba et al., 2011b).

Park et al. (2009b) cross-sectionally examined whether polymorphisms in genes known to alter iron metabolism (HFE, transferrin [TF] C2, heme oxygenase-1 [HMOX-1]) modify the association between Pb biomarker levels and the QT interval. Investigators examined associations in data stratified on polymorphisms in the three genes. They also analyzed interaction models with cross-product terms for genotype and the Pb biomarker. The distributions of all genotypes but the HFE variant, H63D, were in Hardy-Weinberg equilibrium. Subjects homozygous for the other HFE variant, C282Y, had higher bone Pb levels and those homozygous for H63D and heterozygous with both C282Y and H63D had lower bone Pb levels. The antioxidant HMOX-1 L variant (longer repeats of GT, associated with lower enzyme inducibility) alone, compared to the wild type, showed a statistically significant interaction with tibia Pb (11.35 msec longer QTc interval for each 13 µg/g increase in bone Pb in L-allele variants). No other gene variant alone showed different Pb-associated QTc intervals from those in wild types, either for tibia and patella Pb or for (linear) concurrent blood Pb. Lengthening of QTc with higher tibia and blood Pb was more pronounced with an increase in the total number of gene variants, driven by a joint effect between HFE variant and HMOX-1 L allele. There was a trend observed with blood and tibia Pb-associated QTc interval increasing with increasing number of gene variants from 0 to 3. This study provided further evidence of gene variants modifying associations of Pb biomarkers with cardiovascular effects.

The interaction of key markers of the metabolic syndrome with bone Pb levels in affecting HRV was cross-sectionally investigated in a group of 413 older adults with patella Pb measurements in the NAS (Park et al., 2006). Metabolic syndrome was defined to include three or more of the following: waist circumference >102 cm, hypertriglyceridemia (>150 mg/dL), low HDL cholesterol (<40 mg/dL in men), high BP >130/85 mmHg, and high fasting glucose (>110 mg/dL). Men using antihypertensive

medication or diabetes medications were counted as high BP or high fasting glucose, respectively. The strongest relationships between patella Pb levels and lower HRV were observed among those with three or more metabolic abnormalities. A trend was observed for larger patella Pb-associated decreases in HRV with increasing number of metabolic abnormalities. These results suggest multiplicative effects of cumulative Pb exposure and metabolic abnormalities on key predictors of CVD. Park et al. (2006) also reported the penalized spline fits to bone Pb in models assessing only main effects of bone Pb. The optimal degree of smoothing determined by the generalized cross-validation criterion for all HRV measures was 1, which indicated that the associations were nearly linear. The spline fits and associated statistics showed that the bone Pb main effects on HRV measures were linear. However, the relationship with LF/HF was linear with log(LF/HF).

Increased incidence of arrhythmia and atrioventricular conduction block was found in rats after 12 weeks of Pb exposure (100 ppm; mean blood Pb level 26.8 µg/dL) (Reza et al., 2008). Also, Pb exposure for 8 weeks increased heart rate and systolic BP. These increases corresponded with increased cardiac contractile force and prolonged ST interval, without alteration in QRS duration or coronary flow. In contrast, another study using rat right ventricular strips found that Pb (100 µM) exposure, in a concentration-dependent manner, reduced myocardial contraction by reducing sarcolemmal Ca^{2+} influx and myosin ATPase activity (Vassallo et al., 2008). This study also found that Pb exposure changed the response to inotropic agents and blunted the force produced during contraction. Conversely, past studies have found that Pb exposure increases intracellular Ca^{2+} content (Lal et al., 1991; Favalli et al., 1977; Piccinini et al., 1977), which could result in increased cardiac output and hypertension.

5.4.3.5 Peripheral Artery Disease

Peripheral artery disease (PAD) is an indicator of atherosclerosis and measured by the ankle brachial index, which is the ratio of BP between the posterior tibia artery and the brachial artery. PAD is typically defined as an ankle brachial index of less than 0.9. Muntner et al. (2005), whose results describing the association of blood Pb and hypertension in the NHANES 1999-2002 data set for adults were discussed previously, also examined the association of blood Pb with PAD (details found in Table 5-21). The authors observed an increasing trend in the odds of PAD with increasing concurrent blood Pb level. The OR for PAD comparing the fourth quartile of blood Pb (>2.47 µg/dL) to the first quartile of blood Pb (<1.06 µg/dL) was 1.92 (95% CI: 1.02, 3.61). Key potential confounding factors were adjusted for in the analysis. These results are consistent with those from a previous NHANES analysis by Navas-Acien et al. (2004) reviewed in the 2006 Pb AQCD.

Navas-Acien et al. (2004) reported a trend of increasing OR for PAD with increasing quartile of concurrent blood Pb or Cd in adults who were 40 years of age in the 1999-2000 NHANES population. These authors tested both Pb and Cd in separate models, tested the metals simultaneously, and tested the interaction between the metals. The correlation coefficient between natural log Pb and natural log Cd was 0.32 ($p < 0.001$). Although the interaction was not statistically significant, when blood Pb and blood Cd were in the same model, the ORs were diminished slightly. Both showed statistically significant trends of increasing OR with increasing quartile of the metal. These results indicate that blood Cd levels did not confound the association between blood Pb level and PAD. In a subsequent analysis, Navas-Acien et al. (2005) used the same 1999-2000 NHANES dataset, but constructed PAD models using a suite of urine metal concentrations. Power was reduced in this study because only 659-736 subjects (compared to 2,125) had spot urine metal tests in the data set. Urinary Cd, but not urinary Pb, was consistently associated with PAD in all models. Associations also were observed with urinary antimony and tungsten. Spot urine Pb measurements are less reliable compared to blood Pb measurements. In Navas-Acien et al. (2005), the urinary Pb level association with PAD was sensitive to adjustment for urinary creatinine, indicating that spot urine Pb measurements are affected by differences in urine dilution. This finding illustrates the limited reliability of spot urine Pb measurements compared to blood Pb measurements.

5.4.3.6 Ischemic Heart Disease

A few cross-sectional studies discussed in the 2006 Pb AQCD (U.S. EPA, 2006b) indicated associations between Pb biomarker levels and increased risk of cardiovascular outcomes associated with IHD, including left ventricular hypertrophy (Schwartz, 1991) and myocardial infarction (Gustavsson et al., 2001). Recently, Jain et al. (2007) provided prospective evidence for the incidence of IHD (physician confirmed MI, angina pectoris) among older adult males enrolled in the NAS that were followed during the period of September, 1991 to December, 2001 (details found in Table 5-21). All subjects had blood Pb and bone Pb measurements with no IHD at enrollment. Fatal and nonfatal cases were combined for analysis. Baseline blood, tibia, and patella Pb levels were log-transformed. Blood Pb level and patella Pb level were associated with increased risk of IHD over the 10-year follow-up period. When blood Pb and patella Pb were included simultaneously in the model, each of their HRs was only moderately attenuated (HR: 1.24 [95% CI: 0.80, 1.93] per SD increase in blood Pb and HR: 2.62 [95% CI: 0.99, 6.93] per SD increase in patella Pb). When blood Pb and tibia Pb were included simultaneously in the model, their risk estimates were only moderately attenuated (HR: 1.38 [95% CI: 0.89, 2.13] per SD

increase in blood Pb and HR: 1.55 [95% CI: 0.44, 5.53] per SD increase in tibia Pb). These findings indicate that both blood and bone Pb levels are independently associated with IHD incidence.

IHD, characterized by reduced blood supply to the heart, may result from increased thrombosis. In support of the epidemiologic evidence, a recent animal study suggested that Pb exposure promotes a procoagulant state that could contribute to thrombus formation (Shin et al., 2007). In a rat model of venous thrombosis, Pb treatment (i.v. 25 mg/kg) resulted in increased thrombus formation, although i.v. Pb treatment may have uncertain relevance to human routes of Pb exposure. Additionally, Pb treatment to human erythrocytes (red blood cells, RBCs) increased coagulation at a dose of 5 µM and thrombin generation in a concentration-dependent manner at doses from 2-5µM. This enhanced procoagulant activity in Pb-treated RBCs was the result of increased outer cell membrane phosphatidylserine (PS) surfacing (human RBCs: 2-5 µM Pb; rat RBCs: 5 µM Pb). Similar to these in vitro results, PS externalization on erythrocytes was increased in Pb-treated rats (i.v. 50-100 mg/kg, not 25 mg/kg). Increased PS externalization was likely the result of increased intracellular calcium (5 µM Pb), enhanced scramblase activity (5-10 µM Pb), inhibited flippase activity (5-10 µM Pb), and ATP depletion (1-5 µM Pb) after Pb exposure (Shin et al., 2007).

Table 5-21 Characteristics and quantitative data for associations of blood and bone Pb with other CVD measures HRV, PAD, and IHD in recent epidemiologic studies.

5.4.3.7 Summary of Vascular Effects and Cardiotoxicity

There are a limited number of studies in a limited number of populations that investigate the associations between Pb biomarkers and cardiovascular effects other than BP or hypertension (Table 5-21). As presented in Table 5-21, these studies demonstrated associations between various biomarkers of Pb exposure and clinical cardiovascular outcomes such as atherosclerosis, IHD, PAD, and HRV occurrence in adult populations after adjusting for potential confounding by variables such as age, sex, education, BMI, smoking, alcohol consumption, and diabetes. In a limited body of studies, mixed evidence of association between occupational exposure to Pb and altered cholesterol was reported.

Few studies have evaluated markers of subclinical atherosclerosis such as PAD and IMT following Pb exposure in humans or animals. Concurrent blood Pb levels (population means >2.5 µg/dL) were associated with greater odds of PAD in adults in NHANES

analyses (Muntner et al., 2005; Navas-Acien et al., 2004). Since these effects are observed in adults that may have had higher past exposure to Pb, there is uncertainty as to the specific Pb exposure level, timing, frequency, and duration that contributed to the observed associations. A recent study involving both human and toxicological studies observed Pb-mediated arterial IMT, an early event in Pb-induced atherogenesis (Zeller et al., 2010). A second study in rats report increased aortic media thickness following Pb exposure (Zhang et al., 2009a). Toxicological studies of Pb-induced endothelial dysfunction, VMSC invasiveness, and inflammation in isolated vascular tissues and cells provide mechanistic evidence to support the biological plausibility of these vascular effects and cardiotoxicity. Studies in isolated tissues and cells found that Pb stimulated the synthesis and secretion of IL-8 in ECs, which was responsible for stimulating VSMC invasion into the vessel intimal layer. Pb treatment also increased extracellular matrix and elastin, primary sites for lipid deposition in the vessel wall.

Several studies report associations between biomarkers of Pb exposure and diseases associated with coronary heart disease (CHD), such as HRV, IHD, and MI. A prospective NAS study reported that higher baseline tibia Pb was associated with increases in QTc interval and QRSc duration over an 8-year follow-up period (Eum et al., 2011). In addition, in the NAS cohort of older adult men, blood Pb ($\geq$ 5 µg/dL) and patella Pb levels were associated with increased incidence of IHD (Jain et al., 2007). A recent study provided evidence for the interaction between biomarkers of Pb exposure and the HFE C282Y and HMOX-1 L variant on the prolonged QT interval in nonoccupationally-exposed older men (Park et al., 2009b). Also, in the NAS population, bone Pb levels were associated with larger decreases in HRV parameters among subjects identified as having metabolic abnormalities (Park et al., 2006). These metabolic abnormalities, abdominal obesity, hypertriglyceridemia, low HDL cholesterol, high BP/medication use, or high fasting glucose, have been shown to be associated with increased risk of cardiovascular events.

Overall, the relatively few available studies provide support for associations between Pb biomarkers and other cardiovascular conditions including subclinical atherosclerosis and CHD. A number of these are quality studies from two cohorts, NAS and NHANES with adequate sample size that account for potential confounding, with some being conducted prospectively.

5.4.4 Cardiovascular Function and Blood Pressure in Children

5.4.4.1 Introduction

The study of cardiovascular function effects in relation to blood Pb levels in children potentially offers unique information on several topics. First, by examining endpoints predictive of future cardiovascular pathology, these studies may offer information on the potential cardiovascular effects of Pb exposure in an understudied population. Second, examination of cardiovascular changes that are antecedent to increased BP and changes in other CVD-related endpoints at later lifestages may inform uncertainties in regards to the time course of cardiovascular changes associated with Pb exposure. Finally, these studies address gaps in knowledge regarding Pb exposure effects in populations of children with mean blood Pb levels in the range of <10 µg/dL.

An important aspect to the literature about the association between cardiovascular effects and blood Pb levels in children is that the blood Pb levels of children may better reflect relatively recent Pb exposure and its effect on CVD than blood Pb levels do in adults because of the much longer exposure history of adults during which Pb exposures were commonly much higher than they are today. However, in older children there is still uncertainty regarding the frequency, duration, timing, and magnitude of exposure contributing to the blood Pb levels measured. The much lower prevalence of cardiovascular effects in children, however, poses a challenge to investigations of potential relationships with Pb exposures. For example, the prevalence of hypertension in children (9 to 10 years old) ranges from to 2 to 5 percent (Daniels, 2011; Steinthorsdottir et al., 2011), while more than half of people aged 60 to 69 years have hypertension (Chobanian et al., 2003). Accordingly, much larger study populations are required to provide similar statistical power for such studies in children as compared to adult studies. Further, in drawing interpretations from such studies with regard to potential effects of Pb exposures at later ages, it is additionally important to recognize that compensatory mechanisms in children may be more active than in adults, and the cardiovascular tissue of the young may be less susceptible to damage than that of adults.

The limited numbers of cardiovascular studies published on children have examined endpoints such as total peripheral resistance (TPR), BP, and autonomic nervous system activation. These recent and earlier studies are presented in Table 5-22. Multiple single pollutant studies in New York State evaluated two child cohorts born in the 1990s after Pb was removed from gasoline in the U.S. with mean blood Pb levels of 4.62 and 1.01 µg/dL (Gump et al., 2011; Gump et al., 2009; Gump et al., 2007; Gump et al., 2005). Zhang et al. (2011a) examined children in Mexico City born from 1994 to 2003, when Pb was being taken out of gasoline in Mexico as indicated by Martinez et al. (2007). The geometric means for cord and concurrent blood Pb levels of the children in the Mexico City cohort were 4.67 and 2.56 µg/dL.

Table 5-22 Studies of child cardiovascular endpoints and Pb biomarkers.

Study (Ordered as they appear in the text)	Study Population/ Methodology	Parameters	Blood Pb Data[a]	Statistical Analysis	Effect Estimates/Results
Gump et al. (2005)	**Prospective** 122 children age 9.5 yr in Oswego, NY (born at a single hospital in New York from 1991-94)	SBP, TPR (total peripheral vascular resistance)	Cord blood Pb: GM (GSD): 2.56 µg/dL (1.16) Childhood (mean age of measurement: 2.6 yr) blood Pb: GM (GSD): 4.06 µg/dL (1.14)	Multivariate linear regression models examined the relationship of blood Pb with change in z-score for outcome (post- and pre-stress). Potential confounders considered: HOME score, SES, birth weight, child BMI, child sex.	Per 1 µg/dL increase in childhood blood Pb level, 0.088 (95% CI: 0.023, 0.153) dyne-s/cm^5 change in TPR Per 1 µg/dL increase in cord blood Pb level, 12.16 (95% CI: 2.44, 21.88) mmHg higher SBP
Gump et al. (2007)	**Prospective** 122 children age 9.5 yr in Oswego, NY	SBP, TPR	Childhood (mean age of measurement: 2.6 yr) blood Pb: GM (GSD): 4.06 µg/dL (1.14)	Linear regression models adjusting for the same covariates as in Gump et al. (2005). Separate models testing whether Pb is a mediator of SES associations,(Sobel test) and whether Pb moderates SES associations (Pb-SES interaction).	Blood Pb was a mediator of the SES-TPR relationship SES alone: -0.62 dyne-s/cm^5 ($p < 0.05$) SES with Blood Pb: -0.40 dyne-s/cm^5 ($p > 0.10$), change in R^2 attributable to SES: -55.3% Blood Pb was a potential moderator of the SES-TPR relationship. Blood Pb × SES interaction: p = 0.07 . Blood Pb was a moderator of SES-SBP relationship Pb × SES interaction: p = 0.007 At blood Pb levels >4 µg/dL, SES not significantly associated with SBP

Study (Ordered as they appear in the text)	Study Population/ Methodology	Parameters	Blood Pb Data[a]	Statistical Analysis	Effect Estimates/Results
Gump et al. (2009)	**Prospective** 122 children age 9.5 yr in Oswego, NY	Salivary cortisol	Cord blood Pb: GM (GSD): 2.56 µg/dL (1.16) Childhood (mean age of measurement: 2.6 yr) blood Pb: GM (GSD): 4.06 µg/dL (1.14)	Linear regression to examine whether blood Pb level mediates or moderates the relationship between SES and salivary cortisol as in Gump et al. (2007)	Blood Pb was a mediator of the SES-cortisol association. SES was no longer significantly associated with cortisol after adjusting for blood Pb level. R^2 for SES decreased by 40, 33, and 50% for cortisol measured at 21, 40, and 60 min. Blood Pb was not a significant moderator of SES-cortisol association. Blood Pb × SES interaction term was not statistically significant
Gump et al. (2011)	**Cross-sectional** 140 children ages 9-11 yr Oswego, NY	SBP, TPR, HRV (heart rate variability) in response to acute stress (mirror tracing task)	Concurrent blood Pb: GM: 1.01 µg/dL Quartiles: Q1: 0.14-0.68 µg/dL Q2: 0.69-0.93 µg/dL Q3: 0.94-1.20 µg/dL Q4: 1.21-3.76 µg/dL	Outcomes were analyzed as continuous variables for the pre-stress values or the change post- and pre-stress. Regression models were adjusted for sex, SES, BMI, and age.	Blood Pb levels associated with autonomic and cardiovascular dysregulation in response to stress –greater vascular resistance, reduced stroke volume, and cardiac output Change in SBP (mmHg) across quartiles: Q1: 5.30, Q2: 7.33, Q3: 7.07, Q4: 7.23, p for trend = 0.31 Change in TPR (%) across quartiles: Q1: 2.91, Q2: 8.18, Q3: 9.55, Q4: 9.51, p for trend = 0.03 Change in Stroke Volume (%) across quartiles: Q1: 2.23, Q2: 0.91, Q3: -3.47, Q4: -0.89, p for trend = 0.04
Zhang et al. (2011a)	**Prospective** 457 mother child pairs in a birth cohort, born 1994 to 2003 in Mexico City. Children were evaluated 2008-2010 at ages 7-15 yr	SBP	Cord blood Pb: GM (GSD): 4.67 µg/dL (1.18) (N=323) Concurrent blood Pb: GM (GSD): 2.56 µg/dL (1.16) (N=367) Maternal post-partum bone Pb: Median (IQR): Tibia Pb: 9.3 (3.3, 16.1) µg/g Patella Pb: 11.6 (4.5, 19.9) µg/g	Multiple regression models and generalized estimating equations (log linear for cord blood, linear for concurrent blood and maternal bone). The base model considered maternal education, birth weight, BMI, sex, and child concurrent age as covariates.	Prenatal Pb exposure may be associated with higher BP in female offspring. Among girls, an IQR (13 µg/g) increase in maternal tibia Pb was associated with a 2.11 (95% CI: 0.69, 3.52) mmHg increase in SBP IQR (16 µg/g) increase in maternal patella Pb was associated with a 0.87 (95% CI: -0.75, 2.49) mmHg increase in SBP IQR (4 µg/dL) increase in cord blood Pb was associated with a 0.75 (95% CI: -1.13, 2.63) mmHg increase in SBP
Factor-Litvak et al. (1999; 1996)	**Cross-sectional** 260 children ages 5.5 years old in K. Mitrovica and Pristina, Yugoslavia	SBP	Concurrent blood Pb range: 4.1 to 76.4 µg/dL	Linear regression analysis. Potential confounders considered: sex, maternal education, birth weight, HOME score, and BMI.	Per 1 µg/dL increase in concurrent blood Pb level, 0.05 (95% CI: -0.02, 0.13) mmHg higher SBP Blood Pb level at birth and cumulative blood Pb level were not as strongly associated with SBP at age 5.5 yr.

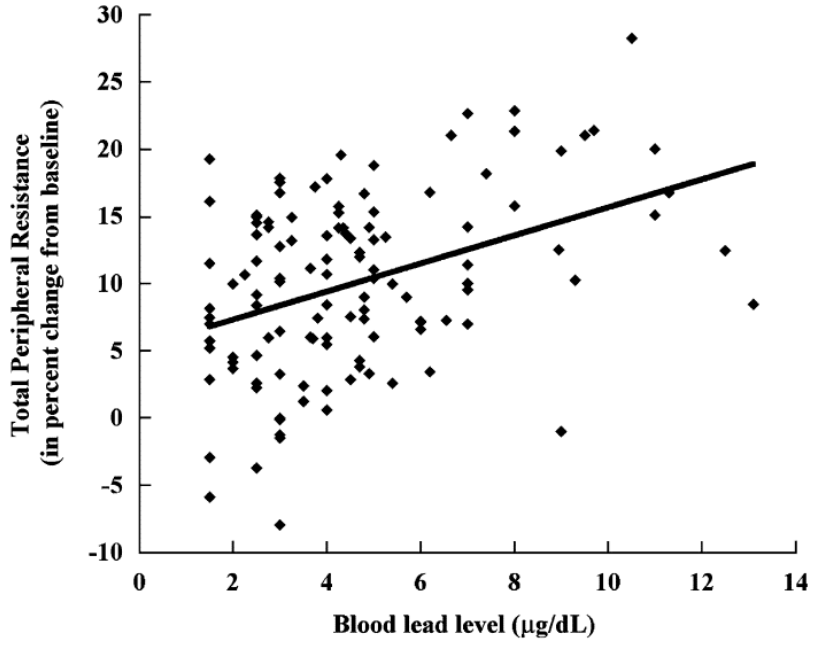
Study (Ordered as they appear in the text)	Study Population/ Methodology	Parameters	Blood Pb Data[a]	Statistical Analysis	Effect Estimates/Results
Gerr et al. (2002)	**Cross-sectional** 508 young adults age 19-29 years, born 1965-1975, male and female; half of the subjects had grown up around an active Pb smelter in Silver Valley, Idaho	BP	While the concurrent mean blood Pb level was 3.15 µg/dL for the highest bone Pb category (>10 µg/g), early childhood mean blood Pb levels in this group were substantially elevated for all bone Pb level categories and were highest among participants in the highest bone Pb level category. The mean blood Pb level was 65 µg/dL among participants with bone Pb level >10 µg/g. Bone Pb was measured at the time of entry into this study.	Multiple linear regression models always included age, sex, height, BMI, current smoking status, frequency of alcohol consumption, current use of birth-control medication, hemoglobin level, serum albumin, and income, regardless of significance levels. Both blood Pb (as a linear term) and bone Pb (a four category ordinal variable from <1 µg/g to >10 µg/g) were tested together.	Group in highest quartile of tibia Pb level (>10 µg/g) had 4.26 (95% CI: 1.36, 7.16) mmHg higher SBP and 2.80 (95% CI: 0.35, 5.25) mmHg higher DBP compared to the lowest tibia Pb group (<1 µg/g).

[a]Blood Pb data are estimates of geometric mean (GM) and geometric standard deviation (GSD) using the arithmetic mean and SD.

5.4.4.2 Cardiovascular Functioning in Children

The relationship between cardiovascular functioning (TPR, BP, stroke volume, and cardiac output,) and blood Pb levels was examined prospectively by Gump et al. (2007; 2005) in a cohort born at a single New York hospital. Higher early childhood Pb levels (average age 2.6 years) were associated with greater TPR response to acute stress induced by mirror tracing on a computer at age 9.5 years as shown in Figure 5-24. Testing blood Pb with linear, quadratic, and cubic terms did not produce significantly different Pb-TPR associations, and the authors suggested that these effects were concentration-dependent and notably, were not emergent at a specific exposure threshold. TPR increased with increasing quartile of blood Pb level. A mediational analysis indicated that Pb was a significant mediator of the SES-TPR reactivity association; some evidence also suggested moderation, whereby the inclusion of blood Pb into the model reduced the effect estimate for SES. Observations that Pb exposure increases TPR in toxicological studies and mechanistic evidence indicating that Pb-induced changes in SNS activity may mediate such effects (Section 5.4.2.3) provides some biological plausibility for a role of Pb in affecting the TPR response to acute stress in this child population. Additionally, higher blood Pb level measured at age 2.6 years was associated with a smaller stroke volume and cardiac output responses to acute stress at age 9.5 years (Gump et al., 2007). In a further analysis in this cohort, Gump et al. (2009) examined the possibility that Pb may mediate an association between SES and cortical responses to acute stress. Elevated

cortisol has been associated with hypertension (Whitworth et al., 2000). Gump et al. (2009) found that lower family income was associated with greater cortisol levels following an acute stress task and that blood Pb was a mediator of this association.



Source: Reprinted with permission of Elsevier (Gump et al., 2005)

Figure 5-24 Children's adjusted total peripheral resistance (dyn-s/cm^5) responses to acute stress tasks, as a function of childhood Pb levels.

In a different cohort of 140 children 9 to 11 years of age recruited from local pediatrician offices and from mailings to homes with children in this age group, Gump et al. (2011) used a similar acute stress-producing paradigm as in previous studies to examine the cross-sectional associations of concurrent blood Pb with cardiovascular responses. TPR significantly increased in a concentration-dependent relationship with blood Pb, with most of the increase occurring between the first quartile blood Pb (0.14-0.68 µg/dL) and the second quartile blood Pb (0.69-0.93 µg/dL). This result is consistent with those of Gump et al. (2005). Also, these newer findings provided evidence of associations with concurrent blood Pb levels and with lower blood Pb levels (Gump et al., 2011) than were previously examined by Gump et al. (2005) and in a large group of children without higher Pb exposures earlier in childhood.

Studies in adults and animals indicate Pb-associated decreases in HRV (Section 5.4.3.4). In Gump et al. (2011), cardiac autonomic regulation decreased in a

concentration-dependent manner with increasing concurrent blood Pb quartile, with the largest change relative to the first quartile (0.14-0.68 µg/dL) measured in the highest blood Pb quartile (1.21-3.76 µg/dL). Also, high frequency HRV, decreased more with acute stress in the highest Pb quartile group (1.21-3.76 µg/dL). In the earlier cohort, early childhood (mean age at collection: 2.6 years) blood Pb level was associated with reduced stroke volume and cardiac output (Gump et al., 2007; Gump et al., 2005). In this recent study, Gump et al. (2011) found the same but for concurrent blood Pb level and at lower blood Pb levels.

5.4.4.3 Blood Pressure in Children

Zhang et al. (2011a) conducted a longitudinal study that examined changes in BP in 323 girls and boys aged 7 to 15 years old in a Mexico City cohort and associations with maternal bone Pb measured one month post-partum (a measure of cumulative exposure that could expose fetuses to Pb through accelerated mobilization of bone Pb during pregnancy) and with cord blood Pb at delivery. This was the first study to examine the association of maternal bone Pb, as a marker of prenatal exposure, with offspring BP. The model including both girls and boys (without adjustment for concurrent blood Pb) showed no statistically significant association overall for any Pb biomarker with child BP. A significant interaction was found between maternal tibia Pb and sex, and in models stratified by sex, maternal tibia Pb was associated with adjusted systolic and diastolic BP in females, but not males. Maternal post-partum median tibia Pb was 9.3 µg/g (IQR: 3.3, 16.1 µg/g) with no significant differences between mothers of male and female offspring. Suboptimal growth in utero is associated with accelerated weight gain in offspring during childhood and greater risk of later hypertension (Barker and Bagby, 2005; te Velde et al., 2004; Barker et al., 1989). The relationship between birth weight and Pb biomarkers is discussed in Section 5.8.3. These may represent biologically plausible mechanisms by which prenatal Pb exposure may result in increased BP later in childhood as was demonstrated in female offspring.

Gump et al. (2011; 2005) examined the relationship of blood Pb level with BP in their two cohorts of contemporary children around age 10 years in New York State. Gump et al. (2005) reported an association of cord blood levels with systolic BP (12.16 mmHg [95% CI: 2.44, 21.88] increase per 1 µg/dL increase in cord blood Pb level). Gump et al. (2011) found that with acute stress, children in higher quartiles of concurrent blood Pb level (>0.69 µg/dL) had larger increases in systolic BP. For example, children with blood Pb levels between 1.21 and 3.76 µg/dL had a 7.23 mmHg change, and children with blood Pb levels between 0.14 and 0.68 µg/dL had a 5.30 mmHg change. A linear trend was not observed across quartiles. An interaction between long-term perceived stress and

bone Pb levels in association with BP and hypertension also was reported in a study of adults (Peters et al., 2007) (described in Section 5.4.2.1). An earlier study (Factor-Litvak et al., 1999; Factor-Litvak et al., 1996) of children with higher blood Pb levels ranging from 4.1 to 76.4 µg/dL found that a 1 µg/dL increase in concurrent blood Pb was associated with a 0.05 (95% CI: -0.02, 0.13) mmHg increase in systolic BP. An additional study (Gerr et al., 2002) reported that systolic BP for young adults (ages 19-29 years) with bone Pb levels greater than 10 µg/g (mean concurrent blood Pb = 65 µg/dL) was 4.26 mmHg higher compared with young adults with bone Pb levels <1 µg/dL compared to young adults with bone Pb levels <1 µg/dL.

The pathogenesis of CVD has been hypothesized to begin in childhood (Kapuku et al., 2006). Early markers observable in youth in association with Pb biomarkers include increased BP during stress, reduced HRV, increased IMT, and vascular endothelium dysfunction. Kapuku et al. (2006) state that endothelial dysfunction is the center of the CVD paradigm. The factors measured in childhood or as a cumulative burden since childhood are predictors of outcomes in young adults who are still too young to experience coronary events (Li et al., 2003), and early-life exposures may induce changes in arteries that contribute to the development of atherosclerosis (Raitakari et al., 2003). Berenson et al. (2002) observed that the effects of multiple risk factors on coronary atherosclerosis support evaluation of cardiovascular risk in young people. Thus, evidence relating levels of biomarkers of Pb exposure in children to cardiovascular function in the groups of studies presented in the preceding text when combined with the evidence for the potential pathogenesis of CVD starting in childhood that yield effects in adulthood, provides coherence with evidence in adults supporting the effects of long-term, cumulative Pb exposures in the development of cardiovascular effects.

Few animal studies have examined the effect of Pb exposure during pregnancy and lactation on BP in offspring as adults and those that have used high levels of exposure. Recently, pups of Pb-exposed dams (1,000 ppm through pregnancy and lactation) exhibited increased blood Pb level (mean blood Pb level: 58.7 µg/dL) and increased arterial systolic BP after weaning (Grizzo and Cordellini, 2008) suggesting a role for childhood Pb exposure leading to adult disease.

5.4.4.4 Summary of Child Cardiovascular Studies

The 2006 Pb AQCD (U.S. EPA, 2006b) described three studies on the effects of Pb on cardiovascular function in children; however, no conclusions were made as to the strength of the evidence. Studies have reported antecedent cardiovascular changes such as TPR responses to acute stress tasks as a function of childhood blood Pb levels. Also, a

study reported associations with acute stress-induced autonomic and cardiovascular dysregulation responses. Biomarkers of prenatal Pb exposure (maternal post-partum patella and tibia Pb levels) were related to later higher BP. Other lines of evidence have linked increased intrauterine growth restriction to later accelerated weight gain in childhood, and this may indicate greater risk of hypertension later in life. The results are not uniform with respect to the important lifestages of Pb exposure and can differ by sex and other factors. Uncertainties in these studies may be related to sample size, single measures of BP, variation in the age of onset of puberty, and cross-sectional design. However, some of these uncertainties may result in the attenuation of observed associations rather than the generation of spurious associations. Overall, recent study findings indicate that in children with mean blood Pb levels in the range of <10 µg/dL, increasing blood Pb level may be associated with small increases in BP and changes in the cardiovascular system that may be related to later development of CVD.

Factors may limit the ability of studies to detect statistically significant Pb-associated changes with BP. The relatively young age of the subjects may have limited the ability of these studies to detect significant BP effects (as opposed to early function effects) if longer duration Pb exposure is necessary to produce the cardiovascular changes considering the lower prevalence and strength of compensatory mechanisms in children. There is uncertainty in the shape of the concentration-response relationship to cardiovascular endpoints at lower blood Pb levels since most studies modeled a linear relationship. A nonlinear concentration-response relationship has been found for Pb with other outcomes in children, most notably, decrements in cognitive function (See Section 5.3.2).

Cardiovascular endpoints other than baseline BP may be more sensitive outcomes for measuring Pb-associated cardiovascular effects in very young children. The series of studies by Gump et al. (2011; 2009; 2007; 2005) evaluating much smaller samples than did the adult studies, was able to demonstrate statistically significant relationships of blood Pb levels with cardiovascular responses such as TPR, related to acute stress. These results suggest that the stress paradigm may be useful to detect associations of blood Pb levels with effects on the cardiovascular system of children. Selection of the appropriate cardiovascular outcome in children is an important factor to consider in the design of future studies. Rather than using indicators of cardiovascular effects, such as BP, evaluation of cardiovascular changes that are antecedent to increased BP and changes in other CVD-related endpoints that present at later lifestages be informative to understanding the time course of cardiovascular changes that may be associated with early Pb exposure.

Overall this small body of evidence, based on different cohorts, locations, and study designs, begins to form a literature base that suggests a relationship between biomarkers of Pb exposure and cardiovascular effects in children. One longitudinal study ties in maternal bone Pb level, and cord and concurrent blood Pb level for the children. Limitations exist in the studies. While blood pressure increases are more prevalent in older adults than in children, BP increases have been related to higher blood Pb level in earlier studies of children and young adults (Gerr et al., 2002; Factor-Litvak et al., 1999; Factor-Litvak et al., 1996). The recent Gump studies of children provide information in populations with mean blood Pb levels in the range of <10 µg/dL for BP and potential antecedents for CVD such as increases in TPR and changes in cardiac autonomic regulation.

5.4.5 Mortality

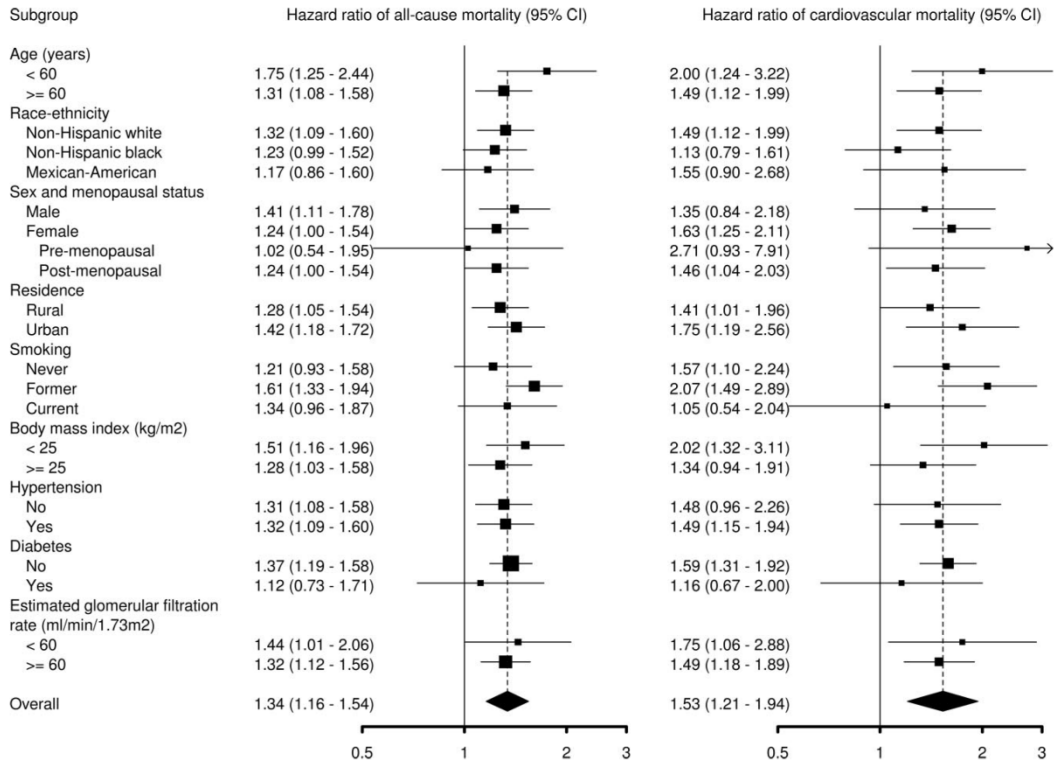
The 2006 Pb AQCD (U.S. EPA, 2006b) stated that available evidence suggested an effect of Pb on cardiovascular mortality in the general U.S. population but cautioned that these findings should be replicated before these estimates for Pb-induced cardiovascular mortality could be used for quantitative risk assessment purposes (U.S. EPA, 2006b). Previous results involved NHANES II and III analyses that examined prospectively the association of adult blood Pb measured at the time of the study with all cause and cause-specific mortality ascertained 8-16 years later (Schober et al., 2006; Lustberg and Silbergeld, 2002). As blood Pb levels in adults reflect contributions from both recent Pb exposure and mobilization of historic Pb from bone, it is unclear to what extent recent, past, or cumulative Pb exposures contributed to the observed associations. Given the decline in ambient air Pb concentrations and population blood Pb levels, it is likely that study subjects had a much higher past Pb exposure compared to exposure during the study period. Using NHANES II (1976-1980) data, Lustberg and Silbergeld (2002) found significant increases in all-cause mortality, circulatory mortality, and cancer mortality, comparing adults with blood Pb levels of 20-29 µg/dL to those with blood Pb levels less than 10 µg/dL (measured 12-16 years before ascertainment of vital status). Using NHANES III data, Schober et al. (2006) found significant increased all-cause, cardiovascular, and cancer mortality comparing adults with blood Pb levels from 5-9 µg/dL and above 10 µg/dL compared to those with blood Pb levels less than 5 µg/dL (measured a median of 8.8 years before ascertainment of vital status).

Several recent studies substantially strengthen the evidence base for Pb-associated mortality. A further analysis of the NHANES III database by a different research group using different methods addressed uncertainties from earlier analyses by considering a greater number of potential confounding factors and by characterizing concentration-

response relationships. Additionally, two longitudinal prospective studies in different U.S. cohorts conducted by different researchers with different methods demonstrate consistency within the evidence base for blood Pb and add new evidence for mortality associated with bone Pb levels.

Menke et al. (2006) examined all-cause and cause-specific mortality using NHANES III data. Subjects at least 18 years of age were followed up to 12 years after their blood Pb was measured, and 1,661 deaths were identified. Those with baseline blood Pb levels from 3.63 to 10 µg/dL had significantly higher risks of all-cause (HR: 1.25 [95% CI: 1.04, 1.51]), cardiovascular (HR: 1.55 [95% CI: 1.08, 2.24]), MI (HR: 1.89 [95% CI: 1.04, 3.43]), and stroke (HR: 2.51 [95% CI: 1.20, 2.26]) mortality compared to those with baseline blood Pb levels less than 1.93 µg/dL and increased risk of cancer mortality (HR: 1.10 [95% CI: 0.82, 1.47]). Effect estimates adjusted for demographic characteristics were robust to the additional adjustment for factors such as smoking, alcohol consumption, diabetes, BMI, hypertension, and level of kidney function. The consistency of HRs across models with a varying number of control variables indicated little residual confounding. Hazard ratios were not higher comparing adults with blood Pb levels from 1.94 to 3.62 µg/dL to those with blood Pb levels <1.93 µg/dL. However, tests for linear trend were statistically significant for all mortality outcomes except for cancer mortality. Menke et al. (2006) evaluated several of the model covariates (e.g., diabetes, hypertension, and glomerular filtration rate [GFR]) in a subgroup analysis. The comparisons for these are shown in Figure 5-25. The authors reported that there were no interactions between blood Pb and other adjusted variables.

The results from Menke et al. (2006) generally were consistent with those from the previous NHANES III analysis of the association of blood Pb with mortality by Schober et al. (2006) that included participants greater than 40 years of age (N = 9686) and adjusted for covariates including age, sex, ethnicity, and smoking rather than the full suite of covariates evaluated by Menke et al. (2006). Schober et al. (2006), which was discussed in the 2006 Pb AQCD (U.S. EPA, 2006b), reported increased HRs comparing adults with blood Pb levels ≥ 10 µg/dL to those with blood Pb levels <5 µg/dL for all-cause (HR: 1.59 [95% CI: 1.28, 1.98]), CVD (HR: 1.55 [95% CI: 1.16, 2.07]), and cancer (HR: 1.69 [95% CI: 1.14, 2.52]) mortality. In general, HRs were higher but nonsignificant, comparing adults with blood Pb levels from 5-9 µg/dL to those with blood Pb levels <5 µg/dL. The median follow-up time between measurement of blood Pb and death ascertainment was 8.55 years.



Note: Hazard ratios were calculated for a 3.4 µg/dL increase in blood Pb level with log-blood Pb as a continuous variable. This increase corresponds to the difference between the 80th and 20th percentiles of the blood Pb distribution (4.92 µg/dL versus 1.46 µg/dL, respectively).

Source: Reprinted with permission of Lippincott Williams & Wilkins, Menke et al. (2006)

Figure 5-25 Multivariate adjusted relative hazards of all-cause and cardiovascular mortality per 3.4 µg/dL increase in blood Pb.

Both Menke et al. (2006) and Schober et al. (2006) presented mortality curves that plot the HRs against blood Pb level. Figure 5-26 shows the mortality hazard ratio curves (not absolute cases of mortality) for both stroke and MI reported by Menke et al. (2006). Nonlinear associations were modeled. The curves were fitted using predetermined restricted quadratic splines with knots at the 10th percentile (1.00 µg/dL), the 50th percentile (2.67 µg/dL), and the 80th percentile (5.98 µg/dL) blood Pb levels. The authors did not explain the shape of the blood Pb-mortality curves in detail; however, the knots corresponded with the inflection points in the curve. In the tails of the blood Pb distribution, hazard ratios decreased with increasing blood Pb level. However, hazard ratios remained above 1 over most of the blood Pb distribution (blood Pb level greater than 2 µg/dL and between 2 and 3 µg/dL for stroke and myocardial infarction, respectively), and in the most heavily populated portion of the blood Pb distribution, hazard ratios increased with increasing blood Pb level. Using a referent group of persons with blood Pb level less than 1.94 µg/dL, the hazard ratio for persons with blood Pb level

greater than 3.63 µg/dL was significant at the 5% level 1.51 (1.07-2.14), but not significant for persons with blood Pb level in the range of 1.94 to 3.62 µg/dL. Hazard ratios peaked for all outcomes at a blood Pb level of approximately 6 µg/dL. Lower concentration-response functions at higher blood Pb levels also have been found for blood Pb-cognitive function relationships in children (Section 5.3.2).

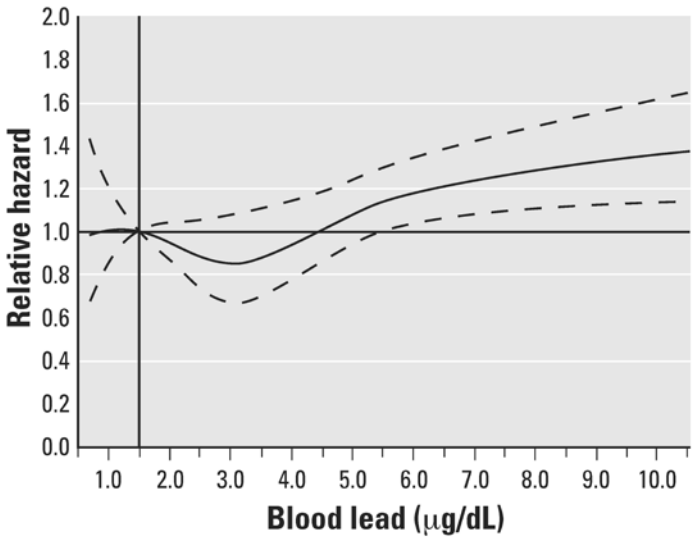
Note: A histogram of blood Pb levels is superimposed in the background and displayed on the right axis.

Figure 5-26 Multivariate-adjusted relative hazard (left axis) of mortality associated with blood Pb levels between 1 µg/dL and 10 µg/dL.

Schober et al. (2006) examined proportional hazard assumptions, tested for a linear trend across blood Pb tertiles, and evaluated log-transformed continuous blood Pb level as a 5-knot cubic spline (position of knots not reported). A statistically significant increasing linear trend for mortality was observed across blood Pb tertiles. The results of the spline fit of the continuous blood Pb level term to relative hazard of all cardiovascular diseases reported by Schober et al. (2006) are shown in Figure 5-27. Schober et al. (2006) shows the upper 95% confidence band (dashed lines) of the relative risk for all cause mortality spline is greater than 1 for all blood Pb levels greater than 1.5 µg/dL using the referent group of persons with blood Pb levels less than 1.5. The hazard ratio was fixed at 1.0 for the referent blood Pb level of 1.5 µg/dL. Also, the lower 95% confidence band is greater

than 1 when the blood Pb levels is greater than about 4.5 µg/dL. Using a referent group of persons with blood Pb levels less than 5 µg/dL, they found statistically significant relative risks of CVD for persons with blood Pb levels in the range of 5 to 9, and those with blood Pb levels greater than 10. In contrast to the curve presented by Menke et al. (2006), Schober et al. (2006) found the relative hazard axis and the blood Pb axis largely to be linear (solid line). Both Menke et al. (2006) and Schober et al. (2006) agree that persons with blood Pb levels greater than 4.5 µg/dL are at increased risk for mortality; however, these studies report different shapes for the concentration-response curves. Despite differences in the age groups included, follow-up time, categorization of blood Pb levels, and differences in hazard ratio across the blood Pb range, results reported by Menke et al. (2006) and Schober et al. (2006) are find associations between higher blood Pb and increased CVD mortality (see Figure 5-30).



Source: Schober et al. (2006)
Note: The solid line shows the fitted five-knot spline relationship; the dashed lines are the point-wise upper and lower 95% CIs.

Figure 5-27 Relative risk of all cause mortality for different blood Pb levels compared with referent level of 1.5 µg/dL (12.5th percentile).

In addition to the NHANES analyses described above, studies of older adult, primarily white, males (Weisskopf et al., 2009) and older adult females (Khalil, 2010; Khalil et al., 2009b) were conducted recently. Weisskopf et al. (2009) used data from the NAS to determine the associations of blood, tibia, and patella Pb with mortality. The authors identified 241 deaths over an average observation period of 8.9 years (7,673 person-years). The strongest associations were observed between mortality and baseline patella

Pb concentration. Baseline tibia Pb levels were more weakly associated with CVD mortality. Tibia bone Pb level is thought to reflect a longer cumulative exposure period than is patella bone Pb level because the residence time of Pb in trabecular bone is shorter than that in cortical bone. IHD contributed most to the relationship between patella Pb and all CVD death with an individual HR of 2.69 (95% CI: 1.42, 5.08). Although there was high correlation between tibia and patella Pb (Pearson r = 0.77), compared with cortical bone Pb, trabecular bone Pb may have more influence on circulating blood Pb level and thus, local organ concentration of Pb because of its shorter residence time in bone. In contrast to the NHANES analyses, the NAS study found that baseline blood Pb was not significantly related to cardiovascular mortality. This discrepancy may be related to differences in sample size and resulting power, modeling strategies (e.g., linear versus log-linear blood Pb level terms), or age range of the study populations. The duration of follow-up was similar across studies. In the Weisskopf et al. (2009) study of NAS data, the youngest subjects at baseline were approximately 50-55 years old, compared to the youngest in the Menke et al. (2006) and Schober et al. (2006) NHANES studies, who were 18 and 40 years, respectively. Further, the blood Pb tertile analysis of Weisskopf et al. (2009) could have been affected if the majority of a hypothesized nonlinear association was contained largely in the lowest (reference) blood Pb tertile.

Weisskopf et al. (2009) also conducted a concentration-response analysis. A linear trend was observed for increasing HR across tertiles of both tibia and patella Pb levels. The linear relationship using tertile patella Pb was confirmed in other models in which continuous patella Pb and nonlinear penalized spline terms (higher order terms) were not statistically significant. The number of knots and their placement within the Pb variable, which can influence these results, were determined by an iterative best fit procedure. Concentration-response relationships shown in Figure 5-28 were approximately linear for patella Pb on the log HR scale for all CVD, but appeared nonlinear for IHD ($p < 0.10$). The peak HR is shown around 60 µg/g, beyond which the HR tends to decrease. It is important to note the wide confidence limits, which increase uncertainty at the lower and upper bounds of patella Pb levels.

Note: The reference logHR = 0 at the mean of patella Pb concentration. The estimates are indicated by the solid line and the 95% pointwise CIs by the dashed lines. The P values for significance of the nonlinear component for all-cause, cardiovascular, and ischemic heart disease mortality were 0.42, 0.80 and 0.10 respectively. Patella Pb concentrations of all individual participants are indicated by short vertical lines on the abscissa. Adjusted for age, education, smoking status, and pack-years of smoking among participants without ischemic heart disease at baseline.

Figure 5-28 Associations between patella bone Pb level and the log of hazard ratio (logHR) for all-cause, cardiovascular, and ischemic heart disease.

The association of adult blood Pb with mortality has also been examined among women enrolled in the Study of Osteoporotic Fractures (SOF) (Khalil et al., 2009b). This prospective cohort (N = 533) enrolled female volunteers (age 65-87 years) from two U.S. locations, Baltimore, MD and Monongahela Valley, PA and followed women for an average of 12 years after blood Pb measurement. All-cause mortality is significantly higher comparing women with blood Pb levels >8 µg/dL to those with blood Pb levels <8 µg/dL (HR: 1.59 [95% CI: 1.02, 2.49]). Hazard ratios for combined cardiovascular disease mortality (HR: 1.78 [95% CI: 0.92, 3.45]), coronary heart disease mortality (HR: 3.08 [95% CI: 1.23, 7.70]), but not stroke mortality (HR: 1.13 [95% CI: 0.34, 3.81]) were higher among the women enrolled in this study with blood Pb levels >8 µg/dL. In addition, analyses of blood Pb tertiles and quintiles indicated that blood Pb-mortality HRs were consistently elevated in groups with blood Pb levels >7 µg/dL (Khalil, 2010). The findings for elevated mortality HRs with the highest blood Pb levels are reinforced by the results displayed in Figure 5-29. The HR curve for all-cause mortality is relatively flat over most of population blood Pb distribution (represented by the blue dots) and increases only in the upper tail of the blood Pb distribution where there are relatively few subjects (i.e., fewer dots).

Other studies also reported Pb-associated increased in mortality but have limited implications due to their weaker analytic methods. Two studies reported standardized mortality ratios (SMR) to compare observed deaths in a Pb-exposed population versus expected deaths, calculated from a reference group (Neuberger et al., 2009; Cocco et al., 2007). Mortality studies that compare populations by calculating SMRs based on an "exposed group" versus the population within which the exposed group resides have several drawbacks, including the ecologic nature of the analysis and the absence of Pb exposure data or biological markers of Pb exposure. Neuberger et al. (2009)carried out a retrospective mortality study of a Superfund site that was highly contaminated with heavy metals, principally Zn, Pb, and Cd. Not knowing the metal concentrations in the population obscures interpretation of the significantly elevated county-state SMRs and the insignificant or significantly lowered SMRs in the county comparison.

A retrospective study of causes of death among Pb smelter workers in Sardinia, Italy followed 933 male production and maintenance workers (Cocco et al., 2007). SMRs for cardiovascular disease-related deaths were calculated based on age-specific and calendar-year specific mortality of the entire region. Significantly reduced mortality was reported in the worker groups. The authors attributed the results to the healthy worker effect based on health criteria applied at hiring and the small size of the cohort. The usual caveats regarding population comparison mortality studies apply.

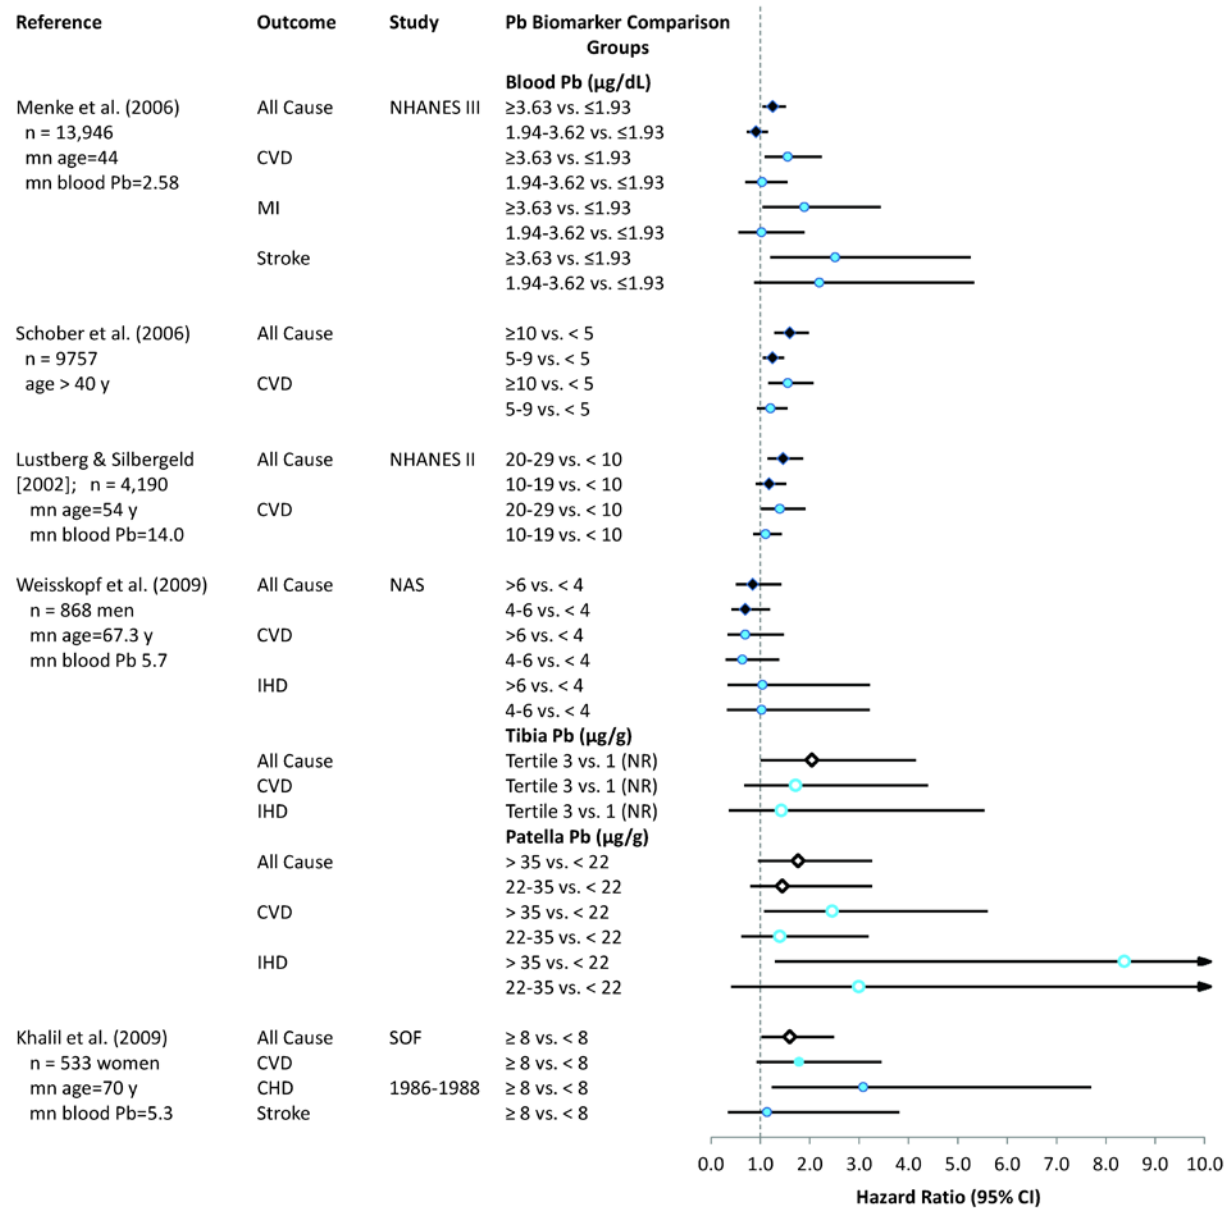
5.4.5.1 Summary of Mortality

The mortality results in this review supported and expanded upon findings from the 2006 Pb AQCD (U.S. EPA, 2006b), which included a few NHANES mortality studies (Schober et al., 2006; Lustberg and Silbergeld, 2002). The recent NHANES mortality study discussed above (Menke et al., 2006) addressed many of the limitations of the earlier studies, including control for a wider range of potential confounders, testing for interactions with Pb, consideration of concentration-response relationships, extensive model evaluations, and examination of mortality from specific CVDs. Further, an association with increased mortality was observed at lower mean population blood Pb levels. The mean blood Pb level of the NHANES III population was 2.58 µg/dL. In the recent analysis, the Pb risk of increased cardiovascular mortality increased with increasing blood Pb level over the most heavily populated portion of the blood Pb

distribution, with maximum blood Pb levels between 6 and 7 µg/dL. It is important to note that the relative contributions of recent, past, and cumulative Pb exposure to associations observed with the baseline blood Pb levels is uncertain. In addition, the first evidence that bone Pb, a metric of cumulative Pb exposure, is associated with increased mortality was reported recently among NAS men (Weisskopf et al., 2009).

Quantitative differences in Pb-associated hazard for death between studies may be influenced by age range of the study groups, follow up time to death, variation in model adjustment, central tendency and range of the Pb biomarker levels, assumptions of linearity in relationship with Pb biomarkers, and choice of Pb biomarker. Quantitative differences in Pb-associated mortality across NHANES II and NHANES III studies or between different NHANES III analyses may be explained by the use of continuous or ordered blood Pb terms and different data selection strategies. Further, studies using ordered categories of blood Pb level may obtain different results, as the range of blood Pb level represented in the reference category will affect the calculated coefficients of the remaining percentiles or groups.

Specifically, Menke et al. (2006) is the strongest study presently published for estimating the effects of Pb on cardiovascular disease-related mortality. The study uses the nationally representative NHANES III (1988-1994) sample of men and women. The results corroborate of earlier published NHANES studies but address some of the key weaknesses noted in those studies. For example, Menke et al. (2006) examined potential confounding by a large number of factors, including hypertension and kidney function. Weisskopf et al. (2009) is the first published mortality study using bone Pb as an exposure index. The study is a prospective study with nearly 100% successful follow-up of deaths. This rigorous study found increased cardiovascular disease mortality in association with patella bone Pb with weaker associations for tibia Pb level. The Khalil et al. (2010; 2009b) study of SOF subjects provides supporting results for a cohort consisting of white females aged 65-87 years. Further, a number of prior studies found associations between accumulated Pb reflected in bone Pb measurements and higher CVD morbidity (Sections 5.4.2.1 and 5.4.3). This evidence base is augmented with new findings indicating that biomarkers of longer-term cumulative Pb exposure increases CVD mortality. The NAS and SOF examine only men and women, respectively. However, the consistency of findings between the two studies indicates that the results of either study may be applicable widely. Despite the differences in design and methods across studies, associations between higher levels of Pb biomarkers and higher risk of mortality were generally observed (Figure 5-30 and Table 5-23). One exception is that stroke mortality was not significantly elevated in the SOF study although it was positive. Mortality from specific CVD causes, MI and IHD mortality, which are related to higher BP and hypertension, were elevated with higher Pb biomarker levels.



Note: Studies are presented in order of strength of study design and follow the order of discussion in the preceding text. Hazard ratios represent the hazard in the higher blood or bone Pb group relative to that in the lowest blood or bone Pb group (reference group).

[a]These references not included in Figure 5-30 because they reported standardized mortality ratios.

5.4.6 Air Pb-PM Studies

5.4.6.1 Cardiovascular Morbidity

A relatively small number of studies used Pb measured in PM_{10} and $PM_{2.5}$ ambient air samples to represent Pb exposures. However, given that size distribution data for Pb-PM are fairly limited, it is difficult to assess the representativeness of these concentrations to population exposure (Section 3.5.3). Moreover, data illustrating the relationships of Pb-PM_{10} and Pb-$PM_{2.5}$ with blood Pb levels are lacking. A few available studies exposed rats, dogs, or humans to concentrated ambient air particles (CAPS) in which Pb and several other components were measured. Consistent with epidemiologic studies of blood and bone Pb and with studies of animals exposed to Pb, these studies show exposure to Pb-containing CAPS resulted in various changes related to increased vasoconstriction (Urch et al., 2004; Wellenius et al., 2003; Batalha et al., 2002). While Pb-containing CAPS indicate cardiovascular effects with short-term exposure (2-6 hours over multiple days), they cannot be attributed specifically to the Pb component of the mixture. It is important to note that Urch et al. (2004) estimated the Pb effect on brachial artery diameter based on the ambient concentration of Pb, not direct exposure to Pb isolated from CAPs.

A U.S. time-series study of almost 3 million pregnant women found that increases in ambient Pb-TSP concentrations were associated with increased odds of pregnancy induced hypertension (PIH) assessed at delivery (Chen et al., 2006c). In contrast, epidemiologic studies provide weak evidence for an association between short-term changes (daily average) in ambient air concentrations of Pb- $PM_{2.5}$ and cardiovascular morbidity in adults adjusting for weather and time trends. Some of these time-series studies analyzed Pb individually, whereas others applied source apportionment techniques to analyze Pb as part of a group of correlated components. In a time-series study of 106 U.S. counties, Bell et al. (2009) found that an increase in lag 0 Pb- $PM_{2.5}$ was associated with an increased risk of cardiovascular hospital admissions among adults ages 65 years and older. Quantitative results were not presented; however, the 95% CI: was wide and included the null value. In this study, statistically significant associations were observed for other PM metal components such as nickel, vanadium, and Zn. In the absence of detailed data on correlations among components or results adjusted for copollutants, it is difficult to exclude confounding by ambient air exposures to these other components or copollutants. To address correlations among PM chemical components, some studies applied source apportionment techniques to group components into common source categories. In these source-factor studies, it is not possible to attribute the observed association (Sarnat et al., 2008) or lack of association (Andersen et al., 2007) specifically to Pb.

5.4.6.2 Mortality

Time-series epidemiologic studies of ambient air Pb- $PM_{2.5}$ reported positive associations with mortality. Although limited in number, these studies indicated associations in multiple cities across the U.S. In the Harvard Six Cities Study, Laden et al. (2000) found a 1.16% (95% CI: 0.20, 2.9%) increased risk in all-cause mortality per 461.4 ng/m^3 (5th-95th percentile) increase in Pb-$PM_{2.5}$. In six California counties, Ostro et al. (2007) found that a 5 ng/m^3 (interquartile range) increase in Pb-$PM_{2.5}$ was associated with a 1.89% (95% CI: -0.57, 4.40%) increased risk of cardiovascular mortality and a 1.74% (95% CI: 0.24, 3.26%) increased risk of all-cause mortality during the cool season. The limitations of air-Pb studies were described in Section 5.4.6.1 above and also are relevant to the interpretation of these findings for mortality.

5.4.7 Summary and Causal Determination

Large bodies of epidemiologic and toxicological evidence indicate effects of Pb exposure on a range of related cardiovascular effects. For evaluation of causal relationships with Pb exposure, evidence was grouped in categories using the U.S. Surgeon General's Report on Smoking as a guideline (CDC, 2004). The categories include hypertension, subclinical atherosclerosis, coronary heart disease, and cerebrovascular disease. The causal determination for hypertension and increased BP is not only informed by evidence for hypertension and blood pressure, but also cardiovascular mortality. Coronary heart disease is informed by evidence for HRV, MI, IHD, mortality from MI, IHD, and CHD, and in animals, increased thrombosis, coagulation, and arrhythmia. The biological plausibility and mode of action for these cardiovascular effects is provided by evidence for oxidative stress, inflammation, vascular cell activation or dysfunction. The sections that follow describe the evaluation of evidence for these four groups of outcomes, hypertension, subclinical atherosclerosis, coronary heart disease, and cerebrovascular disease, with respect to causal relationships with Pb exposure using the framework described in Table II of the Preamble. The key supporting evidence to the causal framework is summarized in Table 5-24.

5.4.7.1 Evidence for Hypertension and Increased Blood Pressure

The 2006 Pb AQCD concluded that there was a relationship between higher blood Pb and bone Pb and cardiovascular effects in adults, in particular increased BP and increased incidence of hypertension (U.S. EPA, 2006b), and recent evidence strengthens this conclusion. This conclusion is informed by the coherence of effects observed between epidemiologic and toxicological findings and among related endpoints. Prospective evidence and animal toxicology studies demonstrate the temporal relationship of the exposure to effect, while meta-analyses provide indications of consistency and strength, and cross-sectional evidence support the consistently observed results. Consideration of numerous potential confounding factors in both the prospective and cross-sectional studies limit uncertainty from bias and other lines of evidence characterizing modes of action provide biological plausibility to the associations.

Longitudinal prospective studies clearly support the relationship between biomarkers of Pb exposure and hypertension incidence and BP changes establishing the directionality of effects. High-quality studies are replicated by different investigators using different designs and in large cohorts in different locations (Peters et al., 2007; Glenn et al., 2006; Cheng et al., 2001). Bone Pb coupled with high perceived stress was associated with an increased risk of developing hypertension in an originally nonhypertensive group of

adults (Peters et al., 2007). Cheng et al. (2001) examined subjects from the NAS cohort without hypertension at baseline measurement and reported a significant increase for hypertension with patella Pb analyzed by linear models. A recent prospective study in Pb workers found independent associations of both baseline blood Pb level and subsequent changes in blood Pb over follow-up with changes in BP over follow-up and bone Pb level with hypertension (Glenn et al., 2006). The results indicated that different mechanisms may mediate short-term Pb-associated increases in BP and long-term Pb-associated development of hypertension. Consideration for key potential confounding factors was appropriate including baseline age, alcohol consumption, BMI, and use of BP lowering medications. Other factors such as smoking and education were evaluated but did not predict systolic BP. When subjects with hypertension were excluded from the model, the predicted change was not altered. Thus, chance, bias, and confounding can be ruled out with reasonable confidence based on the consistent, positive, statistically significant results indicated in these studies. Figure 5-18 and Figure 5-19 and the meta-analysis indicate that results for effects of Pb exposure on BP and hypertension are positive and precise. This provides more confidence in this relationship and reduces the level of uncertainty.

The prospective evidence is supported by meta-analyses that underscore the consistency and reproducibility of Pb-associated increases in BP and hypertension across diverse populations and different study designs (Navas-Acien et al., 2008; Nawrot et al., 2002). Nawrot et al. (2002) found that each doubling of concurrent blood Pb level (between 1 and >40 µg/dL) was associated with a 1 mmHg increase in systolic BP and a 0.6 mmHg increase in diastolic BP. Navas-Acien et al. (2008) found that all included studies showed a relationship between higher bone Pb levels and higher BP. Also, all but one that characterized hypertension showed higher relative risks or odds ratios associated with higher bone Pb levels.

Further support for a causal relationship between blood and bone Pb levels and increased BP and hypertension is provided by many cross-sectional analyses conducted by numerous researchers using different study designs and analyses in large, diverse cohorts in different locations. A recent study in an ethnically diverse community-based cohort of women and men aged 50-70 years found hypertension risk to be associated with blood and tibia Pb levels (Martin et al., 2006). Recent epidemiologic studies in adults found associations with hypertension in populations with relatively low mean blood Pb levels. For example, a positive relationship was found in the nationally representative NHANES III (1988-1994), in which the population geometric mean blood Pb level was 1.64 µg/dL (Muntner et al., 2005). Despite the extensive evidence for associations at relatively low concurrent blood Pb levels, these cardiovascular outcomes were most often examined in adults that have been exposed to higher levels of Pb earlier in life, and uncertainty

remains concerning the Pb exposure level, timing, frequency, and duration contributing to the observed associations. However, evidence presented in the 1990 Pb Supplement to the Addendum (1990a), indicated that in populations aged 20-74 years during 1976-1980 in NHANES II (Schwartz, 1991) across the range of 7-34 µg/dL no evident threshold was found below which the blood Pb level was not significantly related to BP. Further, as described in Section 5.4.1, general population blood Pb levels across those aged 20 to 74 years as indicated by NHANES II and other studies probably peaked in the time frame of 1978-1988 achieving levels that were likely to persist over the long-term ranging from 10 to 30 µg/dL.

Further, recent cross-sectional epidemiologic studies also emphasized the interaction between Pb biomarker levels and factors, such as genetic variants, race/ethnicity, and metabolic syndrome, in modifying the association with BP or hypertension. Evidence was presented for a larger blood Pb-associated increase in BP in carriers of the ALAD2 allele, which is associated with greater binding affinity for Pb in the bloodstream (see Figure 5-18 for results) (Scinicariello et al., 2010). Additionally, bone Pb level was associated with larger increases in PP, which represents a good predictor of cardiovascular morbidity and mortality and an indicator of arterial stiffness, among NAS adults with the HFE H63D and/or C282Y variant (Zhang et al., 2010a) (Figure 5-18 for results). Park et al. (2009b) provided further evidence of HFE and transferrin gene variants, related to iron metabolism, impacting the associations of bone Pb levels with cardiovascular effects, evaluated by QT interval changes in the NAS cohort.

Combined evidence from prospective and cross-sectional studies helps limit the level of uncertainty for bias from confounding with reasonable confidence. While the adjustment for specific factors varied by study, the collective body of evidence adjusted for multiple potential known key confounding factors, including age, diet, sex, BMI, blood pressure lowering medication use, SES, race/ethnicity, alcohol consumption, cholesterol, smoking, pre-existing disease (i.e., diabetes), measures of renal function, and copollutant exposures (i.e., Cd).

Cardiovascular effects of Pb exposure in children are discussed in Section 5.4.4. Overall this body of evidence, based on different cohorts, locations, and study designs provides a preliminary literature base examining the potential for a relationship between biomarkers for Pb exposure and cardiovascular effects in children. Recent studies provide information for BP and antecedents for cardiovascular disease such as increases in TPR and changes in cardiac autonomic regulation.

A causal relationship is further supported by coherence between epidemiologic and toxicological evidence for the effects of long-term exposure on BP. Collectively, all animal toxicological studies providing blood Pb level and BP measurements reported

increases in BP with increasing blood Pb level in the range relevant to humans (Figure 5-21). Whereas the majority of studies examined long-term Pb exposures that resulted in mean blood Pb levels >10 µg/dL, one animal toxicological study found a continuous monotonic increase in BP in animals with a mean blood Pb level from 0.05 to 29 µg/dL with no evidence of a threshold (Tsao et al., 2000). Thus, most evidence demonstrated such effects in adult animals with blood Pb levels >10 µg/dL. Also, recent studies demonstrated only partial reversibility of Pb-induced increased BP following Pb exposure cessation or chelation and the possibility for short-term Pb exposure-induced increases in BP. The short-term effects were found with routes of Pb exposure that may have uncertain relevance to humans.

Coherence for BP and hypertension evidence was also provided by epidemiologic evidence indicating associations with related CV conditions. Studies in the medical literature show that increasing BP, even within the nonhypertensive range, is associated with increased rates of death and cardiovascular disease, including CHD, stroke, and cardiac failure (Ingelsson et al., 2008; Chobanian et al., 2003; Pastor-Barriuso et al., 2003; Prospective Studies Collaboration, 2002; Kannel, 2000a, b; Neaton et al., 1995). Evidence for Pb-induced hypertension and increased BP is supported by, consistently observed associations between Pb biomarkers and both cardiovascular and all-cause mortality in prospective studies with follow-up periods ranging between 8 and 12 years. A recent analysis of the NHANES III sample reported associations of adult blood Pb level with cardiovascular mortality (Menke et al., 2006). These findings were supported by a community-based cohort of women age 65-87 years, in which higher effect estimates were observed for mortality from cardiovascular disease (Khalil et al., 2009b). Weisskopf et al. (2009) published the first mortality study using bone Pb as an exposure index. This prospective study found that patella bone Pb levels were associated with increased mortality from cardiovascular disease.

Animal toxicology studies further indicate coherence and strengthen the evidence for causality by providing strong biological plausibility for Pb-associated increases in BP and hypertension. Hypertension results from dysfunction in the regulation of blood flow and vascular resistance. Many systems, including the central and sympathetic nervous systems, the contractile processes in the vasculature, and various hormonal regulators, contribute to the maintenance of BP and disruption of these systems will alter BP homeostasis. Studies demonstrate that oxidative stress produced following Pb exposure inactivates the vasodilator ˙NO which may lead to increased vasoconstriction and increased BP, leading to hypertension. In addition, oxidative stress can damage the endothelium, further disrupting endothelium-dependent vascular relaxation and increasing the contractile response. Studies also suggest Pb exposure disrupts normal contractile processes by altering the sympathetic nervous system, the renin-angiotensin-

aldosterone system, and the balance between production of vasodilators and vasoconstrictors (Section 5.4.2.3).

Associations between biomarkers of Pb exposure and increased BP and hypertension have been observed in a number of populations, including the large nationally representative NHANES cohort (Menke et al., 2006; Muntner et al., 2005). In addition, associations are found in other cohorts that include both men and women (Martin et al., 2006). Further, the meta-analyses assess cohorts both within the U.S. and international, further supporting the generalizability of the relationship between Pb exposure and increased BP and hypertension.

Changes in BP that have been associated with biomarkers of Pb exposure indicate a modest change for an individual; however, these modest changes can have a substantial public health implication at the population level. The reported effects represent a central tendency of Pb-induced cardiovascular effects among individuals; some individuals may differ in risk and manifest effects that are greater in magnitude. For example, a small increase in BP may shift the population distribution and result in considerable increases in the percentages of individuals with BP values that are clinically significant, i.e., an indication of hypertension and medication use.

Overall, evidence in epidemiologic and toxicological studies demonstrates consistent effects of long-term Pb exposure on increased BP and hypertension in adults; however, uncertainty remains concerning the Pb exposure level, timing, frequency, and duration contributing to the effects. The epidemiologic studies are of high-quality, have been replicated by different researchers in different cohorts, and have adjusted for numerous potential confounding factors. Thus, collectively, they help limit the level of uncertainty for bias from confounding with reasonable confidence. In addition, a biologically plausible potential mode of action is described. Thus, the overall evidence is sufficient to conclude that there is a causal relationship between Pb exposure and hypertension.

5.4.7.2 Evidence for Subclinical Atherosclerosis

Measures of subclinical atherosclerosis provide the opportunity to assess the pathogenesis of vascular disease at an earlier stage. Studies that discuss markers of subclinical atherosclerosis, such as PAD (i.e., ankle-brachial index) and generalized atherosclerosis (i.e., IMT), are included in this category. A limited number of studies have evaluated markers of subclinical atherosclerosis following Pb exposure in adult humans or animals. One study described in the 2006 Pb AQCD (U.S. EPA, 2006b) indicated that Pb was associated with PAD in the NHANES population and coexposure with Cd did not confound the association (Navas-Acien et al., 2004). Recent epidemiologic findings are

limited to cross-sectional analyses, so uncertainty exists as to the specific Pb exposure level, timing, frequency, and duration that contributed to the observed effects. One study reported an increasing trend in the odds of PAD and concurrent blood Pb level in adults within the NHANES population (Muntner et al., 2005), which is consistent with the results from the previous Navas-Acien et al. (2004) analysis. An occupational study of Pb-exposed adults with a mean blood Pb level around 25 µg/dL presented evidence for increased measures of atherosclerosis analyzed by Doppler ultrasound (i.e., greater IMT and atherosclerotic plaque presentation) in the Pb-exposed population (Poreba et al., 2011). Similarly, toxicological studies have provided limited evidence to suggest long-term Pb exposure may initiate atherosclerotic vessel disease. Pb exposure to human radial and internal mammary arteries resulted in a concentration-dependent increase in arterial intimal thickness (Zeller et al., 2010). Also, exposure to Pb in rats increased aortic medial thickness (Zhang et al., 2009a).

Toxicological studies also present evidence to clearly describe a plausible biological mechanism. Atherosclerosis is considered an inflammatory disease with a clear role for oxidative stress in the pathogenesis of the disease. There is consistent evidence that Pb exposure promotes oxidative stress and increased inflammation in animal and cell culture models (Section 5.4.2.3). In addition, there is evidence that Pb will stimulate vascular cell activation and lead to endothelial cell dysfunction. Both events are key to the development and progression of atherosclerosis. Also, epidemiologic and animal toxicology studies have related higher blood Pb levels with higher cholesterol; high cholesterol is one of the principal risk factors for atherosclerosis (Section 5.4.3.3).

In summary, the evidence includes one high-quality epidemiologic study with control for numerous potential confounders (Muntner et al., 2005) and biological plausibility for the effects observed in humans. Thus, the evidence for subclinical atherosclerosis is suggestive of a causal relationship.

5.4.7.3 Evidence for Coronary Heart Disease

Coronary heart disease (CHD) results from interruption of the blood supply to a part of the heart resulting from atherosclerosis of the coronary arteries, with acute injury and scarring leading to permanent damage to the heart muscles. A disrupted HRV has been associated with a higher mortality after MI and is used as a predictor of the physiological processes underlying CHD (Buccelletti et al., 2009). Studies that discuss incidence of MI, IHD, HRV, and mortality from CHD, MI, or IHD are included in this category.

There were a small number of studies discussed in the 2006 Pb AQCD (U.S. EPA, 2006b) that indicated associations between Pb biomarker levels and increased risk of

cardiovascular outcomes associated with CHD. However, recent longitudinal studies in cohorts in different locations with follow-up periods ranging between 8 and 12 years report that biomarkers of Pb exposure are associated with risk of mortality from cardiovascular disease, specifically MI, IHD, or CHD. A recent analysis of the NHANES III sample reported associations of adult blood Pb level with cardiovascular mortality, with stronger associations observed with MI mortality (Menke et al., 2006). These findings were supported by a community-based cohort of women age 65-87 years, in which higher effect estimates were observed for mortality from CHD (Khalil et al., 2009b). Weisskopf et al. (2009) published the first mortality study using bone Pb as an exposure index. This prospective study found that patella bone Pb levels were associated with increased mortality from IHD. Despite the differences in design and methods across studies, with few exceptions associations between higher levels of Pb biomarkers and higher risk of mortality were consistently observed (Figure 5-30 and Table 5-23).

The body of evidence demonstrating associations with mortality from CHD is substantiated by several findings indicating associations between biomarkers of Pb and incidence of CHD-related outcomes. A prospective analysis examined the incidence of IHD (physician confirmed MI, angina pectoris) in the NAS cohort and reported findings indicating that both blood and bone Pb levels contribute independently to IHD incidence (Jain et al., 2007). Earlier studies reported associations of increased Pb biomarkers with increased risk of left ventricular hypertrophy (Schwartz, 1991). Coherence for the associations in humans is provided by a recent animal study that suggested that Pb exposure promotes a procoagulant state that could contribute to thrombus formation which could reduce the blood supply to the heart (Shin et al., 2007).

Further support for a relationship between Pb exposure and CHD is provided by evidence from the NAS cohort for effects on disrupted HRV (Eum et al., 2011; Park et al., 2009b; Park et al., 2006), which has been associated with a higher mortality from MI and is used as a predictor of the physiological processes underlying CHD. A prospective analysis reported that higher tibia Pb, but not blood or patella Pb, was associated with increases in QTc interval and QRSc duration (Eum et al., 2011). Park et al. reported associations of bone Pb with HRV measures and effect modification by increasing number of iron metabolism gene variants from 0 to 3. Park et al. (2006) reported associations of bone Pb with HRV measures and effect modification by increasing number of iron metabolism gene variants from 0 to 3. Park et al. (2006) reported the strongest relationships between patella Pb levels and lower HRV among those with three or more metabolic abnormalities. Also, bone Pb level was associated with larger decreases in HRV among adults with metabolic syndrome, which like reduced HRV is associated with increased risk of cardiovascular events (Park et al., 2006).

As CHD is the result of vascular blockage, the suggestive evidence for subclinical atherosclerosis supports the observations of increased CHD morbidity and mortality. In addition, the strong and consistent evidence for Pb-induced hypertension serves as further biological plausibility for CHD. Hypertension may contribute to CHD development in a number of ways. Hypertension may lead to thickening of the vascular wall or exacerbation of atherosclerotic plaque development and thus contribute to plaque instability. In addition, hypertension may increase the myocardial oxygen demand priming for potential myocardial ischemia (Olafiranye et al., 2011). Both subclinical atherosclerosis and hypertension are supported by consistent evidence describing the mode of action including Pb-induced oxidative stress, inflammation, cellular activation and dysfunction, altered vascular reactivity, RAAS dysfunction, and vasomodulator imbalance.

Building on this strong body of evidence, recent epidemiologic and toxicological studies substantiated the evidence that long-term Pb exposure is associated with CHD in adults; however, uncertainty remains concerning the Pb exposure level, timing, frequency, and duration contributing to the effects. Overall, high-quality studies examining CHD morbidity and mortality and contributing cardiovascular effects have been replicated by different researchers in different cohorts and report consistent associations that increase the confidence that a relationship exists between Pb exposure and CHD. In addition, both animal and human studies describe a biologically plausible potential mode of action. Thus the overall evidence is sufficient to conclude that there is a causal relationship between Pb exposure and coronary heart disease.

5.4.7.4 Evidence for Cerebrovascular Disease

Cerebrovascular disease describes a group of conditions involving the cerebral blood vessels that result in transient or permanent disruption of blood flow to the brain. These conditions include stroke, transient ischemic attack, and subarachnoid hemorrhage. Both hypertension and atherosclerosis are risk factors for cerebrovascular disease and the mechanisms for these outcomes also apply to cerebrovascular disease. Despite strong evidence for hypertension and CHD and long-term Pb exposure, very few studies have examined the effects of Pb exposure on cerebrovascular disease. Lee et al. (2009) examined 153 patients in Taiwan cross-sectionally while adjusting for key confounders and reported increased stenosis greater than 50% in the intracarotid system related to urine Pb but not blood Pb level. Two epidemiologic studies prospectively evaluated mortality from stroke. Menke et al. (2006) reported a positive relationship with wide confidence intervals compared to other outcomes considered for blood Pb levels with stroke mortality in the NHANES study. Khalil et al. (2009b) provides a non significant

result with imprecise confidence intervals. These few studies provide insufficient evidence to inform the causal relationship between cerebrovascular disease and long-term Pb exposure. Thus, the evidence at this time is inadequate to determine that a causal relationship exists between Pb exposure and cerebrovascular disease.

Table 5-24 Summary of evidence supporting cardiovascular causal determinations.

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	References[b]	Pb Exposure or Blood Levels Associated with Effects[c]
Hypertension - Causal			
Consistent associations with relevant blood Pb levels from multiple, high quality epidemiologic studies	Longitudinal prospective evidence for associations with incidence of hypertension and increase in blood pressure in adults. Large body of supportive cross-sectional studies applying differing designs across multiple cohorts of adults in different locations. Meta-analyses provide further support Associations found while adjusting for numerous potential confounding factors Studies provide C-R information	Peters et al. (2007), Glenn et al. (2006), Cheng et al. (2001) Martin et al. (2006), Scinicariello et al. (2010), Park et al. (2009c) Navas-Acien et al. (2008), Nawrot et al. (2002) Section 5.4.2.1	Adult, prospective[d]: Blood Pb level >20 µg/dL; Bone Pb level >20 µg/g Adult, concurrent: Blood Pb level >2 µg/dL; Bone Pb level >19 µg/g
Consistent toxicological results provide coherence with epidemiologic evidence	Consistent cross-sectional evidence for increases in BP in adults are supported by studies in adult rodents with relevant dietary long-term Pb exposure	Rodents: Rizzi et al.(2009), Bravo et al.(2007), Chang et al.(2005), Tsao et al. (2000) Section 5.4.2.2	Rat, adult: Blood Pb level >10 µg/dL
Consistent associations with relevant Pb levels in blood and/or bone and cardiovascular mortality from multiple, high quality epidemiologic studies	Longitudinal, prospective studies find consistent associations of blood and/or bone Pb levels in adults with risk of cardiovascular mortality applying differing designs across multiple cohorts in different locations while controlling for potential confounding.	Khalil et al. (2009b), Weisskopf et al. (2009), Menke et al. (2006) Schober et al. (2006) Lustberg and Silbergeld (2002) Section 5.4.5	Adult, prospective: Blood Pb level >4 µg/dL

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	References[b]	Pb Exposure or Blood Levels Associated with Effects[c]
Evidence clearly describes mode of action			
Oxidative Stress	Consistent evidence of increased oxidative stress leading to inactivation of ˙NO and downregulation of sGC in animals with relevant dietary Pb exposures and cultured vascular cells.		
Alteration of vascular reactivity	Toxicological evidence for activation of the sympathetic nervous system, increased reactivity to catecholamines, and activation of the adrenergic and dopaminergic receptors in rats, isolated vessels, and cultured cells.		
	Mixed evidence for reactivity to other pressor agents (e.g., 5-HT) in rats.	Section 5.4.2.3	
Renin-angiotensin-aldosterone system dysfunction	Toxicological evidence that activation of the RAAS may be involved in development of Pb-induced hypertension		
	Evidence for increased RAAS activity in rats and decreased BP following RAAS inhibition and Pb exposure.		
Vasomodulator imbalance	Limited available toxicological evidence reporting vasomodulator imbalance in Pb-exposed rats and cells.		
Subclinical Atherosclerosis - Suggestive			
Limited evidence in humans of an association with subclinical atherosclerosis and peripheral artery disease	One NHANES analysis reported associations with PAD at relevant adult blood Pb levels with control for potential confounding.	Muntner et al. (2005)	Adult, concurrent: Blood Pb level >2.5 µg/dL
	Limited evidence for increased IMT or arterial stiffness in adult human populations.	Ari et al. (2011)	Adult, concurrent: Serum Pb level >0.4 µg/dL
	Occupational studies report increased IMT and atherosclerotic plaque presentation in highly exposed adult populations.	Poręba et al. (2011; 2011a)	Adult workers: Blood Pb level >24 µg/dL
		Sections 5.4.3.3 and 5.4.3.5	
Limited evidence in animals of initiation or progression of atherosclerosis after Pb exposure	Limited studies reporting increased IMT, vascular morphological changes, and endothelial and SMC alterations in rats and human tissue.	Zeller et al. (2010), Zhang et al. (2009a)	Rat: 28.4 µg/dL Human Tissue: 50 µM
		Section 5.4.3.3	
Evidence clearly describes mode of action			
Oxidative Stress	Consistent evidence of increased oxidative stress in animals with relevant dietary Pb exposures and cultured vascular cells.	Section 5.4.2.3	
Inflammation	Toxicological evidence of increased inflammation as indicated by increased production of TNF-α, IL-6, IL-8, and PGE_2 by macrophages and vascular cells.		
Vascular Cell Activation and Endothelial Dysfunction	Toxicological evidence of VSMC stimulation and endothelial dysfunction and damage in culture.	Section 5.4.3.1	
	Limited available evidence of impaired flow-mediated dilatation in Pb exposed workers.

	One study reporting increased incidence of arrhythmia and atrioventricular conduction block in rats.	Reza et al. (2008) Sections 5.4.3.4 and 5.4.3.6	
Evidence clearly describes mode of action			
Oxidative Stress	Consistent evidence of increased oxidative stress in animals with relevant dietary Pb exposures and cultured vascular cells.	Section 5.4.2.3	
Inflammation	Toxicological evidence of increased inflammation as indicated by increased production of TNF-α, IL-6, IL-8, and PGE_2 by macrophages and vascular cells.	Section 5.4.3.1	
Atherosclerosis	Suggestive evidence of subclinical atherosclerosis in humans and animals with relevant Pb exposure resulting in narrowing of the blood vessels to the heart.	Sections 5.4.3.3 and 5.4.3.5	
Hypertension	Consistent evidence of increased BP and hypertension following Pb exposure in humans and animals at relevant Pb levels across numerous studies with control for confounding. Association of increased blood pressure with manifestation of CHD has been well documented.	Section 5.4.2	
Cerebrovascular Disease - Inadequate			
Evidence for cerebrovascular disease in humans and animals is of insufficient quality and quantity	One study reported an association of intracranial carotid stenosis with urinary Pb level.	Lee et al. (2009) Section 5.4.3.3	Adult, concurrent: Blood Pb level >5 µg/dL

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	References[b]	Pb Exposure or Blood Levels Associated with Effects[c]
Limited evidence for increased mortality from stroke	Limited evidence for increased risk of mortality from stroke across two cohorts in different locations.	Menke et al. (2006), Khalil et al. (2009b) Section 5.4.5	Adult, prospective: Blood Pb level >4 µg/dL
Evidence for possible mode of action			
Hypertension	Consistent evidence of increased BP and hypertension following Pb exposure in humans and animals at relevant Pb levels across numerous studies with control for confounding. Association of increased blood pressure with manifestation of CHD has been well documented.	Section 5.4.2	
Atherosclerosis	Suggestive evidence of subclinical atherosclerosis in humans and animals with relevant Pb exposure resulting in narrowing of the blood vessels to the heart.	Sections 5.4.3.3 and 5.4.3.5	

[a]Described in detail in Table II of the Preamble.

[b]Describes the key evidence and references contributing most heavily to causal determination. Also noted are the sections where full body of evidence is described.

[c]Describes the blood Pb levels in humans with which the evidence is substantiated and blood Pb levels in animals most relevant to humans.

[d]Because blood Pb level in nonoccupationally-exposed adults reflects both recent and past Pb exposures, the magnitude, timing, frequency, and duration of Pb exposure contributing to the observed associations is uncertain.

5.5 Renal Effects

5.5.1 Introduction

This section summarizes key findings with regard to effects of Pb on the kidney in animal toxicology and epidemiologic studies. Findings summarized across epidemiologic and toxicological studies indicate that long-term Pb exposure is associated with pathological changes in the renal system such as proximal tubule (PT) cytomegaly, renal cell apoptosis, mitochondrial dysfunction, aminoaciduria, increased electrolyte excretion, ATPase dysfunction, oxidant redox imbalance, altered glomerular filtration rate (GFR), chronic kidney disease (CKD) development, and altered NO homeostasis with ensuing elevated BP. As several of these outcomes are most often observed in adults with likely higher past Pb exposures, uncertainty exists as to the Pb exposure level, timing, frequency, and duration contributing to the associations observed with blood or bone Pb levels.

The cardiovascular and renal systems are intimately linked. Homeostatic control at the kidney level functions to regulate water and electrolyte balance via filtration, re-absorption and excretion and is under tight hormonal control. Pb exposure has been shown to damage the kidneys and its vasculature with ensuing effects on systemic hypertension and effects on the cardiovascular (Section 5.4) and renal systems. Chronic increases in vascular pressure can contribute to glomerular and renal vasculature injury, which can lead to progressive renal dysfunction and kidney failure. In this manner, Pb-induced hypertension has been regarded as one potential contributor of Pb-induced renal disease. However, the relationship between BP and renal function is more complicated. Not only does hypertension contribute to renal dysfunction but damage to the kidneys can also cause increased BP. Long-term control of arterial pressure is affected by body fluid homeostasis which is regulated by the kidneys. In examination of the physiological definition of BP (i.e., mean BP equates to cardiac output multiplied by total peripheral resistance [TPR]) the role of the kidneys in BP regulation is highlighted. Cardiac output is driven by left ventricular and circulating blood volume. TPR is driven by vasomodulation and electrolyte balance. Thus, it is possible to dissect the causes of hypertension from features of primary kidney disease. Increased extracellular fluid volume results in increased blood volume which enhances venous return of blood to the heart and increases cardiac output. Increased cardiac output not only directly increases BP, but also increases TPR due to a compensatory autoregulation or vessel constriction. In addition, damage to the renal vasculature will alter the intra-renal vascular resistance thereby altering kidney function and affecting the balance between renal function and BP. The interactions between these systems can lead to further exacerbation of vascular and kidney dysfunction following Pb exposure. As kidney dysfunction can increase BP and increased BP can lead to further damage to the kidneys, Pb-induced damage to both systems may result in a cycle of further increased severity of disease.

In general, associations between bone Pb (particularly in the tibia) and health outcomes in adults indicate chronic effects of cumulative Pb exposure. In adults without current occupational Pb exposure, blood Pb level represents both recent and cumulative Pb exposure. In particular, blood Pb level may represent cumulative exposure in physiological circumstances of increased bone remodeling or loss (e.g., osteoporosis and pregnancy) when Pb from bone of adults contributes substantially to blood Pb concentrations. Blood Pb level in children is also influenced by Pb stored in bone due to rapid growth-related bone turnover in children relative to adults. Thus, blood Pb in children is also reflective of cumulative dose. Additional details on the interpretation of Pb in blood and bone are provided in Section 4.3.5. The toxicokinetics of Pb in blood and bone are important considerations in making inferences about etiologically-relevant Pb exposures that contributed to associations observed between blood and bone Pb levels and health outcomes.

5.5.1.1 Kidney Outcome Measures

The primary function of the kidneys is to filter waste from the body while maintaining appropriate levels of water and essential chemicals, such as electrolytes, in the body. Therefore, the gold standard for kidney function assessment involves measurement of the GFR through administration of an exogenous radionuclide or radiocontrast marker (e.g., 125I-iothalamate, iohexol) followed by timed sequential blood samples or, more recently, kidney imaging, to assess clearance through the kidneys. This procedure is invasive and time-consuming. Therefore, serum levels of endogenous compounds are routinely used to estimate GFR in large epidemiologic studies and clinical settings. Creatinine is the most commonly measured endogenous compound; blood urea nitrogen (BUN) has also been examined. Increased serum concentration or decreased kidney clearance of these markers both indicate decreased kidney function. The main limitation of endogenous compounds identified to date is that non-kidney factors impact their serum levels. Specifically, since creatinine is metabolized from creatine in muscle, muscle mass and diet affect serum levels resulting in variation in different population subgroups (e.g., women and children compared to men), that are unrelated to kidney function. Measured creatinine clearance, involving measurement and comparison of creatinine in both serum and urine, can address this problem. However, measured creatinine clearance utilizes timed urine collections, traditionally over a 24-hour period, and the challenge of complete urine collection over an extended time period makes compliance difficult.

Therefore equations to estimate kidney filtration that utilize serum creatinine but also incorporate age, sex, race, and, in some, weight (in an attempt to adjust for differences in muscle mass), have been developed. Although these are imperfect surrogates for muscle mass, such equations are currently the preferred outcome assessment method. Traditionally, the Cockcroft-Gault equation (Cockcroft and Gault, 1976), which estimates creatinine clearance, a GFR surrogate, has been used. In the last decade, the abbreviated Modification of Diet in Kidney Disease (MDRD) Study equation (Levey et al., 2000; Levey et al., 1999), which estimates GFR, has become the standard in the kidney epidemiologic and clinical communities. With widespread use of the MDRD equation, it became clear that the equation underestimates GFR at levels in the normal range. Therefore, the CKD-Epidemiology Collaboration (CKD-EPI) equation was recently developed to be more accurate in this range (Levey et al., 2009). This is a decided advantage in nephrotoxicant research since most participants in occupational and many even in general population studies have GFRs in a range that is underestimated by the MDRD equation.

Both the MDRD and CKD-EPI equations use serum creatinine. Due to the inability to adjust serum creatinine levels for muscle mass, alternative serum biomarkers have been

evaluated such as cystatin C, a cysteine protease inhibitor that is filtered, reabsorbed, and catabolized in the kidney (Fried, 2009). It is produced and secreted by all nucleated cells thus avoiding the muscle mass confounding that exists with serum creatinine (Fried, 2009). However, recent research indicates that serum cystatin C varies by age, sex, and race (Kottgen et al., 2008). Thus, a cystatin C-based eGFR equation was recently developed that includes age, sex, and race (Stevens et al., 2008).

Most of the kidney outcome measures discussed above were developed for use in the clinical setting. Unfortunately, they are insensitive for detection of early kidney damage, as evidenced by the fact that serum creatinine remains normal after kidney donation. Therefore, in the last two decades, the utility of early biological effect (EBE) markers as indicators of preclinical kidney damage has been of interest. These can be categorized as markers of function (i.e., low molecular weight proteins that should be reabsorbed in the PT such as β2-microglobulin and retinol-binding protein [RBP]); biochemical alteration (i.e., urinary eicosanoids such as prostaglandin E2, prostaglandin F2 alpha, 6-keto-prostaglandin F_1 alpha, and thromboxane B2); and cytotoxicity (e.g., N-acetyl-β-D-glucosaminidase [NAG]) (Cardenas et al., 1993). Elevated levels may indicate an increased risk for subsequent kidney dysfunction. However, most of these markers are research tools only, and their prognostic value remains uncertain since prospective studies of most of these markers in nephrotoxicant-exposed populations are quite limited to date. Recently, microalbuminuria has been identified as a PT marker, not just glomerular as previously thought (Comper and Russo, 2009). Kidney EBE markers are a major recent focus for research in patients with acute kidney injury (AKI) and markers such as neutrophil gelatinase-associated lipocalin (NGAL) and kidney injury molecule-1 (Kim-1), developed in AKI research, may prove useful for chronic nephrotoxicant work as well (Ferguson et al., 2008; Devarajan, 2007).

5.5.2 Nephrotoxicity and Renal Pathology

5.5.2.1 Epidemiology in Adults

A number of advances in research on the impact of Pb on the kidney in the 20 years following the 1986 Pb AQCD (U.S. EPA, 1986a) were noted in the 2006 Pb AQCD (U.S. EPA, 2006b). These included research in general and CKD patient populations at much lower blood Pb levels (5-10 µg/dL) at the time of evaluation than were previously studied. These advances contributed to the understanding of the effects of Pb exposure on kidney dysfunction overall in the population. Pb, at much lower doses than those causing chronic Pb nephropathy, may act as a cofactor with other more established kidney risks to

increase the risk of CKD and disease progression in susceptible patients. Maric and Hall (2011) note that data from basic and clinical studies suggest that obesity, hypertension, hyperglycemia, hyperlipedemia, and other elements of the metabolic syndrome are highly interrelated and contribute to the development and progression of diabetic nephropathy and thus represent populations potentially at increased risk for kidney dysfunction.

In the 2006 Pb AQCD (U.S. EPA, 2006b), several key issues could not be completely resolved based on the Pb-kidney literature published to date. These included characterizing the lowest Pb dose at which altered kidney function effects occur, the impact of higher past exposures on associations with concurrent Pb biomarker levels, the impacts of Pb on the kidney in children, the use of paradoxical Pb-kidney associations on risk assessment in the occupational setting, and the impact of co-exposure to other environmental nephrotoxicants, such as Cd. In the intervening five years, relevant data addressing several of these challenges have been published.

General Population Studies

The 2006 Pb AQCD (U.S. EPA, 2006b) reported studies that examined associations between indicators of Pb exposure and kidney function in general populations. This was a new approach to Pb-kidney research in the two decade time period covered by the 2006 Pb AQCD. As illustrated in Figure 5-31 and Table 5-25, studies consistently demonstrate associations between higher blood Pb level and lower renal function in adults. These general population studies provided critical evidence that the effects of Pb on the kidney occur at much lower doses than previously appreciated based on occupational exposure data. However, because blood Pb level in nonoccupationally-exposed adults reflects both recent and past Pb exposures, the magnitude, timing, frequency, and duration of Pb exposure contributing to the observed associations was uncertain. The evidence of Pb-associated renal effects in general population studies was substantiated by results that were adjusted for multiple potential confounding factors including age, race, sex, education, household income, smoking, alcohol use, and various health indicators such as diabetes, SBP, BMI, and history of cardiovascular disease. A few studies also adjusted for Cd exposure.

The landmark Cadmibel Study was the first large environmental study of this type that adjusted for multiple kidney risk factors, including urinary Cd (Staessen et al., 1992). It included 965 men and 1,016 women recruited from Cd exposed and control areas in Belgium. Mean concurrent blood Pb was 11.4 µg/dL (range 2.3-72.5) and 7.5 µg/dL (range 1.7-60.3) in men and women, respectively. After adjustment for covariates (Table 5-25), log transformed blood Pb was negatively associated with measured creatinine clearance. A 10-fold increase in blood Pb was associated with a decrease in creatinine

clearance of 10 and 13 mL/min in men and women, respectively. Blood Pb was also negatively associated with estimated creatinine clearance.

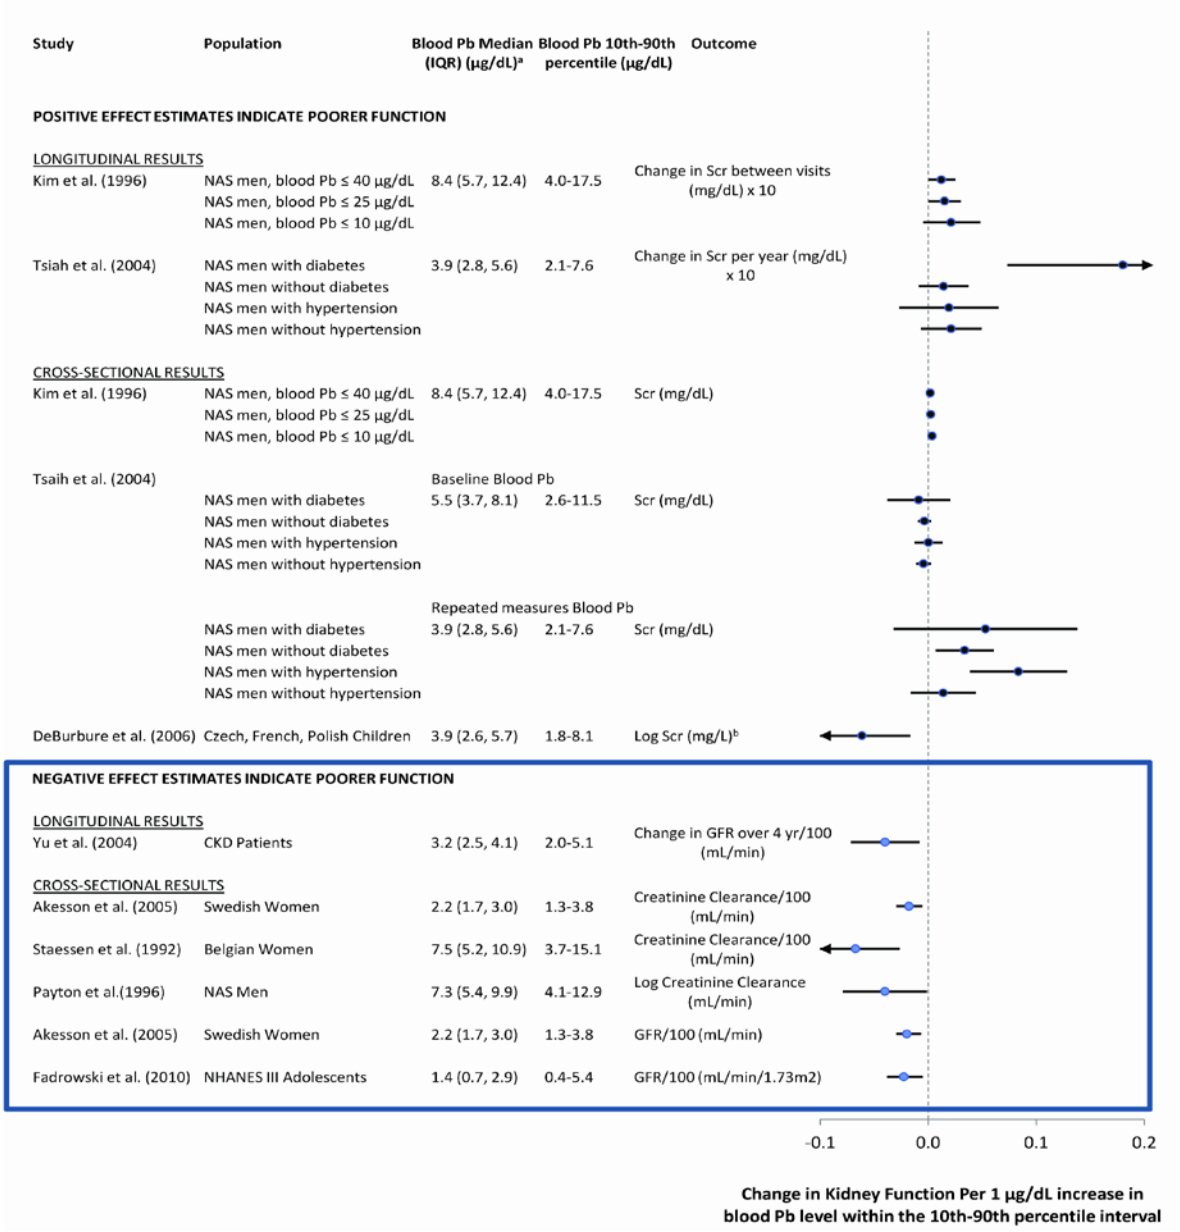
Multiple analyses assessing the kidney impact of Pb exposure have been conducted in the NAS population (Tsaih et al., 2004; Wu et al., 2003a; Kim et al., 1996; Payton et al., 1994). Participants in this study were originally recruited in the 1960s in the Greater Boston area. The inclusion criteria, male sex, age 21 to 80 years, and absence of chronic medical conditions, limit the generalizability of the results to the rest of the U.S. population. Longitudinal data contained in NAS publications remain essential to address the dearth of prospective data on the kidney effects of Pb. The first of these included 459 men whose blood Pb levels from periodic examinations, conducted every 3 to 5 years during 1979-1994, were estimated based on measurements in stored packed red blood cell samples adjusted for hematocrit level (Kim et al., 1996). Participants were randomly selected to be representative of the entire NAS population in terms of age and follow-up. Kidney function was assessed with serum creatinine. Data from four evaluations were available for the majority of participants. At baseline, mean (SD) age, blood Pb level, and serum creatinine, at baseline, were 56.9 (8.3) years, 9.9 (6.1) μg/dL, and 1.2 (0.2) mg/dL, respectively. In the longitudinal analysis with random-effects modeling of repeated measures, ln-transformed blood Pb was associated with an increase in serum creatinine from the previous to current follow-up period in the 428 participants whose highest blood Pb level was ≤ 25 μg/dL (β= 0.027 mg/dL [95% CI: 0.0, 0.054] per unit increase in ln blood Pb); effect estimates in the entire group and subsets with different peak blood Pb levels (≤ 10 or 40 μg/dL) also were positive (and larger for blood Pb levels ≤ 10 μg/dL).

This study made two other key contributions. In order to address the question of whether nephrotoxicity observed at current blood Pb levels is due to higher blood Pb levels from past exposure, these authors performed a sensitivity analysis in participants whose peak blood Pb levels, dating back to 1979, were ≤ 10 μg/dL. A statistically significant positive association between blood Pb and concurrent serum creatinine remained in a cross-sectional analysis. These authors evaluated reverse causality, which attributes increased blood Pb levels to lack of kidney excretion rather than as a causative factor for CKD, by showing in adjusted plots that the association between blood Pb and serum creatinine occurred over the entire serum creatinine range (0.7-2.1 mg/dL), including the normal range where reverse causality would not be expected.

Cortical and trabecular bone Pb measurements were obtained in addition to whole blood Pb in evaluations performed in the NAS between 1991 and 1995. Associations between baseline blood, tibia, and patella Pb and change in serum creatinine over an average of 6 years in 448 men were reported in a subsequent NAS publication (Tsaih et al., 2004). At baseline, eligible participants were similar to nonparticipants with regard to age, BMI,

alcohol consumption, smoking status, diabetic status, hypertensive status, baseline SCr, and blood and bone Pb levels, indicating lack of selective follow-up by blood/bone Pb level or kidney function. At baseline 6 and 26% of subjects had diabetes and hypertension, respectively. Mean blood Pb levels and serum creatinine decreased significantly over the follow-up period in the group. In cross-sectional analyses, both patella and tibia Pb, but not blood Pb level, were positively but nonsignificantly associated with serum creatinine. Baseline blood Pb level was not significantly associated with change in creatinine in all participants. However, diabetes was observed to be an effect modifier of the relations of blood and tibia Pb with change in serum creatinine. Per unit increase in ln blood Pb, the increase in serum creatinine between follow-up periods was substantially stronger in diabetics (β = 0.076 mg/dL [95% CI: 0.031, 0.121]) compared to non-diabetics (β = 0.006 mg/dL [95% CI: -0.004, 0.016]). A similar relationship was observed for tibia Pb. An interaction was also observed between tibia Pb and hypertension, although it is possible that many of the 26 diabetics were also included in the hypertensive group and were influential there as well. A sensitivity analysis was conducted to evaluate the potential for reverse causality by examining participants whose serum creatinine was <1.5 mg/dL; the authors reported that longitudinal associations did not materially change.

In modeling the association between blood Pb level and change in serum creatinine, Tsaih et al. (2004) adjusted for baseline serum creatinine. Glymour et al. (Glymour et al., 2005) discusses how such adjustment may introduce bias. If there is no interaction between Pb exposure and unmeasured causes of kidney disease, the model is linear, and the slope does not change direction prior to and during the study period, the bias should be to underestimate the effect. However, Glymour (2012), noted that the direction of the bias is difficult to predict when the model is nonlinear or the data are restricted to a specific stratum of outcome.



[a]Blood Pb data are presented as median and (IQR) in µg/dL for blood Pb. For uniform presentation, median and IQR were estimated from the given distributional statistics by assuming normal distributions.

[b]The cross product of logged blood Pb and ranked urine Hg was included in the regression to model the interaction between these two variates. The significant hyperfiltrative effect to these children could be due to a biphasic time course sometimes seen in early exposure.

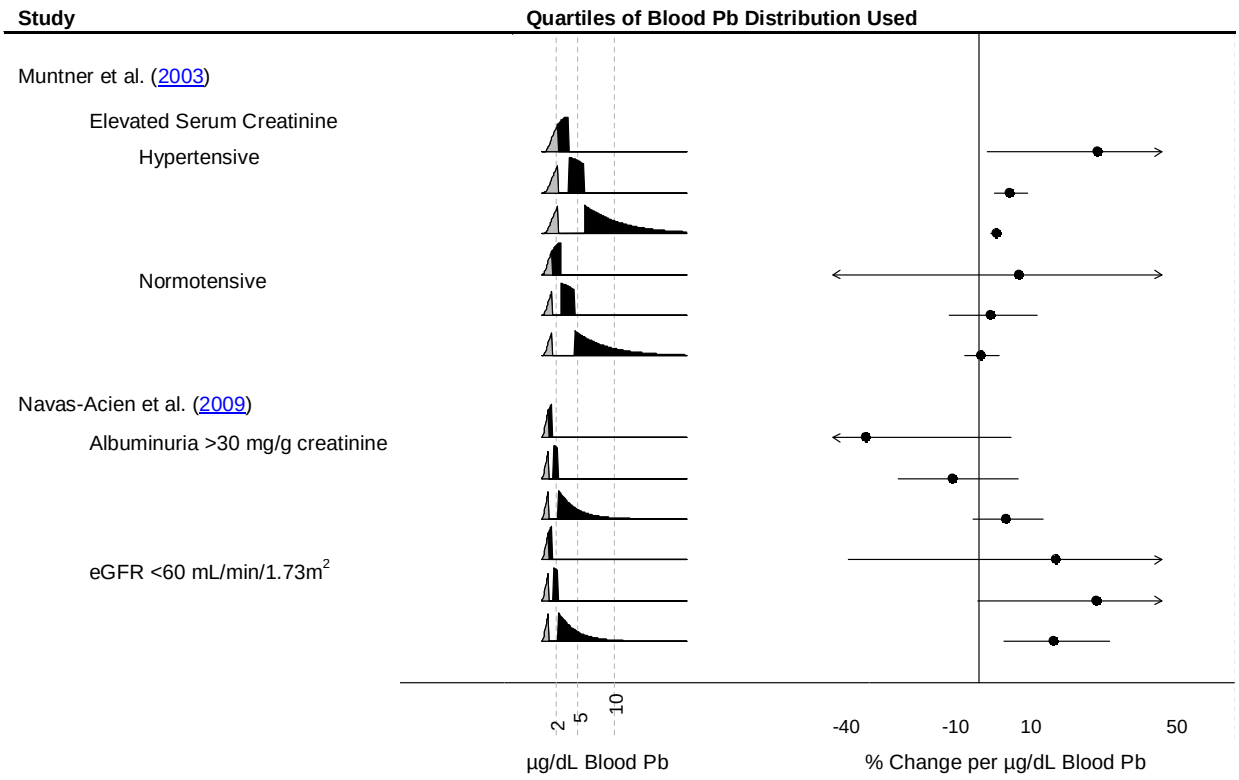
Note: Results are presented first for kidney function tests where an increase is considered impaired function (black circles) then for tests where a decrease is considered impaired function (blue circles, outlined in box). Within a category, results are presented first for longitudinal analyses followed by cross-sectional analyses. To compare results for linear and nonlinear modeling, effect estimates were standardized to a 1 µg/dL increase in blood Pb level within the 10th-90th percentile interval. Magnitudes of the effect should not be compared among different kidney metrics.

Figure 5-31 Concentration-response relationships for associations between blood Pb level or bone Pb level and kidney function outcomes.

The impact of Pb on the kidney has been examined in multiple NHANES datasets obtained over the last few decades (Figure 5-32 and Table 5-25). NHANES data analyses benefit from a number of strengths including large sample size, ability to adjust for numerous potential confounding factors, and the fact that the study population is representative of the U.S. non-institutionalized, civilian population. The results, covering different time frames, have been consistent in providing support for Pb as a CKD risk factor, including NHANES III, conducted from 1988-1994, in which adults with hypertension and diabetes were observed to be potentially at-risk populations (Muntner et al., 2003) and NHANES 1999-2002 (Muntner et al., 2005). However, because the various NHANES analyses were cross-sectional in design, examining associations between concurrent measures of kidney function and blood Pb levels, a common limitation is the uncertainty regarding the temporal sequence between Pb exposure and renal function and the magnitude, timing, frequency, and duration of Pb exposure that contributed to the observed associations.

A recent publication examined NHANES data collected from 1999 through 2006 (Navas-Acien et al., 2009). The geometric mean concurrent blood Pb level was 1.58 μg/dL in 14,778 adults aged ≥ 20 years. After adjustment for survey year, sociodemographic factors, CKD risk factors, and blood Cd, the odds ratios for albuminuria (≥ 30 mg/g creatinine), reduced eGFR (<60 mL/min/1.73 m^2), and both albuminuria and reduced eGFR were 1.19 (95% CI: 0.96, 1.47), 1.56 (95% CI: 1.17, 2.08), and 2.39 (95% CI: 1.31, 4.37), respectively, comparing the highest (>2.4 μg/dL) to the lowest (≤ 1.1 μg/dL) blood Pb quartiles. Thus, in the subset of the population with the most severe kidney disease (both reduced eGFR and albuminuria), the magnitude of association with concurrent blood Pb was greater. When blood Cd was included as a covariate, blood Pb remained significantly associated with renal function. In fact, the most important contribution of this recent NHANES analysis was the evaluation of joint Pb and Cd exposure (discussed in Section 5.5.4.1).

An important contribution of all NHANES publications is that they provide evidence that blood Pb remains associated with reduced kidney function (<60 mL/min/1.73 m^2 as estimated with the MDRD equation cross-sectionally) despite steadily declining blood Pb levels in the U.S. population during the time periods covered. Other studies of adults participating in NHANES have also reported worse kidney function related to blood Pb levels (Lai et al., 2008a; Hernandez-Serrato et al., 2006; Goswami et al., 2005).



Note: These results depicted are from studies that reported ORs of kidney function measures by grouping the population into quartiles of blood Pb and then comparing each group to the quartile with the lowest blood Pb (reference group). The blood Pb distribution of the examined group is shaded black and the reference group is shaded gray. To express these odds ratios in terms of blood Pb concentration, a log normal distribution was fit to the statistics presented and then the medians of each group were determined. The adjusted OR was the exponentiated quantity (log(OR) divided by the difference in the medians of the groups compared). The resulting odds ratio is presented in terms of percent change=100*(OR-1).

Figure 5-32 Percent change in kidney outcomes across quartiles of blood Pb level in NHANES.

Patient Population Studies

CKD as defined by the National Kidney Foundation (NKF) - Kidney Disease Outcomes Quality Initiative workgroup (NKF, 2002) is the presence of markers of kidney damage or GFR <60 mL/min/1.73 m^2 for ≥ 3 months. The MDRD equation is the most common one used in the eGFR determination for this definition. Notably, decreased GFR is not required for the first criterion and markers of kidney damage are not required for the second criterion.

Several key studies in CKD patients provide prospective data that indicate that higher baseline blood Pb level is associated with greater CKD progression over time (kidney function decline) in patient populations (Table 5-26). Yu et al. (2004), discussed in the 2006 Pb AQCD, followed 121 patients over a four year period. Eligibility required well-controlled CKD with serum creatinine between 1.5 and 3.9 mg/dL. Importantly, EDTA-chelatable Pb <600 μg/72 h, a level below that traditionally thought to indicate risk for Pb-related nephrotoxicity, was required at baseline. Patients with potentially unstable kidney disease were excluded (i.e., due to systemic diseases such as diabetes). Mean blood Pb and EDTA-chelatable Pb levels were 4.2 μg/dL and 99.1 μg/72 hours, respectively. Cox proportional hazard modeling indicated lack of significant association between serum creatinine changes and various potential confounding factors (Table 5-25), examined one at a time. Only chelatable Pb (body Pb burden indicator) was significantly associated with overall risk for the primary endpoint (doubling of serum creatinine over the 4-year study period or need for hemodialysis). When the group was dichotomized by EDTA chelatable Pb level, Kaplan-Meier analysis demonstrated that significantly more patients (15/63) in the high-normal group (EDTA chelatable Pb level ≥ 80 but <600 μg/72 hours) reached the primary end point than did those in the lower EDTA chelatable Pb levels (<80 μg Pb/72 hours) group (2/58). Associations between baseline chelatable or blood Pb level and change in serial measurements of eGFR (estimated by the MDRD equation (Levey et al., 1999)) were modeled separately using generalized estimating equations. Based on these models, a 10 μg higher chelatable Pb level or 1 μg/dL higher blood Pb level reduced the GFR by 1.3 and 4.0 mL/min/1.73 m^2, respectively, during the 4-year study period. The use of estimated GFR provides a better estimate of progressive changes of renal function than creatinine clearance used in the other related studies. Recent studies expanded the CKD patient populations in which this effect was observed to include those with diabetic nephropathy (Lin et al., 2006b) and with the lowest blood Pb levels studied to date (Lin et al., 2006a). Results of these observational studies have been summarized in Table 5-26 (Weaver and Jaar, 2010).

Table 5-26 Prospective patient population studies: kidney function decline.

Study	n	Baseline mean (SD) blood Pb (µg/dL)	Baseline mean (SD) chelatable Pb (µg/72 hours)	Baseline mean(SD) eGFR (mL/min /1.73 m^2)	Years of follow-up	Decline in eGFR per 1 SD higher Pb dose at baseline per year	Comments
Lin et al. (2003)	202	5.3 (2.9)	104.5 (106.3)	41.6 (14.4)	2	0.16	Largest study to date
Yu et al. (2004)	121	4.2 (2.2)	99.1 (83.4)	36.0 (9.8)	4	2.7 (chelatable) 2.2 (blood Pb)	Longest follow-up; 1 µg/dL higher blood Pb, at baseline, associated with 4.0 mL/min/1.73 m^2 reduction in eGFR over 4 years
Lin et al. (2006b)	87	6.5 (3.4)	108.5 (53.8)	35.1 (9.0)	1	3.87	Type II diabetics with nephropathy
Lin et al. (2006a)	108	2.9 (1.4)[a]	40.2 (21.2) (all <80)	47.6 (9.8)	2	1.1	Lowest Pb exposed CKD patients

[a]Notably, mean blood Pb level in this study was below that observed in a recent large general population study of 50- to 70-year olds in Baltimore, MD (Martin et al., 2006).

Source: Reprinted with permission of UpToDate.com, Weaver and Jaar (2010)

A recent population-based case-control study examined occupational Pb exposure as a risk factor for severe CKD (Evans et al., 2010). The study included 926 cases with first time elevations of serum creatinine >3.4 mg/dL for men and >2.8 mg/dL for women and 998 population-based controls. Occupational Pb exposure was assessed using an expert rating method based on job histories; no biomarkers of Pb exposure were measured. In multivariable logistic regression modeling, the OR for CKD (adjusted for age, sex, smoking, alcohol consumption, diabetes, education, and BMI) was 0.97 (95% CI: 0.68, 1.38) in Pb-exposed compared to non-exposed participants. In addition, the CKD patients were followed prospectively for a mean of 2.5 years for the 70 Pb-exposed patients and 2.4 years for the 731 patients without past occupational Pb exposure. Mean eGFRs (using the MDRD equation) were 16.0 and 16.6 mL/min/1.73 m^2 in exposed and non-exposed patients, respectively, indicating severe disease in both groups. The results overall did not provide strong evidence that Pb exposure was associated with renal effects. The expert ratings used in this study may have lower validity and reliability as compared to other exposure assessment methods (Teschke et al., 2002) including blood and bone measurements used in the majority of well-conducted studies. Strengths included virtually complete case ascertainment and minimal loss to follow-up. Exposure assessment was listed as both a strength and a limitation. Expert rating methods are commonly used when biological monitoring is not an option and in case-control studies where many occupational exposures are considered. In Pb-kidney research, this approach is uncommon except in the case-control setting. However, given the challenges of

interpreting blood Pb in dialysis patients (discussed below), this approach may have advantages in this study of such severe CKD. Other case-control studies examining occupational risk factors for CKD found Pb exposure to be a risk factor (Nuyts et al., 1995; Steenland et al., 1990). Nuyts et al. (1995) found adults with history of occupational Pb exposure to have elevated odds of CKD (OR for ever- versus never-exposed: 2.11 [95% CI: 1.23, 4.36]). The association was weaker in Steenland et al. (1990) (OR for ever- versus never-exposed: 1.73 [95% CI: 0.82, 3.65]). Regular moonshine consumption, also a potential source of Pb exposure, was a stronger risk factor for CKD (OR: 2.42 [95% CI: 1.10, 5.36]).

The prospective observational aspect of Evans et al. (2010) is similar in design to the work of Lin and colleagues but differs in several important respects. In Evans et al. (2010), only occupational Pb exposure was considered whereas the work in Taiwan excluded occupational exposure and used blood and chelatable Pb measures. In the past in developed countries, environmental exposures were substantial. For example, mean tibia Pb levels were 21.5 and 16.7 μg/g bone mineral, in environmentally-exposed 50- to 70-year-old African-Americans and whites, respectively, in Baltimore (Martin et al., 2006). In Korean Pb workers, mean baseline tibia Pb level was only twofold higher (35.0 μg/g) (Weaver et al., 2003a) which illustrates the substantial body burden in middle- and older-aged Americans from lifetime Pb exposure. Declines in blood Pb levels in Sweden have been reported and attributed to the leaded gasoline phase-out (Strömberg et al., 1995; Elinder et al., 1986), although blood Pb levels were lower than those noted during the U.S. phase-out. Finally, the severe degree of CKD among subjects in Evans et al. (2010) creates a survivor bias at enrollment and limits the eGFR decline possible during follow-up, thus limiting the ability to identify factors that influence that decline.

ESRD Patient Studies

End stage renal disease (ESRD) is a well-established public health concern, and is characterized by the use of dialysis to perform the normal functions of the kidney. Incidence and prevalence in the U.S. continue to increase resulting in rates that are the third highest among nations reporting such data (U.S. Renal Data System, 2009). Studies in patients with CKD requiring chronic hemodialysis have also been published in the past five years. A study of 271 adult patients on regular thrice weekly dialysis reported much higher blood Pb levels than had been appreciated by the treating clinicians (Davenport et al., 2009). Blood Pb levels ranged from 3 to 36.9 μg/dL; 25.5% had levels >20 μg/dL, 59% had values of 10-20 μg/dL, and 15.5% were <10 μg/dL. Few details on the statistical analysis were provided which complicates interpretation of the findings. However, blood Pb was positively correlated with hemodialysis vintage (months on dialysis; Spearman

r = 0.38, p <0.001); negatively correlated with urine output (r = -0.44, p <0.001) and higher in patients using single carbon filter and reverse osmosis water purification devices. Another recent publication reported higher Pb in dialysate than in the tap water used in its preparation (Chen et al., 2009a). A systematic review of a wide range of trace elements in hemodialysis patients reported higher Pb levels in patients compared to controls although the difference was not large (Tonelli et al., 2009). These data suggest that blood Pb monitoring in dialysis patients may be useful.

Interpretation of blood and bone Pb in patients on dialysis is challenging for several reasons. First, renal osteodystrophy, the bone disease related to kidney disease, may result in increased release of Pb from bone stores. Thus, interpretation of blood and even bone Pb levels may require adjustment with one or more of a range of osteoporosis variables. Secondly, as observed above (Davenport et al., 2009), residual kidney function may have a substantial impact on blood Pb levels in populations with such minimal excretion. Third, as illustrated in the studies cited above (Chen et al., 2009a; Davenport et al., 2009), water and concentrates used in dialysis may be variable sources of Pb. A recent study reported decreased blood Pb in post-dialysis compared to pre-dialysis samples (Kazi et al., 2008). Thus, substantial fluctuations in blood Pb are possible while on dialysis. Finally, anemia is common in CKD and Pb is stored in red blood cells. Thus, measurement of blood Pb in anemia may require adjustment for hemoglobin; no standardized approach to this currently exists.

Given these caveats, a small cross-sectional pilot study observed higher median blood Pb levels in 55 African-American dialysis patients compared to 53 age- and sex-matched controls (6 and 3 µg/dL respectively; p <0.001) (Muntner et al., 2007). However, median tibia Pb was higher in ESRD patients although the difference did not reach statistical significance (17 and 13 µg/g bone mineral, respectively [p = 0.13]). Further, the authors note the limitation related to the sample size based on too few cases needed to achieve statistical significance from power calculations.

In order to determine the potential impact of renal osteodystrophy, median blood and tibia Pb levels in the dialysis patients were compared by levels of serum parathyroid hormone, calcium, phosphorus, and albumin and were not found to be significantly different (Ghosh-Narang et al., 2007). A study of 211 diabetic patients on hemodialysis (Lin et al., 2008) found parathyroid hormone and serum creatinine to be associated with blood Pb level in crude but not adjusted associations. In contrast, a study of 315 patients on chronic peritoneal dialysis observed parathyroid hormone to be positively correlated and residual renal function to be negatively correlated with logarithmic-transformed blood Pb levels after adjustment (Lin et al., 2010). In the prospective portion of this study, blood Pb levels at baseline were categorized by tertile (range of 0.1 to 29.9 µg/dL

with cut points of 5.62 and 8.66 μg/dL). Cox multivariate analysis, after adjustment for parathyroid hormone level, residual renal function, and 20 other variables, showed increased all-cause mortality in the middle (5.62-8.66 μg/dL) and highest (>8.66 μg/dL) compared to the lowest (<5.62 μg/dL) tertiles after 18 months of follow-up (hazard ratio= 2.1 [95% CI: 2.0, 2.2] and 3.3 [95% CI: 1.3, 13.5], respectively). A recent publication of an 18-month follow-up of 927 patients on maintenance hemodialysis also reported increased hazard ratios for all-cause (4.7 [95% CI: 1.9, 11.5]), cardiovascular-cause (9.7 [95% CI: 2.1, 23.3]), and infection-cause (5.4 [95% CI: 1.4, 20.8]) 18-month mortality in the highest (>12.64 μg/dL) compared to the lowest tertile (<8.51 μg/dL) of baseline blood Pb level, after adjustment for sex, urban residence, hemodialysis vintage, hemoglobin, serum albumin, and ferritin (Lin et al., 2011). Given other recent publications in hemodialysis patients by this group, it would be valuable to examine these risks after adjustment for hemoglobin A1C (Lin-Tan et al., 2007a), and blood Cd (Yen et al., 2011; Hsu et al., 2009a).

Clinical Trials in Chronic Kidney Disease Patients

Randomized chelation trials in CKD patients, uncommon in nephrotoxicant research, provide unique information on the impact of Pb on the kidney. These studies have been performed by Lin and colleagues at the Chang Gung Memorial Hospital in Taipei, Taiwan and involve similar study designs. Initially, patients were observed to compare CKD progression prior to chelation. Then, CKD patients whose diagnostic EDTA chelatable Pb levels were within certain ranges (generally 60-600 μg/72 hours and thus below the level commonly considered for chelation) were randomized. The treated group received weekly chelation with 1 g EDTA intravenously for up to 3 months. The control group received placebo infusions. In the follow-up period, chelation was repeated for defined indications such as increased serum creatinine or chelatable Pb levels above specified cut-offs. Placebo infusions were repeated in the controls as well. The results of the most recent of these trials are summarized in Table 5-27 below.

Table 5-27 Clinical randomized chelation trials in chronic kidney disease patients.

Reference	Group	n	Baseline mean(SD) blood Pb (μg/dL)	Baseline mean(SD) chelatable Pb (μg/72 hr)	Baseline mean(SD) eGFR (mL/min /1.73 m^2)	Months of treatment / follow-up	Change in eGFR per yr (mL/min /1.73 m^2)	Comments
Lin et al. (2003)	Chelated	32	6.1 (2.5)	150.9 (62.4)	32.0 (12.1)	27	+ 1.07	
	Control	32	5.9 (3.0)	144.5 (87.9)	31.5 (9.0)		- 2.7	
Lin et al. (2006b)	Chelated	15	7.5 (4.6)	148.0 (88.6)	22.4 (4.4)	15	-3.5	Subjects with Type II diabetes and nephropathy
	Control	15	5.9 (2.2)	131.4 (77.4)	26.3 (6.2)		-10.6

	Control	16	3.0 (1.1)	47.1 (15.8)	42.6 (9.7)		-2.0	
Lin-Tan et al. (2007b)	Chelated	58	5.0 (2.2)	164.1 (111.1)	36.8 (12.7)	51	-0.3	Subjects without diabetes
	Control	58	5.1 (2.6)	151.5 (92.6)	36.0 (11.2)		-2.9	

[a]Notably, mean blood Pb level in this study was below that observed in a recent large general population study of 50- to 70-year olds in Baltimore, MD (Martin et al., 2006).

The unique body of work in patient populations by Lin and co-workers, both observational and experimental, has numerous strengths including prospective study design, randomization, Pb assessment that includes estimates of the bioavailable dose, longitudinal statistical analysis, and control for multiple kidney risk factors. However, the generalizability of the results to broader populations is unknown. In addition, the association observed between Pb dose and decline in GFR has been variable; the annual decline in eGFR per standard deviation higher Pb dose at baseline was much lower in the 2003 study than in subsequent publications (Table 5-27 above). Small sample sizes and differences in renal diagnoses between groups may be factors in this variability.

The studies presented in Table 5-26 and Table 5-27 have a number of potential limitations. These include small sample size and lack of blinding and placebo control except for Lin et al. (2003), which attempted to address this potential limitation. Another possible limitation may be the shorter follow-up time in some of the studies. The use of creatinine clearance to assess changes in renal function may limit interpretation of results as discussed in Section 5.5.1.1. Also, the effects observed following chelation therapy

may result from removal of other ions such as Zn, Cu, and Fe. In addition, changes in kidney function after treatment with Pb chelating agents may be by mechanisms other than reduction in Pb body burden. Chelating agents have been shown to act as antioxidants. DMSA abolished reactive oxygen species formation (i.e., MDA and nitrotyrosine in interlobular arteries) and was protective against nonPb-induced nephrosclerosis in rats (Gonick et al., 1996). EDTA administration enhanced endothelial NO production and reduced kidney damage in a rat model of ischemia-induced acute renal failure (Foglieni et al., 2006). Improved renal function following administration of chelating agents have been reported in rodent models of Pb-induced nephrotoxicity (Sanchez-Fructuoso et al., 2002a; Sanchez-Fructuoso et al., 2002b; Khalil-Manesh et al., 1992a). Chelation did not appear to improve Pb-induced structural damage (Khalil-Manesh et al., 1992a); again suggesting that improved hemodynamics may be a result of reduction in reactive oxidant species, which could be due to reduced Pb level and/or directly to the chelating agent (Gonick et al., 1996). Despite these uncertainties and limitations, the most prudent explanation for the combination of the observational and experimental chelation work of Lin and colleagues is that reduced Pb is the underlying reason for improved kidney function. This study design requires replication in larger populations at multiple clinical centers to confirm that the change in renal function may be due to removal of Pb.

Occupational Studies

The vast majority of studies in the literature on the impact of Pb on the kidney have been conducted in the occupational setting. In general, study size and extent of statistical analysis are much more limited than those in general population studies. Publications in few populations have reported adjusted results in occupationally exposed workers in the five years since the 2006 Pb AQCD. In a two-year prospective cohort study, generalized estimating equations were used to model change in kidney function between each evaluation in relation to tibia Pb and concurrent change in blood Pb in 537 current and former Pb workers (Weaver et al., 2009). Tibia Pb was evaluated at the beginning of each follow-up period (yearly on average) and Pb biomarker levels were adjusted for baseline levels and other covariates. In males, serum creatinine decreased and calculated creatinine clearance increased over the course of the study; these changes were largest in participants whose blood Pb declined concurrently or whose tibia Pb was lower at the beginning of the follow-up interval. In females, decreasing serum creatinine was associated with declining blood Pb (as in males); however, increasing blood Pb was associated with a concurrent increase in serum creatinine. Women (25.9% of the study population) were older and more likely to be former Pb workers than were men which may have been important factors in the effect modification observed by sex.

Chia and colleagues observed a significant, positive association between concurrent blood Pb and urine NAG in linear regression models after adjustment for age, sex, race, exposure duration, ALAD G177C polymorphism and the interaction between ALAD genotype and blood Pb (Chia et al., 2006). Similar positive associations were observed between blood Pb and a wider range of EBE markers in models that adjusted for age, sex, race, exposure duration, and the HpyCH4 ALAD polymorphism (Chia et al., 2005). Other studies published in the last 5 years also focused on ALAD polymorphisms but did not find effect modification to be in a consistent direction (Gao et al., 2010a; Wang et al., 2009a; Weaver et al., 2006; Weaver et al., 2005b). In adults with the ALAD2 genotype, Pb has been associated with better and poorer renal function in separate cohorts of Pb workers.

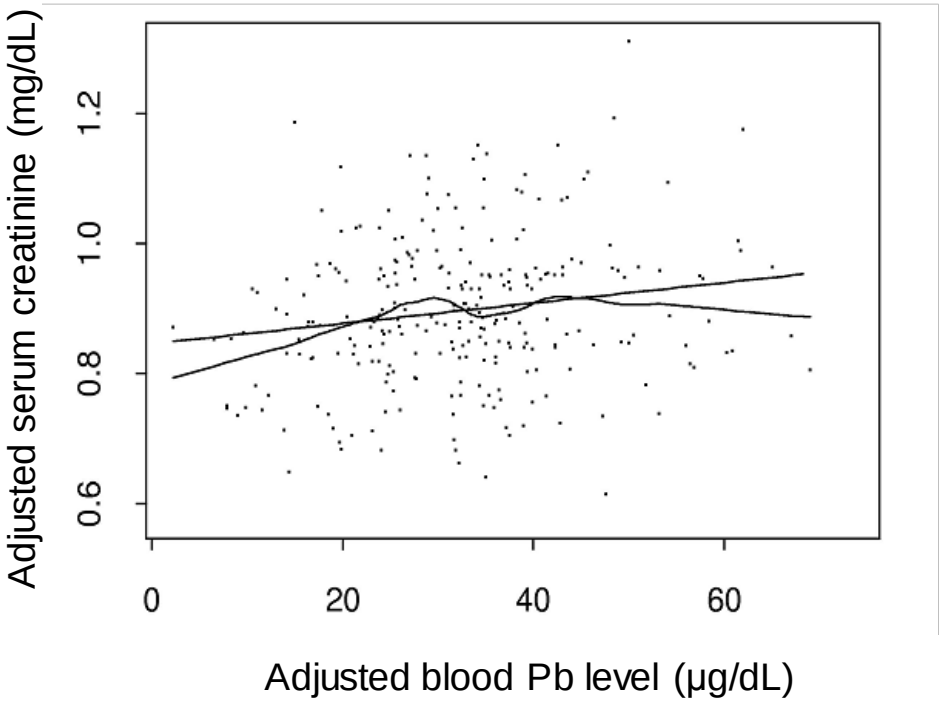
Two studies of occupationally-exposed adults have performed benchmark dose calculations for the effect of Pb on the kidney. Both used only EBE markers and found NAG to be the most sensitive outcome; reported lower confidence limits on the benchmark doses were 10.1 μg/dL (Sun et al., 2008b), and 25.3 μg/dL (Lin and Tai-yi, 2007).

A number of other publications in the five years since the 2006 Pb AQCD, have reported significantly worse kidney outcomes in unadjusted analyses in occupationally-exposed adults compared to unexposed controls (Onuegbu et al., 2011; Patil et al., 2007) and/or significant correlations between higher levels of Pb biomarkers and worse kidney function (Alasia et al., 2010; Khan et al., 2008; Garcon et al., 2007; Lin and Tai-yi, 2007; Alinovi et al., 2005). A study of 155 male workers reported significant, positive correlations between blood and urine Pb and urine NAG and albumin after controlling for age and job duration (Sun et al., 2008b). One small study found no significant differences (Orisakwe et al., 2007). In a study of 108 Pb workers with mean blood Pb level of 36.2 μg/dL, no significant correlations were observed between blood Pb concentration and GFR, creatinine clearance, uric acid clearance or uric acid excretion fraction (Karimooy et al., 2010). However, interpretation of this study is limited by the fact that "only 30 subjects had a correct 24 hours urine volume" and no methods are described for kidney outcome measurement or analysis.

Overall, the occupational literature published in the last five years on the kidney impact of Pb exposure has been more consistent in reporting statistically significant associations than were data reviewed for the 2006 Pb AQCD. This may reflect increased reliance on EBE markers as more sensitive outcome measures, publication bias, or multiple comparisons due to a greater number of outcomes assessed.

In a study of Korean Pb workers, Weaver et al., (2003a) reported inconsistent results with higher Pb measures associated with worse renal function in some models and better renal function in other models. In models of effect modification by age, a pattern emerged in which higher Pb exposure and dose measures were associated with worse renal function in older workers and better renal function in younger workers (Weaver et al., 2003a).

A small number of publications that include concentration-response information provides evidence of Pb-related nephrotoxicity in the occupational setting across the blood Pb ranges analyzed (Weaver et al., 2003a; Ehrlich et al., 1998). Data in 267 Korean Pb workers in the oldest age tertile (mean age = 52 years) did not provide evidence of a threshold for a Pb effect on serum creatinine levels (added variable plot shown in Figure 5-33) (Weaver et al., 2003a). It is important to note the uncertainty regarding whether the concentration-response information provided in these studies applies to lower blood Pb levels or to populations with lower current environmental Pb exposures.



Note: Both the adjusted regression line (straight line) and the line estimated by the smoothing method of the S-PLUS statistical software function lowess (line with curves) are displayed. Both have been adjusted for covariates. For ease of interpretation, axes have been scaled, so that the plotted residuals are centered on the means, rather than zero.

Figure 5-33 Added variable plot of association between serum creatinine and blood Pb in 267 Korean Pb workers in the oldest age tertile.

A major challenge in interpretation of the occupational literature is the potential for Pb-related hyperfiltration. Hyperfiltration involves an initial increase in glomerular hypertension which results in increased GFR. If persistent, the risk for subsequent CKD increases. This pattern has been observed in diabetes, hypertension, and obesity (Nenov et al., 2000). As discussed in the 2006 Pb AQCD (U.S. EPA, 2006b), findings consistent with hyperfiltration have been observed in occupational populations (Weaver et al., 2003a; Hsiao et al., 2001; Roels et al., 1994), a study of adults who were Pb poisoned as children (Hu, 1991), and a study in European children (de Burbure et al., 2006). Longitudinal data in Pb-exposed rodents provide evidence of a hyperfiltration pattern of increased, followed by decreased GFR, associated with Pb exposure and are critical in interpretation of the human Pb-kidney literature (Khalil-Manesh et al., 1992b). Pb could induce glomerular hypertension resulting in hyperfiltration by several mechanisms including increased ROS, changes in eicosanoid levels, and/or an impact on the renin-angiotensin system (Vaziri, 2008b; Roels et al., 1994). Whether hyperfiltration contributes to pathology in humans is unclear; longitudinal studies are needed.

The 2006 Pb AQCD provided several explanations for this inconsistency (U.S. EPA, 2006b) (Chapter 6, pp 99):

> "Some are unique to the occupational literature, such as smaller sample sizes. In addition, employed workers are typically healthier and younger than the general population—resulting in the healthy worker bias. This is a particular problem as susceptible risk groups are identified. Survivor bias in cross-sectional studies is also a concern, since workers whose renal function has declined are generally removed from exposure, particularly if they are followed in a medical surveillance program. Few studies have included former workers. Also, statistical analyses have been more limited in occupational studies. Analyses for some outcomes were limited to comparisons between exposed workers and controls whose Pb levels were in the range associated with adverse renal outcomes in environmental work. Use of multiple linear regression has generally involved more limited adjustment for covariates than in most of the environmental studies. Many of these limitations result in bias towards the null, which increases the risk that true associations may not be detected."

Regardless, significant findings could be obscured if opposite direction associations are present in different segments of the study population and interaction models are not performed to address this. In the Korean Pb workers (Weaver et al., 2003a; Weaver et al., 2003b), significant associations in opposite directions were observed only when relevant effect modifiers such as age or genetic variants in ALAD, VDR, and NOS were included in the model. This is a valid concern for risk assessment, since the factors involved in these inverse associations in Pb-exposed workers are not well defined at present.

5.5.2.2 Epidemiology in Children

Pb Nephrotoxicity in Children

Both the 2006 and 1986 Pb AQCDs noted that the degree of kidney pathology observed in adult survivors of untreated childhood Pb poisoning in the Queensland, Australia epidemic (Inglis et al., 1978) has not been observed in other studies of childhood Pb poisoning. Recent publications remain consistent with that conclusion; a recent study observed an impact of childhood Pb poisoning on IQ but not kidney outcomes (Coria et al., 2009). Chelation was raised as a potential explanation for this discrepancy in the 2006 Pb AQCD.

With declining Pb exposure levels, recent work has focused on studies in children with much lower blood Pb levels. However, insensitivity of the clinical kidney outcome (i.e., GFR) measures for early kidney damage is a particular problem in children who do not have many of the other kidney risk factors that adults do, such as hypertension and diabetes. As a result, such studies have utilized EBE markers. However, data to determine the predictive value of such biomarkers for subsequent kidney function decline in Pb exposed populations are extremely limited (Coratelli et al., 1988) and may pose particular challenges in children due to puberty-related biomarker changes (Sarasua et al., 2003). The few studies included the 2006 Pb AQCD (U.S. EPA, 2006b) that analyzed clinical kidney outcomes in children found associations with indicators of Pb exposure that were inconsistent in direction. Fels et al. (1998) found no difference in mean serum creatinine between 62 children living near Pb-producing factories and 50 control children living in communities without Pb emission sources. In a study of 200 Belgian adolescents aged 17 years, higher concurrent blood Pb level was associated with higher serum cystatin-C (de Burbure et al., 2006); however, among 300-600 European children (n varied by outcome), higher concurrent blood Pb level was associated with lower serum creatinine and cystatin C (Staessen et al., 2001).

Recent studies of children with elevated Pb exposure did not consistently indicate that Pb exposure was associated with reduced kidney function. A study in 123 children of workers in Pakistani Pb smelters and battery recycling plants and 123 control children, ages 1-6 years, reported elevated blood Pb levels, serum creatinine and urea in children of Pb-exposed workers compared to controls (medians: 8.1 versus 6.7 µg/dL; 56 versus 52 µM; and 4,500 versus 4,300 µM, respectively ($p \leq 0.01$ for all) in unadjusted analyses (Khan et al., 2010a). Blood Pb levels were correlated with serum creatinine (Spearman $r = 0.13$; $p = 0.05$). However, a study of 77 participants, ages 10-25 years, who were previously Pb poisoned through contaminated flour and chelated, reported no difference in renal effects between children with blood Pb levels >48 µg/dL and <43 µg/dL although

lower IQ was observed in the subset who were exposed before the age of six years (Coria et al., 2009).

One of the key gaps identified in the 2006 Pb AQCD (U.S. EPA, 2006b) was limited data in children and adolescents particularly with respect to GFR measures and in populations without the elevated Pb exposure associated with Pb poisoning, living near a Pb source, or having parents with occupational Pb exposures. A recently published NHANES analysis in adolescents begins to fill this gap (Fadrowski et al., 2010). Associations between concurrent blood Pb and kidney function were investigated in 769 adolescents aged 12-20 years in the U.S. NHANES III, conducted 1988-1994. Kidney function was assessed with two eGFR equations. One utilized serum cystatin C and the other used the more traditional marker, serum creatinine. Median concurrent blood Pb and cystatin C-based eGFR levels were 1.5 μg/dL and 112.9 mL/min/1.73 m^2, respectively. Cystatin C-based eGFR was lower (-6.6 mL/min/1.73 m^2 [95% CI: -0.7, -12.6]) in participants with blood Pb levels in the highest quartile (≥ 3.0 μg/dL) compared with those in the lowest (<1 μg/dL). A doubling of blood Pb level was associated with a -2.9 mL/min/1.73 m^2 (95% CI: -0.7, -5.0) lower eGFR. In contrast, the association between blood Pb and creatinine-based eGFR, although in the same direction, was not statistically significant. As these children were born between 1968 and 1982, some likely had higher Pb exposures in earlier childhood, although notably, not as high or as long in duration as did older adults examined in aforementioned studies. Nonetheless, in this study of NHANES adolescents, there also is uncertainty regarding the magnitude, timing, frequency, and duration of Pb exposure that contributed to the observed associations. Additional research in children is warranted, in particular studies with longitudinal follow-up, multiple outcome assessment methods, and examination of children born after Pb was banned from gasoline.

5.5.2.3 Associations between Pb Dose and New Kidney Outcome Measures

As noted above, in an effort to more accurately estimate kidney outcomes, new equations to estimate GFR based on serum creatinine have been developed, and the utility of other biomarkers, such as cystatin C, as well as equations based on them, are being studied. However, few publications have utilized these state-of-the-art techniques when evaluating associations between Pb or Cd dose and renal function. In addition to the study in NHANES adolescents discussed above (Fadrowski et al., 2010), a cross-sectional study of Swedish women reported that higher concurrent blood Pb (median: 2.2 μg/dL) and Cd (median: 0.38 μg/L) levels were associated with lower eGFR based on serum cystatin C alone (without age, sex, and race) after adjustment for socio-

demographic and CKD risk factors (Akesson et al., 2005). Associations were comparable to those using creatinine clearance as the kidney outcome for Pb; however associations of Cd dose measures were stronger for the cystatin C based outcome. Staessen et al. (2001) found a statistically significant association between concurrent blood Pb level and serum cystatin C in a cross-sectional study of adolescents; creatinine-based measures were not reported. However, in a cross-sectional study of 804 European children aged range 8.5 to 12.3 years, higher concurrent blood Pb levels were associated with lower serum cystatin C and creatinine; these inverse associations were attributed to hyperfiltration (de Burbure et al., 2006). A recent publication compared associations of blood Pb and eGFR using the traditional MDRD equation to those with four new equations: CKD-EPI, and cystatin C single variable, multivariable, and combined creatinine/cystatin C, in 3,941 adults who participated in the 1999-2002 NHANES cystatin C subsample (Spector et al., 2011). Similar to the NHANES adolescent analysis, associations with the cystatin C outcomes were stronger. After multivariable adjustment, differences in mean eGFR for a doubling blood Pb were -1.9 (95% CI: -3.2, -0.7), -1.7 (95% CI: -3.0, -0.5), and -1.4 (95% CI: -2.3, -0.5) mL/min/1.73 m^2, using the cystatin C single variable, multivariable and combined creatinine/cystatin C equations, respectively, reflecting lower eGFR with increased blood Pb. The corresponding differences were -0.9 (95% CI: -1.9, 0.02) and -0.9 (95% CI: -1.8, 0.01) using the creatinine-based CKD-EPI and MDRD equations, respectively.

5.5.2.4 Reverse Causality

The reverse causality hypothesis suggests that the associations between blood Pb and kidney function may be due to reduced excretion of Pb rather than a causal association between Pb exposure and this outcome. Cross-sectional studies of populations that include participants with CKD frequently note the potential for their findings to be explained by reverse causality as a limitation of the study (Muntner et al., 2003). There are several techniques that can be used to assess the potential for reverse causality to underlie associations between higher Pb dose and worse kidney function. Prospective studies in which associations between baseline measurements of Pb biomarkers and subsequent changes in renal function are demonstrated provide the strongest evidence to evaluate the possibility of reverse causality. In the NAS, baseline blood Pb levels were associated with subsequent declines in renal function over follow-up periods ranging from 3 to 6 years (Tsaih et al., 2004; Kim et al., 1996). Prospective data in CKD patients also revealed an association between baseline Pb dose and decline in eGFR over follow-up periods as long as four years (Yu et al., 2004). Another approach involves sensitivity analyses in which associations are explored in participants with normal glomerular filtration. This approach has been used in the NAS with plots which revealed that the

association between blood Pb level and serum creatinine was present across the entire range of serum creatinine levels, including those in the normal range where excretion is not impaired (Tsaih et al., 2004; Kim et al., 1996). Analyses restricted to the population with serum creatinine below 1.5 mg/dL were conducted in a later publication; the authors reported that associations were consistent (Tsaih et al., 2004). The use of a serum creatinine rather than an eGFR cut-off is a limitation since there can be substantial decrements in renal function with 'normal' serum creatinine. The associations observed in both NAS studies were not limited to the segment of the population with potentially clinically significant renal dysfunction in whom reduced Pb excretion would be more likely.

Research in which EDTA chelation decreases body Pb burden and improves kidney function also provides evidence informing the possibility of reverse causality but is not without limitation because EDTA may independently improve kidney function (Lin et al., 2006b; Lin et al., 2006a; Lin et al., 2003). Additional evidence evaluating reverse causality was provided by findings among 153 adults with chronic kidney disease, in which renal failure was not associated with increases in blood or bone Pb levels or chelatable Pb levels (Van de Vyver et al., 1988). Batuman et al. (1983) found that chelatable Pb levels were similar in 27 adults with renal disease of unknown and known non Pb-related causes where bone Pb levels (group means: 18 and 19 µg/g) are in the range of those measured in recent epidemiologic studies. A pilot study of 55 ESRD cases at Tulane clinics (Muntner et al., 2007) reported the median blood Pb level was significantly higher among the ESRD cases compared to their control counterparts. For ESRD patients the distribution of blood Pb was shown by pre-defined levels: 18.5% less than 5 µg/dl; 66.7% of ESRD cases had blood Pb levels between 5 and 9.9 µg/dL; and 14.8% equal or greater 10 µg/dL.

The reverse causality hypothesis can be broadened to include a physiologic process in which Pb levels are influenced over the entire range of kidney filtration rates. If this occurs, even normal kidney function would impact blood Pb levels such that higher GFR would result in greater Pb excretion and lower blood Pb levels. Serum creatinine levels are influenced in this way over the entire range of kidney function; as a result, these levels are used to estimate kidney function. However, creatinine is produced and excreted at a steady state in the body which is one reason it was selected as a biomarker to assess kidney function. This expanded hypothesis implies that low blood and bone Pb levels may reflect kidney function in addition to exposure. If so, this would increase misclassification bias, with Pb biomarkers reflecting both exposure and kidney function. Given the longstanding use of blood Pb as a dose marker in research for many non-kidney outcomes this seems unlikely. Thus, published research has not directly addressed this. One such approach involves comparing associations of blood and urine Pb in models

of kidney function. If they are consistent, this hypothesis is not valid. However, urine Pb is rarely used and may not be as reliable a biomarker as blood Pb (Gulson et al., 1998c).

In summary, several lines of evidence support that reverse causality does not contribute substantially to associations between higher blood Pb levels and worse kidney function. These lines of evidence include prospective data observing that baseline Pb measures are associated with subsequent declines in renal function, that associations in prospective studies persist among adults with normal renal function, that renal failure does not increase Pb biomarker levels and that reduction of Pb levels by chelation improves kidney function. However, this bidirectional relationship is still possible and additional research is needed to fully exclude the hypothesis. In particular prospective data are required as is research to determine if normal kidney function influences blood Pb levels.

5.5.2.5 Toxicology

In animals, Pb has been found to induce changes in a wide range of indicators of renal function. Most studies examined Pb exposure concentrations that resulted in higher blood Pb levels (>20 µg/dL) than those in the current U.S. general population. While toxicological information on renal dysfunction with blood Pb levels <10 µg/dL generally is not available, dysfunction in kidney function measures, including urinary flow, ALP, microalbumin, and NAG, was observed at blood Pb levels above 20 µg/dL.

Table 5-28 Animal toxicological studies reporting the effects of Pb exposure (as blood Pb level) on kidney function.

Reference	Species; Lifestage; Sex	Pb Dose; Exposure Duration	Blood Pb Level with Response (µg/dL)	Responses
Berrahal et al. (2011)	Rat; Adult	50 ppm Pb acetate in drinking water; lactation day 1 to PND40 or PND65	PND40: 12.7 PND65: 7.5	Oxidative stress – Increased renal MDA (PND40 and PND65), decreased renal SOD activity (PND40) Morphology – Increased relative kidney weight (PND65) Kidney function – Increased blood creatinine (PND40 and PND65), increased BUN (PND40), decreased uric acid (PND65), increased kidney proteins (PND65).
Massó-González et al. (2009)	Rat; Weanling pups	300 ppm Pb acetate in drinking water; GD1 to PND21	23	Oxidative stress – Elevated TBARS and catalase activity Morphology – Elevated relative kidney weight at PND21
Roncal et al. (2007)	Rat; Adult; Male	150 ppm Pb acetate in drinking water; 16 weeks with remnant kidney surgery at week 4	26	Inflammation – Increased the number of macrophages & renal MCP-1 mRNA. Morphology – Pb induced pre-glomerular vascular disease of kidney (i.e., sclerosis, fibrosis, peritubular capillary loss) Kidney function – Decreased creatinine clearance, increased serum creatinine, increased BUN, and increased serum uric acid.

Reference	Species; Lifestage; Sex	Pb Dose; Exposure Duration	Blood Pb Level with Response (µg/dL)	Responses
Khalil-Manesh et al. (1993a)	Rat; Adult; Male	100 ppm Pb acetate in drinking water; 12 months	Mean at 3 months 29.4 Mean at 12 months 22 Range 9-34	Morphology – Mild tubular atrophy and interstitial fibrosis seen at 12 months, otherwise normal. Kidney function –Increased GFR at 1 and 3 months, increased NAG, and no change in GST.
Khalil-Manesh et al. (1992a)	Rat; Adult; Male	5,000 ppm Pb acetate in drinking water; 1, 6, or 9 months	At 1 month 7.9 At 6 months ~30 At 9 months 52	At 1 month Kidney function – no functional or pathological changes At 6 months Morphology – Prominent tubulointerstitial fibrosis and segmental sclerosis. Increased kidney weight Kidney function – Decreased GFR, increased serum creatinine and SUN, no change urinary NAG or GST At 9 months Morphology – Severe tubulointerstitial disease Kidney function – Decreased GFR, increased serum creatinine and SUN
Vyskocil et al. (1995)	Rat, Adult, Female	1,000 ppm Pb acetate in drinking water; 2 or 4 months	37.6	Kidney function – No change in kidney function or nephrotoxicity
Ademuyiwa et al. (2009)	Rat; Adult	200, 300, and 400 ppm Pb acetate in drinking water; 12 weeks	200 ppm: 41 300 ppm: 61 400 ppm: 39	Kidney function – Renal phospholipidosis and depletion of renal cholesterol.
Navarro-Moreno et al. (2009)	Rat; Adult; Male	500 ppm Pb acetate in drinking water; 28 weeks	43	Oxidative stress – Increased kidney lipid peroxidation (i.e., TBARS) Morphology – Electron micrography showed lumen reduction, microvilli loss, brush border loss, and mitochondrial damage Kidney function – Elevated urinary pH and protein, and glucose and blood in the urine.
Khalil-Manesh et al. (1992b)	Rat; Adult; Male	5,000 ppm Pb acetate in drinking water; 12 months	Max 125 Mean 45	Morphology – Tubular atrophy and interstitial fibrosis after 6 months. Increased urinary brush border antigens. Kidney function – Hyperfiltration at 3 months and decreased GFR at 12 months. After 3 months, elevated urinary NAG and GST.
Wang et al. (2010d)	Rat; Adult; Female	300 ppm Pb acetate in drinking water; 8 weeks	20 (serum)	Biomarker – Aberrant NAG, GGT, β2-microgobulin expression Oxidative Stress – Increased lipid peroxidation (i.e., MDA production), elevated kidney antioxidant enzymes (SOD, GPx, CAT), and depleted GSH Morphology – Electron micrography showed Pb damages mitochondria, basement membrane, and brush border in kidney tissue. Some focal tubal necrosis observed. Kidney function – Elevated urinary total protein, urinary albumin, and serum urea nitrogen.

Renal Function and Interstitial Fibrosis

Past studies have shown that chronic continuous or repeated Pb exposure can result in interstitial nephritis and focal or tubular atrophy. A series of studies on Pb exposure in rats (longitudinal 12-month exposure study to either 100 ppm or 5,000 ppm Pb in drinking water) report an initially elevated GFR, consistent with hyperfiltration, and renal hypertrophy (Khalil-Manesh et al., 1993a; Khalil-Manesh et al., 1992b; Khalil-Manesh et

al., 1992a). After 6 months of exposure, GFR decreased, albuminuria was present, and pathology ensued with focal tubular atrophy and interstitial fibrosis formation. This pathology and functional decrement was persistent out to 12 months, and at 12 months glomeruli developed focal and segmental sclerosis.

The toxicological evidence for differences in GFR according to duration of Pb exposure (i.e., hyperfiltration with 3-month exposure versus decreased GFR with 6- or 12-month exposure) provides biological plausibility for epidemiological studies that observed a similar phenomenon by age in adults in association with Pb biomarker levels. However, the toxicological studies report blood Pb levels at some exposure durations much higher than relevant to blood Pb levels in current human populations. Still, these duration-dependent dichotomous changes in GFR are consistent between the toxicological and epidemiologic literature.

At exposure concentrations resulting in blood Pb levels within one order of magnitude of the upper range of current human population blood Pb level, animal toxicological studies present inconsistent results for the effects of Pb on kidney function. There are studies that have corroborated the previously observed increase in serum creatinine following Pb exposure in rats. Berrahal et al. (2011) reported on the effects of age-dependent exposure to Pb on nephrotoxicity in male rats (Table 5-29). Pups were exposed to Pb lactationally (as a result of dams consuming water containing 50 ppm Pb acetate) until weaning. Thereafter, the offspring were exposed to the same solution from weaning (day 21) until sacrifice. Male pups were sacrificed at age 40 days (puberty; blood Pb level 12.7 µg/dL) and at age 65 days (post-puberty; blood Pb level 7.5 µg/dL). Serum creatinine was elevated at both 40 days and 65 days (0.54 and 0.60 mg/dL compared to control values of 0.45 mg/dL [$p < 0.001$]). Various parameters of Pb-induced renal dysfunction are listed in Table 5-29 below. The elevated serum creatinine in the Pb-exposed animals compared to controls suggests that animals exposed to low dose (i.e., 50 ppm) Pb from birth may develop renal abnormalities. However, the lack of measurements of GFR or renal pathology weakens the conclusions.

Table 5-29 Indicators of renal damage in male rats exposed to 50 ppm Pb for 40 and 65 days, starting at parturition.

Biomarker (Mean ± SD)	PND40 Control	PND40 Pb	PND65 Control	PND65 Pb
Blood Pb level (µg/dL)	1.8 ± 0.33	12.7 ± 1.7	2.1 ±n0.35	7.5n± 0.78
Plasma Creatinine (mg/L)	4.5 ± 0.21	5.35 ± 0.25[a]	4.55n± 0.27	6.04 ± 0.29[a]

Roncal et al. (2007) found that Pb accelerated renal function decrements, tubulointerstitial injury, and arteriolopathy in non-Pb-related CKD. Sprague-Dawley rats were administered Pb acetate at 150 ppm for 4 weeks, then subjected to remnant kidney surgery (left kidney mass reduced by 2/3 and right kidney removed), and subsequently exposed to Pb for an additional 12 weeks resulting in a blood Pb level of 26 µg/dL. Pb-treated rats had higher systolic BP, increased serum creatinine, lower creatinine clearance, and higher proteinuria than did controls. Most striking was development of worse arteriolar disease, peritubular capillary loss, tubulointerstitial damage, and macrophage infiltration. Pb treatment was associated with significant worsening of pre-glomerular vascular disease, as characterized by an increase in the media-to-lumen ratio. There was also a higher percentage of segmental sclerosis within glomeruli and a tendency for a higher number of sclerotic glomeruli. Additionally, a loss of peritubular capillaries, as reflected by a reduction in thrombomodulin staining, was observed. This was associated with worse tubular injury (osteopontin staining) due to more interstitial fibrosis (type III collagen staining) and a greater macrophage infiltration in the interstitium. The increase in macrophages was associated with higher renal MCP-1 mRNA. As a whole, these findings indicate that Pb exposure concomitant with existing renal insufficiency due to surgical kidney resection accelerated vascular disease and glomerular pathology. These findings are consistent with the previous work of Bagchi and Preuss (2005) also showing that Pb-exposed animals with non-Pb-related CKD (remnant surgery) had kidney dysfunction including impairment of the renin-angiotensin system (Losartan challenge), elevated systolic BP, and alterations in renal excretion of Pb, K^+, and Na^+. Thus, this model shows that Pb exposure may exacerbate pre-existing underlying kidney disease.

Other investigators have shown that chronic Pb exposure has detrimental effects on renal function at higher blood Pb levels. A number of studies report increased serum creatinine following high level Pb exposure (e.g., blood Pb levels >55.6 µg/dL) (Abdel Moneim et al., 2011b; Ozsoy et al., 2010; Jayakumar et al., 2009; Kharoubi et al., 2008a). In

addition, studies reporting high blood Pb levels and high Pb exposure levels report increased urine, serum, or blood urea nitrogen (Wang et al., 2010d; El-Nekeety et al., 2009; Jayakumar et al., 2009; Kharoubi et al., 2008a). Jayakumar et al. (2009) reported alterations in other markers of kidney toxicity, lysosomal marker and brush border enzymes (i.e., ALP, ACP, γ-GT, NAG, β-D-glucuronidase), following Pb exposure (2,000 ppm for 6 weeks). Similarly, Wang et al. (2010d) reported time-related increases in urinary alkaline phosphatase, urinary GGT, urinary NAG, urinary total protein, urinary β-2 microglobulin, and urinary microalbumin following Pb exposure (300 ppm in drinking water, serum Pb level 20 µg/dL). Pb-exposed male rats (500 ppm Pb acetate in drinking water for 7 months, blood Pb level 43 µg/dL) had elevated urinary pH, urinary glucose, and proteinuria (Navarro-Moreno et al., 2009).

Qiao et al. (2006) measured the effect of Pb on the expression of the renal nuclear factor-kappa B (NF-κB), transforming growth factor (TGF-β) and fibronectin in Sprague-Dawley rat kidney. These growth (TGF-β) and transcription (NF-κB) factors modulate the progression of renal function decrements through promotion of extracellular matrix (fibronectin) synthesis and promotion of fibrosis. Pb was administered at a dose of 5,000 ppm Pb acetate, continuously for either one, two, or three months. All factors increased by the end of three months of treatment, but only NF-κB increased progressively at each time period. These changes were hypothetically related to the development of Pb-induced renal fibrosis in rats, but no histology was performed.

The renal effects of chronic Pb exposure as detailed above were partially rescued in rats following lowering of blood Pb level with chelation therapy (i.e., DMSA) (Khalil-Manesh et al., 1992a) and after treatment with antioxidants (Abdel Moneim et al., 2011b; Ozsoy et al., 2010; Wang et al., 2010d; El-Nekeety et al., 2009; Jayakumar et al., 2009; Kharoubi et al., 2008a). DMSA treatment improved renal function; however, Pb-induced pathology remained (Khalil-Manesh et al., 1992a). Improvements include increased GFR, decreased albuminuria, and decreased inclusion body numbers but little change in tubulointerstitial scarring. DMSA also acts as an antioxidant, so the protective effects may not be entirely attributed to the lowering of blood Pb level. Similarly, several studies found that treatment with antioxidant compounds could protect against Pb-induced kidney dysfunction. Administration of flaxseed oil, L-carnitine, NAC, and several medicinal plants including, *Achyranthes aspera*, *Artemisia absinthium*, and *Aquilegia vulgaris*, to Pb-exposed rodents protected against injury to the kidney or restored kidney function (Abdel Moneim et al., 2011b; Ozsoy et al., 2010; Wang et al., 2010d; El-Nekeety et al., 2009; Jayakumar et al., 2009; Kharoubi et al., 2008a). These studies suggest that a reduction in reactive oxygen species may attenuate the effects of Pb on kidney function implicating oxidative stress as a predominant mechanism for Pb-induced reduced kidney function.

Histological Changes

Earlier studies discussed in previous Pb AQCDs have identified Pb-related renal damage by the presence of dense intranuclear inclusion bodies, which are capable of sequestering Pb (Goyer et al., 1970b). Pb-induced formation of intranuclear inclusion bodies in the proximal tubule (PT) is considered protective; Pb is sequestered such that it is not in its bioavailable, free, toxicologically active form. Intranuclear inclusion bodies are found in the kidney with short-term (i.e., <4 weeks) Pb exposure but present to a lesser degree with chronic exposures (See Section 5.2.3 for further discussion). Chelators such as $CaNa_2EDTA$ have removed these inclusion bodies from affected nuclei (Goyer et al., 1978).

Multiple ultrastructural changes indicate dysfunction in the PT and nephropathy after Pb exposure, including changes to the PT epithelium, endoplasmic reticulum dilation, nuclear membrane blebbing, and autophagosome enlargement (Fowler et al., 1980; Goyer et al., 1970a). Indications similar to the PT transport-associated Fanconi syndrome appear with Pb exposure, albeit often at high doses of Pb, i.e., Pb poisoning. These indications, which include increased urinary electrolyte excretion (Zn), decreased Na^+/K^+ATPase activity, mitochondrial aberrations, and aminoaciduria, also have been associated with blood Pb levels in children.

Recent studies since the 2006 Pb AQCD are consistent with the earlier findings and build upon the literature base by including the role of antioxidants. Jabeen et al. (2010) exposed pregnant albino BALB/c mice to a daily oral dose of Pb acetate (10 mg/kg body weight, daily throughout pregnancy) until GD18, at which point the fetal kidneys were processed for histological examination. Histology revealed Pb exposure induced decreased kidney cortical thickness, decreased diameter of renal corpuscles, and increased renal tubular atrophy (with desquamated epithelium and degenerated nuclei in the distal and proximal tubules). Blood Pb levels were not reported in this study. Nonetheless, these data show that in utero Pb exposure had significant histological effects on the fetal kidney, which could contribute to altered renal function including clearance of waste products, electrolyte balance, and vasoregulation.

Massanyi et al. (2007) reported on Pb-induced alterations in male Wistar rat kidneys after single i.p. doses of Pb acetate (50, 25, and 12.5 mg/kg); kidneys were removed and analyzed 48 hours after Pb administration. Qualitative microscopic analysis detected dilated Bowman's capsules and dilated blood vessels in the interstitium with evident hemorrhagic alterations. Quantitative histomorphometric analysis revealed increased relative volume of interstitium and increased relative volume of tubules in the experimental groups. The diameter of renal corpuscles and the diameter of glomeruli and Bowman's capsule were significantly increased. Measurement of tubular diameter

showed dilatation of the tubule with a significant decrease of the height of tubular epithelium compatible with degenerative renal alterations. These findings extend the observations of Fowler et al. (1980) and Khalil-Manesh et al. (1992b; 1992a); in particular, the enlarged glomeruli are consistent with the early hyperfiltration caused by Pb.

Abdel Moneim et al. (2011b) reported histological evidence of inflammation after Pb treatment in rats (i.p. 20 ppm, 5 days). This evidence included increased inflammatory cellular infiltrations, cytoplasmic vacuolation, and dilatation of some kidney tubules. Inflammation was accompanied by an increase in apoptotic cells and increased oxidative stress.

A recent study has also reported inclusion body formation in the nuclei, cytoplasm, and mitochondria of PT cells of Pb-treated rats (50 mg Pb/kg bw i.p., every 48 hours for 14 days) (Navarro-Moreno et al., 2009). These inclusion bodies were not observed in chronically Pb-exposed rats (500 ppm Pb in drinking water, 7 months). However, chronic Pb exposure resulted in morphological alterations including loss of PT apical membrane brush border, collapse and closure of the PT lumen, and formation of abnormal intercellular junctions.

Vogetseder et al. (2008) examined the proliferative capacity of the renal PT (particularly the S3 segment) following i.v. administration of Pb to juvenile and adult male Wistar rats. Proliferation induction was examined by detection of Bromo-2'-deoxyuridine (BrdU), Ki-67 (labels S, G2, and M phase cells), and cyclin D1 (an essential cell cycle progression protein). The cycling marker Ki-67 revealed a much higher proliferation rate in the S3 segment in control juvenile rats (4.8 ± 0.3%) compared with control adult rats (0.4 ± 0.1%). Pb administration (3.8 mg/100 g bw) increased the proportion of Ki-67-positive cells to 26.1 ± 0.3% in juvenile rats and 31.9 ± 0.3% in adult rats. Thus, the increased proliferation caused by Pb was age independent. The proliferation induction caused by Pb administration may be a result of reduced cell cycle inhibition by $p27^{kip-1}$. Acute Pb treatment increased the incidence of cyclin D1 labeling in the BrdU-positive cells suggesting Pb was able to accelerate re-entry of cells into the cell cycle and cause proliferation in the PT. Pb-induced cellular proliferation has also been reported in the retina with gestational and early postnatal rodent Pb exposure (Giddabasappa et al., 2011).

Ademuyiwa et al. (2009) examined Pb-induced phospholipidosis and cholesterogenesis in rat tissues. Sprague-Dawley rats were exposed to 200, 300 and 400 ppm Pb acetate for 12 weeks. The Pb exposure resulted in induction of phospholipidosis in kidney tissue, accompanied by depletion of renal cholesterol. The authors suggested that induction of cholesterogenesis and phospholipidosis in kidney may be responsible for some of the

subtle and insidious cellular effects found with Pb-mediated nephrotoxicity. Drug-induced PT phospholipidosis is seen clinically with use of the potentially nephrotoxic aminoglycoside drugs, including gentamicin (Baronas et al., 2007).

Various antioxidants have been shown to attenuate Pb-induced histopathological changes to the kidney. Ozsoy et al. (2010) found L-carnitine to be protective in a model of experimental Pb toxicity in female rats. Markers of histopathological change in the kidney, including tubule dilatation, degeneration, necrosis, and interstitial inflammation were rescued by L-carnitine treatment in females. Male rats exposed to Pb (2,000 ppm for 6 weeks) also displayed tubular damage, whereas concomitant treatment with Pb and an extract of *Achyranthes aspera* ameliorated the observed damage (Jayakumar et al., 2009). El-Sokkary et al. (2005) reported Pb-induced (100 ppm s.c. for 30 days) tubular degeneration with necrotic cells that could be prevented with melatonin treatment. Melatonin is known to be an efficacious free radical scavenger and indirect antioxidant. El-Nekeety et al. (2009) found an extract of the folk medicine plant *Aquilegia vulgaris* to be protective against Pb acetate-induced tubular dilatation, vacuolar and cloudy epithelial cell lining, interstitial inflammatory cell infiltration, hemorrhage, cellular debris, and glomerulus hypercellularity. Concomitant exposure to Pb and extract produced histology indiscernible from that in controls. Post treatment with extract partially rescued the Pb-induced histopathology. El-Neweshy and El-Sayed (2011) studied the influence of vitamin C supplementation (20 mg/kg pretreatment every other day) on histopathological alterations in Pb-exposed male rats (20 mg/kg by intragastric feeding once daily for 60 days). Control rats showed normal histology, while Pb-treated rats exhibited karyomegaly with eosinophilic intranuclear inclusion bodies in the epithelial cells of the proximal tubules. Glomerular damage and tubular necrosis with invading inflammatory cells were also found. Rats treated with Pb acetate plus vitamin C exhibited relatively mild or no karyomegaly with eosinophilic intranuclear inclusion bodies in the proximal tubules. Normal glomeruli were noted in animals exposed to Pb and vitamin C. These findings consistently show that some antioxidants are capable of preventing or rescuing Pb-induced renal histopathological changes, suggesting a role for oxidative stress in the development of Pb-induced nephropathy.

Table 5-30 presents the acute and chronic renal effects of Pb exposure observed in recent and past animal toxicology studies.

Table 5-30 Effects of Pb on the kidney/renal system related to exposure duration– evidence from animal toxicology studies.

Effects with less than 3 months of exposure	Effects with 6 or 12 months of exposure
Mitochondrial dysfunction	Mitochondrial dysfunction
Renal cell apoptosis	Renal cell apoptosis
Nuclear Inclusion Body Formation	Oxidant redox imbalance
Proximal Tubule Cytomegaly	Altered NO homeostasis
Glomerular Hypertrophy	ATPase dysfunction
Increased GFR	Aminoaciduria
	Increased electrolyte excretion
	Elevated blood pressure
	Decreased GFR

5.5.3 Modes of Action for Pb-Induced Nephrotoxicity

5.5.3.1 Oxidative Damage

A role for ROS in the pathogenesis of experimental Pb-induced hypertension and renal disease has been well characterized (Vaziri, 2008a, b; Vaziri and Khan, 2007). The production of oxidative stress following Pb exposure is detailed in respect to modes of action of Pb (Section 5.2.4). Past studies have shown that Pb treatment (single or three daily i.p. injections) can elevate kidney GST levels, affecting glutathione metabolism (Daggett et al., 1998; Moser et al., 1995; Oberley et al., 1995).

Animal studies continue to provide evidence for increased oxidative stress playing a role in the pathogenesis of Pb-induced renal toxicity. Increased ROS, serum NO, and renal NO were observed after Pb injections in rats (i.p. 20 mg/kg, 5 days) (Abdel Moneim et al., 2011b). Pb exposure to rat proximal tubular cells (0.5-1 µM) also increased ROS production, in a concentration-dependent manner (Wang et al., 2011b). Increased lipid peroxidation (i.e., MDA) was demonstrated in serum and renal tissue after Pb exposure (Abdel Moneim et al., 2011b; Lodi et al., 2011; Wang et al., 2011b). Berrahal et al. (2011) reported increased MDA in Pb-exposed (50 ppm Pb acetate pre- and post-natally) rat kidney relative to controls at both 40 (puberty; blood Pb 12.7 µg/dL) and 65 (post-puberty; blood Pb 7.5 µg/dL) days of age. In addition, total sulfhydryl groups were significantly decreased at 65 days. These increases in oxidative stress were accompanied by age-dependent Pb nephrotoxicity in male rats.

Alterations in endogenous antioxidants and antioxidant enzymes that may lead to oxidative stress have also been reported after Pb exposure. Pb treatment decreased the

activity of the renal antioxidant enzymes, CAT, SOD, GST, GPx, and GR (Abdel Moneim et al., 2011b) and protein levels of CAT and GSH (Lodi et al., 2011). Additionally, proteomic analysis of high-level Pb treated (1,500 ppm, 5 weeks; resulting in blood Pb level of 53.4 µg/dL) rat kidney identified decreased abundance of a rate-limiting enzyme in the synthesis of GSH (glutamate cysteine ligase) (Chen et al., 2011b).

Conterato et al. (2007) examined the effect of Pb acetate on the cytosolic thioredoxin reductase activity and oxidative stress parameters in rat kidneys. A single injection of Pb acetate consisted of a single i.p. injection of 25 or 50 mg/kg Pb acetate, while repeated injections consisted of one daily i.p. injection of Pb acetate (5 or 25 mg/kg) for 30 days. Measured were thioredoxin reductase-1, a selenoprotein involved in many cellular redox processes, SOD, δ-ALAD, GST, GPx, non protein thiol groups (NPSH), CAT, as well as plasma creatinine, uric acid, and inorganic phosphate levels. The single injection at the 25 mg Pb dose level resulted in increased SOD and thioredoxin reductase-1 activity, while the 50 mg dose level increased CAT activity and inhibited δ-ALAD activity in the kidney. Repeated injections at the 5 mg dose level of Pb inhibited δ-ALAD and increased GST, NPSH, CAT, and thioredoxin reductase-1. Repeated injections at the 25-mg dose level reduced δ-ALAD but increased GST, NPSH, and plasma uric acid levels. No changes were observed in TBARS, GPx, creatinine or inorganic phosphate levels after either single or repeated injection dosing. As both dosing regimens increased thioredoxin reductase-1 activity, the authors suggest that this enzyme may be a sensitive indicator of renal changes with low dose Pb treatment.

Jurczuk et al. (2006) published a study of the involvement of some low molecular weight thiols in the peroxidative mechanisms of action of Pb in the rat kidney. Wistar rats were fed a diet containing 500 ppm Pb acetate for a period of 12 weeks and were compared to a control group receiving distilled water for the same time period. GSH, metallothionein (MT), total and nonprotein SH groups (TSH and NPSH) were measured, as were the blood activity and urinary concentration of δ-ALA. The concentrations of GSH and NPSH were decreased by Pb administration, while MT concentration was unchanged. δ-ALAD in blood was decreased, whereas urinary δ-ALA was increased by Pb administration. Negative correlations were found between the kidney GSH concentrations and previously reported concentrations of Pb and MDA in kidneys of these rats. It is apparent from graphical presentation of the data that GSH was reduced by more than 50% following Pb administration, while TSH was reduced by approximately 15%. No values for either blood or kidney Pb levels or kidney MDA were reported in this article. In 2007, the same authors (Jurczuk et al., 2007) reported on the renal concentrations of the antioxidants, vitamins C and E, in the kidneys of the same Pb-treated and control rats. Exposure to Pb significantly decreased vitamin E concentration by 13% and vitamin C concentration by 26%. The kidney concentration of vitamin C negatively correlated with

MDA concentration. The authors concluded that vitamins E and C were involved in the mechanism of peroxidative action of Pb in the kidney, and their protective effect may be related to scavenging of free radicals.

Studies have used antioxidant compounds to investigate the role of oxidative stress in Pb-induced nephrotoxicity. Abdel Moneim et al. (2011b) reported that flaxseed oil treatment protected rats from Pb-induced (i.p. 20 mg/kg, 5 days) oxidative stress, inflammation, and apoptosis. However, the flaxseed oil also decreased the accumulation of Pb in renal tissue making it difficult to ascertain whether the protection was due to decreased oxidative stress or to altered Pb uptake kinetics.

El-Neweshy and El-Sayed (2011) studied the influence of vitamin C supplementation on Pb-induced histopathological alterations in male rats. Rats were given Pb acetate, 20 mg/kg by intragastric feeding once daily for 60 days. Control rats were given 15 mg of sodium acetate per kg once daily, and an additional group was given Pb acetate plus vitamin C (20 mg/kg every other day) 30 minutes before Pb feeding. Control rats showed normal histology, while Pb-treated rats exhibited karyomegaly with eosinophilic intranuclear inclusion bodies in the epithelial cells of the proximal tubules. Glomerular damage and tubular necrosis with invading inflammatory cells were also seen in Pb-treated animals. Among rats treated with Pb acetate plus vitamin C, five exhibited relatively mild karyomegaly and eosinophilic intranuclear inclusion bodies of proximal tubules and an additional five rats were normal. Normal glomeruli were noted in all. Thus, vitamin C was shown to ameliorate the renal histopathological effects of Pb intoxication, however no measures of Pb accumulation were provided to clarify the mechanism of action of vitamin C.

Masso-Gonzalez and Antonio-Garcia (2009) studied the protective effect of natural antioxidants (Zn, vitamin A, vitamin C, vitamin E, and vitamin B6) against Pb-induced damage during pregnancy and lactation in rat pups. At weaning, pups were sacrificed and kidneys were analyzed. Pb-exposed pups had decreased body weights. Blood Pb levels were 1.43 μg/dL in the control group, 22.8 μg/dL in the Pb group, 21.2 μg/dL in the Pb plus Zn plus vitamins group, and 0.98 μg/dL in the Zn plus vitamin group. The kidney TBARS were significantly elevated in Pb exposed pups, while treatment with vitamins and Zn returned TBARS to control levels. Kidney CAT activity was significantly increased above control with Pb treatment; however supplementation with Zn and vitamins reduced CAT activity toward normal. Pb exposure inhibited kidney Mn-dependent SOD but not Cu-Zn-dependent SOD activity. Thus, supplementation with Zn and vitamins during gestation and lactation was effective in attenuating the redox imbalance induced by developmental, chronic low-level Pb exposure, likely through the alteration of Pb accumulation.

Bravo et al. (2007) reported further that mycophenolate mofetil (an immunosuppressive agent used in renal transplantation which inhibits T and B cell proliferation) administration reduces renal inflammation, oxidative stress and hypertension in Pb-exposed rats. Thus, an inflammatory immune and oxidative stress component can be seen as contributing to Pb-induced renal effects and hypertension.

Although the majority of studies of the effects of Pb exposure have been conducted in male rats, a couple of studies have compared the response of male rats with female rats (Sobekova et al., 2009; Alghazal et al., 2008a). Sobekova et al. (2009) contrasted the activity response to Pb on the antioxidant enzymes, GPx and GR, and on TBARS in both male and female Wistar rats of equal age. Males weighing 412 ± 47 g and females weighing 290 ± 19 g were fed diets containing either 100 ppm or 1,000 ppm Pb acetate for 18 weeks. In the male rats, kidney Pb content increased by 492% on the 100 ppm Pb diet and by 7,000% on the 1,000 ppm Pb diet. In the female rats, kidney Pb content increased by 410% on the 100 ppm Pb diet and by 23,000% on the 1,000 ppm Pb diet. There was virtually no change in GPx in the kidney of male rats given the 100 ppm Pb diet but there was a significant reduction in GPx in the female rats on both the 100 ppm diet and 1,000 ppm diet. In male rats, GR was increased from 182 units/gram of protein in control kidneys to 220 units on the 100 ppm Pb diet and 350 units on the 1,000 ppm diet. In female rats, kidney GR decreased from 242 units in control animals to 164 units in animals on the 100 ppm Pb diet and 190 units in animals on the 1,000 ppm diet. In male rats, kidney TBARS content increased from 7.5 units/gram protein to 10.0 units (1,000 ppm Pb diet group). In female rats, there was a reduction in TBARS from 14.4 units per gram protein to 10.0 units in rats on the 100 ppm Pb diet and to 11 units in rats on the 1,000 ppm Pb diet.

Alghazal et al. (2008a) compared the activity responses of the antioxidant enzyme, SOD and the detoxifying enzyme, GST, of the same rats exposed to 100 ppm or 1,000 ppm Pb acetate for 18 weeks. Similar to the previous study, kidney TBARS were increased only in male rats given the higher dose of Pb. Kidney SOD activity, on the other hand, was increased in both males and females at the higher dose of Pb, while GST activity was increased in kidney of males at the higher dose of Pb and decreased at the lower dose, but was decreased at both doses of Pb in females. Thus there were significant differences in the responses of male and female rats to Pb exposure. Differences may be accounted for in part due to the greater deposition of Pb in female rat kidneys. Another explanation, offered by the authors, is that male rats are known to metabolize some foreign compounds faster than do females, so the biological half-life of xenobiotics in the females may be longer.

5.5.3.2 Hypertension and Alteration of Renal Vasculature and Reactivity

As discussed in Section 5.5.1, changes in renal vasculature function or induction of hypertension can contribute to further renal dysfunction. Pb exposure increases BP, resulting in hypertension, through the promotion of oxidative stress and altered vascular reactivity (Section 5.4). Antioxidants attenuated Pb-related oxidative/nitrosative stress in the kidney and abrogated the Pb-induced increased BP (Vaziri et al., 1999a). Chronic increases in vascular pressure can contribute to glomerular and renal vasculature injury, which can lead to progressive renal dysfunction and kidney failure. In this manner, Pb-induced hypertension has been noted as one contributer to Pb-induced renal disease.

Also, Pb has been shown to act on known vasomodulating systems in the kidney. In the kidney, two vascular tone mediators, NO and ET-1, are found to be affected by Pb exposure. Administration of the vasoconstrictor endothelin-1 (ET-1) affected mean arterial pressure (MAP) and decreased GFR (Novak and Banks, 1995). Acute high-dose Pb exposure (24 nmol/min for 15 or 30 minutes) completely blocked this ET-1-mediated GFR decrease but had no effect on MAP. Depletion of the endogenous antioxidant glutathione using the drug buthionine sulfoximine, a GSH synthase inhibitor, increased BP and increased kidney nitrotyrosine formation without Pb exposure, demonstrating the importance of GSH in maintenance of BP (Vaziri et al., 2000). Multiple studies have shown that Pb exposure depletes GSH stores. Catecholamines are vascular moderators that are also affected by Pb exposure (Carmignani et al., 2000). The effect on BP with Pb exposure is especially relevant to the kidney because it is both a target of Pb deposition and a mitigator of BP. These earlier data detail the interaction of known modulators of vascular tone with Pb.

The renin-angiotensin-aldosterone system plays an important role in kidney homeostasis and alteration of this pathway may affect renal function. Simões et al. (2011) reported that acute Pb treatment (Pb acetate i.v. bolus dose of 320 µg/kg bw, blood Pb of 37 µg/dL at 120 minutes after Pb administration) in adult male Wistar rats increased serum angiotensin converting enzyme (ACE) activity. Systolic arterial pressure, but not diastolic arterial pressure or heart rate, was also elevated 60 minutes after treatment. The Pb-induced altered systolic BP attenuated in animals co-treated with Losartan (Ang II receptor blocker) or Enalapril (ACE inhibitor), suggesting a regulatory role for the renin-angiotensin system (Simões et al., 2011). These data agree with earlier reports of Pb-related increases in ACE activity in young rats exposed to Pb for 2-8 weeks (Sharifi et al., 2004) and adult rats exposed to Pb for 10 months (Carmignani et al., 1999).

Recently, Vargas-Robles et al. (2007) examined the effect of Pb exposure (100 ppm Pb acetate for 12 weeks) on BP and angiotensin II vasoconstriction in isolated perfused

kidney and interlobar arteries. Vascular reactivity was evaluated in the presence and absence of the nitric oxide synthase inhibitor L-NAME in both Pb-treated and control animals. Pb exposure significantly increased BP (134 ± 3 versus 100 ± 6 mmHg), eNOS protein expression, oxidative stress, and vascular reactivity to angiotensin II. L-NAME potentiated the vascular response to angiotensin II in the control group, but had no effect on the Pb-treated group. Conversely, passive microvessel distensibility, measured after deactivation of myogenic tone by papaverine, was significantly lower in the arteries of Pb-exposed rats. Nitrites released from the kidney under the influence of angiotensin II in the Pb group were lower as compared to the control group whereas 3-nitrotyrosine was higher in the Pb group. The authors concluded that Pb exposure increases vascular tone through nitric oxide-dependent and -independent mechanisms, increasing renal vascular sensitivity to vasoconstrictors.

5.5.3.3 Apoptosis and/or Ischemic Necrosis of Tubules and Glomeruli

Apoptosis or programmed cell death in excess can cause cell atrophy while an insufficiency can lead to uncontrolled cell proliferation, such as cancer. Pb exposure has been shown to cause morphological changes to the kidney structure. Some of these Pb-induced changes are a result of cellular apoptosis or necrosis. Past studies have shown Pb-induced necrosis in proximal tubule cells (Fowler et al., 1980). Pb-induced apoptosis is known to act through the mitochondria (Rana, 2008). Pb-induced calcium overload may depolarize the mitochondria, resulting in cytochrome *c* release, caspase activation, and apoptosis. The apoptosis is mediated by Bax translocation to the mitochondria and can be blocked by overexpression of Bcl-xl. Also, Pb-induced ALA accumulation can generate ROS, which may damage DNA leading to apoptosis.

Mitochondria are targets of Pb toxicity and often involved in apoptosis. Pb can induce uncoupling of oxidative phosphorylation, decreased substrate utilization, and modification of mitochondrial ion transport. ATP energetics are affected when ATP-Pb chelates are formed and ATPase activity is decreased. ROS formation can contribute to these mitochondrial changes and to other changes within the kidney. Antioxidant supplementation after Pb exposure can remedy some changes. All of these outcomes, in conjunction with Pb-related depletion of antioxidants (e.g., GSH) and elevation of lipid peroxidation point to possible susceptibility of the kidney to apoptosis or necrosis.

Rodriguez-Iturbe et al. (2005) reported that chronic exposure to low doses of Pb (100 ppm in drinking water for 14 weeks) results in renal infiltration of immune cells, apoptosis, NF-κB activation and overexpression of tubulointerstitial Ang(II). Similarly,

higher level Pb treatment in rats (i.p. 20 mg/kg, 5 days) induced inflammatory cellular infiltrations and an increase in apoptotic cells, accompanied by more pronounced BAX staining in kidney tubule epithelial cells (Abdel Moneim et al., 2011b). Pb treatment (0.5-1 µM) of isolated rat proximal tubular cells increased cell death by apoptosis and necrosis in a concentration- and time-dependent manner (Wang et al., 2011b). This was accompanied by increased morphological changes typical of apoptosis such as fragmented chromatin, condensed chromatin, and shrunken nuclei. These cells also exhibited decreased mitochondrial membrane potential, decreased intracellular pH, inhibition of Na^+/K^+ATPase and Ca^{2+}ATPase activity, and increased intracellular Ca^{2+} following Pb treatment.

Navarro-Moreno et al. (2009) examined the effect of 500 ppm Pb in drinking water over 7 months on the structure (including intercellular junctions), function, and biochemical properties of PT cells of Wistar rats. Pb effects in epithelial cells consisted of an early loss of the apical microvilli, followed by a decrement of the luminal space and the respective apposition and proximity of apical membranes, resulting in the formation of atypical intercellular contacts and adhesion structures. Inclusion bodies were found in nuclei, cytoplasm, and mitochondria. Lipid peroxidation (TBARS measurement) was increased in the Pb-treated animals as compared to controls. Calcium uptake was diminished and neither proline nor serine incorporation that was present in controls was noted in the PT of Pb-exposed animals. The authors speculated that Pb may compete with calcium in the establishment and maintenance of intercellular junctions.

Tubular necrosis was also observed in rats treated with Pb acetate (100 ppm s.c.) for 30 days (El-Sokkary et al., 2005). Histological sections of kidneys from Pb-treated rats showed tubular degeneration with some necrotic cells. Similarly, El-Neweshy and El-Sayed (2011) reported glomerular damage and tubular necrosis with invading inflammatory cells after Pb treatment (20 mg/kg by intragastric feeding once daily for 60 days) to male rats. The incidence of necrosis was decreased in both of these studies by pretreatment with either melatonin or vitamin C. Pretreatment with melatonin (10 mg/kg), an efficacious free radical scavenger and indirect antioxidant, resulted in a near normal tubular structure. The authors concluded that melatonin protected the liver and kidneys from the damaging effects of exposure to Pb through inhibition of lipid peroxidation and stimulation of endogenous antioxidative defense systems (El-Sokkary et al., 2005). Vitamin C supplementation (20 mg/kg pretreatment every other day) protected the renal architecture and histology (El-Neweshy and El-Sayed, 2011).

Wang et al. (2009c) examined the effect of Pb acetate (0.25, 0.5 and 1 µM) on cell death in cultured rat primary PT cells. A progressive loss in cell viability, due to both apoptosis and necrosis, was observed in cells exposed to Pb. Apoptosis predominated and could be

ameliorated with concomitant N-acetylcysteine exposure, whereas necrosis was unaffected. Elevation of ROS levels and intercellular calcium, depletion of mitochondrial membrane potential, and intracellular glutathione levels was observed during Pb exposure. Pb-induced apoptosis was demonstrated morphologically (Hoechst 33258 staining) with condensed/fragmented chromatin and apoptotic body formation. CAT and SOD activities were significantly elevated, reflecting the response to accumulation of ROS.

5.5.3.4 Renal Gangliosides

Gangliosides are constituents of the plasma membrane that are important for control of renal GFR because they can act as receptors for various molecules and have been shown to take part in cell-cell interactions, cell adhesion, cellular recognition, and signal transduction. Aguilar et al. (2008) studied changes in renal gangliosides following Pb exposure (600 ppm Pb acetate in drinking water for 4 months) in adult male Wistar rats. Pb exposure caused an increase in blood Pb from 2.1 to 35.9 µg/dL. There was no change in serum creatinine or in hemoglobin, but there was an increase in urinary δ-ALA. The following renal gangliosides were measured by immunohistochemistry and by thin layer chromatography: GM1, GM2, GM4, and 9-O-acetylated modified form of the GD3 ganglioside (9-O-Ac-GD3). The ganglioside pattern was mainly characterized by a decrease in the GM1 ganglioside as well as by a mild increase in GM4 and GM2 gangliosides, while the strongest alteration was observed in the 9-O-Ac-GD3, which was overexpressed. The latter was observed only in the glomerular zone. This was associated with a decrease in apoptotic glomerular cells, as assessed by the TUNEL assay. The authors hypothesized that the increase in GD3-O-acetylation could represent a strategy to attenuate the normal renal apoptotic process and therefore contribute to cell survival during Pb exposure.

5.5.3.5 Altered Uric Acid

Higher occupational Pb exposure or blood Pb levels have been linked to increased risk for both gout and kidney disease (Shadick et al., 2000; Batuman, 1993). Pb is thought to increase serum uric acid by decreasing its kidney excretion (Emmerson and Ravenscroft, 1975; Ball and Sorensen, 1969; Emmerson, 1965). Research during the past decade indicates that uric acid is nephrotoxic at lower levels than previously recognized (Johnson et al., 2003). Therefore, the 2006 Pb AQCD (U.S. EPA, 2006b) reviewed literature implicating increased uric acid as a mechanism for Pb-related nephrotoxicity (Weaver et al., 2005a; Shadick et al., 2000). However, this does not appear to be the only

mechanism, since associations between blood Pb and serum creatinine have remained significant even after adjustment for uric acid (Weaver et al., 2005a).

Alterations in serum uric acid have been studied in animal models exposed to Pb. In male rats exposed to Pb in drinking water from lactation to puberty (40 days) or post-puberty (65 days), Berrahal et al. (2011) found that plasma urea levels increased after 40 days of exposure (puberty blood Pb level of 12.7 µg/dL) but decreased after 65 days of Pb exposure (post-puberty blood Pb level of 7.5 µg/dL) (Table 5-29). Serum uric acid was increased in male rats following long-term Pb exposure (2,000 ppm for 6 weeks) (Jayakumar et al., 2009). Conterato et al. (2007) followed various parameters of kidney function after single or multiple Pb injections in rats. The single dosing regimen consisted of a single i.p. injection of 25 or 50 mg/kg Pb acetate, while the multiple injections involved once daily i.p. injection of either vehicle or Pb acetate (5 or 25 mg/kg) for 30 days. Single and multiple injections at both dose levels increased plasma uric acid levels. Similarly, Abdel Moneim et al. (2011b) reported increased serum uric acid and urea levels after 5 days of Pb acetate treatment (i.p. 20 mg/kg).

5.5.3.6 Role of Metallothionein

The metal-binding protein, metallothionein, may play a role in inclusion body formation and thus block potential interaction of Pb with cellular targets. Yu et al. (2009) described dichotomous effects of Pb acetate on the expression of MT in the liver and kidney of mice. Male mice were i.p. injected with Pb acetate in doses of 100, 200, and 300 µmol/kg and sacrificed 4, 8, and 24 hours after Pb treatment. Administration of Pb increased the levels of MT-1 mRNA in the liver and kidneys but increased MT protein only in the liver. Treatment of mouse PT cells in vitro with Pb also resulted in an increase in MT mRNA but little increase in MT protein. Thus, Pb appears to exert a dual effect on MT expression in the kidney: enhancement of MT gene transcription but suppression of MT mRNA translation.

Zuo et al. (2009) examined the potential role of α-Synuclein (Scna) and MT in Pb-induced inclusion body formation. Unlike the parental wild type (WT) cells, MT-I/II double knockout (MT-null) cells did not form inclusion bodies after Pb treatment; however, transfection of MT-1 into MT-null cells allowed inclusion body formation after Pb treatment. As inclusion bodies formed during Pb treatment, soluble MT protein in WT cells was lost. As Scna is a protein with a natural tendency to aggregate into oligomers, Scna was measured in WT cells and MT-null cells after Pb treatment. In both cell lines Pb-induced Scna expression rapidly increased and then decreased over 48 hours as Pb-induced inclusion bodies were formed. Pb exposure caused increased colocalization

of MT and Scna proteins and MT was localized to the surface of inclusion bodies in WT renal cortex samples following Pb treatment. Thus, Scna may be a component of Pb-induced inclusion bodies and, with MT, may play a role in inclusion body formation.

5.5.4 Effects of Exposure to Pb Mixtures

The effect of Pb on other cations, specifically calcium, is well established in the kidney literature. Calcium-mediated processes involving receptors, transport proteins, and second messenger signaling among other endpoints have been shown to be significantly affected by Pb exposure. The disposition of Pb in the soft tissues (kidney and spleen) can change with exposure to Pb and other compounds. Pb plus Cd exposure changed Pb disposition with increased blood Pb (versus Pb alone group) and decreased metal concentration in the kidney and liver (versus Pb alone). An iron deficient diet significantly increased Pb deposition in adult animals (Hashmi et al., 1989), pregnant dams, and maternally-exposed fetuses (Singh et al., 1991). Dietary thiamine plus Zn slightly reduced blood and kidney Pb in exposed animals (Flora et al., 1989). Selenium (Se), a cofactor for GPx, attenuated Pb-induced lipid peroxidation and abrogated the Pb-induced attenuation of GR and SOD. Concomitant exposure to the cations aluminum and Pb protected animals from ensuing nephropathy (Shakoor et al., 2000). In summary, Pb has been shown to affect processes mediated by endogenous divalent cations. In addition, exposure to other metals or divalent cations can modulate Pb disposition and its effects in the body.

5.5.4.1 Lead(Pb) and Cadmium(Cd)

Cd shares many similarities with Pb; it has been shown to be a ubiquitous PT nephrotoxicant and accumulates in the body. Despite the similarities, few studies have evaluated associations between Cd exposure and CKD or the impact of joint exposure of Pb and Cd or other metals on CKD. As discussed in the 2006 Pb AQCD (U.S. EPA, 2006b), environmental exposure to Cd, at levels common in the U.S. and other developed countries, has been shown to impact substantially associations between indicators of Pb exposure and the kidney EBE marker, NAG, even in the presence of occupational level Pb exposure. In an occupational study, mean NAG, although higher in the Pb-exposed worker group compared to controls, was correlated with urine Cd but not blood or tibia Pb (Roels et al., 1994). In another occupational population where both metals were significantly associated with NAG, a 0.5 μg/g creatinine increase in Cd had the same effect on NAG as did a 66.9 μg/g bone mineral increase in tibia Pb (Weaver et al., 2003a).

The 2006 Pb AQCD noted that data examining the concentration-response relation between environmental Cd and the kidney were too scarce to determine the impact of Cd exposure on relations between Pb exposure and other kidney outcomes. A recent publication in NHANES data collected from 1999 through 2006 addresses this need; (results pertaining solely to Pb were discussed in Section 5.5.2.1) (Navas-Acien et al., 2009). Geometric mean concurrent blood Cd level was 0.41 μg/L in 14,778 adults aged ≥ 20 years. After adjustment for survey year, sociodemographic factors, CKD risk factors, and blood Pb, the ORs for albuminuria (≥ 30 mg/g creatinine), reduced eGFR (<60 mL/min/1.73 m^2), and both albuminuria and reduced eGFR were 1.92 (95% CI: 1.53, 2.43), 1.32 (95% CI: 1.04, 1.68), and 2.91 (95% CI: 1.76, 4.81), respectively, comparing the highest with the lowest blood Cd quartiles. Both Pb and Cd remained significantly associated after adjustment for the other. Effect modification was not observed; however, ORs were higher for adults in the highest quartiles of both metals compared with the ORs for the highest quartiles of concurrent blood Cd or Pb alone (Table 5-25). Compared with adults with blood Cd levels ≤ 0.2 μg/L and blood Pb levels ≤ 1.1 μg/dL, adults with blood Cd levels >0.6 μg/L and blood Pb levels >2.4 μg/dL had ORs (95% CIs) of 2.34 (95% CI: 1.72, 3.18) for albuminuria, 1.98 (95% CI: 1.27, 3.10) for reduced eGFR, and 4.10 (95% CI: 1.58, 10.65) for albuminuria and reduced eGFR together. These findings are consistent with other recent publications (Akesson et al., 2005; Hellstrom et al., 2001), support consideration of both metals as independent CKD risk factors in the general population, and provide novel evidence of increased risk in those with higher environmental exposure to both metals.

However, a very recent study suggests that interpretation of Cd associations with GFR measures may be much more complex. Conducted in Pb workers to address the fact that few studies have examined the impact of environmental Cd exposure in workers who are occupationally exposed to other nephrotoxicants such as Pb, the study assessed Cd dose with urine Cd, which is widely considered the optimal dose metric of cumulative Cd exposure. In 712 Pb workers, mean (SD) blood and tibia Pb, urine Cd, and eGFR using the MDRD equation were 23.1 (14.1) μg/dL, 26.6 (28.9) μg/g, 1.15 (0.66) μg/g creatinine, and 97.4 (19.2) mL/min/1.73m^2, respectively (Weaver et al., 2011). After adjustment for age, sex, BMI, urine creatinine, smoking, alcohol use, education, annual income, diastolic BP, current or former Pb worker job status, new or returning study participant, and blood and tibia Pb, higher urine Cd was associated with higher calculated creatinine clearance, eGFR (β = 8.7 mL/min/1.73 m^2 [95% CI: 5.4, 12.1] per unit increase in ln-transformed urine Cd) and ln-NAG, but lower serum creatinine. These unexpected paradoxical associations have been reported in a few other publications (de Burbure et al., 2006; Hotz et al., 1999) and have been observed in other populations. Potential explanations for these paradoxical results included a normal physiologic

response in which urine Cd levels reflect renal filtration; the impact of adjustment for urine dilution with creatinine in models of kidney outcomes; and Cd-related hyperfiltration.

Wang et al. (2009c) studied the effects of Pb and/or Cd on oxidative damage to rat kidney cortex mitochondria. In this study young female Sprague Dawley rats were fed for 8 weeks with either Pb acetate (300 ppm), Cd chloride (50 ppm), or Pb and Cd together in the same dosage. Lipid peroxidation was assessed as MDA content. Renal cortex pieces were also processed for ultrastructural analysis and for quantitative rtPCR to identify the mitochondrial damage and to quantify the relative expression levels of cytochrome oxidase subunits (COX-I/II/III). Cytochrome oxidase is the marker enzyme of mitochondrial function, and COX-I, II, and III are the three largest mitochondrially-encoded subunits which constitute the catalytic functional core of the COX holoenzyme. Mitochondria were altered by either Pb or Cd administration, but more strikingly by Pb plus Cd administration, as indicated by disruption and loss of mitochondrion cristae. Kidney cortex MDA levels were increased significantly by either Pb or Cd, given individually, but more so by Pb plus Cd. COX-I/II/III were all reduced by either Pb or Cd administration, but more prominently by Pb plus Cd administration. This study adds to knowledge of the synergistic effects of Pb and Cd on kidney mitochondria.

5.5.4.2 Lead(Pb), Cadmium(Cd), and Arsenic(As)

Wang and Fowler (2008) present a general review of the roles of biomarkers in evaluating interactions among mixtures of Pb, Cd, and As. Past studies have found that addition of Cd to treatment of rats with Pb or Pb and As significantly reduced the histological signs of renal toxicity from each element alone, including swelling of the proximal tubule cells and intranuclear inclusion body formation. On the other hand, animals exposed to Cd in addition to Pb or Pb and As showed an additive increase in the urinary excretion of porphyrins, indicating that, although measured tissue burdens of Pb were reduced, the biologically available fraction of Pb is actually increased (Mahaffey et al., 1981; Mahaffey and Fowler, 1977).

Stress proteins were examined after exposure to mixtures of Pb and other metals. Induction of MT was strongest in groups with Cd treatment. However, co-exposure to Pb and As induced higher levels of MT protein than did either Pb or As exposure alone in kidney tubule cells. Heat shock proteins (Hsps) are commonly altered with exposure to metal mixtures. A study found in vitro (low dose) and in vivo that Pb induced Hsps in a metal/metalloid-, concentration- and time-specific manner (Wang et al., 2005a). Additive or more than additive interactions occurred among Pb, Cd and As under combined exposure conditions.

5.5.4.3 Lead (Pb) and Zinc (Zn)

Zinc has been investigated as a protective compound against the effects of Pb. Pb treatment (35 mg/kg i.p. for 3 days) caused a significant fall in hemoglobin content, significant increases in lipid peroxidation and decreased level of reduced glutathione in liver, together with diminished total protein content in liver and kidney. Co-treatment of Pb with Zn (10 mg/kg i.p.) or ascorbic acid (10, 20 and 30 mg/kg i.p.) showed a moderate therapeutic effect when administered individually, but more pronounced protective effects after combined therapy (Upadhyay et al., 2009).

Jamieson et al. (2008) studied the effect of dietary Zn content on renal Pb deposition. Weanling Sprague Dawley rats were assigned to marginal zinc (MZ, 8 mg Zn/kg diet), zinc adequate control (CT, 30 mg Zn/kg), zinc-adequate diet-restricted (30 mg Zn/kg), or supplemental zinc (SZn, 300 mg Zn/kg) groups, with or without Pb acetate (200 ppm for 3 weeks). Pb exposure did not result in nephromegaly or histological alterations. The MZ rats had higher renal Pb (35%) and lower renal Zn (16%) concentrations than did CT rats. On the other hand, SZn was more protective than the CT diet was against renal Pb accumulation (33% lower). Standard procedures for indirect immunoperoxidase staining were used to determine MT localization in the kidney. Pb had no effect on MT staining intensity, distribution, or relative protein amounts. Western blot analysis confirmed that MT levels were responsive to dietary Zn but not to Pb exposure.

5.5.4.4 Lead(Pb) and Mercury(Hg)

Stacchiotti et al. (2009) studied stress proteins and oxidative damage in a renal-derived cell line exposed to inorganic Hg and Pb. The time course of the expression of several Hsps, glucose-regulating proteins and MTs in a rat proximal tubular cell line (NRK-52E) exposed to subcytotoxic doses of inorganic mercury ($HgCl_2$, 1-40 μM) and Pb ($PbCl_2$, 2-500 μM) were analyzed. ROS and reactive nitrogen species (RNS) were detected by

flow cytometric analysis. Endogenous total GSH content and the enzymatic activity of GST were determined in cell homogenates. Western blot analysis and immunohistochemistry were used for quantification of hsps and MTs. Reverse transcription PCR was used for quantification of metallothionein. The higher doses of Hg (20 μM and 40 μM) were shown to markedly inhibit growth of the cell line while the higher doses of Pb (60 μM to 500 μM) inhibited cell growth to a lesser degree. After 24 hours of exposure of 20 μM Hg, the cells presented abnormal size and pyknotic nuclei, swollen mitochondria and both apoptosis and overt necrosis. In the presence of 60 or 300 μM Pb, the cells lost cell-cell and cell-matrix contacts, showed a round size, irregular nuclear contour and often mitotic arrest, but no apoptosis or overt necrosis at 24 hours. Mercury (Hg) induced a significant increase in both ROS and RNS, maximal RNS at 24 hours, and maximal ROS at 48 hours. Pb (60 or 300 μM) did not cause an increase in ROS or RNS beyond the levels measured in control cells. Total GSH significantly increased in cells grown in the presence of Pb; the effect was concentration-dependent and GSH reached its maximal value at a dose of 300 μM Pb. The effect of Hg was biphasic: 10 μM significantly enhanced GSH by 600%, while the amount of GSH detected after 20 μM Hg only increased by 50% compared to control levels. GST activity was enhanced by both Pb and Hg. Hsp25 and Hsp72 were up-regulated by Hg but there was no effect on Grp78 as compared to control. On the contrary, Pb treatment only upregulated Grp78. Mercury (Hg) induced a time-dependent effect on MT mRNA expression, which reached its maximal value 3 hours after beginning treatment and reverted to control values at 24 hours. With Pb, on the other hand, mRNA transcription was concentration- and time-dependent. The transcripts remained overexpressed compared to controls up to 72 hours. The results of this study with regard to the Pb effect on MT synthesis clearly differ from those of Jamieson et al. (2008), which found no increase in MT following Pb exposure. This discrepancy remains to be clarified.

5.5.5 Summary and Causal Determination

A large body of epidemiologic evidence and limited toxicological evidence indicates Pb exposure leads to reduced kidney function. The causal determination for reduced kidney function is informed by evidence for reduced GFR, reduced creatinine clearance, and increased serum creatinine. Biological plausibility and mode of action for these effects is provided by evidence for hypertension, oxidative stress, inflammation, vascular reactivity and injury, increased uric acid, morphological changes, and apoptosis or necrosis. The section that follows describes the evaluation of evidence for reduced kidney function, with respect to causal relationships with Pb exposure using the framework described in Table II of the Preamble. The key supporting evidence to the causal framework is summarized in Table 5-31.

5.5.5.1 Evidence for Reduced Kidney Function

The 2006 Pb AQCD (U.S. EPA, 2006b) concluded that "in the general population, both circulating and cumulative Pb was found to be associated with a longitudinal decline in renal function," evidenced by increased serum creatinine and decreased creatinine clearance or eGFR over follow-up of 4 to 15 years in association with higher baseline blood and bone Pb levels (U.S. EPA, 2006b). Data in general and patient populations of adults provided consistent evidence of Pb-associated lower renal function in populations with mean concurrent or baseline blood Pb levels of 2-10 μg/dL (Akesson et al., 2005; Tsaih et al., 2004; Yu et al., 2004; Kim et al., 1996); associations with lower eGFR were observed in adults with hypertension with a mean concurrent blood Pb level of 4.2 μg/dL (Muntner et al., 2003). The conclusion from the 2006 Pb AQCD was substantiated by the coherence of effects observed across epidemiologic and toxicological studies. However, a number of the animal toxicological studies were conducted at Pb exposure concentrations that resulted in blood Pb levels higher than what is relevant to the general U.S. adult human population. Both human and animal studies observed Pb-associated hyperfiltration. In animals during the first 3 months after Pb exposure, effects were characterized by increased GFR and increased kidney weight due to glomerular hypertrophy. However, exposure for 6 or 12 months resulted in decreased GFR, interstitial fibrosis, and kidney dysfunction. Additionally, toxicological studies found that early effects of Pb on tubular cells were generally reversible, but continued exposure resulted in chronic irreversible damage. Toxicological studies provided mechanistic evidence to support the biological plausibility of Pb-induced renal effects, including oxidative stress leading to NO inactivation. Despite the strong body of evidence presented in the 2006 Pb AQCD, uncertainty remained on the contribution of past Pb

exposures to associations observed in adults, the impact in children, the implication of hyperfiltration, and reverse causality.

Consideration of results from recent epidemiologic studies does not alter the conclusions of the previous AQCD. Prospective studies in adult men in the general population (Tsaih et al., 2004; Kim et al., 1996); an adult patient population study (Yu et al., 2004); CKD patient studies (Lin et al., 2006b; Lin et al., 2006a; Lin et al., 2003), and a Pb worker cohort (Weaver et al., 2009) provide evidence of a relationship between blood Pb level and subsequent decreases in kidney function and better establish the temporal sequence between Pb exposure and kidney function. The study designs and analysis are well designed with careful measurement of exposure, outcomes, and covariates, and adjustment for numerous potential confounding factors including age, race, sex, education, household income, smoking, alcohol use, Cd exposure, and various health indicators such as diabetes, systolic BP, BMI, and history of cardiovascular disease. Large sample sizes provide strength to the general population studies, whereas some caution may be appropriate for the CKD patient studies where the smallest study has 87 subjects. Confidence in the relationship between Pb exposure and renal effects is provided by the combined results of a body of studies from different research groups using different designs in different cohorts.

Limitations of these studies produce some uncertainty in the relationship between Pb exposure and reduced kidney function. Since the prospective studies are reported in patients, workers, and primarily white men with a mean age of 60, they may not be generalizable to the entire U.S. population. Also, as these studies report effects most often observed in adults with likely higher past Pb exposures, uncertainty exists as to the Pb exposure level, timing, frequency, and duration contributing to the associations observed with blood or bone Pb levels. In addition, it is possible that the CKD patient studies (Lin et al., 2006b; Lin et al., 2006a; Lin et al., 2003), in which blood Pb level was lowered compared to control groups by chelation, demonstrate an improvement in renal function by reducing reactive oxygen species, blood Pb level or both. The uncertainty related to this may reflect an involvement of both lowering of blood Pb levels and a reduction of reactive oxygen species following chelation as both are possible to a varying extent. The potential for a bidirectional relationship because of reverse causality is possible in observational epidemiologic studies and must be weighed in this discussion (see Section 5.5.2.4).

Cross-sectional studies add support to the associations observed in prospective epidemiologic studies (Section 5.5.2.1). The majority of cross-sectional studies report associations between higher measures of Pb exposure and worse renal function. These studies include analyses from the NHANES cohort which provides a representative U.S.

population sample that may be generalizable to the total U.S. population. Re-examination of a study from the 2006 Pb AQCD (U.S. EPA, 2006b) provided data to conclude that in a population with likely higher past exposures to Pb, a 10-fold increase in concurrent blood Pb was associated with an 18 mL/min decrease in estimated creatinine clearance or a 25% decrease from the mean, and that an increase in blood Pb from the 5th to the 95th percentile (3.5 μg/dL) had the same negative impact on eGFR as did an increase of 4.7 years in age or 7 kg/m^2 in body mass index (Akesson et al., 2005). However, a small number of studies report findings that are less consistent with the body of evidence (Section 5.5.2.1). Overall, a relationship between higher Pb exposure and various indicators of lower kidney function is indicated by a set of high-quality studies that control for important potential confounders such as age, sex, BMI, comorbid cardiovascular conditions, smoking and alcohol use, and that are conducted with different designs in different cohorts by different researchers.

At current blood Pb levels in the U.S. adult population, a downward shift in kidney function of the entire population due to Pb may not result in CKD in identifiable individuals; however, that segment of the population with the lowest kidney reserve may be at increased risk for CKD when Pb is combined with other kidney risk factors. For example, in adults with mean (concurrent or baseline measured 4-6 years before kidney function tests) blood Pb levels that are comparable to that of the general U.S. population (1.6 to 4.2 μg/dL), higher blood Pb level was found to be associated with clinically-relevant effects (e.g., eGFR <60 mL/min/1.73 m^2, doubling of serum creatinine) (Fadrowski et al., 2010; Yu et al., 2004) and larger magnitudes of effect in potentially at-risk populations with cormorbidities for CKD such as diabetes mellitus (Tsaih et al., 2004) and hypertension (Tsaih et al., 2004; Muntner et al., 2003) or higher co-exposure to other environmental nephrotoxicants such as Cd (Navas-Acien et al., 2009).

Research in the occupational setting has traditionally been far less consistent than that in environmentally exposed populations (Section 5.5.2.1). Limitations of the occupational evidence, which are discussed earlier in this section have been used to explain this inconsistency. The actual cause of paradoxical or inverse associations (higher Pb dose with lower serum creatinine, and/or higher eGFR or calculated or measured creatinine clearance) in several of these studies may not be known. If associations are in opposite directions in different subgroups of the population and the relevant effect modifier is not considered, null associations will be observed. For these reasons, nonsignificant associations or paradoxical associations in the occupational setting cannot be used as a rationale for discounting Pb-related nephrotoxicity at lower environmental levels.

CKD is an important risk factor for cardiac disease. As kidney dysfunction can increase BP and increased BP can lead to further damage to the kidneys, Pb-induced damage to

either or both renal or cardiovascular systems may result in a cycle of further increased severity of disease. Pb exposure has been causally linked to both increased BP and other cardiovascular effects (Section 5.4). Interestingly, animal studies have shown Pb-induced vascular injury in the kidney was associated with increased glomerular sclerosis, tubulointerstitial injury, increased collagen staining, and an increase in macrophages associated with higher levels of MCP-1 mRNA. It is possible that the cardiovascular and renal effects of Pb observed are mechanistically linked and thus, Pb-induced hypertension has been noted as one cause of Pb-induced renal disease.

Recently available animal toxicological studies strengthen the evidence regarding the modes of action for Pb exposure leading to renal alterations, including the influence of Pb-induced oxidative stress. The mode of action of Pb in the kidneys has been extended to the field of immunology, evidenced by observations that Pb exposure resulted in infiltration of lymphocytes and macrophages associated with increased expression of NF-κB in proximal tubules and infiltrating cells (Roncal et al., 2007). Additionally, recent findings expand on the evidence of acute effects of Pb, including mitochondrial dysfunction, renal cell apoptosis, and glomerular hypertrophy. These mechanisms are useful in understanding the occurrence of acute hyperfiltration followed by chronic kidney dysfunction. Lower concentration Pb exposures and lower blood Pb levels in animals have not been widely examined. As indicated in Table 5-28, studies found dysfunction in various kidney function measures, including urinary flow, ALP, microalbumin, and NAG at blood Pb levels greater than 20 µg/dL.

Changes in renal function that have been associated with biomarkers of Pb exposure may indicate a modest change for an individual; however, these modest changes can have a substantial public health implication at the population level. The reported effects represent a central tendency of Pb-induced renal function effects among individuals; some individuals may differ in risk and manifest effects that are greater in magnitude. For example, a small worsening of renal function may shift the population distribution and result in considerable increases in the percentages of individuals with worse renal function that are clinically significant.

Overall, recent studies evaluated in the current review support and expand upon the body of evidence presented in the 2006 Pb AQCD indicating that Pb exposure is associated with reduced kidney function. In addition, animal studies provide biological plausibility for the associations observed in epidemiologic studies between blood Pb levels and reduced kidney function with evidence for Pb-induced hypertension, renal oxidative stress, inflammation, apoptosis, and glomerular hypertrophy. However, a number of limitations remain including the representativeness of worker studies and older all male cohorts to the U.S. population, the potential for reverse causality to play a role in the

findings of cross-sectional studies, and inconsistent findings in occupational studies. Collectively, the evidence integrated across epidemiologic and toxicological studies is sufficient to conclude that a causal relationship is likely to exist between Pb exposures and reduced kidney function.

Table 5-31 Summary of evidence supporting renal causal determinations.

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	References[b]	Pb Exposure or Blood Levels Associated with Effects[c]
Reduced Kidney Function – Likely Causal			
Consistent associations in multiple high quality epidemiologic studies with relevant blood Pb levels	Multiple prospective epidemiologic studies in nonoccupationally exposed adults for associations with change in serum creatinine and GFR in NAS, Korean workers, and CKD patients	Tsaih (2004), Kim (1996), Yu (2004), Weaver (2009)	Blood Pb level: Adults, <10 µg/dL[d]
	Studies provide concentration-response information	Section 5.5.2.1	
	Associations found with adjustment for potential confounding factors including age, pre-existing cardiovascular disease, baseline kidney function, and SES.	Muntner (2003), Navas-Acien (2009)	Concurrent Blood Pb level: Adults, means 1.58-4.2 µg/dL
	Supporting cross-sectional evidence for associations between concurrent blood Pb level and serum creatinine, creatinine clearance, and GFR	Section 5.5.2.1	
	Studies had population based recruitment (NHANES) with high follow-up participation	Akesson (2005), Staessen (1992), Payton (1994)	Concurrent Blood Pb level: Adults, medians 2.2-11.4 µg/dL
	Uncertainty related to reverse causality; the bidirectional association is possible	Section 5.5.2.4	
	Uncertainty due to baseline serum creatinine adjustment		
Limited toxicological evidence to support epidemiologic evidence	Mixed evidence in animals report decreased creatinine clearance, increased serum creatinine, and decreased GFR at both relevant and high level long-term exposures.	Berrahal et al. (2011), Roncal et al. (2007), Khalil-Manesh et al. (1993a; 1992b; 1992a)	Blood Pb level: Rodents: >7.5 µg/dL <65 days from birth, 26 µg/dL 12 weeks as adults, 29-125 µg/dL
Evidence clearly describes mode of action			
Hypertension	Consistent evidence of increased BP and hypertension following Pb exposure in humans and animals at relevant Pb levels across numerous studies with control for confounding. Association of increased blood pressure with manifestation of CHD has been well documented.	Sections 5.4 and 5.5.3.2	
Oxidative Stress	Consistent evidence for increased ROS, enhanced lipid peroxidation, and antioxidant enzyme disruption in Pb exposed animals.	Section 5.5.3.1	
Increased Uric Acid	Evidence of increased plasma uric acid and urea in animals. Mixed results in humans	Section 5.5.3.5	
Inflammation	Lymphocyte and macrophage infiltration Increased MCP-1 expression	Sections 5.5.2.5 and 5.2.5	
Morphology	Glomerular hypertrophy Cellular apoptosis and necrosis leading to PT damage	Sections 5.5.2.5 and 5.5.3.3	

[a]Described in detail in Table II of the Preamble.

[b]Describes the key evidence and references contributing most heavily to causal determination. Also noted are the sections where full body of evidence is described.

[c]Describes the blood Pb levels in humans with which the evidence is substantiated and blood Pb levels in animals most relevant to humans.

[d]Because blood Pb level in nonoccupationally-exposed adults reflects both recent and past Pb exposures, the magnitude, timing, frequency, and duration of Pb exposure contributing to the observed associations is uncertain.

5.6 Immune System Effects

5.6.1 Introduction

With respect to studies conducted in laboratory animal and in vitro models, the immune effects of Pb exposure have been extensively examined over several decades. Animal studies of the effects of Pb exposure on host resistance date back to the 1960s while those focusing on Pb-induced immune functional alterations, including developmental immunotoxicity, were first conducted during the 1970s. Despite this long history of research, Pb-associated immune effects in animals with blood Pb levels in the range of current U.S. population levels (i.e., <10 µg/dL), particularly early in life, have been observed only within the last 10-15 years (Dietert and McCabe, 2007). Recent findings of Pb-associated changes in immunological parameters in humans have increased understanding of the immune effects of environmental exposure to Pb.

The pathways by which Pb exposure may alter immune cell function and consequently increase the risk of immune-related diseases are presented in (Figure 5-34). Rather than producing overt cytotoxicity, Pb exposure has been associated with functional alterations in cellular and humoral immunity. In the 2006 Pb AQCD (U.S. EPA, 2006b), the hallmarks reported for Pb-induced changes in immune functional pathways were: (1) suppression of T cell-derived helper (Th)1-mediated immunity (i.e., suppressed Th1 cytokine production and delayed type hypersensitivity [DTH] response); (2) stimulation of Th2 immunity (i.e., increased production of Th2 cytokines and immunoglobulin (Ig)E antibody); and (3) altered macrophage function (U.S. EPA, 2006b). The latter was characterized by increased production of reactive oxygen species (ROS), prostaglandin E_2 (PGE_2), and inflammatory cytokines such as tumor necrosis factor-*alpha* (TNF-α) and interleukin (IL)-6 and decreased production of nitric oxide (NO). Changes in immune cells can alter cell-to-cell interactions, multiple signaling pathways, and inflammation, that in turn, can influence the risk of developing infectious, allergic, and autoimmune diseases and exacerbate inflammatory responses in other organ systems. Studies conducted in animal and in vitro models provided consistent evidence for Pb exposure inducing effects on the range of immune effects presented in this continuum. In the much smaller epidemiologic evidence base, most studies examined Pb-exposed male workers and a limited range of immune-related endpoints.

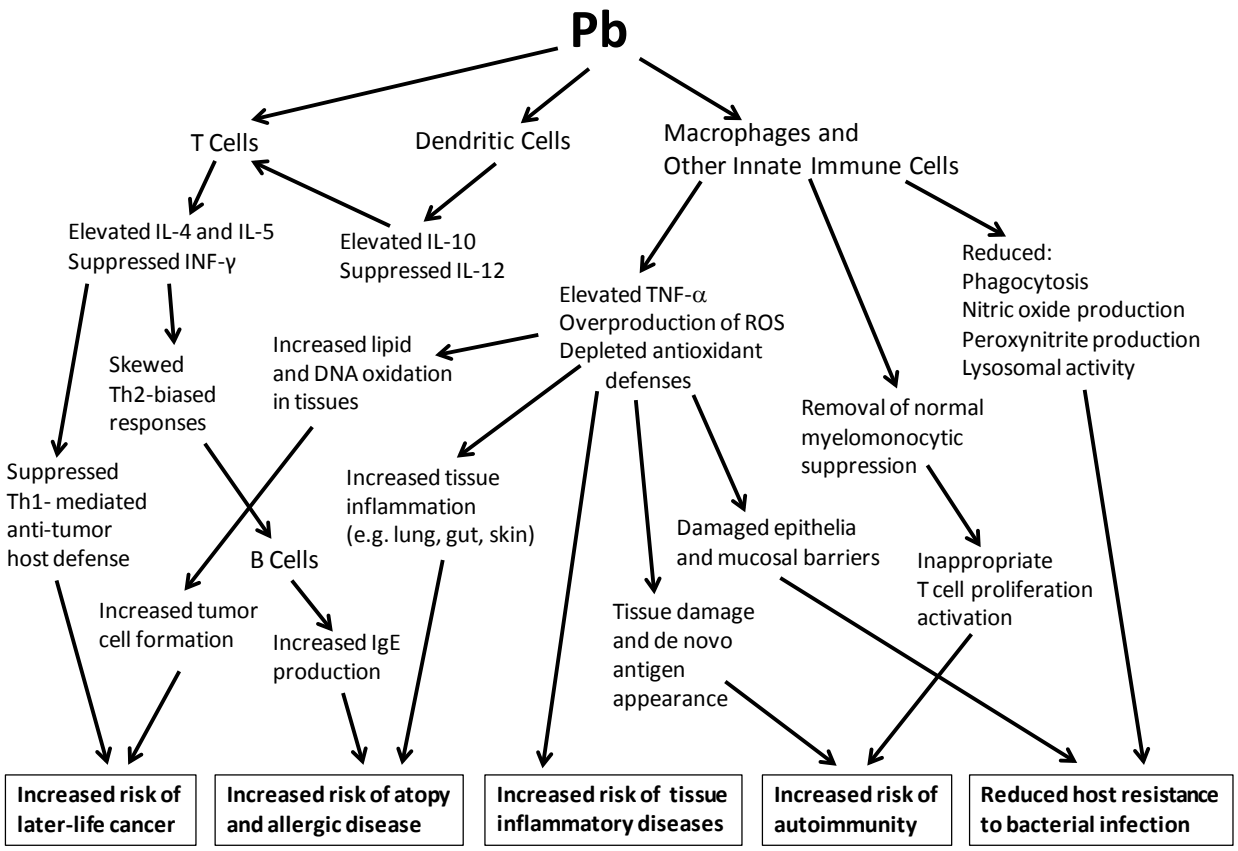

Figure 5-34 Immunological pathways by which Pb exposure may increase risk of immune-related diseases.

Reflecting suppressed Th1 activity, toxicological evidence presented in the 2006 Pb AQCD linked Pb exposure of animals to impaired host resistance to viruses and bacteria (U.S. EPA, 2006b). Indicating a hyperinflammatory state and local tissue damage, a few available toxicological studies found Pb exposure-induced generation of auto-antibodies, suggesting an elevated risk of autoimmune reactions. Additionally, the shift toward Th2 responses suggested that Pb could elevate the risk of atopic and inflammatory responses. While the biological plausibility of such effects was supported by toxicological evidence for Pb-induced increases in Th2 cytokines, IgE, and inflammation, epidemiologic evidence was too sparse to draw conclusions about the effects of Pb exposure on these broader indicators of immune dysfunction in humans. However, in concordance with toxicological evidence, a shift to a Th2 phenotype was indicated in the few available studies by associations observed between higher concurrent blood Pb level and higher serum IgE levels in children. Because of lack of examination, the immune effects of Pb exposure in adults without occupational exposures were not well characterized.

Changes in the spectrum of immune endpoints were found in association with a wide range of blood Pb levels. Juvenile and adult animals with Pb levels in the range of 7-100 µg/dL were found to have suppressed DTH, elevated IgE, and changes in cytokine levels. Most epidemiologic studies examined and found lower T cell abundance and higher serum IgE levels in association with population mean (or group) concurrent blood Pb levels >10 µg/dL.

With respect to important lifestages of Pb exposure, animal studies provided strong evidence for immune effects in juvenile animals induced by prenatal Pb exposures and in adult animals by postnatal exposures. There was uncertainty regarding important lifestages of Pb exposure in humans as epidemiologic studies of children primarily were cross-sectional and examined concurrent blood Pb levels. Several other limitations of epidemiologic studies were noted, including small sample sizes; little consideration for potential confounding factors such as age, sex, smoking, SES indicators, and allergen exposures; and comparisons of immune endpoints among groups with different blood Pb levels that provided little information on the concentration-response relationship.

Collectively, the small numbers of toxicological and epidemiologic studies published since the 2006 Pb AQCD, supported the previous findings of Pb-associated immune effects. Epidemiologic studies supported previous findings in children and provided new evidence for effects in nonoccupationally-exposed adults. Recent studies also expanded on the array of immunological parameters affected by Pb exposure as presented in Figure 5-34. For example, a recent toxicological study indicated that Pb may modulate the function of dendritic cells. Results from recent toxicological and epidemiologic studies supported the link between Pb-associated effects on immune cells and immune- and inflammatory-related diseases by providing evidence for changes in intermediary signaling and inflammatory pathways (Figure 5-34). Several recent epidemiologic studies examined signaling molecules such as pro-inflammatory cytokines to provide coherence with toxicological findings. Recent toxicological studies further supported the broader role of Pb-associated immune modulation in mediating Pb effects in nonlymphoid tissues (e.g., nervous, reproductive, respiratory systems). Recent epidemiologic studies improved on the design of previous studies through greater examination of children and adults with blood Pb levels more comparable to current levels in the U.S. population and greater consideration for confounding by age, sex, smoking, SES indicators, and allergen exposures. This epidemiologic evidence particularly that from prospective studies, combined with the extensive toxicological evidence formed the basis of conclusions about the immune effects of Pb exposure (Section 5.6.8).

5.6.2 Cell-Mediated Immunity

5.6.2.1 T Cells

T cells have a central role in cell-mediated immunity including maturation of B cells, activation of cytotoxic T cells and macrophages, and interactions with antigen presenting cells (APCs). A majority of the evidence for the effects of Pb exposure on T cells was provided by toxicological and epidemiologic studies reviewed in the 2006 Pb AQCD (U.S. EPA, 2006b). Toxicological evidence consistently links Pb exposure with alterations in T cells with observations of Pb-induced shifts in the partitioning of CD4+ (T helper) cell populations to favor Th2 cells in vitro (25-50 µM Pb chloride, 3-5 days) (Heo et al., 1998; 1996), proliferation of Th2 cells over Th1 cells in vitro (10, 100 µM Pb chloride, 7 days) (McCabe and Lawrence, 1991), and the production of Th2 cytokines over Th1 cytokines in vitro and in vivo (wide range of Pb concentrations, Section 5.6.6.1). Epidemiologic findings are limited largely to associations observed between higher concurrent blood Pb level and lower T cell abundance in children.

In vitro results indicated various mechanisms by which Pb exposure may induce a shift to Th2 responses including activation of transcription factor NF-κB (regulates T cell activation) in cultures of human CD4+ T cells (1 µM Pb acetate, 30 minutes) (Pyatt et al., 1996) and a concentration-dependent (10, 50 µM Pb chloride, 24 hours) increased expression of MHC class II surface antigens (e.g., HLA-DR), which mediate the CD4+ response to exogenous antigens (Guo et al., 1996b). The few available recent toxicological studies described T cell-dependent and -independent pathways. Kasten-Jolly et al. (2010) provided evidence in vivo and with relevant dietary Pb exposures. While results were based on a microarray analysis of hundreds of genes, which is subject to higher probability of chance findings, they were supported by the extant evidence base. In this study, gestational-lactational Pb acetate exposure of BALB/c mice (100 µM in drinking water of dams GD8-PND21, resultant spleen homogenate level <3 µg/dL) altered splenic cell gene expression of cytokines well documented in the literature to be affected by Pb, including the Th2 cytokine IL-4 and the Th1 cytokine interferon-gamma (IFN-γ). These changes occurred with increases in adenylate cyclase 8 and phosphatidylinositol 3-kinase in the absence of signaling molecules STAT4 or STAT6, which comprise the preferential signaling pathway for T cells. Similarly, in cultures of stimulated mouse T cells, Heo et al. (2007) showed that Pb chloride (25 µM, 12-24 hours) decreased the IFN-γ to IL-4 ratio (indicating a shift to Th2) in the absence of STAT6. Additionally, Pb blocked production of IFN-γ not by affecting gene expression but by suppressing translation of the protein. This blockage was rescued with the addition of IL-12, which is a T cell stimulating factor. The STAT results indicated a T cell-

independent pathway to skewing toward Th2 responses whereas the IL-12 results pointed to a T cell-dependent pathway.

While a few available recent epidemiologic studies found associations of blood Pb levels with Th1 and Th2 cytokines in humans (Section 5.6.6.1), the extant evidence for effects on T cells in humans is derived largely from previous cross-sectional studies describing differences in the abundance of several T cell subtypes that mediate acquired immunity responses to antigens. Most studies of children found that higher blood Pb levels were associated with lower T cell abundance in serum, primarily CD3+ cells. These associations were observed in studies that adjusted for some potential confounding factors (as described below) (Karmaus et al., 2005; Sarasua et al., 2000) and studies without consideration for potential confounding (Zhao et al., 2004; Lutz et al., 1999). In children, blood Pb level was less consistently associated with lower abundance of other T cell subtypes such as CD4+ (helper T) or CD8+ (cytotoxic T). Some studies did not provide evidence of blood Pb-associated decreases in T cell abundance but did not consider potential confounding (Hegazy et al., 2011; Belles-Isles et al., 2002).

Associations between blood Pb level and T cell abundance were found in studies that generally had population-based recruitment. Most studies did not provide sufficient information to assess the potential for biased participation by Pb exposure and immune conditions. Most studies had multiple comparisons; however, associations were not isolated to T cell abundance. Most studies found lower T cell abundance in groups of U.S. and non-U.S. children (ages 6 months-10 years, n = 73-331) with concurrent blood Pb levels >10 µg/dL (Zhao et al., 2004; Sarasua et al., 2000; Lutz et al., 1999). Associations were inconsistent in comparisons of children with lower blood Pb levels. Among 331 children in Germany living near (15 km) and distant from industrial facilities, Karmaus et al. (2005) found that children (ages 7-10 years) with concurrent blood Pb levels 2.2-2.8 µg/dL (2nd quartile) had a 9 to 11% lower abundance of several T cell subtypes (for some subtypes, $p < 0.05$, t-test) compared with children with blood Pb levels <2.2 µg/dL (lowest quartile). This study recruited children from schools and examined multiple exposures, reducing the likelihood of biased participation by Pb exposure. Monotonic decreases were not found across blood Pb groups. Compared with other studies of T cells, Karmaus et al. (2005) had greater consideration for potential confounding, adjusting for sex, age, number of infections in the previous 12 months, number of cigarettes/day smoked in the home in the previous 12 months, serum lipids, and blood organochlorine levels. SES was not examined. Cord blood levels of organochlorine and Hg but not Pb were associated with T cell abundance in 96 newborns from a subsistence fishing community and an urban center in Quebec, Canada with a population mean cord blood Pb level <2 µg/dL (Belles-Isles et al., 2002).

Another study of children from multiple unspecified U.S. locations with and without mining and smelting operations that considered confounding also found an association between higher concurrent blood Pb level and lower T cell abundance, albeit limited to the youngest subjects (Sarasua et al., 2000). Among 241 children ages 6-35 months, a 1 µg/dL higher blood Pb level was associated with a 0.18% (95% CI: -0.34, -0.02) lower CD3+ cell count, a 0.10% (95% CI: -0.24, 0.04) lower CD4+ cell count, and a 0.04% (95% CI: -0.15, 0.07) lower CD8+ cell count, with adjustment for location of residence, age, and sex. In older age groups (36-71 months, 6-15 years), many effect estimates were positive. Analysis of blood Pb level categories indicated that associations were influenced by lower T cell abundance (3-6%) among children ages 6-35 months with blood Pb levels >15 µg/dL. Notably, 76% of subjects lived near a Pb smelting operation, were likely to have higher blood Pb levels, and may have influenced the observed associations. Neither Karmaus et al. (2005) nor Sarasua et al. (2000) found a monotonic decrease in T cell abundance across blood Pb level groups. Neither of these studies adjusted for SES, which has been associated with blood Pb levels and immune-related conditions such as asthma, allergy, and respiratory infections.

In the few studies with nonoccupationally-exposed adults (U.S, Italy), higher concurrent blood Pb levels were associated with higher T cell abundance (Boscolo et al., 2000; Sarasua et al., 2000; Boscolo et al., 1999), the functional relevance of which is unclear. These studies included healthy subjects and those with allergies, a wide range of samples sizes (17-433), ages (16-75 years), and mean blood Pb levels (4.3-11.4 µg/dL). Pb-exposed workers in the U.S. and Asia did not consistently have lower or higher abundance of various T cell subtypes than unexposed controls (Mishra et al., 2010; Pinkerton et al., 1998; Yücesoy et al., 1997b; Ündeger et al., 1996; Fischbein et al., 1993). The inconsistency among studies was not related to differences in sample size (20-145), age (means: 22-58 years), or blood Pb levels (14.6-132 µg/dL) among Pb workers. None of the studies of adults considered potential confounding factors, including other workplace exposures in occupational studies.

In summary, toxicological studies provided clear evidence for the effects of Pb exposure on T cells by demonstrating Pb-induced expansion of Th2 cells and increased Th2 cytokine production. Providing mechanistic evidence, a few recent toxicological studies found that Pb-induced Th2 skewing may occur via T cell-dependent (Heo et al., 2007) and -independent pathways (Kasten-Jolly et al., 2010; Heo et al., 2007). The most consistent epidemiologic findings were associations between higher concurrent blood Pb level (>10 µg/dL) and lower T cell abundance observed in children ages 6 months to 10 years (Karmaus et al., 2005; Zhao et al., 2004; Sarasua et al., 2000; Lutz et al., 1999). An association was found with lower blood Pb levels, i.e., <3 µg/dL (Karmaus et al., 2005), albeit in children ages 7-10 years who may have had higher Pb exposures in earlier

childhood. The uncertainties regarding blood Pb levels and the timing and duration of Pb exposure contributing to the associations with T cell abundance apply to the evidence as a whole since concurrent blood Pb levels in children also reflect past Pb exposures. There are several other uncertainties in this evidence, including the temporal sequence between Pb exposure and T cell changes, potential selection bias, the concentration-response relationship, and potential confounding by factors such as SES and other environmental exposures. The implications of Pb-associated changes in T cell abundance are limited further by the uncertain functional relevance of small magnitudes of change in T cell abundance (1-9% lower CD3+ abundance in groups of children with higher blood Pb levels) to downstream immune responses. Because toxicological studies examined effects related specifically to Th1 or Th2 responses, toxicological evidence is the major consideration in drawing conclusions about the effects of Pb exposure on T cells.

5.6.2.2 Lymphocyte Activation

Lymphocytes (T, B, and natural killer [NK] cells) are activated by reversing the normal suppression mediated by macrophage-like cells. Their activation is an indicator of response to antigens. A majority of data on the effects of Pb exposure on lymphocyte activation is provided by toxicological studies reviewed in the 2006 Pb AQCD that showed both mitogen-induced expansion and suppression of alloreactive B and T lymphocytes proliferation with Pb exposures in vivo and in vitro (U.S. EPA, 2006b). Adding to the mixed nature of evidence, a recent study found that 4-week oral exposure of 7 week-old Wistar rats to 200 ppm Pb acetate induced proliferation of lymphocytes within the thymus and submaxillary lymph nodes, primarily by affecting B cells (Teijón et al., 2010). Overall T cell proliferation did not change or was suppressed. Specific T cell subtypes, CD4+, CD8+ (decreased), CD4-CD8- (elevated) were affected only with i.p. Pb dosing ($p < 0.05$) and not oral exposure. Using the local lymph node assay, Carey et al. (2006) found that Pb chloride increased antigen-induced (ovalbumin, OVA) T cell proliferation in adult female BALB/c mice but administered Pb via injection (25-50 µg). The mechanistic basis for Pb effects on lymphocyte activation is not well characterized. As discussed in Section 5.6.6.2, changes in NO production appear to be involved (Farrer et al., 2008). Gao et al. (2007) described a potential role for dendritic cells. Dendritic cells that matured in the presence of 25 µM Pb chloride enhanced alloreactive T cell proliferation in vitro compared to control dendritic cells.

A few available cross-sectional epidemiologic studies in children and nonoccupationally-exposed adults provided indirect evidence for Pb-associated lymphocyte activation. Instead of directly measuring lymphocyte proliferation, these studies measured the abundance of cells that expressed HLA-DR, a cell surface marker that indicates both

activated lymphocytes and monocytes. These studies had limited consideration for potential confounding, which also limits the implications of findings. In the study of children (ages 9 months-6 years, Missouri), the mean percentage of HLA-DR+ cells was about 2-fold higher ($p > 0.05$, Kruskal-Wallis) in the 19 children with concurrent blood Pb levels 15-19 µg/dL than in children with blood Pb levels 10-14 µg/dL (n = 61) or <10 µg/dL (n = 178) with adjustment for age (Lutz et al., 1999). However, activated cells were not elevated in 16 children with blood Pb levels 20-44 µg/dL. Small studies of adults without occupational Pb exposure in Italy found that concurrent blood Pb level was correlated positively with the percentage of HLA-DR expressing cells in men ages 19-52 years with and without allergies (Spearman $r = 0.51$, $p < 0.002$, n=17 each, overall median blood Pb level: 11 µg/dL) (Boscolo et al., 1999) but only in women ages 19-49 years without allergies (Spearman $r = 0.44$, $p < 0.05$, n=25, median blood Pb level: 5.5 µg/dL) (Boscolo et al., 2000). Associations also were found with other metals.

Comparisons of Pb-exposed workers and unexposed controls indicated similar levels of lymphocyte proliferation (≤ 1% difference) in Pb-exposed workers (n = 10-33, mean age: 32-40 years, blood Pb level range: 12-80 µg/dL) (Queiroz et al., 1994b; Cohen et al., 1989) or lower lymphocyte proliferation (8-25%) among Pb-exposed workers (n = 15-39, mean age: 30-49 years, mean blood Pb level: 14.6-129 µg/dL) (Mishra et al., 2003; Fischbein et al., 1993; Alomran and Shleamoon, 1988; Kimber et al., 1986). In the combined epidemiologic and toxicological evidence, Pb was associated with both activation and suppression of lymphocyte activation. None of the studies considered potential confounding factors, including other workplace exposures, and inconsistency among studies could not be explained by differences in sample size, age of subjects, or blood Pb level either. None of the studies provided concentration-response information. Toxicological studies have demonstrated the selective expansion of Th2 cells and suppression of Th1 cells (Section 5.6.2.1). Therefore, the differential activation of specific subtypes may not be discernible in studies that measure overall lymphocyte proliferation.

5.6.2.3 Delayed-type Hypersensitivity

Although not widely examined recently, several toxicological studies reviewed in the 2006 Pb AQCD (U.S. EPA, 2006b) and recent reviews (Mishra, 2009; Dietert and McCabe, 2007) identified a suppressed DTH response as one of the most consistently observed immune effects of Pb exposure in animal models. A recent study indicated that this effect may be mediated by dendritic cells. The DTH assay commonly is used to assess the T cell-mediated response to antigens, i.e., induration and erythema resulting from T cell activation and recruitment of monocytes to the site of antigen deposition. The

DTH response is largely Th1-dependent in that Th1 cytokines induce the production of T cells specifically directed against the antigen (sensitization) and recruitment of antigen-specific T cells and monocytes to the site of antigen deposition (elicitation phase).

Previous studies demonstrated suppressed DTH in animals after gestational (Chen et al., 2004; Bunn et al., 2001a; 2001b, c; Lee et al., 2001b; Chen et al., 1999; Miller et al., 1998; Faith et al., 1979) and postnatal (McCabe et al., 1999; Laschi-Loquerie et al., 1984; Müller et al., 1977) Pb acetate exposures. Such observations were made in F344 and CD rats, BALB/c and Swiss mice, and chickens. Most studies exposed animals to Pb in drinking water and found suppressed DTH in animals with blood Pb levels relevant to humans (means: 6.75, 25 µg/dL) (Chen et al., 2004; Bunn et al., 2001a) and higher (51 to >100 µg/dL) (Bunn et al., 2001b; Chen et al., 1999; McCabe et al., 1999). The associations of DTH with lower blood Pb levels occurred with gestational Pb exposure.

In some studies that examined Pb exposures at multiple stages of gestation, exposures later in gestation suppressed DTH in animals (Bunn et al., 2001c; Lee et al., 2001b). These latter findings may reflect the status of thymus and T cell development. A recent study contributed to the robust evidence by indicating a role for dendritic cells in the Pb-induced suppression of the DTH response. Gao et al. (2007) exposed bone marrow-derived dendritic cells in vitro to Pb chloride (25 µM, 10 days) then the antigen OVA and injected the cells into naïve adult mice. Mice treated with Pb-exposed dendritic cells had a diminished OVA-specific DTH footpad response compared with mice treated with dendritic cells not exposed to Pb.

Evidence indicates Pb-induced suppression of DTH in animals with blood Pb levels relevant to humans (6.75-25 µg/dL) produced by gestational Pb exposure via drinking water of dams. The mode of action is strongly supported by observations that Pb suppresses production of the Th1 cytokine IFN-γ (Section 5.6.6.1). IFN-γ is the primary cytokine that stimulates recruitment of macrophages, a key component of the DTH response. In animal studies that also examined IFN-γ, the suppressed DTH response was accompanied by a decreased production of IFN-γ (Lee et al., 2001b; Chen et al., 1999). Observations of a concomitant decrease in IFN-γ strengthen the link between Pb-induced inhibition of Th1 functional activities and suppression of the DTH response.

5.6.2.4 Macrophages and Monocytes

As reported in the 2006 Pb AQCD, based on a large body of toxicological evidence and some supporting epidemiologic evidence, Pb-induced alteration of macrophage function was considered to be a hallmark of Pb-associated immune effects (U.S. EPA, 2006b). Macrophages, which are produced by the differentiation of blood monocytes in tissues,

mediate host defense through their role in phagocytosing pathogens and stimulating other immune cells. Pb exposure was found to induce macrophages into a hyperinflammatory phenotype as indicated by enhanced production of TNF-α, IL-6, and ROS and increased metabolism of arachidonic acid into PGE_2. Observations in macrophages of Pb-induced enhanced production of ROS, suppressed production of NO, impaired growth and differentiation, and potentially altered receptor expression [e.g., toll-like receptors]) provided coherence with the effects of Pb observed on tissue damage and diminished host resistance in animals. Several of these findings are described in detail in Sections 5.6.6.2 and 5.6.6.3. Because macrophages are major resident populations in most tissues and organs and also are highly mobile in response to microbial signals and tissue alterations, their functional impairment in response to Pb exposure may serve as a link between Pb-induced immune effects and impaired host defense, tissue integrity, and organ homeostasis in numerous physiological systems.

Some rodent studies indicated reduced macrophage generation or phagocytosis with gestational or postnatal dietary Pb acetate exposure that produced blood Pb levels (upon cessation of exposure) relevant to humans, i.e., 8.2 µg/dL in F344 rats (Bunn et al., 2001c) and 18 µg/dL in CBA/J mice (Kowolenko et al., 1991). Similarly, Knowles and Donaldson (1997) found that Pb acetate trihydrate (PND1-PND21) induced a decrease in macrophage phagocytosis but in turkeys with higher blood Pb levels, 42 µg/dL. In one set of experiments, CBA/J mice exposed to Pb acetate for 2 weeks with blood Pb levels of 18 µg/dL had reduced macrophage generation (Kowolenko et al., 1991) in response to *Listeria* infection but no change in macrophage phagocytosis (Kowolenko et al., 1988). Other animal studies administered Pb through routes that may not be directly relevant to those in humans. Effects such as decreased macrophage yield, viability, phagocytosis, chemotaxis, and killing ability were reported in Swiss mice following bacterial infection and Pb treatment by oral gavage (40 mg/kg Pb nitrate, oral gavage, 40 days) (Lodi et al., 2011) or injection 10 mg/kg, i.p., 15 days) (Bishayi and Sengupta, 2006). Lee et al. (2002) found no change in monocyte abundance in 5-6 week-old chickens treated with 200 µg Pb acetate via the air sac in ovo at embryonic day 5 or 12. Some (Bussolaro et al., 2008; Zhou et al., 1985) but not all in vitro studies (De Guise et al., 2000) also found Pb-induced (0.2-1,000 µM Pb chloride or Pb nitrate) reduced phagocytosis. In particular, Bussolaro et al. (2008) found such effects with a relatively low concentration of Pb exposure (0.2 µM Pb nitrate, 72 hours).

The effects of Pb exposure on macrophages in humans have not been widely examined. Pineda-Zavaleta et al. (2004) was unique in examining the hyperinflammatory state specifically in macrophages, and consistent with the large body of toxicological studies, found associations of higher concurrent blood Pb level with lower NO release and higher superoxide anion release from macrophages isolated from child sera (Sections 5.6.6.2 and

5.6.6.3). Other studies in humans examined macrophage abundance in Pb-exposed workers, and evidence overall did not clearly indicate an association with concurrent blood Pb level. Pinkerton et al. (1998) considered potential confounding and found a <1-fold lower ($p = 0.03$) abundance of monocytes among 145 U.S. Pb smelter workers with a mean blood Pb level and age of 39 µg/dL and 33 years, respectively, than among 84 unexposed controls with a mean blood Pb level and age of <2 µg/dL and 30 years, respectively. Results were adjusted for age, race, current smoking, and workshift, but other workplace exposures were not examined. Other occupational studies did not consider potential confounding factors. Conterato et al. (In Press) examined male Pb-exposed painters in Brazil with blood Pb levels 1.4-14.0 µg/dL (mean: 5.4 µg/dL), lower than those in other occupational studies. Monocyte abundance in the 50 painters (mean age: 33.5 years) was similar to that in 36 controls (mean blood Pb level: 1.5 µg/dL, mean age: 33.5 years) and 23 battery workers with much higher blood Pb levels (mean: 50 µg/dL, mean age: 37.3 years). Fischbein et al. (1993) found a <2-fold lower ($p < 0.001$) abundance of HLA-DR+ cells in two groups of New York metropolitan area firearms instructors with mean blood Pb levels of 14.6 µg/dL ($n = 36$, mean age: 49 years) and 31.4 µg/dL ($n = 15$, mean age: 48 years) than among the 36 unexposed controls (mean age: 47 years). Investigators cited other observations that 70% of monocytes express HLA-DR antigen compared with 15% of lymphocytes to attribute the reduced expression of HLA-DR in Pb-exposed workers to a reduction in activated monocytes. However, lower HLA-DR+ may have indicated activation of other APCs such as dendritic or T cells.

The 2006 Pb AQCD (U.S. EPA, 2006b) also described the effects of Pb on specialized macrophages in nonlymphoid tissue, including increased ROS production and impaired phagocytosis by Kupffer cells in the liver and alveolar macrophages in the lung and suggested a link between these effects and organ/tissue dysfunction, cell death, tissue pathology and tissue-specific autoimmune reactions. The limited available investigation provides additional evidence for effects on Kupffer cells and alveolar macrophages as well as microglia and astrocytes in the brain, osteoclasts in the bone, and testicular macrophages.

Fan et al. (2009b) reported major changes in phenotypic expression (e.g., CD68 and ferritin light chain), organization, and functional activity of Kupffer cells connected to apoptosis in the liver of 6-7 week old Sprague-Dawley rats treated with a single 2.5×10^4 µM Pb nitrate injection. Dosing of juvenile Wistar rats with Pb injections (15 mg/kg of Pb acetate daily for 2 weeks, resulting in a mean blood Pb level of 30 µg/dL) during early postnatal maturation resulted in an increase in GFAP, indicating chronic activation of glial cells; an increase in pro-inflammatory cytokines (i.e., IL-1β, TNF-α and IL-6); and a decrease in synaptophysin (component of presynaptic vesicles), indicating

neurodegeneration in brain tissue (Strużyńska et al., 2007). Bone osteoblasts have been shown to be affected by Pb exposure (Section 5.9.4), which, given the interactions between osteoblasts and osteoclasts (Chang et al., 2008a), could have implications for development of arthritis [reviewed in Zoeger et al. (2006)]. In vitro, 1 µM Pb acetate elevated TGF-β production and cartilage formation in limb bud mesenchymal cells (Zuscik et al., 2007). Kaczynska et al. (2011) reported effects on alveolar macrophages after Pb acetate treatment (i.p. 25 mg/kg, 3 days, resulting in blood Pb levels of 2.1 µg/dL) in Wistar rats. Macrophages infiltrated airways, limiting air space available to gas exchange and contained parts of phagocytized surfactant and alveolar lining. Resident immune cells in reproductive organs have been shown to be affected by high concentration Pb exposure. In male BALB/c mice, Pace et al. (2005) found that 0.1 ppm Pb acetate exposure in drinking water PND1-PND42 (mean peak blood Pb level: 59.5 µg/dL) resulted in sterility concomitantly with a decrease in the testicular macrophage population and an increase in apoptotic testicular cells.

In summary, an extensive toxicological evidence base demonstrates that Pb exposure decreases functionality of macrophages and promotes a hyperinflammatory phenotype. Animals with dietary Pb exposure resulting in blood Pb levels (upon cessation of exposure) relevant to humans, 8.2 and 18 µg/dL, had reduced macrophage generation and phagocytosis (Bunn et al., 2001c; Kowolenko et al., 1991). Some in vitro studies (Bussolaro et al., 2008; Zhou et al., 1985) provided supporting evidence. Several observations link Pb exposure to impaired function and/or structure of specialized macrophages in nonlymphoid tissue, including liver Kupffer cells and alveolar macrophages. The results suggest that immune dysfunction may contribute to the effects of Pb on dysfunction in nonlymphoid tissues and provides a link between immune dysfunction and disease in other organ systems. However, the implications of findings to effects in humans are uncertain because in several studies, animals were treated with Pb by injection and/or had high blood Pb levels. Evidence for Pb-induced decreases in macrophage functionality provides mode of action support for observations of Pb-induced decreased host resistance in animals (Section 5.6.5.1). The sparse epidemiologic evidence is not conclusive but was a lesser consideration than the toxicological evidence in drawing conclusions about the effects of Pb exposure on macrophages because most epidemiologic studies did not examine the functional state of macrophages. The study that examined the functional state of macrophages, i.e., mediators of host defense or inflammation, found an association with blood Pb level in children (Pineda-Zavaleta et al., 2004) consistent with toxicological evidence. Occupational studies examined abundance of monocytes or markers of activated macrophages plus other antigen presenting cells, and evidence did not clearly indicate a difference in Pb-exposed workers. Inconsistency among studies was not related to differences in sample size, age, or blood Pb levels of Pb-exposed workers. None of the

studies considered the potential influence of other occupational exposures or provided concentration-response information.

5.6.2.5 Neutrophils

In the 2006 Pb AQCD, Pb exposure was not judged to have a strong effect on neutrophils, which comprise the majority of polymorphonuclear cells (PMNs) (U.S. EPA, 2006b). This conclusion was based on the limited available toxicological evidence as compared with that for effects on other immune cells. However, the modulation of neutrophil activity may have important consequences on the dysregulation of inflammation and ability of organisms to respond to infectious agents. Studies of cultured human PMNs (Governa et al., 1987) and occupationally-exposed adults (Queiroz et al., 1994a; Queiroz et al., 1993; Valentino et al., 1991; Bergeret et al., 1990) found Pb-associated reductions in PMN functionality, as indicated by reduced chemotactic response, phagocytic activity, respiratory oxidative burst activity, or reduced ability to kill ingested antigen. These observations were made in groups of Pb-exposed workers (n = 10-60) with range of mean age 34-41 years and blood Pb levels 14.8-91.4 µg/dL. These studies were focused on neutrophil function, and while the evidence did not appear to be influenced by multiple comparisons, it could have been influenced by publication bias. In these cross-sectional studies, the temporal sequence between Pb exposure and neutrophil function cannot be determined. Other limitations across all studies include the lack of consideration for potential confounding factors, including other workplace exposures, and high blood Pb levels of Pb-exposed workers.

Instead of examining neutrophil functional activities, the few available recent studies of animals and occupationally-exposed adults examined neutrophil counts, an increase in which has been interpreted by some investigators to be a compensatory response to Pb-induced impairment in neutrophil chemotactic activity and a hyperinflammatory response. A study in male Wistar rats found that 12 mg Pb spheres implanted in brains (compared with control glass spheres) resulted in greater neutrophil filtration from day 7-28 with inflammatory-related damage that included apoptosis and indications of neurodegeneration (Nakao et al., 2010). However, the route of Pb administration has uncertain relevance to the typical routes of Pb exposure in humans.

Occupational studies produced contrasting results that were not related to the blood Pb levels of workers. DiLorenzo et al. (2006) found a Pb-associated higher absolute neutrophil count (ANC) in analyses that adjusted for potential confounding factors and showed a concentration-dependent relationship. In an analysis combining 68 ceramic, Pb recycling, or bullet manufacturing workers and 50 control food plant workers in Italy, a

1 µg/dL higher concurrent blood Pb level was associated with a 21.8 cells/µL (95% CI:
2 11.2, 32.4 cells/µL) higher ANC. While these results were adjusted for age, current BMI,
3 and current smoking status, other workplace exposures were not examined. Pb-exposed
4 workers had a mean age 44 years and a geometric mean concurrent blood Pb level of
5 20.5 µg/dL. Controls had a mean age 46.8 years and mean blood Pb level of 3.5 µg/dL.
6 Neutrophilia (n >7,500 cells/mm^3) was found in 8 workers described to have medium to
7 high Pb exposures (exact blood Pb levels not reported) but no controls had suggesting
8 that long-term, higher-level Pb exposures can lead to a biologically meaningful excess of
9 circulating neutrophils. Additionally, a blood Pb concentration-dependent relationship
10 was indicated by observations of a monotonic increase in ANC across increasing blood
11 Pb level groups: controls, workers with blood Pb levels ≤ 30 µg/dL, and workers with
12 blood Pb levels >30 µg/dL. Results further indicated an interaction between concurrent
13 blood Pb level and current smoking. ANC increased across the three blood Pb groups
14 among current smokers but not nonsmokers. In contrast, in a study that did not consider
15 any potential confounding factors, Conterato et al. (In Press) found lower neutrophil
16 concentrations among 23 battery workers and 50 painters in Brazil with mean concurrent
17 blood Pb levels of 50.0 and 5.4 µg/dL, respectively, than among 36 controls with a mean
18 blood Pb level of 1.5 µg/dL. Pb-exposed workers did not consistently have higher levels
19 of eosinophils, basophils, monocytes, or total lymphocytes either.

20 Support for the decreased neutrophil function found in Pb-exposed workers is provided
21 by findings of Pb-associated increases in TNF-α (Section 5.6.6.1) and complement,
22 which are mediators of neutrophil proliferation, survival, maturation, and functional
23 activation. The complement system is a component of the innate immune system that is
24 involved in chemotaxis of macrophages and neutrophils and phagocytosis of antigens.
25 The few available occupational studies found lower complement in Pb-exposed workers
26 with mean blood Pb levels >60 µg/dL (Ündeger et al., 1996; Ewers et al., 1982), higher
27 than those relevant to the U.S. general population. Neither study considered potential
28 confounding factors, including other workplace exposures. The evidence has limited
29 implications also because the cross-sectional nature of studies cannot establish the
30 temporal sequence between Pb exposure and complement.

31 In summary, previous occupational studies provided evidence for the effects of Pb
32 exposure on neutrophils by finding that compared with controls, Pb-exposed workers had
33 lower neutrophil functionality (Queiroz et al., 1994a; Queiroz et al., 1993; Valentino et
34 al., 1991; Bergeret et al., 1990) and lower complement (Ündeger et al., 1996; Ewers et
35 al., 1982), which is a mediator of phagocyte functionality. The limited number of recent
36 epidemiologic studies examined only neutrophil abundance and conclusively did not find
37 Pb-exposed workers to have higher or lower neutrophil abundance. While there is
38 evidence for Pb-associated reduced neutrophil functionality, firm conclusions are not

warranted because the results are based on cross-sectional examination of male workers with relatively high blood Pb levels (range: 18.6-100 µg/dL), and they lack consideration for potential confounding factors including other occupational exposures, concentration-response information, and analogous toxicological evidence.

5.6.2.6 Dendritic Cells

Whereas as research reviewed in the 2006 Pb AQCD (U.S. EPA, 2006b) focused on examining T cells (Section 5.6.2.1), recent ex vivo and in vitro results suggest that the effects of Pb on suppressing Th1 activity and promoting Th2 activity may be a consequence of the direct action of Pb on the function of dendritic cells, a major APC. Gao et al. (2007) found that 25 µM Pb chloride exposure for 10 days stimulated dendritic cell maturation in bone marrow cultures by changing the ratio of cell surface markers (e.g., CD86/CD80) that promote Th2 cell development. Additionally, upon activation with LPS, Pb-matured dendritic cells produced less IL-6, TNF-α, and IL-12 (stimulates growth and differentiation of T cells) than did control cells but the same amount of IL-10 (inhibits production of Th1 cytokines). The effect of Pb in altering the cytokine expression profile of dendritic cells, in particular, the lower IL-12/IL-10 ratio, may serve as an important signal to shift naïve T cell populations toward a Th2 phenotype. Supporting a role for dendritic cells in skewing to a Th2 phenotype, ex vivo results from the same study showed that Pb-naïve adult BALB/c mice implanted with Pb-exposed dendritic cells had suppressed DTH (Section 5.6.2.3) and IgG2a antibody (Section 5.6.3) responses (Gao et al., 2007).

5.6.2.7 Natural Killer Cells

Based mostly on studies reviewed in the 2006 Pb AQCD, evidence does not clearly indicate that Pb exposure affects the innate immune NK cells, which mediate host defense by killing infected cells. Some epidemiologic studies adjusted for factors such as age, sex, and smoking but did not find differences in NK cell abundance or level of functional activity by blood Pb level in children or adults with or without occupational exposures (n = 145-675) (Karmaus et al., 2005; Sarasua et al., 2000; Pinkerton et al., 1998). Studies in children did not examine potential confounding by SES, and the study in Pb-exposed workers did not examine other workplace exposures. Other smaller (n = 30-108) studies that did not consider potential confounding factors found a positive correlation between blood Pb level and NK cell abundance in adults in Italy (Boscolo et al., 2000; 1999) or reported no significant association in children (quantitative results not reported) (Belles-Isles et al., 2002). Pb-exposed workers in the U.S., Europe, and Asia

(n = 25-141, mean ages: 26-49 years) with higher concurrent blood Pb levels (means: 6.5-128 µg/dL) had similar means of NK cell abundance or functional activity as did unexposed controls (n = 10-84, mean blood Pb levels: <2-16.7 µg/dL, mean ages: 28-47 years) (García-Lestón et al., 2011; Mishra et al., 2003; Pinkerton et al., 1998; Yücesoy et al., 1997b; Ündeger et al., 1996; Fischbein et al., 1993; Kimber et al., 1986).

The epidemiologic evidence is not sufficiently informative for drawing conclusions about the effects of Pb exposure on NK cells because of its many limitations including cross-sectional nature, limited consideration for potential confounding, and lack of concentration-response information. However, toxicological evidence equally does not clearly indicate an effect of Pb on NK cells. A decrease in NK cell activity was found in 6-8 week-old BALB/c mice but with higher Pb exposure than that relevant to humans (1,300 ppm Pb acetate in drinking water, 10 days, blood Pb level ~100 µg/dL) (Queiroz et al., 2011). In an in vitro study, Fortier et al. (2008) found that Pb chloride (7.5-20.7 µg/dL) did not affect NK cytotoxicity compared with the control. However, Pb chloride was not found to affect monocytes or lymphocytes either.

5.6.3 Humoral Immunity

The 2006 Pb AQCD (U.S. EPA, 2006b) described another hallmark effect of Pb on the immune system to be an enhanced humoral immune response as characterized by increased production of IgE antibodies (U.S. EPA, 2006b). Several toxicological and epidemiologic studies (Table 5-32) demonstrated Pb-associated increases in IgE, which mediates inflammation in allergic and allergic asthma responses by binding to mast cells and releasing histamines, leukotrienes, and interleukins upon exposure to an allergen. Neither toxicological nor epidemiologic evidence (Table 5-32) consistently indicated that Pb exposure was associated with changes in other classes of Igs including IgG, IgM, and IgA, which function in complement activation and host resistance or activation of immune cells.

In toxicological evidence, there was a lack of coherence between results for IgE and activation of B cells, which regulate IgE production through differentiation into antibody-producing cells. Pb chloride exposure in vitro (10 µM up to 5 days) was found to increase markers of B cell activation, including cell surface markers and levels of plaque forming cells (PFC), which are a measure of antibody-forming cells (McCabe and Lawrence, 1990; Lawrence, 1981a). However, several studies in animals (Swiss mice and rabbits) found a wide range of Pb concentrations (0.5 to 250 ppm Pb acetate or tetraethyl Pb for 3-10 weeks, postnatal via drinking water) to decrease levels of PFC (Blakley et al., 1980; Koller and Kovacic, 1974; Koller, 1973). Among many mice strains tested, Mudzinski et

al. (1986) found an increase in PFC only in BALB/c mice with 8-week postnatal dietary Pb acetate exposure that produced high blood Pb levels, 70 µg/dL. Epidemiologic studies of children (Table 5-32) and adults (Table 5-32) with group comparisons and (Boscolo et al., 2000; Boscolo et al., 1999) with correlation analyses) did not find a consistent association between blood Pb level and the abundance of B cells, which may not reflect activation. Inconsistencies among studies did not appear to be related to differences in age, group blood Pb levels, or the extent of consideration for potential confounding (Table 5-32).

Most animal studies found Pb-induced increases in IgE, with key evidence provided by studies that examined Pb acetate exposure through drinking water during the gestation and/or lactation period and IgE (Snyder et al., 2000; Miller et al., 1998). In particular, Snyder et al. (2000) found elevated IgE in juvenile BALB/c mice with relevant blood Pb levels, means 5-20 µg/dL measured 0-1 week after gestational and/or lactational Pb exposure. In Miller et al. (1998), elevated IgE was found in adult mice exposed gestationally to Pb via drinking water of dams who had blood Pb levels of 30-39 µg/dL. Chen et al. (2004) did not find gestational dietary Pb acetate exposure to result in an increase in IgE in adult F344 rats who had blood Pb levels of 6.75 and 8 µg/dL, measured one week postweaning. In BALB/c and OVA-transgenic (produce OVA-specific T cells) mice, Heo et al. (1997; 1996) found concomitant Pb-induced increases in IgE and IL-4, consistent with the mode of action of IL-4 to induce class switching of B cells to IgE producing cells. However, these effects were observed with Pb administered via s.c. injection (50 µg/100 µL, 3 times per week for 3 weeks) and with higher blood Pb levels, 38 µg/dL, than those relevant to humans. Some of these studies examined multiple immune endpoints; however, chance findings due to multiple comparisons likely are not responsible for the findings because the pattern of results consistently pointed to a shift from Th1 to Th2 responses (Miller et al., 1998; Heo et al., 1997; 1996).

Table 5-32 Comparison of serum immunoglobulin levels and B cell abundance among various blood Pb groups.

Note: Results are presented in order of quality of study design and methodology.

[a]IgE data are presented as IU/mL unless otherwise specified. (In parentheses are ratios of IgE in the higher blood Pb group to IgE in the lowest blood Pb group.)

[b]Other Ig data are presented as mg/dL unless otherwise specified.

[c]B cell data are presented as the percentage of B cells among all lymphocytes unless otherwise specified. (In parentheses are the ratio of B cells in the higher blood Pb group to B cells in the lowest blood Pb group.)

[d]p <0.05 for group differences.

[e]Data represent the number of cells/µL serum.

[f]Data represent the mean rank for Mann-Whitney U test, p = 0.07 for IgE.

[g]Data are presented as IU/mL.

A small number of available recent toxicological studies examined IgG subtypes, and as in previous studies, found inconsistent effects of Pb exposure. Kasten-Jolly et al. (2010) examined 100 µM Pb acetate in drinking water of BALB/c dams GD8-PND21 because it produced blood Pb levels relevant to humans in another study, i.e., 10-30 µg/dL (Snyder et al., 2000). Pb-exposed pups had increases in the expression of genes encoding Ig antibodies and those involved in B lymphocyte function and activation. These genes included those for the heavy chain of IgM, IL-4, IL-7 and IL-7 receptor, IL-21, RAG-2, CD antigen 27, B-cell leukemia/lymphoma 6, RNA binding motif protein 24, Histocompatibility class II antigen A (beta 1), Notch gene homolog 2, and histone deacetylase 7A. These results were produced by a microarray analysis of hundreds of genes, which is subject to a higher probability of finding an effect by chance.

Other recent studies examined specific IgG subtypes, did not find Pb-induced changes in a consistent direction, and thus did not clearly indicate a shift to Th2 responses. A limitation of this evidence is the higher blood Pb levels of animals than those relevant to humans. Fernandez-Cabezudo et al. (2007) reported evidence for a shift to Th2 responses following Salmonella infection in C3H/HeN mice exposed postnatally to $1x10^4$ µM Pb acetate in drinking water for 16 weeks (resultant mean blood Pb level: 106 µg/dL). Relative to control mice, production of the Th2 cytokine IL-4 increased in spleen cells of Pb-exposed mice after infection as did serum levels of Salmonella-specific IgG1. Infection increased Th1-mediated IgG2a levels in control but not Pb-exposed mice.

In contrast, Gao et al. (2006) found a Pb-induced increased IgG2a/IgG1 ratio, albeit via i.p. injection (50 µg Pb chloride, 3 times per week for 3 weeks), high blood Pb levels (65 µg/dL), and in a highly-specialized strain of adult knockout mice lacking the ability to produce IFN-γ. This result was surprising given evidence that IFN-γ usually directs secretion of IgG2a; however, the authors suggested that in these knockout mice, Pb may initiate a Th1 response via an IFN-γ independent pathway to enhance IgG2a production. Carey et al. (2006) found concentration-dependent increases in both IgG2a- and IgG1-producing cells (after 7 days) in adult BALB/c mice treated with subsensitizing doses of a T cell-independent (Trinitrophenyl-Ficoll [TNP-Ficoll]) or T cell-dependent (TNP-ovalbumin [TNP-OVA]) hapten-protein conjugate and 25-50 µg Pb chloride by bolus injection. These results indicated stimulation of both Th1- and Th2-mediated mechanisms. Pb treatment also increased the numbers of T and B cells and IgM-producing cells in the lymph node against both TNP-Ficoll and TNP-OVA. The increase in IgM-producing cells against TNP-Ficoll indicated a T-cell independent mechanism. Despite finding increases in both IgG1- and IgG2a-producing cells, the authors concluded that Pb skewed the response toward Th2 based on observations of Pb-induced increases in T and B cells and suppression of DTH. Thus, the results indicated the potential for Pb to promote allergic sensitization against T-dependent antigens.

Observations of Pb-induced increases in IgE in animals provide biological plausibility for associations observed between higher Pb biomarkers levels and higher serum IgE levels in various populations of children, although a monotonic concentration-dependent increase was not consistently observed (Hegazy et al., 2011; Hon et al., 2010; Hon et al., 2009; Karmaus et al., 2005; Annesi-Maesano et al., 2003; Sun et al., 2003; Lutz et al., 1999) (Table 5-32). The evidence was based on cross-sectional analyses which preclude establishing the temporal sequence between Pb exposure and IgE. Associations between blood Pb level and IgE were found in studies that generally had population-based recruitment. Most studies did not provide sufficient information to assess the potential for biased participation by Pb exposure and immune conditions. Most studies examined multiple immune endpoints; however, associations were not isolated to IgE.

Karmaus et al. (2005) had greater adjustment for potential confounding factors and examined associations with lower blood Pb levels. Compared with 82 children (ages 7-10 years) in Germany with concurrent blood Pb level <2.2 µg/dL, children with blood Pb levels 2.84-3.41 µg/dL (n = 86) and >3.4 µg/dL (n = 82) had 28% higher serum IgE levels (p = 0.03, F-test). These differences were found with the adjustment for age, blood organochlorine levels, serum lipid levels, number of infections in the previous 12 months, and number of cigarettes/day smoked in the home in the previous 12 months. SES was not examined. A monotonic increase in IgE was found across blood Pb quartiles, except for the highest group (Table 5-32). Although IgE was elevated in children with relatively

low blood Pb levels (>2.84 µg/dL), in these children ages 7-10 years, the contribution of higher past Pb exposures cannot be excluded. Similar differences in IgE count on basophils were not found among the blood Pb quartiles. Although serum IgE and basophil-bound IgE have been correlated in adults (Malveaux et al., 1978; Conroy et al., 1977), few data are available in children (Dehlink et al., 2010). A study in children found that serum IgE levels were not correlated with basophil-bound IgE (Spearman r = -0.003) but were correlated with other IgE receptor-expressing cells such as dendritic cells and monocytes (Spearman r = 0.43 to 0.65, p <0.05) (Dehlink et al., 2010). The number of IgE-bound basophils also has been highly variable across individuals, particularly children (Hausmann et al., 2011; Dehlink et al., 2010). Thus, it is not unexpected that higher blood Pb level was associated with higher serum IgE but not basophil-bound IgE counts in Karmaus et al. (2005). In this study, blood Pb level was not associated with serum levels of IgG, IgA, IgM or B cell abundance. Lutz et al. (1999) found higher serum IgE in low SES children (9 months-6 years) on public assistance in Springfield, MO after only adjusting for age, albeit with concurrent blood Pb levels >10 µg/dL (n = 105/279).

Recent studies in children (non-U.S.) also reported associations between concurrent blood Pb level and elevated serum IgE but did not adjust for potential confounding factors (Hegazy et al., 2011; Hon et al., 2010; Hon et al., 2009). Hon et al. (2010; 2009) demonstrated associations in 110 children (mean age 9.9 years) with atopic dermatitis in Hong Kong with low blood Pb levels (range: 1.4-6.0 µg/dL) and found that blood Pb level also was correlated with severity of atopic dermatitis, a condition commonly characterized by elevated IgE levels. Among 318 children, ages 6 months to 7 years, in Egypt, Hegazy et al. (2011) did not find a monotonic increase across the blood Pb groups.

Sarasua et al. (2000) did not examine IgE but found associations of higher concurrent blood Pb level with higher IgA, IgG, and IgM in 372 U.S. children ages 6-35 months but not older (36-71 months, 6-15 years, 16-75 years, n = 433-673). In the youngest age group, a 1 µg/dL higher blood Pb level was associated with a 0.8 [95% CI: 0.2, 1.4], 4.8 [95% CI: 1.2, 8.4], and 1.0 [95% CI: 0.1, 1.9] mg/dL higher IgA, IgG, and IgM, respectively, adjusted for age, sex, and location. In the youngest children, serum levels of all three examined Igs were elevated among the 24 children with concurrent blood Pb levels ≥ 15 µg/dL than among the 165 children with blood Pb levels <5 µg/dL.

While most epidemiologic studies examined concurrent blood Pb levels, some studies indicated that prenatal Pb exposure may impact Ig levels in newborns (Annesi-Maesano et al., 2003; Belles-Isles et al., 2002). While these studies better indicated the temporal sequence between Pb exposure and Ig levels, an important limitation was the lack of extensive consideration for potential confounding factors. Belles-Isles et al. (2002) examined 97 newborns in Quebec, Canada (from subsistence fishing communities and

two other towns, geometric mean blood Pb levels: 1.64 and 1.32 µg/dL, respectively) and found an association between higher cord blood Pb level and higher cord serum IgG adjusted for prenatal maternal smoking status. However, IgG also was associated with cord plasma organochlorines, which also are elevated with high fish diets. Annesi-Maesano et al. (2003) found that Pb level in infant hair (mean: 1.38 ppm, n = 234) but not cord blood (mean: 6.7 µg/dL, n = 326) or placenta (mean: 9.6 µg/dL, n = 332) was associated with cord serum IgE in newborns in Paris. Potential confounding was not considered. The authors inferred a stronger effect of Pb exposure integrated over the entire gestational period compared to exposures closer to birth. However, an empirical basis for interpreting Pb levels in hair has not been established (Section 4.3.4.2). Cotinine was not associated significantly with Pb biomarker levels or IgE. The correlation (Spearman r = 0.21, p <0.01) was larger among the 67% infants with mothers without allergies than infants with maternal allergies (Spearman r = 0.12), pointing to the possible masking of a blood Pb-IgE association by the stronger association of family history of allergy.

Blood Pb level also was associated with IgE in adults without (Pizent et al., 2008) and with occupational Pb exposure (Heo et al., 2004). Pizent et al. (2008) adjusted for potential confounding by age, pack years smoking, and alcohol consumption and found that higher concurrent blood Pb level was associated with higher IgE in 166 women in Zagreb, Croatia of similar SES (i.e., white-collar office workers) (Pizent et al., 2008). Among women not on hormone replacement therapy or oral contraceptives, a 1 µg/dL higher blood Pb level was associated with a 0.60 (95% CI: 0.58, 1.18) higher log of IgE. Concurrent blood Pb levels were low in these women who were aged 19-67 years (mean: 2.16 µg/dL, range: 0.56-7.35 µg/dL); however, the cross-sectional study design makes it difficult to characterize the temporal sequence between exposure and outcome or the timing, level, frequency, and duration of Pb exposure that contributed to the observed association. Authors did not report an effect estimate in men because it did not attain statistical significance. Without quantitative results, it is difficult to ascertain whether there was suggestion of association in men but insufficient power to indicate statistical significance due to the smaller number of men examined (50 men versus 166 females). Another study of 34 men with and without allergy in Italy also did not report quantitative results and only indicated a lack of statistically significant correlation between concurrent blood Pb level (median: 11 µg/dL) and IgE without considering potential confounding (Boscolo et al., 1999).

Limitations of the collective epidemiologic evidence for IgE include the cross-sectional analyses with limited adjustment for potential confounding. Karmaus et al. (2005) found a blood Pb-IgE association with adjustment for age, blood organochlorine levels, serum lipid levels, number of infections in the previous 12 months, and number of cigarettes

a day smoked in the home in the previous 12 months. Lutz et al. (1999) comprised a low SES population on public assistance; however, none of the studies adjusted for SES or allergen exposure. Lower SES has been associated with poorer housing conditions, higher exposures to Pb, allergens, and other factors associated with allergy and asthma. Allergen exposure and lower SES are associated with higher IgE and related conditions such as allergy and asthma (Bryant-Stephens, 2009; Dowd and Aiello, 2009; Aligne et al., 2000). Most studies did not provide detailed demographic or residential information. Thus, there is uncertainty as to the extent to which the blood Pb-IgE associations observed in children may be confounded by unmeasured SES and/or allergen exposure.

The cross-sectional nature of evidence raises the possibility that associations are due to reverse causality, i.e., children with higher IgE may have increased lung permeability, and consequently, greater uptake of inhaled Pb into the blood. Studies have not directly compared Pb uptake in groups with different IgE levels; however, animals sensitized with allergens to produce higher IgE have not had greater uptake of radiolabeled particles than controls (Turi et al., 2011; Erjefält and Persson, 1991). Histamine was shown only transiently to increase uptake of particles in a baboon (n = 1) (Yeates and Hameister, 1992) and in humans, in both those with and without asthma (Rees et al., 1985; Braude et al., 1984; O'Byrne et al., 1982). Histamine is released by IgE-bound mast cells and basophils upon exposure to sensitized antigens and leads to inflammation. Compared with healthy controls (n = 6-9), subjects with asthma (n = 9-13) did not consistently have greater particle uptake into blood (Del Donno et al., 1997; Rees et al., 1985; O'Byrne et al., 1984; Elwood et al., 1983). Thus, evidence does not strongly link higher inflammation with increased uptake of particles into the blood which reduces the likelihood that blood Pb-IgE associations observed in children or adults are attributable to reverse causality.

Most of the epidemiologic evidence about the effects of Pb on IgA, IgG, and IgM levels is provided by previous studies of Pb-exposed workers (mostly males) from various industries with mean ages 32-36 years and mean blood Pb levels 38-74.8 µg/dL (Anetor and Adeniyi, 1998; Pinkerton et al., 1998; Ündeger et al., 1996; Queiroz et al., 1994b; Alomran and Shleamoon, 1988; Kimber et al., 1986; Ewers et al., 1982). As are toxicological findings for these other Ig classes, epidemiologic evidence is mixed, with studies reporting higher, lower, and similar Ig levels in Pb-exposed workers (n = 25-145) compared with unexposed controls (n = 18-84). Some studies reporting lower Ig levels in Pb-exposed workers included workers with the highest mean blood Pb levels (>50 µg/dL) (Anetor and Adeniyi, 1998; Ündeger et al., 1996; Ewers et al., 1982). The lack of analysis of potential confounding factors, including other workplace exposures, precludes characterization of others factors that may contribute to inconsistent associations in occupational studies.

In summary, evidence for the effects of Pb exposure on humoral immunity largely comprises consistent toxicological and epidemiologic observations of Pb-associated increases in IgE. The combined toxicological and epidemiologic results do not clearly indicate whether Pb exposure affects IgG, IgM, or IgA. Collectively, epidemiologic studies conducted in the U.S., Europe, and Asia, some with large study populations (n = 279-331) indicate higher serum IgE in children with concurrent blood Pb levels >10 µg/dL. There was some evidence of associations in non-U.S. children with lower blood Pb level; however, the contribution of higher Pb exposures earlier in childhood cannot be excluded (Hon et al., 2010; Karmaus et al., 2005). Pb-associated increases in IgE were found in children with atopic dermatitis (Hon et al., 2010; 2009) and children without immune conditions (Sun et al., 2003). Other studies did not report the health status of subjects. Thus, sufficient information was not provided to assess the potential for selection bias. Among studies that provided concentration-response information, some found serum IgE to increase across blood Pb level groups, except for the highest blood Pb groups (Karmaus et al., 2005; Lutz et al., 1999). In Hegazy et al. (2011), IgE did not increase monotonically across blood Pb groups. All evidence in humans is based on cross-sectional analyses, making it difficult to establish the temporal sequence between Pb exposure and increase in IgE. Findings of similar particle uptake in subjects with and without acute inflammation of inflammatory conditions increase confidence that blood Pb-IgE associations are not due to reverse causality. Most studies did not consider potential confounding, and none adjusted for SES. A study in children in Germany and a study in adults in Croatia adjusted for age and smoking, with additional adjustment for blood organochlorine levels in children (Karmaus et al., 2005) and alcohol consumption in adults (Pizent et al., 2008). Blood Pb level was associated with IgE in a low SES population of children in Michigan (Lutz et al., 1999) and in a population of female office workers of similar SES in Croatia (Pizent et al., 2008). However, uncertainty remains regarding confounding in the associations observed between blood Pb level and IgE in humans. Biological plausibility for the epidemiologic evidence is provided by the Pb-induced increases in IgE observed in most of the animal studies, with some evidence at blood Pb levels relevant to humans (Snyder et al., 2000; Miller et al., 1998). Toxicological evidence indicates increases in IgE with gestational and/or postnatal juvenile Pb exposure, whereas epidemiologic evidence points to associations with concurrent blood Pb levels. Because concurrent blood Pb levels in children reflect both recent and past Pb exposures, the combined evidence indicates that cumulative Pb exposures during childhood may affect IgE levels. While evidence for B cell activation is inconsistent, the mode of action for Pb-induced IgE production is well supported by extensive toxicological evidence for Pb-induced increases in the Th2 cytokine, IL-4 (Section 5.6.6.1). The coherence between epidemiologic and toxicological findings for

IgE and evidence describing modes of action for increases in IgE supports a relationship between Pb exposure and increases in IgE.

5.6.4 Inflammation

The 2006 Pb AQCD (U.S. EPA, 2006b) identified misregulated inflammation a major immune-related effect of Pb based primarily on consistent toxicological evidence for Pb-induced increases in pro-inflammatory cytokines (Section 5.6.6.1), PGE_2, and ROS (Section 5.6.6.3). Inflammation has been characterized as a major mode of action for Pb effects in multiple organ systems such as the liver, kidney, and vasculature given that immune cells make up permanent residents and infiltrating cell populations of these other organ systems (Section 5.2.5). Inflammation also provides a link between the evidence for the effects of Pb on modulating immune cell function and production of cytokines and IgE and the evidence for the effects of Pb on immune-based conditions such as infections and asthma and allergy. For example, IL-4-induces increases in IgE, which primes basophils and mast cells to secrete histamine, leukotrienes, and cytokines, which in turn, produce the inflammation associated with asthma and allergy, i.e., airway responsiveness, mucus secretion, respiratory symptoms. Pb-induced inflammation also has been associated with diminished host resistance by inducing local tissue damage. As described in Section 5.6.6, the few available recent toxicological studies support the effects of Pb exposure on inflammation with findings of Pb-induced increases in pro-inflammatory cytokines, ROS and PGE_2.

The few available epidemiologic studies have found Pb-associated changes in ROS release from macrophages (Section 5.6.6.3) and cytokine levels (Section 5.6.6.1) in children and adults. Adding to this evidence, recent cross-sectional studies found associations between blood Pb level and indicators of inflammation that may be related to multisystemic effects. As discussed in Section 5.6.3, evidence has not provided strong evidence for increased particle uptake in subjects with acute inflammation or inflammatory conditions, reducing the likelihood of reverse causality. However, because of the cross-sectional design of studies, the temporal sequence between Pb exposure and inflammation cannot be established. The most compelling epidemiologic evidence was provided by studies in adults, which were larger had greater consideration for potential confounding. The consistent pattern of association observed across endpoints reduces the likelihood of chance findings due to multiple comparisons.

Strengths of the study of adults (age $\geq$ 40 years, n = 4,663- 7,342) participating in 1999-2004 NHANES included the examination of several potential confounding factors, multiple exposures and outcomes in predominately healthy adults and statistical analyses

to provide nationally-representative results. Higher concurrent blood Pb level was associated with higher serum inflammation markers, C-reactive protein (CRP), fibrinogen, and white blood cell (WBC) count, particularly among men (Songdej et al., 2010). Results were adjusted for age; sex; race/ethnicity; education; current income; physical activity; and several factors related to inflammation including, BMI, smoking status, and history of diabetes, inflammatory disease, or cardiovascular disease. For women, most ORs for associations between quintiles of blood Pb and tertiles of CRP, fibrinogen, and WBC count were <1.0 whereas corresponding ORs in men mostly were >1.0. For example, compared with men with concurrent blood Pb level <1.16 µg/dL, men with blood Pb levels of 1.16-<1.63 µg/dL, 1.63-<2.17, 2.17-<3.09 µg/dL, and ≥ 3.09 µg/dL had elevated odds of higher CRP (OR [95% CI]: 2.22 [1.14, 4.32], 1.67 [0.85, 3.28], 2.12 [1.07, 4.21], and 2.85 [1.49, 5.45], respectively). For all inflammation markers, although the highest OR was found in the highest quintile of blood Pb level (≥ 3.09 µg/dL), monotonic concentration-dependent increases were not observed. Consistent with NHANES findings, higher concurrent blood Pb level was associated with higher levels of WBCs and IL-6 with adjustment for age, BMI, and current smoking status among 300 university students in Incheon, Korea (Kim et al., 2007). Adults with allergic conditions or using anti-inflammatory medication were excluded; however, sufficient information was not provided to assess potential selection bias. Larger effects were estimated for the 147 men in the upper two quartiles of blood Pb levels, 2.51-10.47 µg/dL than for the full range of blood Pb levels (n = 150).

Low blood Pb levels also were associated with inflammation in a small genome-wide association study that included 37 children with autism and 15 children without autism (ages 2-5 years; blood Pb level range: 0.37 to 5.2 µg/dL) in California who were unlikely to have had higher past Pb exposures. In models that included age, sex, and autism diagnosis, concurrent blood Pb level was associated with the expression of several genes related to immune function and inflammation, including HLA-DRB and MHC Class II-associated invariant chain CD74 (involved in antigen presentation) (Tian et al., 2011). Although blood Pb levels were similar between children with and without autism and correlations with gene expression were observed in both groups, they were in opposite directions (positive among children with autism and negative among children without autism). With gene expression arrays, there is a higher probability of chance. Further, there was limited consideration for potential confounding in this study, and the representativeness of findings in children with autism may be limited. However, the results are supported by observations that Pb chloride (10-100 µM) increases MHC molecule surface expression in mouse and human HLA antigen presenting cells (Guo et al., 1996a; McCabe and Lawrence, 1991).

In summary, Pb-associated increases in indicators of inflammation such as CRP, WBCs, and IL-6 were found in populations mostly comprising healthy adults with concurrent blood Pb levels 1.16-10 µg/dL with adjustment for several potential confounding factors (Songdej et al., 2010; Kim et al., 2007). The analysis of adults participating in NHANES was particularly noteworthy for its representative population and adjustment for age, sex, race/ethnicity, education, current income, physical activity, and several inflammatory conditions (Songdej et al., 2010). Because all evidence was based on cross-sectional analyses, the relative contributions of recent and past Pb exposures to the observed associations are uncertain. Other lines of evidence do not strongly support reverse causality; however, the temporal sequence between Pb exposure and inflammation is difficult to establish. Despite the limited extent and cross-sectional nature of epidemiologic evidence, the biological plausibility is provided by findings of Pb-induced increases in Th2 cell partitioning (Section 5.6.2.1) and IL-6 (Section 5.6.6.1) in toxicological studies. Th2 cells produce IL-6 which is the primary stimulus for expression of CRP and fibrinogen (Hage and Szalai, 2007; Fuller and Zhang, 2001).

5.6.5 Immune-based Diseases

5.6.5.1 Host Resistance

The capability of Pb to reduce host resistance of animals to bacteria has been recognized for almost 40 years and was supported by several animal studies described in the 2006 Pb AQCD. Several studies demonstrated increased mortality following Pb exposure through drinking water and infection with *Listeria monocytogenes*. Multiple investigations in the same laboratory indicated increases in body burdens of viable bacteria, mortality, and sickness behavior induced by *Listeria* exposure in juvenile or adult BALB/c or CBA/J mice exposed postnatally to 500 to 2,000 µM Pb acetate in drinking water for 3 to 8 weeks (Dyatlov and Lawrence, 2002; Kim and Lawrence, 2000; Kishikawa et al., 1997; Lawrence, 1981b). Decreased bacterial resistance was observed in mice with blood Pb levels (upon cessation of Pb exposure) relevant to humans, i.e., 25 µg/dL in BALB/c mice exposed PND1-PND22 (Dyatlov and Lawrence, 2002) and 20 µg/dL in adult C3H/HeN mice with 16-week exposure (Fernandez-Cabezudo et al., 2007). Other studies found mortality from *Salmonella* or *E. coli* or reduced clearance of *Staphylococcus* in mice or rats administered Pb acetate or nitrate via injection, a route of Pb exposure less relevant to humans (Bishayi and Sengupta, 2006; Cook et al., 1975; Hemphill et al., 1971; Selye et al., 1966). Although not examined as much, postnatal dietary Pb (mostly Pb acetate) exposure for 4-10 weeks increased mortality of mice and chickens from viral infection (Gupta et al., 2002; Youssef et al., 1996; Exon et al., 1979;

Thind and Khan, 1978; Gainer, 1977). These effects were observed in animals with high blood (71-313 µg/dL) (Gupta et al., 2002; Thind and Khan, 1978) or tissue Pb levels (0.12-0.71 ppm) (Exon et al., 1979).

The mode of action for Pb-induced decreased host resistance is well characterized by observations that Pb suppresses Th1-driven acquired immune responses and increases inflammatory responses in target tissue, which may compromise host protective barriers. Host resistance to bacteria such as Listeria requires effective Th1-driven responses including the production of IL-12 and IFN-γ (Lara-Tejero and Pamer, 2004) and these have been found to be inhibited by Pb exposure (Section 5.6.6.1). The lack of IFN-γ can inhibit appropriate and timely macrophage activation. Strengthening the evidence for Pb-induced decreased host resistance, Fernandez-Cabezudo et al. (2007) found both increased mortality and decreased production of IL-12 and IFN-γ (ex vivo in spleen cells) in *Salmonella*-exposed CH3/HeN mice with blood Pb levels of 20 µg/dL. Nitric oxide is produced by activated macrophages and has been found to be suppressed by Pb exposure (Section 5.6.6.2). Pb-induced decreases in bacterial clearance have been found in conjunction with reduced NO and macrophage functionality (Bishayi and Sengupta, 2006). Further, Pb-induced inflammation has been demonstrated as increases in ROS and PGE_2 (Section 5.6.6.3). Additional mode of action evidence was provided recently with observations that developmental Pb exposure of BALB/c mice (100 µM Pb acetate in drinking water of dams from GD8 to PND21) upregulated splenic gene expression of caspase-12 (Kasten-Jolly et al., 2010). Caspase-12 is a cysteine protease that functions in apoptosis and activation of pro-inflammatory cytokines and has been linked with a role in the inhibition of bacterial clearance both systemically and in the gut mucosa (Saleh et al., 2006).

In the few available epidemiologic studies, a range of Pb exposure indicators (i.e., cord or concurrent blood Pb, Pb content in total deposition samples or lichen) was associated with viral and bacterial infections in children. An increase in infections was associated with cord blood Pb levels ≥ 10 µg/dL in children in Boston, MA (n = 283) (Rabinowitz et al., 1990) and a mean concurrent blood Pb level of 3.34 µg/dL in children in Germany (n = 311) (Karmaus et al., 2005). Similarly, a study found higher frequency of self-reported colds or influenza among 66 Pb battery or smelter plant workers with blood Pb levels 21.3-85.2 µg/dL than among 53 controls with blood Pb levels 6.6-20.8 µg/dL (Ewers et al., 1982). Because of the many limitations, the lack of consideration for potential confounding (Karmaus et al., 2005; Rabinowitz et al., 1990; Ewers et al., 1982), lack statistical rigor in comparisons of mean blood Pb levels by number of infections (Karmaus et al., 2005; Ewers et al., 1982), and ecological design (Carreras et al., 2009), conclusions about the effects of Pb exposure on viral or bacterial infections cannot be drawn based on epidemiologic evidence alone. And, the weak epidemiologic data do not

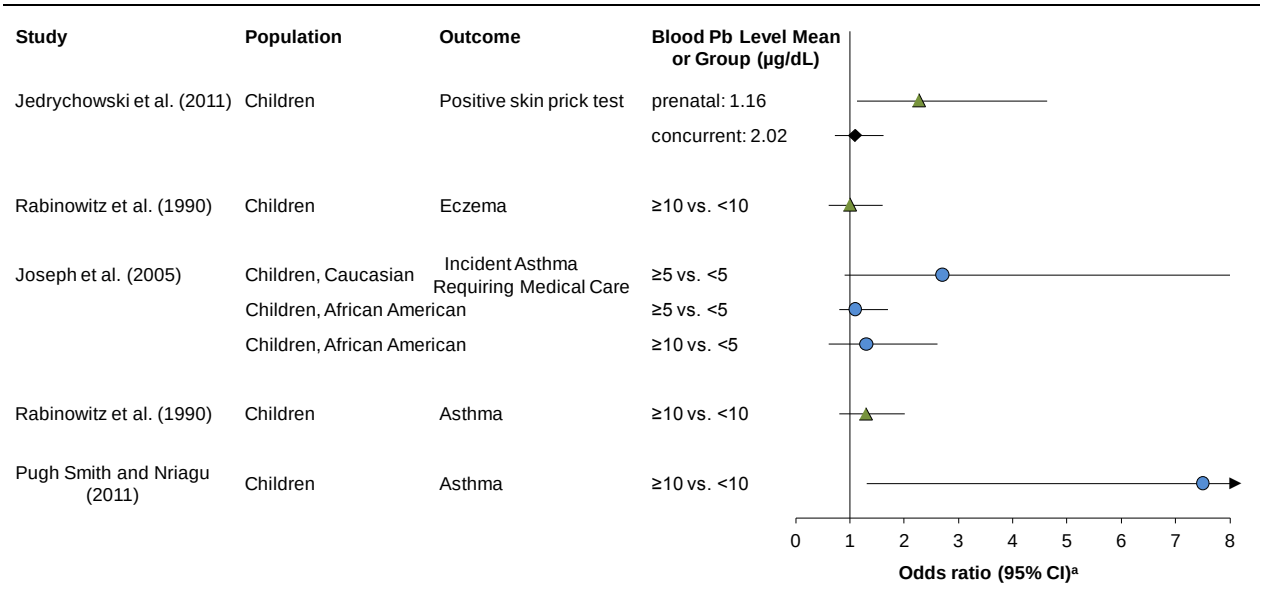
detract from the consistent findings in animals for Pb-induced decreased host resistance, including those in animals with relevant blood Pb levels, and evidence for modes of action including decreased macrophage function and Th1 cytokine production.

With few studies available, the effect of Pb on resistance to eukaryotic parasites is not clear. High concentration Pb acetate (≥ 30 µM) diminished the ability of macrophages to kill *Leishmania enrietti* protozoa in vitro (Mauël et al., 1989). Survival of malaria-infected mice was enhanced with 100 µM Pb nitrate exposure via drinking water (Koka et al., 2007), which was attributed to Pb inducing eryptosis and removal of infected erythrocytes and not to Pb-induced alterations in immune function. Nriagu et al. (2008) found that higher blood Pb level was associated with lower malaria prevalence among 653 children (ages 2-9 years) from three Nigerian cities with a mean blood Pb level of 8.9 µg/dL. Results were adjusted for age, sex, number of siblings, and other comorbidities such as depressed mood, headaches, and irritability. Given the well-characterized effect of Pb in promoting Th2 activity, it is plausible for Pb to enhance host resistance to parasites that require robust Th2 responses such as helminths. However, this relationship is not well characterized.

5.6.5.2 Asthma and Allergy

Toxicological evidence and to a lesser extent, epidemiologic evidence, have supported the effects of Pb exposure on stimulating Th2 activity, including increasing production of Th2 cytokines such as IL-4 (Section 5.6.6.1), IgE antibody (Section 5.6.3), and inflammation (Section 5.6.4). These endpoints comprise a well-recognized mode of action for the development and exacerbation of asthma and allergy, which are atopic and inflammatory conditions. Thus, this mechanistic evidence provides support for the small body of epidemiologic evidence indicating associations of blood Pb levels with asthma or allergy in children (Figure 5-35 and Table 5-33). Whereas such evidence reviewed in the 2006 Pb AQCD was too sparse to permit conclusions, findings from recent studies add supporting evidence. Children examined in studies of asthma and allergy encompassed a wide age range (i.e., <1-12 years) and across studies, blood Pb was measured at different lifestages. Studies ascertained outcomes with parent report of doctor diagnosis but also more objectively using a surveillance database or and clinical testing. This variability in could contribute to between-study heterogeneity in results; however, the objective assessment of outcomes in some studies is not likely to produce a spurious association. Further, some of the evidence was provided by large studies that prospectively ascertained outcome incidence after the measurement of blood Pb levels, did not indicate selection bias, and considered potential confounding by SES and other environmental exposures. These strengths reduce the likelihood of reverse causality and the influence of

other risk factors and increase confidence that the observed associations reflect a relationship with Pb exposure.



[a]For analyses with blood Pb level as a continuous variable, odds ratios are standardized to a 1 µg/dL increase in blood Pb level.

Note: Results are presented first for allergy-related outcomes then for asthma. All results are from prospective analyses, except for Pugh Smith and Nriagu (2011). Black diamond represents associations with concurrent blood Pb levels, green triangles represent associations with prenatal (cord) blood Pb levels, and blue circles represent associations with blood Pb levels measured in childhood up to 12 months prior to outcome assessment.

Figure 5-35 Associations of blood Pb levels with asthma and allergy in children.

Table 5-33 Additional characteristics and quantitative results for studies presented in Figure 5-35.

Study	Study Population and Methodological Details	Blood Pb Level Data (µg/dL)	Outcome	Odds Ratio or Relative Risk (95% CI)
Jedrychowski et al. (2011)	224 children followed prenatally to age 5 yr, Krakow, Poland Prospective. Study of multiple exposures and outcomes. Clinical assessment of atopy. No information on follow-up participation but no selective attrition. Logistic regression adjusted for sex, parity, maternal age, education, and atopy, cord blood cotinine, smoker in home during follow-up. Also considered potential confounding by breastfeeding and allergen levels in house dust.	Prenatal (cord): Geometric mean: 1.16 (95% CI: 1.12, 1.22) Concurrent: Geometric means: 2.02 (95% CI: 1.95, 2.12)	Positive Skin Prick Test	2.3 (1.1, 4.6)[a] 1.1 (0.7, 1.6)[a]
Rabinowitz et al. (1990)	159 children followed from birth to unspecified age, Boston area, MA Prospective. Low participation among eligibles. No information on differences with nonparticipants. Logistic regression with parental report of eczema. No consideration of potential confounding factors.	Prenatal (cord) ≥ 10 vs. <10	Eczema	1.0 (0.6, 1.6)[b]
Hon et al. (2010; 2009)[c]	110 children with atopic dermatitis, mean (SD) age: 9.9 (4.6) yr, Hong Kong, China, Not clear whether subjects were free of atopic dermatitis at time of blood Pb measurement. Recruitment from dermatology clinic. Clinical assessment of atopic dermatitis. No information on participation rate. Examination of multiple metals. Lack of rigorous statistical methods. No consideration of potential confounding factors.	Serum Pb mean (SD): 1.86 (0.83)	Atopic dermatitis severity	r = 0.329, p <0.001
Joseph et al. (2005)	4,634 children, ages 1-3 yr followed for 12 months, Southeastern MI Prospective. Large sample size. Indirect assessment of asthma diagnosis but ascertained from managed care organization claims database. Logistic regression adjusted for sex, birth weight, and average annual income available only at census block level. Lack of information on other environmental exposures.	Caucasian ≥ 5 vs. Caucasian <5 African American ≥ 5 vs. African American <5 African American ≥ 10 vs. African American <5 Measured up to 12 mo before outcome	Incident asthma requiring medical care	2.7 (0.9, 8.1)[d] 1.1 (0.8, 1.7)[d] 1.3 (0.6, 2.6)[d]
Rabinowitz et al. (1990)	204 children followed from birth to unspecified age, Boston area, MA Same methodology as above.	Prenatal (cord blood) ≥ 10 vs. <10	Prevalent asthma	1.3 (0.8, 2.0)[b]

Study	Study Population and Methodological Details	Blood Pb Level Data (µg/dL)	Outcome	Odds Ratio or Relative Risk (95% CI)
Pugh Smith and Nriagu (2011)	356 children, ages 0-12 yr, Saginaw, MI Cross-sectional. Recruitment from blood Pb database. Moderate participation rate. Parental report of asthma diagnosis. Logistic regression adjusted for age, sex, family income, number of stories in unit, cat in home, dog in home, cockroach problem, number of persons in home, smoker in home, clutter, candles/incense, type of cooking stove, main heating source, months of residency, housing tenure, type of air conditioning, peeling paint, ceiling/wall damage, age of housing, water dampness/mold/mildew.	Highest blood Pb level at address ≥ 10 vs. <10 Levels ascertained from statewide database, specific timing unreported but varied among subjects	Prevalent asthma diagnosed within previous 12 months	7.5 (1.3, 42.9)[b]

[a]Odds ratio presented per 1 µg/dL increase in blood Pb level.

[b]Odds ratio in children with blood Pb level ≥ 10 µg/dL with children with blood Pb level <10 µg/dL serving as the reference group.

[c]Results are not included in Figure 5-35 because only correlations are presented.

[d]Relative risk in each specified subgroup with children with blood Pb level <5 µg/dL serving as the reference group.

Key evidence for Pb-associated effects on allergy-related outcomes was provided by a prospective study in 224 children in Poland at age 5 years that compared associations of prenatal (cord and maternal) and concurrent blood Pb levels with incidence of allergic sensitization, as ascertained by investigators (Jedrychowski et al., 2011). Subjects assessed at five years did not differ from the full cohort, indicating lack of selective attrition of subjects by blood Pb level or health status. The potential for selection bias also is reduced because multiple exposures and outcomes were examined in this cohort. A 1 µg/dL increase in prenatal cord blood level was associated with greater risk of positive skin prick test (SPT, rash/inflammatory reaction) to dust mite, dog, or cat allergen with an RR of 2.3 (95% CI: 1.1, 4.6). Concurrent blood Pb level was more weakly associated with risk of positive SPT (Figure 5-35 and Table 5-33). For prenatal Pb biomarkers, similar effect estimates were obtained before and after adjustment for sex, parity, maternal age, education, and atopy, and prenatal (cord blood cotinine) and postnatal (smoker in the home) smoking exposure. Results were not altered by the addition of house dust allergen levels. Cord and concurrent blood Pb levels were weakly correlated (r = 0.29), providing support for an independent association for prenatal Pb biomarkers. A relationship with Pb was substantiated by observations that indicators of other exposures, including blood levels of Hg, polycyclic aromatic hydrocarbon DNA adducts, and residential levels of dust mite or pet allergen were associated with lower risks of SPT than was blood Pb level. These associations were observed with relatively low cord blood Pb levels (geometric mean: 1.16 µg/dL [95% CI: 0.12, 1.22]). However, cord blood Pb levels reflect the pregnancy blood Pb levels of mothers. Evidence indicates

increased mobilization of Pb from bone to blood in pregnant women (Sections 4.2.2.4 and 4.3.5.2). Thus, there is uncertainty regarding the Pb exposure scenarios that contributed to associations between cord blood Pb level and allergic sensitization in children examined in Jedrychowski et al. (2011).

Contrasting results were produced by prospective studies of eczema or atopic dermatitis, which are reactions of the skin to sensitized allergens; however, neither study considered potential confounding factors. Rabinowitz et al. (1990) found no elevated risk of parental reported eczema in children (n = 159) in the Boston, MA area with cord blood Pb levels ≥ 10 µg/dL. Hon et al. (2010; 2009) found a correlation between concurrent serum Pb levels (mean: 1.86 µg/dL) and clinical diagnosis of atopic dermatitis severity (e.g., skin area affected, intensity of rash and inflammation, symptoms) in 110 children approximately age 10 years in Hong Kong (Spearman r = 0.33, p <0.005). The various other metals were examined were negatively correlated with atopic dermatitis. Although Hon et al. (2010; 2009) examined incidence of atopic dermatitis, subjects were selected from patients referred to a dermatology clinic. The representativeness of the children to the source population is uncertain, and allergies may already have developed by the time serum Pb levels were measured.

Prospective and cross-sectional evidence indicated associations with blood Pb levels with asthma in children. Among prospective studies, Joseph et al. (2005) accounted for potential confounding factors. Asthma-free children, ages 1-3 years, (n = 4,634) all members of the same managed care organization in southeastern Michigan were selected based on availability of blood Pb level data in the database then tracked for the following 12 months for incidence of asthma. Incident asthma requiring a doctor visit or medication was defined from the medical claims database as four or more asthma medication dispensing events and one or more asthma emergency department visit, hospitalizations, or outpatient visits with at least two asthma medication dispensing events in the previous 12 months. While this definition is not a direct diagnosis, it is used to define persistent asthma by the Healthcare Effectiveness Data and Information Set, which most U.S. health plans use to measure health care performance. The records-based analysis precluded bias due to selective participation of subjects by blood Pb level and health status. However, because a blood Pb measurement was required, it is uncertain whether the study population is representative of the managed care organization population. In analyses that adjusted for average annual income at the census block level, birth weight, and sex, an elevated risk of incident asthma requiring a doctor visit or medication was associated with blood Pb levels ≥ 5 µg/dL in Caucasian children (RR: 2.7 [95% CI: 0.9, 8.1] compared with Caucasian children with blood Pb levels <5 µg/dL) (Figure 5-35 and Table 5-33). In analyses restricted to African Americans, children with blood Pb levels ≥ 10 µg/dL had an elevated risk of asthma requiring medical care (RR: 1.3 [95% CI: 0.6,

2.6] compared with children with blood Pb level <5 µg/dL). There were small numbers of children with asthma requiring medical care in the higher blood Pb level categories, which could have accounted for the wide 95% CIs (5 Caucasian children with blood Pb ≥ 5 µg/dL and 9 African American children with blood Pb level ≥ 10 µg/dL). In analyses that used Caucasian children with blood Pb level <5 µg/dL as the reference group, blood Pb level was associated with increased risk of asthma requiring medical care among African American children in all blood Pb level categories, which indicated a stronger association with race. Nonetheless, results within race groups pointed to an association with blood Pb level.

Similarly, the prospective study of 204 children in the Boston, MA area found a Pb-associated increased risk of parental-reported asthma (age of assessment not reported), specifically in children with cord blood Pb levels >10 µg/dL relative to cord blood Pb levels ≤ 10 µg/dL (Rabinowitz et al., 1990) (Figure 5-35 and Table 5-33). However, potential confounding factors were not examined.

Supporting the prospective evidence, a cross-sectional study conducted in Saginaw, MI found a higher prevalence of parental report of doctor-diagnosed asthma in children (ages ≤ 12 years) with blood Pb levels ≥ 10 µg/dL (Pugh Smith and Nriagu, 2011). Similar to Joseph et al. (2005), the study population was predominately African American (78% of 356). Children were randomly selected from a statewide database of initial blood Pb measurements collected at unspecified ages, and a positive bias is possible if parents of children with higher blood Pb levels and asthma were more likely to participate or recall an asthma diagnosis. Data were collected on asthma diagnosis in the previous 12 months; thus, for some subjects, blood Pb measurement likely preceded asthma diagnosis. A strength of this study was the adjustment for a large number of potential confounding factors such as age, sex, household pets, housing characteristics, and household smoking family income. Compared with children with initial blood Pb levels <10 µg/dL, children with initial blood Pb levels ≥ 10 µg/dL had a higher odds of having a doctor diagnosis of asthma within the past 12 months (OR: 7.5 [95% CI: 1.3, 42.9]). The results were imprecise, and while this study had more children with blood Pb levels ≥ 10 µg/dL (18.6%) than did Joseph et al. (2005), the analyses considered a much large number of covariates.

As was discussed in Section 5.6.3, one may speculate that cross-sectional associations could be attributed to reverse causality. Individuals with asthma and animal models of asthma have been shown to have epithelial cell damage and exudation of cells and fluids into airways, which are indicators of increased lung permeability. With increased lung permeability, one may speculate the potential for greater uptake of Pb from airways into blood. Most evidence does not demonstrate greater uptake of particles into the blood in

subjects with asthma than in healthy controls (Del Donno et al., 1997; Rees et al., 1985; O'Byrne et al., 1984; Elwood et al., 1983). Histamine was found to increase particle uptake transiently. In Rees et al. (1985), histamine equally increased particle uptake in subjects with and without asthma whose mean lung function decreased by 33% and 55%, respectively. This evidence combined with that from prospective epidemiologic studies and that characterizing modes of action (i.e., increases in IgE, Th2 cytokines, and inflammation) increases confidence that the associations observed between blood Pb level and asthma and allergy in children are not due to reverse causality.

Among the studies in children that found associations of blood Pb level with asthma and allergy, several adjusted for potential confounding by indicators of SES and other environmental exposures. Joseph et al. (2005) adjusted for census block annual income, which may measure individual-level income with error. However, Pugh Smith and Nriagu (2011), which examined a primarily low SES population of children in Michigan, adjusted for family annual income. In this study, a Pb-associated higher asthma prevalence was found with adjustment for various additional factors associated with SES and allergen exposure, including multiple indices of housing condition and presence of pets and cockroaches in the home. Jedrychowski et al. (2011) adjusted for maternal education, and found similar magnitudes of association between cord blood Pb level and positive SPT as those in the unadjusted analysis. Further, residential levels of dust mite or pet allergen were associated with lower risks of SPT than was blood Pb level. Blood Pb level also was associated with asthma or allergy after adjusting for concurrent exposure to smoking in the home (Jedrychowski et al., 2011; Pugh Smith and Nriagu, 2011), with Jedrychowski et al. (2011) additionally adjusting for prenatal smoke exposure assessed as cord blood cotinine levels. The studies varied in the specific confounding factors considered, the method of measurement, and the method of control. Some studies examined several potential confounding factors (Jedrychowski et al., 2011; Pugh Smith and Nriagu, 2011), which increases confidence that the observed associations with asthma and allergy reflect a relationship with Pb. However, in the small evidence base, uncertainty remains regarding residual confounding, particularly by SES. While there is no single complete measure of SES, these studies adjusted for different indicators of SES that may vary in the adequacy of control for confounding. Residual confounding also is possible by factors not examined.

Cross-sectional evidence did not strongly indicate associations of biomarkers of Pb exposure with asthma or allergy in nonoccupationally-exposed adults (Mendy et al., 2012; Pizent et al., 2008). However, study limitations make the evidence less informative for drawing conclusions about the effects of Pb on asthma compared with evidence in children. Higher Pb level in a spot urine sample was not associated with an increase in asthma prevalence (OR: 0.72 [95% CI: 0.46, 1.12] per 1 µg Pb/g creatinine increase in

urine) in the large U.S. NHANES 2007-2008 analysis of 1,857 adults ages 20 years and older (geometric mean urinary Pb level: 0.59 µg/g creatinine (Mendy et al., 2012). Associations were not found with other respiratory conditions such as emphysema or chronic bronchitis either. This study examined several potential confounding factors, adjusting for sex, race/ethnicity, education, income to poverty ratio, number of alcoholic drinks/day, and current smoking status. However, spot urinary Pb level has an uncertain relationship with long-term Pb exposure (Section 4.3.3). In a study of adult (19-67 years) office workers in Zagreb, Croatia, Pizent et al. (2008) found a lower concurrent blood Pb-associated odds of positive SPT to common inhaled allergens among 50 men (median blood Pb level: 3.2 µg/dL) and lack of statistically significant association among 166 women (median blood Pb level: 2.2 µg/dL), adjusting for age, smoking (current and history), and number of alcoholic drinks/day. The findings in women appeared to be discordant because there was an association between concurrent blood Pb level and serum IgE, which commonly mediates the acute inflammatory response to allergens. However, the interpretation of the findings is difficult because only statistically significant effect estimates were reported; thus it is not known whether odds ratios were in the same direction for SPT and IgE in women. Bener et al. (2001a) found higher prevalence of asthma and allergy-related conditions in 110 Pb industrial workers (mean age: 35.5 years) than in 110 age-matched controls. However, the implications are limited because blood Pb levels in both Pb-exposed workers and controls (geometric means: 77.5 and 19.8 µg/dL, respectively) were higher than those in the current U.S. adult general population, and potential confounding factors, including other occupational exposures, were not evaluated.

In summary, evidence supports associations of higher Pb biomarker levels with asthma and allergy (Jedrychowski et al., 2011; Pugh Smith and Nriagu, 2011; Joseph et al., 2005) in children. Because of study limitations, the evidence in adults does not largely inform the conclusion (Mendy et al., 2012; Pizent et al., 2008; Bener et al., 2001a). In children, evidence was limited to a few populations. Because of the heterogeneity in the relatively small body of evidence, it was difficult to identify whether the strength of association with asthma and allergy differed by age of children, lifestage of blood Pb measurement (prenatal, sometime in childhood prior to outcome assessment, concurrent), or blood Pb level. The prospective analysis in Jedrychowski et al. (2011) and Joseph et al. (2005) increase confidence that the observed associations are not due to reverse causality. Lack of reverse causality also is indicated by observations that particle uptake generally does not differ between subjects with and without asthma and between animals sensitized with allergens and unsensitized controls. In these studies, the lack of selective participation of subjects and objective assessment of outcomes indicates lack biased reporting of asthma and allergy in children with higher blood Pb levels. In some studies, the method of recruitment of subjects from blood Pb surveillance databases may limit generalizability

of findings. The adjustment for maternal education and exposure to smoking or allergens in Jedrychowski et al. (2011) and family income, smoking, housing conditions, pets, or pests in Pugh Smith and Nriagu (2011) increase confidence that the observed associations in these studies are not due to confounding by SES, smoking, or allergen exposure. Further, biological plausibility is well supported by evidence describing modes of action for asthma and allergy, including Pb-associated increases in IgE (Section 5.6.3), Th2 cytokines (Section 5.6.6.1), and inflammation (Section 5.6.4). However, because there are few studies, uncertainty remains regarding residual confounding, particularly by SES, which was examined with different indicators across studies.

5.6.5.3 Other Respiratory Effects

Other respiratory effects associated with blood or air Pb levels were not well characterized in the 2006 Pb AQCD (U.S. EPA, 2006b) but have been examined recently in a small number of studies. As with asthma, associations between blood Pb level and respiratory effects in adults is inconsistent. Studies were cross-sectional, included similarly aged subjects, and considered similar confounding factors. Increased bronchial responsiveness (BR) is a characteristic feature of asthma and other respiratory diseases and can result from the activation of innate immune responses and increased airway inflammation. In the larger study of 523 adults (ages 19-58 years) in Seoul, Korea, Min et al. (2008a) found an association between concurrent blood Pb level and BR. A 1 µg/dL higher concurrent blood Pb level was associated with a higher BR index (log [% decline in forced expiratory volume in 1 second (FEV_1)/log of final methacholine concentration in mg/dL]) of 0.018 (95% CI: 0.004, 0.03), with adjustment for age, sex, height, smoking status, baseline FEV_1, and presence of asthma (Min et al., 2008a). The concurrent blood Pb levels in these adults were low (mean [SD]: 2.90 [1.59] µg/dL); however, it is uncertain what timing, level, frequency, and duration of Pb exposures contributed to the observed association. In contrast to Min et al. (2008a), Pizent et al. (2008) found that higher concurrent blood Pb level was associated with lower BR in 47 men (2.4% decrease [95% CI: -4.2, -0.52%] in percent change FEV_1 post-histamine challenge per 1 µg/dL increase in blood Pb level adjusted for age and serum Se). Smoking intensity and alcohol consumption were excluded as covariates by stepwise regression. Similarly, among these men, higher blood Pb level was associated with lower odds of positive SPT.

Pb-associated respiratory effects were not clearly indicated in adults with occupational Pb exposures either. However, the lack of direct analysis of blood Pb levels and consideration for potential confounding limit the utility of this evidence in drawing conclusion about the respiratory effects of Pb related to airway responses. In bus drivers (mean age: 46 years) in Hong Kong (Jones et al., 2008; Jones et al., 2006), 129 drivers of

non-air conditioned buses had lower exposures to PM_{10}, lower blood Pb levels (mean 3.7 µg/dL versus 5.0 µg/dL in air conditioned buses) but lower indices of lung function than did 358 drivers of air conditioned buses (Jones et al., 2006). The authors attributed the slightly higher blood Pb levels of air conditioned bus drivers to the poor efficiency in the filters resulting in higher PM_{10} levels on those buses. Blood Pb levels and various lung function parameters were similar between 33 roadside vendors and 31 adjacent shopkeepers (mean ages: 45.1 and 42.8 years, respectively and mean blood Pb levels: 5.61 and 5.14 µg/dL) (Jones et al., 2008). Pb industrial workers (n = 100, mean age: 34.6 years) in the United Arab Emirates had higher prevalence of respiratory symptoms such as cough, phlegm, shortness of breath, and wheeze than did 100 age- and sex-matched unexposed controls (Bener et al., 2001a). Blood Pb levels in both the Pb industrial workers and the control group (geometric means: 77.5 and 19.8 µg/dL, respectively) were higher than those in most of the current U.S. adult general population.

An effect of Pb specifically on the lung was demonstrated in a recent study of Wistar rats with low blood Pb levels (2.1 µg/dL) but produced by Pb acetate given by injection (25 mg/kg, 3 consecutive days) (Kaczynska et al., 2011). The lungs of Pb-treated rats exhibited pulmonary fibrosis, epithelial cell damage, an increase in mast cells, an increased recruitment of monocytes and thrombocytes into capillaries, and increased macrophage accumulation in the alveolar space. While these pulmonary changes have been linked with functional pulmonary decrements and inflammation in other studies (unrelated to Pb exposure), the implications are uncertain because the results were obtained with a route of Pb exposure less relevant to those in humans.

Air-Pb Studies

The 2006 Pb AQCD (U.S. EPA, 2006b) did not review studies that represent Pb exposure by Pb measured in PM_{10} and $PM_{2.5}$ air samples. However, recent studies have examined the respiratory effects of PM-Pb by analyzing the Pb component individually or as part of a group of correlated components using source apportionment or principal component analysis. Daily ambient air Pb-PM concentrations were associated with daily respiratory morbidity in children (Gent et al., 2009; Hong et al., 2007b). Gent et al. (2009) found that increases in lag 0 and 0-2 average Pb-$PM_{2.5}$ were associated with increases in respiratory symptoms and asthma medication use in 149 children with asthma in Southern New England (ages 4-12 years), adjusting for season, day of the week, and date. Hong et al. (2007b) found that an increase in lag 1 Pb-PM_{10} was associated with a decrease in lung function in 43 mostly healthy children in Korea, adjusting for age, sex, height, weight, household smoking, and weather. In support of these results in children, toxicological studies found Pb-containing CAPs to induce pulmonary inflammation. Uzu et al. (2011) found that Pb-rich PM from a Pb recycling plant increased the release of the cytokine

granulocyte-macrophage colony-stimulating factor from human epithelial cells. Pulmonary inflammation was found in animals exposed to CAPs in which Pb was one of numerous components (Wei et al., 2011; Duvall et al., 2008; Godleski et al., 2002; Saldiva et al., 2002).

As with blood Pb, daily ambient air Pb-$PM_{2.5}$ concentrations were not consistently associated with daily respiratory effects in older adults with adjustment for weather and temporal trends. Among adults ages 65 years and older in 6 California counties, a 4 ng/m^3 increase in lag 3 Pb-$PM_{2.5}$ was associated with an relative risk of respiratory mortality of 1.01 (95% CI: 0.99, 1.03) in the all-year analysis and in a summer-only analysis (RR not reported) (Ostro et al., 2007). However, among adults ages 65 years and older in 106 U.S. counties, Bell et al. (2009) found that an increase in lag 0 Pb-$PM_{2.5}$ was associated with a decrease in respiratory hospital admissions.

Despite evidence that indicates a relationship between respiratory effects in children and short-term (over a few days) changes in ambient air Pb-PM concentrations, uncertainties limit the utility of these findings in evaluating Pb-associated respiratory effects. Few data on size distribution of Pb-PM are available, so it is difficult to assess the representativeness of these concentrations to population exposure (Section 3.5.3). Moreover, few data are available on the relationship between blood Pb and air Pb for the varying Pb-PM size distributions (see Section 4.5.1). In several air-Pb studies, other PM components such as elemental carbon (EC), copper (Cu), and zinc (Zn) also were associated with respiratory effects. In the absence of data on correlations among PM components, measurements on co-occurring ambient pollutants, or results adjusted for copollutants, it is difficult to exclude confounding by ambient air exposures to other PM components or ambient pollutants. In several studies that analyzed PM component mixtures, of which Pb-PM comprised one component, it is not possible to attribute the observed associations or lack of associations specifically to Pb (Sarnat et al., 2008; Andersen et al., 2007; Veranth et al., 2006; Maciejczyk and Chen, 2005).

In summary, while air Pb-PM has been associated with respiratory effects in children, main limitations of this recent evidence include the confounding by other PM components and the uncertain representativeness of Pb-PM to population exposures. In adults, neither blood Pb nor Pb-PM was consistently associated with respiratory effects. Blood Pb studies of nonoccupationally-exposed adults were similar in cross-sectional design, age of subjects, potential confounding factors examined, and respiratory endpoints which exhibit short-term changes. Studies of Pb-exposed workers were similarly limited by lack of rigorous statistical analysis with blood Pb levels and lack of consideration for potential confounding factors, including other occupational exposures.

5.6.5.4 Autoimmunity

Autoimmunity is an immune response against self (e.g., generation of antibodies against self antigens) and is linked with diseases such as lupus and rheumatoid arthritis. Evidence for the effects of Pb on increasing the risk of autoimmunity is provided primarily by a small number of toxicological studies reviewed in the 2006 Pb AQCD in which pre- and post-natal Pb acetate exposure of animals, several by injection, was associated with the generation of autoantibodies (Hudson et al., 2003; Bunn et al., 2000; El-Fawal et al., 1999; Waterman et al., 1994). El-Fawal et al. (1999) found elevated auto-antibodies in F344 rats with blood Pb levels 11-50 µg/dL. Evidence was mixed in indicating a shift toward Th2 or Th1 responses as the underlying mechanism. While recent studies did not examine Pb-induced production of auto-antibodies, some provided indirect evidence by indicating that Pb had the potential to induce formation of neo-antigens which in turn could induce the formation of auto-antibodies. For example, Kasten-Jolly et al. (2010) found that developmental Pb acetate exposure of BALB/c mice (100 µM in drinking water, GD8-PND21) upregulated genes for digestive and catabolizing enzymes, which could lead to the generation of self-peptides, which combined with other Pb-induced immune effects, had the potential to induce the generation of auto-antibodies. The potential for auto-antibody generation also was indicated by the activation of neo-antigen-specific T cells in adult BALB/c mice injected once with 25-50 µg Pb chloride (Carey et al., 2006). Evidence of Pb-associated autoimmune responses in humans is limited to findings of higher levels of IgM and IgG auto-antibodies to neural proteins in male battery-plant workers (n = 20, 56) with blood Pb level range 10-40 µg/dL compared with controls (n = 7, 15, blood Pb levels not reported) (El-Fawal et al., 1999). Pb workers and controls were matched by demographic and SES characteristics, but potential confounding by other workplace exposures was not examined. Similar to findings in Pb-exposed workers, modified neural proteins were found in CBA/J rats injected with native protein altered by Pb acetate in vitro (Waterman et al., 1994).

5.6.5.5 Tumors

Toxicological evidence indicates that high concentration Pb exposures directly promote tumor formation or induce mutagenesis and genotoxicity (Section 5.10), and a study provided evidence for involvement of the immune system. Kerkvliet and Baecher-Steppan (1982) found that postnatal exposure of 6-8 week old male C57BL/6 mice to 130 and 1,300 ppm Pb acetate in drinking water for 10-12 weeks transiently enhanced moloney sarcoma virus-induced tumor growth compared with control animals but did not prevent subsequent tumor regression. The Pb-induced tumor growth was accompanied by impaired macrophage phagocytosis (indicating suppressed Th1 responses) but not

cytotoxicity. Cancer promotion is a relatively common outcome in chemical-induced immunotoxicology, particularly when early life exposures are involved (Dietert, 2011).

5.6.6 Modes of Action for Pb Immune Effects

5.6.6.1 Cytokine Production

As referenced in preceding sections, cytokines are signaling molecules that affect immune cell function. For example, IL-4 induces B cells into IgE-producing cells, and IFN-γ induces macrophage recruitment and antigen presenting activity. The 2006 Pb AQCD (U.S. EPA, 2006b) presented a large body of evidence that clearly demonstrated that pre- and postnatal Pb exposure of animals such as rodents and chickens suppressed the production of Th1 cytokine IFN-γ and/or increased production of Th2 cytokines such as IL-4 [Table 5-7 of the 2006 Pb AQCD (U.S. EPA, 2006g)]. The combined evidence for Pb-induced cytokine changes in multiple cell types, including T cells and macrophages, indicates a shift of acquired immunity responses away from Th1 responses and toward Th2 responses. In turn, the Th1 to Th2 shift provides mode of action support for downstream effects (Figure 5-34) such as inflammation, ROS production, impaired macrophage function, decreased host resistance observed primarily in toxicological studies, increased IgE production observed in both epidemiologic and toxicological studies, and asthma and allergy observed in epidemiologic studies. Previous toxicological studies found Pb to affect cytokine production via action on T cells and macrophages, and a recent study provided new evidence that Th2 skewing may be mediated via effects on dendritic cells.

Many studies found a shift to Th2 cytokine production in animals with long-term (>4 weeks) dietary Pb exposure, and in some studies, the effects of prenatal exposure on cytokine production persisted to the adult lifestage (Chen et al., 2004; Miller et al., 1998). In the few studies that measured blood Pb levels shortly after cessation of Pb exposure (gestational plus postnatal or postnatal only), higher IL-4 and/or lower IFN- γ were found in rodents with relevant blood Pb levels, means 6.75 and 17 µg/dL (Chen et al., 2004; Dyatlov and Lawrence, 2002). Some studies found an increase in IL-4 or decrease in IFN- γ concomitantly with an increase in IgE (Heo et al., 1997; 1996) or decrease in host resistance (Fernandez-Cabezudo et al., 2007) further supporting changes in cytokine production as a mode of action for Pb-induced effects on downstream immune endpoints. A recent study found a shift to Th2 cytokine production in mice over wide range of Pb exposures, and provided evidence of effects at lower Pb exposures and a concentration-dependent relationship. In this study, lifetime (gestation through adulthood) exposure of

Swiss mice to 0.06-400 ppm dietary Pb acetate produced blood Pb levels (upon termination of exposure) of 1.23 to 61.48 µg/dL (Iavicoli et al., 2006b). For IL-2 and IL-4, nonlinear concentration-response relationships were found, with the largest decrease and increase, respectively, found between animals with blood Pb levels of 0.8 µg/dL (0.02 ppm Pb acetate, controls) and 1.23 µg/dL. A linear concentration-dependent decrease in IFN-γ was observed in animals with blood Pb levels of 0.8-61.48 µg/dL. Although examined in few in vivo studies, increases in IL-6 and IL-10, also Th2 cytokines, were reported in juvenile and adult rodents exposed to Pb gestationally or postnatally in drinking water [Table 5-7 of the 2006 Pb AQCD (U.S. EPA, 2006g)].

In vitro studies also reported a Pb-induced shift to production of Th2 cytokines. In concordance with other indicators of Th2 skewing (i.e., suppressed DTH) in BALB/c mice treated with Pb-exposed dendritic cells, Gao et al. (2007) observed that 10-day 25 µM Pb chloride exposure lowered the ratio of IL-12:IL-10 production by dendritic cells in vitro. Pb did not affect dendritic cell production of IL-6, IL-10, or TNF-α; however, in co-cultures of Pb-treated dendritic cells and T cells, most results indicated that dendritic cells stimulated T cells to produce Th2 cytokines. For example, although T cell production of the Th1 cytokine IL-2 increased, production of Th2 cytokines, IL-6 and IL-10 increased. Further, Pb-treated dendritic cells increased IL-4 production in OVA-specific T cells, indicating that Pb affected the antigen presenting cell function of dendritic cells. In another in vitro study, 24-hour Pb acetate exposures of 0.15 µg/dL and higher suppressed expression of Th1 cytokines, IFN-γ, IL-1β, and TNF-α, and increased secretion of Th2 cytokines, IL-5, IL-6, and IL-10 in cultures of human PMNs activated with *Salmonella enteritidis* or with monoclonal antibodies of CD3, CD28, and CD40, (Hemdan et al., 2005).

Several toxicological studies found Pb-induced increases in the cytokine TNF-α, in some cases, specifically from macrophages (Khan et al., 2011; Cheng et al., 2006; Flohé et al., 2002; Zelikoff et al., 1993). This provides mode of action support for toxicological evidence indicating Pb-induced decreases in resistance to bacterial infection since TNF-α is produced primarily by activated macrophages, is increased in response to infection, and induces inflammation. Among the in vivo studies, increases in TNF-α were found with prenatal dietary Pb acetate exposure (250 ppm) of F344 rats (Chen et al., 1999; Miller et al., 1998), postnatal Pb oxide air exposure (31 µg/m^3, 3 hours/day, 4 days) of rabbits (Zelikoff et al., 1993), and postnatal i.p. Pb acetate treatment (5.0 mg) of Swiss mice (Dentener et al., 1989). The effects of prenatal dietary Pb exposure were found to persist to adulthood. In animals, the Pb-induced increases in TNF-α were accompanied by functional changes in host responses such as decreased macrophage phagocytosis (Zelikoff et al., 1993), suppressed DTH (Miller et al., 1998), and increased mortality to

E.coli endotoxin (Dentener et al., 1989). Blood Pb levels of animals were infrequently reported; however, Chen et al. (1999) found increased TNF-α in rats with embryonic blood Pb levels of 149 µg/dL. In addition to finding Pb-induced increases in TNF-α (Khan et al., 2011; Gao et al., 2007; Cheng et al., 2006; Flohé et al., 2002; Krocova et al., 2000; Guo et al., 1996a), some in vitro studies provided mechanistic explanation by finding that Pb acetate or chloride (10-50 µM, 1.5 hours-10 days) induced phosphorylation of mitogen-activated protein kinase (MAPK) signaling molecules (Khan et al., 2011; Gao et al., 2007; Cheng et al., 2006). Further, Cheng et al. (2006) found that blocking protein kinase C or MAPK reduced TNF-α production by macrophages in vitro, which in turn, protected against Pb acetate + LPS-induced liver injury in A/J mice.

The few available epidemiologic studies that examined cytokines found higher concurrent blood Pb levels in children and adults to be associated with higher Th2 cytokine and lower Th1 cytokine levels in serum. The epidemiologic evidence overall was based on cross-sectional analyses, which precludes identifying the temporal sequence between Pb exposure and cytokine changes. Other limitations include the lack of rigorous statistical analysis and limited consideration of potential confounding. Because of these limitations, the epidemiologic evidence is not a primary consideration in drawing conclusions about Pb-associated cytokine changes. However, it does not mitigate the consistent toxicological evidence. Among children ages 9 months to 6 years in Missouri recruited from a public assistance or Pb poisoning prevention program, Lutz et al. (1999) found that 8 children with concurrent blood Pb levels 15-19 µg/dL had 4-5 fold higher serum levels of IL-4 ($p = 0.08$, Kruskal Wallis) and 3-fold higher IgE (Section 5.6.3) than did 90 children with lower blood Pb levels. IL-4 levels in 9 children with blood Pb levels 20-44 µg/dL were lower than those in 90 children with blood Pb levels <15 µg/dL. The elevated IL-4 and IgE in children with blood Pb levels 15-19 µg/dL were consistent with the action of IL-4 to activate B cells to induce class switching to IgE. In another study of 214 children in grades 5 and 6 in Taiwan, investigators compared cytokine levels not by blood Pb level groups but by potential for Pb exposures due to age of home and location of residence (Hsiao et al., 2011). Elevated concurrent blood Pb levels were found only among 64 children living near an oil refinery, in particular, among 34 children with known respiratory allergies (mean: 8.8 µg/dL versus 3.2-3.8 µg/dL in urban and rural groups). Children with allergies near the oil refinery also had the lowest serum levels of IFN-γ (45-fold) and highest levels of IL-4 (6-fold) (lower $p < 0.05$ for comparisons with any subgroup). While the results suggested that residence near the oil refinery contributed to differences in cytokine levels between healthy and allergic children, they do not specify a contribution of Pb, other exposures or co-occurring factors, or a combination of factors.

Evidence of association between blood Pb levels and cytokine levels in is unclear. However, a larger study that considered potential confounding found an association. Sufficient information was not provided to assess potential selection bias. Among 300 (93% male, mean age 24 years) healthy university students in Incheon, Korea, higher concurrent blood Pb level was associated with higher serum levels of TNF-α and IL-6, adjusting for age, BMI, and smoking status (Kim et al., 2007). Associations were larger in magnitude among the 147 males in the upper two quartiles of blood Pb levels, 2.51-10.47 µg/dL. Associations with these blood Pb levels may reflect contributions of higher past Pb exposures. A 1 µg/dL higher blood Pb level was associated with a 0.75 (95% CI: 0.14, 1.36) pg/mL higher TNF-α and a 0.18 (95% CI: -0.02, 0.38) pg/mL higher IL-6. The association between levels of blood Pb and plasma TNF-α was greater among men who were GSTM1 null (n = 77) than men who were GSTM1 positive and men who had the TNF-α GG genotype (n = 131) than men who had the GA or AA genotype. For the association between blood Pb level and plasma IL-6, the effect estimate was slightly elevated in TNF-α GG genotype but similar between GSTM1 genotypes. In this study, there were multiple comparisons, but a consistent pattern of association was observed across the immune endpoints examined. Subgroup analyses had fairly large sample sizes, and some results had biological plausibility, but they are prone to higher probability of findings by chance. Pb has been shown to increase ROS (Section 5.2.4), and cytokine expression has been shown to be modulated by ROS-sensitive transcription factors. Thus, it is biologically plausible that the null variant of GSTM1, which is associated with reduced elimination of ROS, may be associated with increased cytokine levels. The results for the TNF-α variant are difficult to interpret. The GG genotype is associated with lower expression of TNF-α, but the literature is mixed with respect to which variant increases risk of inflammation-related conditions.

A much smaller study of adults that did not consider potential confounding, did not report quantitative results but only reported lack of statistically significant correlations between concurrent blood Pb level and serum Th2 and Th1 cytokine levels in men (n = 17 with and 17 without allergy, ages 19-52 years, median blood Pb levels: ~11 µg/dL) (Boscolo et al., 1999) and women in Italy (n = 23 with and 25 without allergy, ages 19-49 years, median blood Pb levels: 6.4 and 5.5 µg/dL, respectively) (Boscolo et al., 2000).

Results from studies of occupationally-exposed adults also suggested that Pb exposure may be associated with decreases in Th1 cytokines and increases in Th2 cytokines (Di Lorenzo et al., 2007; Valentino et al., 2007; Yücesoy et al., 1997a). Valentino et al. (2007) had the most rigorous statistical methods comprising regression analyses with adjustment for age, BMI, smoking status, and alcohol consumption status but not other occupational exposures. Regression coefficients describing the concentration-response functions were not reported; however, 44 male foundry workers in Italy (mean blood Pb

levels: 21.7 µg/dL) and 14 pottery workers (mean blood Pb level: 9.7 µg/dL, ages of all workers 30-61 years) had higher plasma IL-10 (ANOVA, $p < 0.05$) than did the 59 unexposed controls (mean blood Pb level: 3.9 µg/dL, ages 25-61 years). Levels of Th2 cytokines IL-2, IL-6, and IL-10 also increased from the lowest to highest blood Pb group (ANOVA, $p > 0.05$). In contrast with most other studies, both exposed worker groups had lower IL-4 levels compared with controls (ANOVA, $p > 0.05$). In Yucesoy et al. (1997a), serum levels of the Th1 cytokines, IL-1β and IFN-γ, were lower in 20 Pb-exposed workers (mean blood Pb level: 59.4 µg/dL, ages 19-49 years) than in the 12 age-matched controls in Turkey (mean blood Pb level: 4.8 µg/dL). Some (Di Lorenzo et al., 2007; Valentino et al., 2007) but not all (Yücesoy et al., 1997a) studies found higher serum TNF-α in Pb-exposed workers. DiLorenzo et al. (2007) found a monotonic increase from the 28 unexposed (blood Pb levels not reported, mean age: 48.2 years) to 17 intermediate worker (9.1-29.4 µg/dL) and 19 high worker (29.4-81.1 µg/dL) blood Pb level groups (mean age of workers: 45.3 years) in Italy. Results also indicated a potential interaction between blood Pb level and smoking. Among current smokers (n = 9 to 20), a 12- to 16-fold difference in TNF-α levels was observed among blood Pb groups. Among nonsmokers (n = 2 to 8), the differences were less than two fold.

In summary, the few epidemiologic studies indicate associations of higher concurrent blood Pb level with higher levels of IL-4 and/or lower levels of IFN-γ in children (Hsiao et al., 2011; Lutz et al., 1999) and occupationally-exposed adults (Di Lorenzo et al., 2007; Valentino et al., 2007; Yücesoy et al., 1997a). Because quantitative results were not reported in each study of nonoccupationally-exposed adults, implications of findings are difficult to assess. Limitations of the epidemiologic evidence overall include the cross-sectional design of studies and lack of rigorous statistical analysis that considered potential confounding factors. Sufficient data were not reported to assess potential selection bias. Because of the many limitations, the epidemiologic evidence alone is not used to draw conclusions about Pb-associated cytokine changes. However, they are useful in indicating the relevance of toxicological evidence to humans. Biological plausibility for an effect of Pb on cytokine production is provided by a large body of toxicological evidence that clearly demonstrates a Pb-induced shift to a Th2 phenotype with increases in the Th2 cytokine IL-4 and decreases in the Th1 cytokine IFN-γ. Several of these observations were made in juvenile and adult animals exposed prenatally or postnatally via diet that resulted in blood Pb levels (upon cessation of Pb exposure) relevant to humans, 1.23-17 µg/dL (Iavicoli et al., 2006b; Chen et al., 2004; Dyatlov and Lawrence, 2002). While results were not uniform for other cytokines (i.e., Th1 cytokine IL-2), most available results pointed to increases in Th2 cytokines, specifically, IL-6 and IL-10, in Pb-exposed animals. Several studies demonstrated Pb-induced increases in TNF-α but in animals with high prenatal dietary or postnatal air Pb exposure (e.g.,

149 µg/dL) (Chen et al., 1999; Miller et al., 1998; Zelikoff et al., 1993). Gao et al. (2007) described a role for dendritic cells in skewing T cells to Th2 cytokine production. In vitro evidence indicates that Pb may induce increases in TNF-α via MAPK signaling pathways (Khan et al., 2011; Gao et al., 2007; Cheng et al., 2006). Toxicological evidence indicates effects on cytokine production of prenatal and postnatal Pb exposures, whereas epidemiologic studies examined only concurrent blood Pb level. Because concurrent blood Pb level in children and adults reflects both previous and current Pb exposures, associations with concurrent blood Pb level may reflect an effect of cumulative Pb exposure. Overall, the consistent toxicological evidence for Pb-induced decreases in Th1 cytokines and increases in Th2 cytokines and pro-inflammatory cytokines such as TNF-α provides clear mode of action support for the evidence indicating the effects of Pb on both increases in IgE and inflammation and decreased host resistance.

5.6.6.2 Decreased Nitric Oxide

As described in the 2006 Pb AQCD (U.S. EPA, 2006b), key mode of action support for the effects of Pb on impairing macrophage function and decreasing host defense was provided by consistent toxicological findings for Pb-induced decreases in NO, which is involved in the cytotoxic activity of macrophages in host defense processes [see 2006 Annex Table AX5.9.6 (U.S. EPA, 2006h)]. In adult rodents, decreases in NO from macrophages were observed with short-term Pb acetate exposures (1 or 6 days) during early gestation (Bunn et al., 2001b; Lee et al., 2001b) but not long-term exposures occurring during the full gestational period (Bunn et al., 2001c; Chen et al., 1999; Miller et al., 1998). With short-term exposure, decreases in NO were found in Sprague-Dawley rats with blood Pb level 4.5 µg/dL in males and 5.3 µg/dL in females measured 2 weeks after Pb exposure in drinking water of dams was terminated (Bunn et al., 2001b) and in chicks with blood Pb levels that did not exceed 11 µg/dL but with Pb injected into eggs embryos (Lee et al., 2001b).

The short-term in vivo findings are supported by several in vitro observations of decreases in NO in macrophages and splenocytes induced by a wide range of Pb exposure concentrations (0.625-5 µM) and durations (2 hours-6 days) (Farrer et al., 2008; Mishra et al., 2006a; Krocova et al., 2000; Chen et al., 1997; Tian and Lawrence, 1996, 1995). Farrer et al. (2008) further indicated that the mode of action for Pb (5 µM) may involve a decrease in inducible NO synthase function in myeloid cells without a change in its gene expression. Additionally, Pb glutamate abrogated the myeloid cell (CD11b+)-mediated suppression of CD4+ T cell proliferation, and exogenous NO restored suppression. Together, these findings indicated that Pb may indirectly enhance T cell proliferation through its effect on decreasing NO production. Combined with the observation that Pb

can alter antigen processing (Farrer et al., 2005) and, hence, the quality and magnitude of the acquired immune response against pathogen exposure, evidence indicated that multiple arms of host defense against infectious challenge can be compromised. Diminished production of NO in innate immune cells such as macrophages could affect other physiological systems (e.g., neurological, cardiovascular, endocrine) that require NO signaling cascades.

Consistent with the toxicological evidence, cross-sectional studies found associations between concurrent blood Pb level with lower NO in populations living near Pb sources (Barbosa et al., 2006c; Pineda-Zavaleta et al., 2004). These studies did not provide sufficient information on participation rates; however, examination of populations near Pb sources could limit generalizability of findings. Additional limitations include the cross-sectional design that does not permit determining the temporal sequence between Pb exposure and NO suppression and the limited consideration for potential confounding. Because of these limitations, epidemiologic evidence is not a major consideration in drawing conclusions about the effects of Pb on NO. However, they are useful in that they show Pb-associated decreases in NO in humans, similar to toxicological studies.

In a study of 65 children (ages 6-11 years) in Lagunera, Mexico, mean concurrent blood Pb levels increased (7.02 to 20.6 to 30.38 µg/dL) with increasing school proximity (650-8,100 meters) to a Pb smelter (Pineda-Zavaleta et al., 2004). With adjustment for age and sex, a 1 µg/dL higher blood Pb level was associated with a 0.00089 (95% CI: -0.0017, -0.00005) nmol/µg protein lower NO release from macrophages activated by phytohemagglutinin (PHA). Because PHA activates macrophages indirectly through the activation of lymphocytes, the results indicated that Pb suppressed T cell-mediated macrophage activation. Blood Pb group comparisons indicated that associations were due largely to the lower NO in the 23 children closest to the smelter who had blood Pb levels 10.31-47.49 µg/dL. Though not described in detail, higher blood Pb level was not associated with lower NO in girls.

Among 104 adults (ages 18-60 years) in Sao Paolo, Brazil residing near a closed battery plant, Barbosa et al. (2006c) observed an association between higher concurrent blood Pb level and lower plasma NO in the 69 adults (mean blood Pb level: 6.4 µg/dL) with the TC or CC eNOS genotype ($r = 0.23$, $p = 0.048$). The results are consistent with the reduced promoter activity and potentially reduced gene expression of the TC/CC variants. Results were not adjusted for potential confounding factors, but subjects were nonsmoking, nonalcohol drinking with normal mean BMI and SBP. The exclusion criteria may further limit the generalizability of findings. Because NO was measured in plasma, immune cells could not be identified as the source of NO. In contrast, Valentino et al. (2007) found similar plasma NO levels in 44 male foundry workers (mean blood Pb level: 21.7 µg/dL),

14 male pottery workers (mean blood Pb level: 9.7 µg/dL), and 59 male unexposed workers of similar age (mean blood Pb level: 3.9 µg/dL, ages 25-61 years). Quantitative results were not reported, but blood Pb level was reported not to be correlated with NO. Potential confounding factors, including other workplace exposures were not examined.

In summary, toxicological evidence indicates that short-term dietary Pb exposure early in gestation but not long-term exposure for the full gestational period results in reduced NO production by macrophages. Evidence consistently demonstrates Pb-induced decreases in NO in cell cultures. The relevance of toxicological evidence is supported by observations of an association between higher concurrent blood Pb level and lower release of NO from macrophages of children in Mexico. The association in children was due largely to lower NO in macrophages from children living near a Pb smelter with concurrent blood Pb levels >10 µg/dL, higher than those in most of the current U.S. population. This study had limited consideration for potential confounding factors. However, the toxicological evidence provides clear mode of action support for the effects of Pb on decreasing host resistance given the role of NO in mediating cytotoxic activity of macrophages.

5.6.6.3 Increased Reactive Oxygen Species and Prostaglandins

ROS are released from macrophages during phagocytosis and are involved in killing invading bacteria. ROS and PGE_2 are important mediators of inflammation which can result in local tissue damage (Figure 5-34). The roles of ROS and PGE_2 in both host defense and injury may explain some of the inconsistencies in the evidence as reported in the 2006 Pb AQCD. In activated macrophages undergoing phagocytosis, high concentration (10-1,000 µM, 15 minutes-20 hours) Pb chloride or acetate exposures were found to reduce release of ROS (Hilbertz et al., 1986; Castranova et al., 1980), consistent with observations of Pb-induced decreased bacterial and viral resistance. In resting macrophages, Hilbertz et al. (1986) found that Pb acetate induced an increase in ROS one hour but not 20 hours after exposure, indicating a transient response. Chen et al. (1997) also found a Pb-induced (4 µM Pb-glutamate, 18 hours) decrease in ROS but did not indicate the functional state of macrophages. Shabani and Rabbani (2000) found a Pb-induced (240 µM Pb nitrate, 3 hours) increased ROS from alveolar macrophages that was linked to their apoptosis, also consistent with impaired host defense. Other studies reported depletion of antioxidants such as glutathione and catalase in conjunction with reduced macrophage function in Swiss mice treated with Pb nitrate by oral gavage (40 mg/kg/day, 30 days) (Lodi et al., 2011) or increases in PGE_2 and apoptosis in vitro with 0.01-10 µM Pb nitrate (3 hours) (Chetty et al., 2005). While several processes have been proposed to explain the mechanisms of Pb-induced oxidative damage, the exact combination of processes involved remains to be determined (Section 5.2.4).

In adult animals, Pb exposure increased ROS release from macrophages immediately upon cessation of exposure (Baykov et al., 1996; Zelikoff et al., 1993) but not 9-10 weeks after exposure (Miller et al., 1998), consistent with in vitro findings. These Pb exposures occurred through relevant routes of exposure, i.e., diet or air, but with high concentrations, 31 µg/m^3 Pb oxide in air for 3 hours/day for 4 days in rabbits (Zelikoff et al., 1993) and 1.5 mg/kg Pb acetate in diet for 30 days in Swiss mice (Baykov et al., 1996). Neither study measured the blood Pb levels of animals.

Pb-associated increases in ROS also were found in macrophages of humans. However, the findings are based on cross-sectional design, higher blood Pb levels (means: 7.02, 20.6, and 30.38 µg/dL) than most of those in the current U.S. population, and limited consideration for potential confounding. In addition to finding suppressed NO production (Section 5.6.6.2), Pineda-Zavaleta et al. (2004) found a Pb-associated increase in ROS production from macrophages in children in Mexico living in varying proximities to a Pb smelter. With adjustment for age and sex, a 1 µg/dL higher concurrent blood Pb level was associated with a 0.00389 (95% CI: 0.00031, 0.00748) µmol/mg higher release of superoxide anion from macrophages directly activated by IFN-γ/LPS. The blood Pb-associated superoxide anion release was larger from macrophages of males. Because IFN-γ directly activates macrophages, these results indicated that Pb stimulated cytokine-induced macrophage activation. Blood Pb level was not associated with ROS from neutrophils in a study of male Pb recycling workers (ages 19-45 years) in India. Despite large differences in blood Pb levels between 30 Pb workers (mean: 106 µg/dL) and 27 unexposed controls (mean: 4.5 µg/dL), levels of ROS released from neutrophils (indicators of respiratory burst) were similar between groups (Mishra et al., 2006a). Evidence does not clearly indicate that neutrophils are a major responding cell to Pb exposure (Section 5.6.2.5).

PGE_2 is produced from the metabolism of cell membrane phospholipids and may be released by macrophages to modulate their function in a paracrine or autocrine manner. Toxicological studies have found Pb-induced increases in PGE_2 in macrophages with high concentration Pb exposures. Increases in PGE_2 were found in turkeys exposed to Pb acetate in feed PND1-PND21 and with a mean blood Pb level of 42 µg/dL (Knowles and Donaldson, 1997). Dietary Pb acetate exposure (250-2,000 ppm) of chicks PND1-PND19 resulted in an increase in serum arachidonic acid but not PGE_2 or other prostaglandins (Knowles and Donaldson, 1990). In vitro studies also used high Pb exposure concentrations, >20 µM Pb chloride (Flohé et al., 2002; Lee and Battles, 1994). A recent in vitro study with human neuroblastoma cells found increases in PGE_2 with lower Pb concentrations (0.01-1 µM Pb acetate) than previously reported (Chetty et al., 2005).

In summary, ROS and PGE_2 function in modulating macrophage function, aiding in bacterial killing, and inducing tissue damage as part of an inflammatory response. Consistent with these diverse roles, toxicological studies have found both Pb-associated increases and decreases in ROS and PGE_2. Consistent with toxicological findings, a cross-sectional study found an association between higher concurrent blood Pb level (>10 µg/dL) higher ROS release from macrophages in children in Mexico that was adjusted for potential cofounding by only age and sex. In animals, Pb-induced increases in macrophage production of ROS and PGE_2 have occurred concomitantly with functional alterations such as impaired macrophage phagocytosis and apoptosis. Although toxicological results were based on examination of high Pb concentrations, they nonetheless provide clear evidence for modes of action underlying the effects of Pb on reduced macrophage function and decreased host resistance.

5.6.6.4 Cellular Death (Apoptosis, Necrosis)

The 2006 Pb AQCD reported contrasting effects of Pb on the apoptosis of macrophages in vitro. However, with recent studies in mice, evidence suggests that Pb exposure may induce apoptosis or mediators of apoptosis in immune cells. Xu et al. (2008) found that 4-week dietary exposure of juvenile ICR mice to Pb acetate (50-100 mg/kg) induced DNA damage in peripheral blood lymphocytes, increased p53 and Bax expression in the liver, but did not change Bcl-2 expression (creating a Bax/Bcl-2 imbalance). Bax promotes apoptosis, whereas Bcl-2 inhibits apoptosis. Concomitant increases in indicators of oxidative stress in liver homogenate suggested that oxidative stress mediated Pb-induced apoptosis. In Swiss mice, Bishayi and Sengupta (2006) found splenic macrophages to have elevated DNA fragmentation, a key event in apoptosis, but with i.p. Pb acetate treatment (10 mg/kg). Consistent with in vivo findings, Gargioni et al. (2006) found 20 and 40 µM Pb nitrate to induce cell death in mouse peritoneal macrophages in vitro with a concomitant loss of cell membrane integrity, indicating that Pb primarily induced macrophage necrosis or cell lysis. While evidence for Pb-induced apoptosis of immune cells with routes of Pb exposure relevant to humans is sparse, the evidence suggests that the induction of cell death may be a potential mode of action for the effects of Pb on macrophage function and decreased host resistance.

5.6.7 Immune Effects of Pb within Mixtures

In the 2006 Pb AQCD (U.S. EPA, 2006b), the immune effects resulting from Pb within metal mixtures were not well characterized; however some recent studies indicated that immune effects may be observed with lower levels of Pb exposure when they occur in conjunction with other metals. In Swiss mice treated with Pb acetate (10 mg/kg i.p., daily for 15 days), As (0.5 mg/kg i.p., daily for 15 days), or both, Bishayi and Sengupta (2006) reported a greater than additive effect of co-administered Pb and As on decreasing bacterial resistance, decreasing macrophage myeloperoxidase release, and NO production.

Epidemiologic studies have not widely examined interactions between Pb and other metals. However, consistent with Bishayi and Sengupta (2006), Pineda-Zavaleta et al. (2004) (Section 5.6.6.2) found interactions between Pb and As among 65 children in Mexico ages 6-11 years. Contamination of drinking water by both Pb and As was a concern in the study area; however, urinary As levels were higher in children who had lower blood Pb levels. Higher urinary As was associated with lower NO release from macrophages (similar to blood Pb). Higher As and Pb internal dose was associated with a larger decrease in NO (p for interaction = 0.037) than was either metal alone. Higher urinary As was associated with lower superoxide anion release (opposite direction of Pb). However, higher Pb and As internal dose was associated with a larger increase in superoxide anion (p for interaction = 0.042) than was blood Pb level alone. Due to the high blood Pb in these children (means in three groups at varying distances from a Pb smelter: 7, 20.6, 30.4 µg/dL), it is not clear whether these relationships would apply to the current U.S. population of children.

Institoris et al. (2006) found that Cd or Hg co-exposure potentiated the effects of Pb. Lymph node weight decreased in 4 week-old Wistar rats exposed to 20 mg/kg Pb acetate by drinking water plus another metal but not with Pb alone. In contrast, Fortier et al. (2008) did not find metal co-exposure to increase the effects of Pb. Pb chloride (7.5-20.7 µg/dL) did not alter lymphocyte proliferation, monocyte phagocytosis, or NK cell activity in human leukocytes. A mixture of 20.7 µg/dL Pb chloride plus 12.0 µg/dL methylmercuric chloride (MeHgCl) decreased lymphocyte proliferation; however, these effects were attributed to MeHgCl, which singly had a stronger suppressive effect. Other toxicological studies found metal mixtures that included Pb to decrease antibody titers or increase neutrophil counts (Jadhav et al., 2007; Massadeh et al., 2007) but did not test each metal individually. The latter findings cannot be attributed to interactions between Pb and other components within the mixture. Overall, several results indicated that exposures to Pb-containing metal mixtures are associated with immune effects. However,

not all results showed that co-exposures to metals such as As, Cd, or Hg produce increase the immune effects of Pb.

5.6.8 Summary and Causal Determination

The cumulative body of epidemiologic and toxicological evidence describes several effects of Pb exposure on the immune system related to a shift from Th1- to Th2-type responses, including an increase in atopic and inflammatory conditions and a decrease in host resistance. Outcomes related to an increase in atopic and inflammatory conditions include asthma, allergy, increased IgE, and mode of action endpoints such as selective differentiation of Th2 cells, increased production of Th2 cytokines, B cell activation, and inflammation. Outcomes related to decreased host resistance include enhanced susceptibility to bacterial and viral infection, suppressed DTH, and those describing mode of action, i.e., decreased production of Th1 cytokines, reduced phagocyte function, and increased inflammation. A small body of studies indicates the effects of Pb exposure on autoimmunity. The sections that follow describe the evaluation of evidence for these three groups of outcomes, decreased host resistance, increased atopic and inflammatory conditions, and autoimmunity, with respect to causal relationships with Pb exposure using the framework described in Table II of the Preamble. The application of the key supporting evidence to the causal framework is summarized in Table 5-34.

5.6.8.1 Evidence for an Increase in Atopic and Inflammatory Conditions

Collective epidemiologic and toxicological evidence indicates that a causal relationship is likely to exist between Pb exposure and atopic and inflammatory conditions. This relationship is supported by evidence for associations of blood Pb levels with asthma and allergy in studies in children (Jedrychowski et al., 2011; Pugh Smith and Nriagu, 2011; Joseph et al., 2005), Pb-associated increases in IgE in children and animals, and evidence describing modes of action including increases in Th2 cytokines and inflammation.

Recent studies on asthma and allergy expand upon the evidence presented in the 2006 Pb AQCD by providing additional evidence from prospective analyses, and by better addressing uncertainties regarding potential confounding by factors such as SES, smoking exposures, and residential allergen exposures (Table 5-34). Findings from studies that prospectively ascertained outcomes increase confidence that associations are not due to reverse causation (Jedrychowski et al., 2011; Joseph et al., 2005). In these studies, the lack of selective participation and objective assessment of outcomes of

asthma and allergy through medical records and clinical testing, respectively, indicates lack of biased reporting of asthma and allergy in children with higher blood Pb levels (Section 5.6.5.2 and Table 5-34). Among children age 5 years in Poland, Jedrychowski et al. (2011) found that a 1 µg/dL increase in prenatal cord blood Pb level was associated with an increased risk of allergic sensitization of 2.3 (95% CI: 1.1, 4.6). The magnitude of risk did not differ with and without adjustment for maternal education or residential allergen levels. An additional strength of this study was the adjustment for prenatal cotinine levels and postnatal smoker in the home. A large study of 4,634 children in Michigan ages 1-3 years found that compared with Caucasian children with blood Pb levels <5 µg/dL measured up to 12 months before asthma assessment, Caucasian children with blood Pb levels ≥ 5 µg/dL had an increased risk of incident asthma of 2.7 (95% CI: 0.9, 8.1) (Joseph et al., 2005). Adjustment was made for census block average income, which may not adequately control for potential confounding by individual subject-level SES.

Supporting evidence was provided by a cross-sectional study of 356 children ages 0-12 years in Michigan, which found that compared with children with concurrent blood Pb levels <10 µg/dL, children with concurrent blood Pb level ≥ 10 µg/dL had increased parental report of an asthma diagnosis in the previous 12 months with an OR of 7.5 (95% CI: 1.3, 42.9) (Pugh Smith and Nriagu, 2011). This study was cross-sectional and produced an imprecise effect estimate; however, a strength of the study was the relatively extensive consideration for potential confounding, including adjustment for family-level income. As with Jedrychowski et al. (2011), Pugh Smith and Nriagu (2011) found an association with adjustment for smoking exposures in the home plus other indicators of housing exposures and condition (Table 5-34). The studies of asthma and allergy differed in which and how potential confounding factors were considered, particularly SES. While there is no single complete measure of SES, the various indicators used across these few studies produces uncertainty regarding residual confounding. Residual confounding also is possible by factors not examined. The examination of maternal education and exposure to smoking or allergens in Jedrychowski et al. (2011) and family income, smoking, housing conditions, pets, or pests in Pugh Smith and Nriagu (2011) increase confidence in the associations observed for blood Pb levels. However, because evidence is limited to a few populations, there is uncertainty regarding potential confounding by SES and other exposures well characterized in the literature to be associated with asthma and allergy.

With respect to blood Pb levels associated with atopic and inflammatory conditions, Joseph et al. (2005) found elevated incidence of asthma in Caucasian children with earlier childhood blood Pb levels ≥ 5 µg/dL and in African American children with blood Pb levels ≥ 10 µg/dL. Pugh Smith and Nriagu (2011) found higher asthma prevalence in children with concurrent blood Pb levels ≥ 10 µg/dL. Jedrychowski et al. (2011) found

increased allergic sensitization in association with cord blood Pb levels that were low (geometric mean: 1.16 µg/dL) but that may have been affected by maternal higher past Pb exposures mobilized from bone to blood during pregnancy.

Biological plausibility for the relationships found between blood Pb levels and asthma and allergy in children is provided by evidence characterizing modes of action, namely, a Pb-associated shift in production from Th1 cytokines (e.g., IFN-γ) to Th2 cytokines (e.g., IL-4) and increase in Th2-dependent IgE levels (Table 5-34). A majority of this evidence was available in the 2006 Pb AQCD (U.S. EPA, 2006b). The shift from Th1 to Th2 cytokine production in animals was found with prenatal or postnatal (4 weeks in juveniles, 3 weeks or 8 weeks in adults) dietary Pb exposures. In the studies available in humans (Table 5-34), higher concurrent blood Pb levels were associated with higher serum IL-4 in children (Lutz et al., 1999) and higher serum IL-6 in nonoccupationally-exposed adults (adjusted for age, BMI, and current smoking status and additional adjustment for income, physical activity, education, and history of inflammatory conditions in the large NHANES analysis) (Songdej et al., 2010; Kim et al., 2007). Because of the limitations in the small body of epidemiologic studies, i.e., the cross-sectional design of studies and inconsistent consideration for potential confounding, the epidemiologic evidence is a lesser consideration in drawing conclusions about Pb-associated cytokine changes. However, epidemiologic evidence does not detract from the clear toxicological evidence for Pb-induced increases in Th2 cytokine production. Coherence for a shift from Th1 to Th2 cytokine production is found in the in vitro evidence for Pb-induced selective differentiation of naïve T cells to a Th2 subtype (Heo et al., 1998; 1996; McCabe and Lawrence, 1991). A recent study in adult mice and in vitro provided new evidence that Pb may promote the shift to Th2 responses by increasing production of Th2 cytokines in dendritic cells, the major effector in antigen response (Gao et al., 2007).

Additional mode of action support is provided by associations observed between higher concurrent blood Pb levels and higher serum IgE in several different populations of children (Section 5.6.3, Table 5-34). While most studies found elevated IgE in groups of children with concurrent blood Pb levels >10 µg/dL, Karmaus et al. (2005) found higher serum IgE in children ages 7-10 years in Germany with blood Pb levels 2.8-3.4 µg/dL compared with children with lower blood Pb levels. Some studies found increasing IgE across increasing blood Pb groups, except in the highest group (Karmaus et al., 2005; Lutz et al., 1999); however, a monotonic concentration-response relationship was not found in a recent study of children in Egypt (Hegazy et al., 2011). Lutz et al. (1999) recruited children in Michigan from a public assistance program, and Karmaus et al. (2005) recruited schoolchildren but excluded those from homes where more than 12 cigarettes were smoked per day. The nature of recruitment may limit generalizability of

findings. Sufficient information was not reported to assess biased participation by Pb exposure and history of allergy or asthma. The limited consideration for potential confounding comprised adjustment for age (Karmaus et al., 2005; Lutz et al., 1999), smoking exposure, serum lipids, blood organochlorine levels, and previous infections (Karmaus et al., 2005) but not SES or allergen exposure. Although these findings were based on cross-sectional analyses and had limited consideration for potential confounding, they were supported by similar findings in animals, which are not subject to reverse causation and confounding bias. Despite clear evidence in animals overall, there was some inconsistency for Pb-induced increases in IgE in animals with gestational or gestational/lactational dietary Pb exposures that resulted in blood Pb levels 5-20 µg/dL, which are more relevant to humans (Chen et al., 2004; Snyder et al., 2000). Miller et al. (1998) found elevated IgE in adult F344 rats after gestational Pb exposure via drinking water of dams whose blood Pb levels peaked at 30-39 µg/dL. There is lack of coherence between the consistent results for IgE and the inconsistent findings for Pb-induced activation of B cells, which differentiate into allergic antibody-producing cells (Section 5.6.3). However, there is strong mode of action support in animals for Pb-induced increases in IL-4, which stimulates differentiation of B cells.

Further support for the effects of Pb exposure on increasing risk of atopic and inflammatory conditions is provided by evidence of Pb-associated inflammation (Section 5.6.4 and Table 5-34). Coherence for this evidence is found with findings for Pb-induced increases in IgE which primes basophils and mast cells to release pro-inflammatory mediators. Pb-induced inflammation is clearly demonstrated by a large toxicological evidence base for the effects of Pb exposure on inducing macrophages into a hyperinflammatory state as characterized by enhanced production of TNF-α, PGE_2, and ROS. Inflammation was observed in rabbits exposed to Pb via air for 4 days (31 $\mu g/m^3$) (Zelikoff et al., 1993) and rodents exposed via diet (250 ppm drinking water during gestation, 1.5 mg/kg food postnatally for 30 days) (Miller et al., 1998; Baykov et al., 1996). Consistent with previous toxicological evidence, a large analysis of adults participating in NHANES found an association between concurrent blood Pb levels and serum CRP, an indicator of systemic inflammation, in 4,278 men with adjustment for age, BMI, income, physical activity, education, history of inflammatory conditions, cardiovascular disease, diabetes, and smoking status (Songdej et al., 2010). Because only concurrent blood Pb levels were examined, there is uncertainty regarding the temporal sequence between Pb exposure and inflammation and the magnitude, timing, frequency, and duration of Pb exposures that contributed to the observed associations. Because of the sparse epidemiologic evidence, it is a lesser consideration in drawing conclusions regarding the effects of Pb exposure on inflammation.

With respect to important lifestages of Pb exposure, gestational Pb exposures, producing blood Pb levels 8 and 20 µg/dL, were found to affect endpoints such as IgE and/or cytokine levels in juvenile and adult rodents (Chen et al., 2004; Snyder et al., 2000). However, increases in Th2 cytokines also were found in adult animals with lifetime Pb exposures beginning in gestation and producing blood Pb levels 1-12 µg/dL (Iavicoli et al., 2006b). The Pb exposure lifestage, magnitude, frequency, and duration associated with atopic and inflammatory conditions are not well characterized in humans. Cord blood Pb level was associated with allergic sensitization in children (Jedrychowski et al., 2011), whereas other studies of children and adults examined only concurrent blood Pb levels. Neither toxicological nor epidemiologic evidence clearly identifies an individual critical lifestage or duration of Pb exposure that is more strongly associated with atopic and inflammatory conditions. In children and adults, concurrent blood Pb levels are influenced by cumulative (from remodeling of bone) and recent Pb exposures. The combined evidence indicates that gestational and cumulative postnatal Pb exposures may influence atopic and inflammatory conditions.

In conclusion, prospective studies in a few populations of children indicate associations of prenatal cord and earlier childhood blood Pb levels with asthma and allergy, with a cross-sectional study providing supporting evidence with associations with concurrent blood Pb level. Prospective design, lack of selective participation of subjects, and objective assessment of outcomes reduce the likelihood of undue selection bias and reverse causation. These few studies varied in their consideration for potential confounding by SES and exposure to smoking or allergens. Thus, uncertainty remains regarding residual confounding in associations observed between blood Pb levels and asthma and allergy in children. The evidence for asthma and allergy is supported by cross-sectional associations found between higher concurrent blood Pb levels in children and higher IgE, an important mediator of asthma and allergy. The biological plausibility for the effects of Pb on IgE is provided by consistent findings in animals with gestational or gestational-lactational Pb exposures, with some evidence at blood Pb levels relevant to humans. In epidemiologic studies, higher IgE and higher asthma prevalence were examined and found in children with concurrent blood Pb levels >10 µg/dL. Coherence for the evidence of Pb-associated increases in asthma, allergy, and IgE is found with evidence for most of the examined endpoints related to mode of action, i.e., Pb-induced increases in Th2 cytokine production and inflammation in animals. Neither toxicological nor epidemiologic evidence clearly identifies an individual critical lifestage or duration of Pb exposure associated with atopic and inflammatory conditions but indicates that gestational and cumulative postnatal Pb exposures may influence atopic and inflammatory conditions. The strong toxicological evidence supporting modes of action for a shift to a Th2 phenotype combined with the epidemiologic evidence for asthma and allergy in a few populations with some uncertainty regarding potential confounding is

sufficient to conclude that a causal relationship is likely to exist between Pb exposures and an increase in atopic and inflammatory conditions.

5.6.8.2 Evidence for Decreases in Host Resistance

Evidence indicates that a causal relationship is likely to exist between Pb exposure and decreased host resistance based on consistent observations that relevant Pb exposures decrease responses to antigens (i.e., suppresses DTH) and increase bacterial titers and subsequent mortality in rodents (Table 5-34, Sections 5.6.2.3 and 5.6.5.1). A majority of this evidence was available in the 2006 Pb AQCD (U.S. EPA, 2006b). The studies that reported blood Pb levels demonstrated increased bacterial titers and mortality with adult-only 16 week Pb exposure via drinking water in adult mice with Salmonella infection and blood Pb level 20 µg/dL (Fernandez-Cabezudo et al., 2007) and with lactational (PND1-PND22) Pb exposure in juvenile mice with Listeria infection and blood Pb level 25 µg/dL (Dyatlov and Lawrence, 2002). DTH was suppressed in adult rats with blood Pb levels 6 and 25 µg/dL after gestational Pb exposure in drinking water (Chen et al., 2004; Bunn et al., 2001a). While a few epidemiologic studies found higher prevalence of respiratory infections in children with higher concurrent blood Pb levels (Karmaus et al., 2005; Rabinowitz et al., 1990) and Pb-exposed workers (Ewers et al., 1982), the implications are limited by the lack of rigorous statistical analysis (i.e., regression) and consideration for potential confounding. These limitations also apply to the recent cross-sectional evidence of Pb-related increases in respiratory infections in children (Carreras et al., 2009) (Table 5-34). These limitations produce uncertainty about the effects of Pb exposure on decreased host resistance in humans but do not detract from the consistent evidence in animals.

The effects of Pb on decreased host resistance are well supported by evidence describing underlying modes of action (Table 5-34). Evidence in animals indicates Pb-induced functional impairment of macrophages, which phagocytize pathogens. Decreased macrophage colony formation was found in rats after gestational Pb exposure (Bunn et al., 2001b), and decreased phagocytic activity was found in mice and turkeys after lactational or 2-week juvenile Pb exposure (Knowles and Donaldson, 1997; Kowolenko et al., 1991). Additional coherence for Pb-induced decreased host resistance is found with observations in animals that gestational Pb exposure suppressed macrophage production of NO which is involved in bacteria killing (Section 5.6.6.2) and postnatal Pb exposure (air for 4 days, food for 30 days) increased production of ROS and PGE_2, which mediate tissue damage (Section 5.6.6.3). Similarly, a cross-sectional epidemiologic study found a smaller release of NO and larger release of superoxide anion from macrophages of children with higher concurrent blood Pb levels (10.3-47.5 versus <10.3 µg/dL) (Pineda-

Zavaleta et al., 2004) after adjustment for age and sex. Because of the limited consideration for potential confounding in this study and examination of higher blood Pb levels than those in most of contemporary U.S. children, the results are a lesser consideration in drawing conclusions about the effects of Pb on macrophages. However, they do suggest the relevance of toxicological observations to humans. The killing capability of macrophages is enhanced by the Th1 cytokine IFN-γ. Therefore, an effect of Pb exposure on decreased host resistance is additionally supported by clear evidence in animals for the effects of Pb exposure on suppressing IFN-γ production (Section 5.6.6.1). A recent study in mice indicated that Pb-induced suppression of DTH may be mediated by a shift in production from Th1 to Th2 cytokines specifically in dendritic cells (Gao et al., 2007).

Some evidence did not contribute strong support for the mode of action for Pb-induced decreased host resistance. Pb-exposed workers were found to have reduced functionality of neutrophils, which respond to bacterial infection (Table 5-34, Section 5.6.2.5) but without consideration for potential confounding or analogous toxicological evidence. Neither epidemiologic nor toxicological evidence clearly demonstrated an effect of Pb exposure on NK cells, which respond to viral infection (Section 5.6.2.7).

With respect to important lifestages of Pb exposure, animal studies found that gestational Pb exposures, producing blood Pb levels of 6 and 25 µg/dL, resulted in decreases in Th1 cytokines, suppression of DTH, and greater susceptibility to bacterial infection (Chen et al., 2004; Bunn et al., 2001a). However, these effects related to decreased host resistance in mice also were affected by postnatal lactational (Dyatlov and Lawrence, 2002), adult long-term (>4 weeks) (Fernandez-Cabezudo et al., 2007), and lifetime Pb exposures beginning in gestation in adult mice (Iavicoli et al., 2006b) that produced blood Pb levels 1-25 µg/dL. Thus, the animal toxicological evidence does not clearly identify a particular lifestage of Pb exposure that is more strongly associated with decreased host resistance.

In conclusion, decreased host resistance is demonstrated by several toxicological observations that dietary Pb exposure producing relevant blood Pb levels increased susceptibility to bacterial infection and suppressed DTH in rodents and by the coherence with evidence describing modes of action, including suppressed production of Th1 cytokines and decreased macrophage function in animals. These effects were found with gestational, lactational, adult-only, and lifetime Pb exposures of animals. Cross-sectional epidemiologic evidence indicates Pb-associated increases in respiratory infections but limitations, including the lack of rigorous methodology and consideration for potential confounding produce uncertainty in the epidemiologic evidence for decreased host resistance in humans. The consistent toxicological evidence in animals but uncertainty in the epidemiologic evidence for decreased host resistance in humans is sufficient to

conclude that a causal relationship is likely to exist between Pb exposure and decreased host resistance.

5.6.8.3 Evidence for Autoimmunity

Toxicological evidence indicates the potential of Pb to increase autoimmunity, with a few previous studies showing Pb-induced generation of auto-antibodies (Hudson et al., 2003; Bunn et al., 2000; El-Fawal et al., 1999; Waterman et al., 1994) and recent studies providing indirect evidence by showing formation of neoantigens that could result in the formation of auto-antibodies (Table 5-34). Several observations were made in animals injected with Pb, which is a route of exposure with less relevance to humans. Higher levels of auto-antibodies also were found in Pb-exposed battery workers; however, implications are limited because of the high blood Pb levels (range: 10-40 µg/dL) of some of the workers and lack of consideration for potential confounding by several factors, including other occupational exposures (El-Fawal et al., 1999). Because results from available toxicological and epidemiologic studies do not sufficiently inform Pb-induced generation of auto-antibodies with relevant Pb exposures, the evidence is inadequate to determine if there is a causal relationship between Pb exposure and autoimmunity.

Table 5-34 Summary of evidence supporting immune causal determinations.

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	References[b]	Pb Exposure or Blood Levels Associated with Effects[c]
Increase in Atopic and Inflammatory Conditions – Likely Causal			
Associations consistently found in high-quality epidemiologic studies with relevant blood Pb levels	Prospective studies indicate higher asthma and allergy incidence in association with earlier childhood or prenatal blood Pb levels in children (ages 1-5 yr) in a few populations (U.S., Poland)	Joseph et al. (2005), Jedrychowski et al. (2011), Section 5.6.5.2	Children (ages 1-3 yr) with blood Pb levels measured earlier in childhood >10 µg/dL Prenatal (cord): geometric mean 1.16 µg/dL
	Some studies report high participation and/or follow-up retention, not conditional on Pb exposure or outcome.	Joseph et al. (2005), Jedrychowski et al. (2011)	
	Some studies objectively assessed outcomes with clinical testing, medical records.	Jedrychowski et al. (2011), Pugh Smith and Nriagu (2011)	
	Adjustment or consideration for potential confounding by SES, exposure to smoking, and/or allergen exposure. Heterogeneity in evaluation of potential confounding among the few available studies produces uncertainty regarding potential confounding.	Jedrychowski et al. (2011), Pugh Smith and Nriagu (2011)	
	Supporting cross-sectional evidence in children (ages 6 mo-10 yr) for increases in IgE but with limited consideration for potential confounding factors, particularly SES. Associations observed in studies in U.S., Europe, Asia; insufficient information to assess potential selection bias.	Children: Karmaus et al. (2005), Hegazy et al. (2011), Lutz et al. (1999), Hon et al. (2010; 2009), Sun et al. (2003) Section 5.6.3	Groups (ages 6 mo – 10 yr) with concurrent blood Pb levels >10 µg/dL
	Evidence for C-R varies for IgE. Some studies show increasing IgE across blood Pb groups, except in highest group.	Karmaus et al. (2005), Lutz et al. (1999)	
	Another study did not show monotonic C-R relationship.	Hegazy et al. (2011)	
Epidemiologic evidence supported by toxicological evidence at relevant exposures	Most animal studies show elevated IgE in animals with prenatal and postnatal dietary Pb exposures. Some inconsistency in animals with relevant Pb concentrations.	Increase in IgE: Snyder et al. (2000), Miller et al. (1998)	Increased IgE with gestational-lactational Pb exposure, blood Pb means 5, 20 µg/dL Gestational Pb exposure producing maternal blood Pb peak: 30-39 µg/dL
		No IgE increase in Chen et al. (2004) Also see Section 5.6.3	No increase with gestational Pb exposure, blood Pb means 7-8 µg/dL

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	References[b]	Pb Exposure or Blood Levels Associated with Effects[c]
Evidence clearly describes mode of action			
Stimulation of Th2 phenotype	Extensive, consistent evidence of increased production of Th2 cytokines (e.g., IL-4, IL-6, IL-10) in animals with prenatal and postnatal (4 weeks juvenile, 3, 8 weeks adults) dietary Pb exposures. Recent evidence for the role of dendritic cells in mediating Th2 shift.	Section 5.6.6.1 & Table 5-7 of the 2006 Pb AQCD (U.S. EPA, 2006g)	
	Limited available cross-sectional evidence in children, adults. Epidemiologic evidence has limited consideration for potential confounding. Is not a major consideration in conclusions.	Children: Lutz et al. (1999) Adults: Kim et al. (2007) Section 5.6.6.1	Children (ages 6 mo-6 yr): Concurrent blood Pb group range 15-19 µg/dL Adults: Group range 2.5-10.5 µg/dL
	The few available in vitro studies indicate activation Th2 cells from naïve T cells or over Th1 cells.	Section 5.6.2.1	
Inflammation	Extensive evidence for increased production of TNF-α, IL-6, ROS, PGE_2 by macrophages from animal with prenatal and postnatal (dietary 4 weeks juvenile, dietary 3, 8 weeks adults, air 4 days adults) Pb exposure. Supported by in vitro evidence.	Sections 5.6.6.1 and 5.6.6.3	
	Cross-sectional association observed in children living near Pb source, adjusted for confounding by age and sex but not other factors such as SES. Cross-sectional evidence in adults in NHANES that adjust for inflammatory conditions, smoking and SES. Is not a major consideration in conclusions.	Children: Pineda-Zavaleta et al. (2004) Sections 5.6.6.2, and 5.6.6.3 Adults: Songdej et al. (2010) Sections 5.6.4	Children (ages 6-11 yr): Concurrent blood Pb group >10 µg/dL Adults: Concurrent group >1.16 µg/dL
B cell activation	Inconsistent toxicological evidence in animals for B cell activation by Pb exposure concentration and duration and strain.	Section 5.6.3	
	Inconsistent epidemiologic evidence for B cell abundance, B cell activation not examined.	Table 5-32 and Section 5.6.3	
Decreases in Host Resistance – Likely Causal			
Consistent toxicological evidence with relevant exposures	The few studies with relevant dietary Pb exposures demonstrate increased bacterial infection, sickness behavior, and mortality in mice. Similar observations in several other studies with higher Pb exposures.	Dyatlov and Lawrence (2002), Fernandez-Cabezudo et al. [a]Described in detail in Table II of the Preamble.

[b]Describes the key evidence and references contributing the most heavily to causal determination. References to earlier sections indicate where full body of evidence is described.

[c]Describes the blood Pb levels in children with which the evidence is substantiated and blood Pb levels in animals most relevant to humans.

5.7 Hematological Effects

5.7.1 Introduction

The effects of Pb exposure on red blood cell function and heme synthesis have been extensively studied over several decades in both human and animal studies. The 1978 *National Ambient Air Quality Standard for Lead* was set to protect blood Pb levels in children from exceeding 30 µg/dL as such levels were associated with impaired heme synthesis, evidenced by accumulation of protoporphyrin in erythrocytes (U.S. EPA, 1978).

The 2006 Pb AQCD (U.S. EPA, 2006b) reported that Pb exposure significantly decreases several hematological parameters including hemoglobin (Hb), hematocrit (Hct), mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC). Further, the 2006 Pb AQCD reported that Pb affects developing red blood cells (RBCs) in children and occupationally exposed adults as noted by anemia observed with blood Pb >40 µg/dL. Pb-induced anemia is thought to occur due to decreased RBC life span and effects on Hb synthesis. The exact mechanism for these effects is not known, although Pb-induced changes on iron uptake or inhibition of enzymes in the heme synthetic pathway may be responsible. Once Pb enters the cells, it is predominantly found in protein-bound form, with Hb and aminolevulinic acid dehydratase (ALAD) both identified as targets.

Consistent with the majority of human evidence that high Pb blood levels (i.e., >20 µg/dL) are associated with decreased hematological indices, blood Pb levels >100 µg/dL were associated with decreased RBC survival in laboratory animals. Effects on RBC membrane mobility were observed at blood Pb levels as low as 10 µg/dL, although the precise mechanisms underlying these effects of Pb are not known. Studies conducted in animal and in vitro models provide evidence of multiple other effects on RBC membranes, including altered microviscosity and fluidity, decreased sialic acid content, decreased lamellar organization, decreased lipid resistance to oxidation (possibly mediated by perturbations in RBC membrane lipid profiles), and increased permeability. These alterations to RBC membranes may indicate potential modes of action by which Pb induces RBC fragility, abnormal cellular function, RBC destruction, and ultimately anemic conditions. Pb exposure also has been shown to result in increased activation of RBC scramblase, an enzyme responsible for the expression of phosphatidylserine (PS) on RBC membranes. This expression of PS decreases the life span of RBCs via phagocytosis by macrophages. Pb exposure has been observed to alter the phosphorylation profiles of

membrane proteins, which may influence the activity of membrane enzymes and the functioning of receptors and channels located on the membrane.

The 2006 Pb AQCD reported that Pb exposure affects heme synthesis in humans and animals through the inhibition of multiple key enzymes, most notably ALAD, the enzyme that catalyzes the second, rate-limiting step in heme biosynthesis (Figure 5-36 presents a schematic representation of the heme biosynthetic pathway). The 2006 Pb AQCD (U.S. EPA, 2006b) further reported that decreased RBC ALAD activity is the most sensitive measure of human Pb exposure, in that measurement of ALAD activity is correlated with blood Pb levels. Concentration-response changes in the ratio of activated/nonactivated ALAD activity in avian RBCs were observed to be not dependent on the method of Pb administration. The Pb-associated inhibition of the ALAD enzyme was consistently observed in RBCs from multiple species, including birds, cynomolgous monkeys, and humans. Pb was also observed to inhibit other enzymes responsible for heme biosynthesis, including ferrochelatase, porphobilinogen (PBG) deaminase, and coproporphyrinogen oxidase. Pb also potentially alters heme biosynthesis through inhibition of transferrin (TF) endocytosis and iron transport.

Pb has been found to alter RBC energy metabolism through inhibition of enzymes involved in anaerobic glycolysis and the pentose phosphate pathway. Pb was also found to inhibit pyrimidine 5'-nucleotidase (P5N) activity, and the 2006 Pb AQCD indicated that this might be another biomarker of Pb exposure. Inhibition of P5N results in an intracellular increase in pyrimidine nucleotides leading to hemolysis and potentially ultimately resulting in anemic conditions. The 2006 Pb AQCD indicated that perturbations in RBC energy metabolism may be related to significant decreases in levels of nucleotide pools, including nicotinamide adenine nucleotide (NAD), possibly due to decreased NAD synthase activity, and nicotinamide adenine nucleotide phosphate (NADP) accompanying significant increases in purine degradation products.

The 2006 Pb AQCD identified oxidative stress as an important potential mode of action by which Pb exposure induced effects on RBCs. Increased lipid peroxidation and inhibition of antioxidant enzymes in RBCs (e.g., superoxide dismutase [SOD], catalase [CAT]) were observed following exposure to Pb.

The epidemiologic and toxicological studies published since the 2006 Pb AQCD, largely support the reported Pb-associated effects on RBC function and heme synthesis. Epidemiologic studies support previous observations that occupationally-exposed adults with higher blood Pb levels than the current U.S. general population (>26 µg/dL) have decreased RBC numbers. However, a few epidemiological studies investigating occupationally-exposed adults and pregnant women provide some evidence that more relevant blood Pb levels, <10 µg/dL, are associated with decreased RBC numbers,

possibly through decreased survival of the RBCs. Effects seen in children are largely consistent with those observed in adults, and a number of toxicological studies support findings observed in human populations. Recent epidemiologic and toxicological studies also support previous findings that Pb exposure in adults, children, and laboratory animals decreases ALAD activity, as well as the activity of other enzymes in the heme biosynthetic pathway. Recent epidemiologic and toxicological studies expand upon the evidence that Pb exposure results in oxidative stress in RBCs. Although the epidemiologic studies included below are cross-sectional in study design, they do improve upon earlier studies as more studies characterize the effects in children, and investigate effects in populations with blood Pb levels more comparable to those in the current U.S. population. Additionally, the associations observed in these cross-sectional studies are supported by a large number of animal toxicology studies.

5.7.2 Red Blood Cell Function

As stated in the 2006 Pb AQCD (U.S. EPA, 2006b), Pb poisoning in children has been associated with anemia. As of 2006, the mechanism for this was not clear, but it was determined not to be due to iron deficiency, which can be found to occur independently of Pb exposure. However, Zimmerman et al. (2006) found that blood Pb level differences were statistically significant, and lower in non-anemic (or mildly-anemic) iron-deficient 5- to 9-year-old children in India fed an iron-fortified diet for 30 weeks, compared to 14 weeks (mean [range]: 8.1 [3.1–219] µg/dL versus 12.1 [3.7–26.8] µg/dL; $p < 0.02$); however, blood Pb levels were not significantly lower in children receiving the no-iron diet for 30 weeks compared to 14 weeks (mean [range]: 10.2 [4.4–25.3] µg/dL versus 12.0 [3.8–25.5] µg/dL). Although a number of epidemiologic studies found decreases in RBCs and/or Hct levels associated with higher blood Pb levels, it is not known whether this is due to reduced RBC survival or a decrease in RBC production. Regardless, decreased RBC survival and hematopoiesis can be expected to occur simultaneously, and any effect on RBC numbers is likely a combination of the two modes of action.

5.7.2.1 Pb Uptake, Binding, and Transport into Red Blood Cells

The 2006 Pb AQCD (U.S. EPA, 2006b) reported that Pb uptake into human RBCs occurs via passive anion transport mechanisms. Although Pb can passively cross the membrane in both directions, little of the Pb is found to leave the cell after entry. Simons (1993b) found that in vitro uptake of ^{203}Pb (1–10 µM) occurred via an anion exchanger while the efflux occurred via a vanadate-sensitive pathway. After entry into the RBC, radioactive

Pb was found to partition with Hb at a ratio estimated to be about 6000:1 bound to unbound (Simons, 1986). However, Bergdahl et al. (1997a) suggested that ALAD was the primary Pb-binding protein and not Hb. The 2006 Pb AQCD also reported that the majority (approximately 98%) of Pb accumulates in RBC cytoplasm bound to protein, and only about 2% is found in the membrane. This is related to the high ratio of Pb in RBCs compared to plasma Pb. Further information on Pb binding and transport in blood can be found in the kinetics section of Chapter 4 (Section 4.2).

Although no recent studies were identified that examined transport of Pb into RBCs, Lind et al. (2009) recently observed that several Zn ionophores (8-hydroxyquinoline derivatives and Zn and Na pyrithione) were able to effectively transport Pb out of RBCs into the extracellular space.

5.7.2.2 Red Blood Cell Survival, Mobility, and Membrane Integrity

A number of cross-sectional studies have investigated the effect of exposure to Pb on various inter-connected and related hematological parameters in children and adults. As these studies were cross-sectional in design, there is uncertainty regarding the directionality of effects and the magnitude, timing, frequency, and duration of Pb exposure that contributed to the observed associations. Additionally, unless explicitly noted, potential confounding by subject characteristics and other workplace or residential exposures was not accounted for in these studies. Adults and children exposed to Pb may also have been co-exposed to other contaminants that can affect the hematological system, and the potential for co-exposure was not assessed in most studies.

In an earlier cross-sectional study of children in Idaho (aged 1-9 years) with blood Pb levels ranging from 11 to 165 µg/dL (approximately 40% were >40 µg/dL), a 10% probability of anemia (Hct <35%) was predicted (in association with blood Pb levels of ~20 µg/dL [age 1 year], 50 µg/dL [age 3 years] and 75 µg/dL [age 5 years]) (Schwartz et al., 1990). More recent studies have also demonstrated adverse effects on hematological parameters in children due to the Pb exposure. Ahamed et al. (2006) studied 39 male urban adolescents in India who were separated into groups according to their blood Pb level (Group 1: <10 µg/dL [mean 7.4 µg/dL], Group 2: >10 µg/dL [mean 13.27 µg/dL]). Although the groups were similar in age (mean [SD]: 16.59 [0.91] versus 16.76 [0.90] years, respectively), height, weight, and BMI (therefore, not considered to be potential confounders), Group 2 had a significantly lower packed cell volume (PCV) compared to Group 1. In a related study, Ahamed et al. (2007) investigated the relationship between blood Pb level, anemia, and other hematological parameters in urban children in India (n = 75). Children were split into two groups as above: Group 1 had blood Pb levels

<10 µg/dL (mean [SD]: 6.89 [2.44] µg/dL, n = 19), whereas Group 2 had blood Pb levels >10 µg/dL (mean [SD]: 21.86 [7.58] µg/dL, n = 56). As with the earlier study, ages were similar between the two groups: mean [SD]: 4.68 [1.49] and 4.11 [1.77] years, respectively. Hb and Hct were significantly decreased in Group 2, compared to Group 1 after adjusting for age, sex, and area of residence. Children in Group 2 had an increased odds ratio of anemia (OR: 2.87 [95% CI: 1.60, 2.87]) compared to Group 1 after adjustment for age, sex, and area of residence.

In a cross-sectional study measuring blood Hb as the independent variable, blood Pb levels were observed to decrease with increasing blood Hb. Riddell et al. (2007) found that 21% of children, who were 6 months to 5 years of age living in the rural Philippines, had concurrent blood Pb levels >10 µg/dL (total population mean: 6.9 µg/dL). After controlling for potential confounding by age, sex, birth weight, and history of breastfeeding, Hb levels were inversely related to blood Pb level, with a decrease of 3% blood Pb associated with every 1 g/dL increase in Hb. Among children aged 6-36 months (n = 222) living in Montevideo, Uruguay, 32.9% had blood Pb levels greater than 10 µg/dL (population mean [SD]: 9.0 [6.0] µg/dL) (Queirolo et al., 2010). The mean [SD] Hb concentration was 10.5 [1.5] g/dL, and 44.1% of children were diagnosed as anemic (Hb <10.5 g/dL). Blood Pb levels were significantly higher in anemic children compared to non-anemic (mean [SD]: 10.4 [6.8] versus 7.9 [5.1] µg/dL), and anemic children were more likely to have elevated blood Pb after controlling for age and mouthing behavior (OR = 1.9, 95% CI: [1.098, 3.350]). The likelihood of elevated blood Pb was more pronounced in anemic children younger than 18 months (OR = 3.1, 95% CI: [1.3, 7.4]).

Similarly, in a cross-sectional study of 340 children (aged 1–5 years) from Karachi, Pakistan, mildly-anemic and severely-anemic children (mean [SD] Hb levels: 8.9 [0.9] and 7.4 [0.5] g/dL, respectively) had lower Hb levels but higher blood Pb levels compared to non-anemic children (mean [SD] Hb: 12.1 [1.3] g/dL). Mean [SD] blood Pb levels in the mildly-anemic, severely-anemic, and non-anemic children were 14.9 [0.81], 21.4 [2.7], and 7.9 [1.7] µg/dL, respectively ($p < 0.01$) (Shah et al., 2010). Additionally, Hct, RBC count, and MCV were all decreased in anemic children versus non-anemic children. Although statistical analyses were not reported, the levels of Hb, Hct, RBC count, and MCV in anemic children all fell outside of the reported normal range for these parameters, whereas the reported values in non-anemic children did not. Blood Pb level was negatively correlated with Hb level in all groups, with the magnitude of negative correlation increasing with increasing severity of anemia: r = -0.315 (non-anemic children), -0.514 (mildly-anemic), and -0.685 (severely- anemic). In iron-deficient anemic children (n = 23) from Denizli, Turkey, mean (SD) serum Pb levels were statistically ($p < 0.05$) increased compared to healthy children (n = 179): 0.013 (0.004)

versus 0.008 (0.001) µg/dL, respectively (Turgut et al., 2007). The iron-deficient children were observed to have decreased Hb, MCV, RBC, and ferritin compared to controls, but increased RDW. In 140 children from southern Brazil aged 2–11 years, living within 25 km of a Pb smelter, blood Pb levels were not observed to differ between anemic and non-anemic children (mean [SD]: 10.36 [6.8] versus 9.73 [5.8] µg/dL, p = 0.98) (Rondo et al., 2006). However, blood Pb levels were significantly negatively correlated with Hb in anemic children (r = -0.41, p = 0.01); this relationship was not observed in non-anemic children (r = 0.018, p = 0.84).

In children aged 5–9 years (n = 189) without anemia living in Cartagena, Columbia, a smaller percentage (4.7%) of children had blood Pb >10 µg/dL (mean [SD]: 5.49 [0.23] µg/dL). The only hematological parameters that fell outside of their reference values were MCV and MCH, which were negatively correlated with blood Pb levels (r = -0.159 [p = 0.029] and -0.171 [p = 0.019], respectively) (Olivero-Verbel et al., 2007). RBC count, which was not observed to differ from reference values, was positively correlated with blood Pb level (r = 0.208, [p = 0.004]). In a group of 268 Lebanese children, children aged 11–23 months with blood Pb levels >10 µg/dL had increased likelihood of having iron-dependent anemia and transferrin saturation (TF <12%) compared to age-matched children with blood Pb levels <10 µg/dL (OR = 4.59, 95% CI: [1.51, 13.92]) (Muwakkit et al., 2008). In children aged 24-35 months, higher blood Pb level was not associated with increased likelihood of either effect. Huo et al. (2007) found that children (less than 6 years of age) living near an area where electronic waste was recycled in China had significantly higher mean blood Pb levels than did children in the neighboring town with no waste recycling (15.3 versus 9.94 µg/dL). However, contrary to the findings above, no difference was detected in the mean Hb levels of the children in the two towns (12.76 g/dL in children from the waste recycling town versus 12.35 g/dL in children from the town with no recycling).

In adult, occupationally exposed populations, decreased erythrocyte numbers and Hb were observed in multiple, earlier cross-sectional studies investigating workers with blood Pb levels >40 µg/dL (Solliway et al., 1996; Horiguchi et al., 1991; Poulos et al., 1986). However, a larger, longitudinal study (Hsiao et al., 2001) observed that occupationally-exposed adults exhibited erythrocyte counts and Hct that were positively associated with blood Pb levels. Most of the recent occupationally-exposed groups represent populations highly exposed to Pb, with mean blood Pb levels ranging from 26–74 µg/dL. Although effects observed within these groups may not be generalizable to the general population as a whole, they are useful in demonstrating consistent effects on a number of hematological parameters, including Hb, MCV, MCH, MCHC, total RBCs, and packed cell volume (PCV) (Khan et al., 2008; Patil et al., 2006a; Patil et al., 2006b; Karita et al., 2005).

A few recent cross-sectional occupational studies did investigate the effect of moderate occupational Pb exposure on hematological parameters. In gas station attendants in Sarajevo (Bosnia and Herzegovina), workers (mean [SD] duration of exposure: 12.1 [9.1] years) had significantly increased blood Pb levels (mean: 5.96 µg/dL) in 2008, compared to the same population that were previously examined in 2003 (mean: 4.07 µg/dL; mean [SD] duration of exposure: 10.4 [5.5]). Levels of MCH and MCHC were significantly decreased when assessed in 2008, compared to the 2003 measurements, although RBC numbers, Hb, Hct, and MCV were increased in 2008 compared to 2003. Positive correlations were observed in all subjects between blood Pb and RBC count, Hb, and MCH ($r = 0.241$, 0.201, and 0.213, respectively; $p < 0.05$). No control group was included in this study (Cabaravdic et al., 2010). Ukaejiofo et al. (2009) studied the hematological effects of Pb in 81 male subjects moderately exposed to Pb at three different manufacturing companies in Nigeria for durations between six months and 20 years. The exposed individuals had a mean blood Pb level of 7.00 µg/dL compared to 3 µg/dL in controls drawn from industries not involved in Pb handling (control group I) and 2 µg/dL in controls drawn from the general population (control group II). Pb-exposed workers had significantly reduced Hb and PCV levels and increased percentage of reticulocytes compared to controls. Although the differences were statistically significant between the exposed and control subjects, the study authors stated that the levels in the exposed subjects were at the lower range of normal for Nigerians. The percent cell lysis did not significantly differ between controls and exposed workers; however, when workers and controls were stratified by age, there was a significant increase in cell lysis in workers under age 30 compared to similarly aged controls in group II ($p < 0.01$). Similarly, stratification of subjects by duration of exposure revealed that MCHC was decreased in exposed workers (6–60 months of exposure). Conterato et al. (In Press) investigated hematological parameters in automotive painters exposed to Pb in Brazil. Exposed painters had a mean [SEM] blood Pb concentration of 5.4 [0.4] µg/dL compared to 1.5 [0.1] µg/dL in controls. The mean [SEM] duration of exposure to Pb in painters was 133.9 [14.5] months, whereas the controls were not occupationally exposed to Pb. Although differences in Hct, Hb concentration, and the number of RBCs were significantly decreased in painters compared to controls, these differences were not correlated with blood Pb levels; however, these parameters were correlated with blood Cd^{2+} levels, which were also significantly elevated in painters compared to controls.

Taken together, the above occupational studies provide consistent evidence that high (mean blood Pb >26 µg/dL) occupational exposure to Pb reduces the number of RBCs in circulation. Additionally, the Ukaejiofo et al. (2009) study suggests that blood Pb levels below 10 µg/dL (7.0 µg/dL) may also result in decreased RBC survival. Although the decrease in RBCs observed in highly exposed worker populations may be explained by both decreased RBC survival and/or disruption of hematopoiesis, the observation of

increased reticulocytes in Ukaejiofo et al. (2009) seems to represent compensation for decreased RBC survival due to Pb exposure.

In a non-occupational study, the associations between blood Pb levels, Ca^{2+}, Fe, and Hb were investigated in 55 pregnant Brazilian women (21.9% were 14–19 years old, 74.5% were 20–34 years olds, and 3.6% were ≥ 35 years old) (Zentner et al., 2008). The majority of women (across all age groups) had concurrent blood Pb levels <5 µg/dL (58.2%), although the mean blood Pb level was not reported; only 5.4% of women had blood Pb levels >10 µg/dL. The vast majority of the women (78.2%) were also observed to have adequate levels of Hb (≥ 11 g/dL). In a multiple linear regression model, blood Pb level was observed to be negatively associated with Hb (β = -0.359), when controlling for age, BMI, income, energy intake, Ca^{2+} intake, vitamin C intake, and Fe intake.

The associations of blood Pb levels with hematological parameters observed in epidemiologic studies are clearly supported by a number of animal toxicology studies reporting blood Pb levels relevant to humans, i.e., <10 µg/dL. Hb concentrations in plasma (a marker of RBC hemolysis) was significantly increased in rats exposed to Pb acetate (1,000 ppm in drinking water for 9 months; blood Pb level: 7.1 µg/dL) compared to controls (Baranowska-Bosiacka et al., 2009). In a complementary in vitro experiment, a concentration-dependent increase in the amount of hemolysis was observed in human RBCs exposed to Pb at concentrations ranging from 0.1–100 µM for 5–30 minutes. Hemolysis was increased even at the lowest concentration tested (i.e., 0.1 µM). Pb-induced hemolysis in these experiments may be due to inhibition of RBC phosphoribosyltransferases (Section 5.7.2.5). In weanling rats (PND25 days, n = 10) whose dams were exposed to Pb acetate in drinking water (2.84 mg/mL, approximating mean [SD] daily exposures of 342.57 [28.11] and 744.47 [29.27] mg/kg [dam weight] during gestation and lactation, respectively), blood Pb level was significantly elevated compared to controls (mean [SE]: 69.8. [7.82] versus 0.54 [0.08] µg/dL). The only hematological parameter affected by Pb exposure was Hct, which was decreased in exposed rats (mean [SE]: 27.3 [0.5]%) versus controls (33.4 [0.3]%) (Molina et al., 2011). In rats treated with 25 mg Pb/kg by oral gavage for 4 weeks, average plasma Pb concentrations were 6.5 µg/dL (9.6-fold higher than controls), and statistically significant decreases in Hct, Hb, and RBCs were observed (Lee et al., 2005). Effects on erythrocyte survival were similar in mice treated with Pb nitrate (50 mg/kg via gavage for 40 days): mean [SD] blood Pb levels were 1.72 [0.02] µg/dL versus 0.09 [0.011] µg/dL in control mice, and exposed mice had significantly reduced total RBC counts, total leukocyte counts, Hb, lymphocytes, and monocytes compared to controls ($p < 0.001$) (Sharma et al., 2010b).

A number of toxicological studies also reported similar hematological effects, but did not report final blood Pb concentrations. Rats exposed to Pb acetate (2 g/L in drinking water for 30 days) had significantly decreased RBCs, Hb, PCV, MCH, and MCHC compared to controls ($p < 0.05$) (Simsek et al., 2009), but not a disruption of hematopoiesis. Mice exposed to Pb acetate (1 g/L in drinking water for 90 days, but not those exposed for 15 or 45 days), had significantly decreased RBC counts and Hct compared to controls ($p<0.05$) (Marques et al., 2006). Spleen weights were observed to be increased relative to body weight in animals exposed to Pb for 45 days. Mice injected daily with Pb acetate (50 mg/kg subcutaneously) had significantly reduced Hb, MCV, MCH, and MCHC compared to controls injected with 5% dextrose (Wang et al., 2010g).

Some toxicological studies found no evidence of hematological effects in animals following exposure to Pb. Male rats exposed to Pb acetate in their drinking water for 4 weeks at concentrations ranging from 100–1,000 ppm had a concentration-dependent increase in blood Pb levels (range: 6.57–22.39 µg/dL) compared to controls (0.36 µg/dL), but there were no significant changes in any of the hematological parameters (complete blood cell count performed) measured at the end of treatment (Lee et al., 2006b). Slight, statistically nonsignificant increases in PS expression on RBC membranes were also observed. Similarly, exposure of male rats to 5,000 ppm Pb nitrate in drinking water (blood Pb not reported) for three weeks had no affect on any measured hematological parameter (Gautam and Flora, 2010). In vitro experiments with rat and human blood did not demonstrate a significant increase in hemolysis after 4 hours of treatment with Pb acetate at concentrations up to 10 µM.

Although Pb exposure has been consistently shown to shorten RBC life span and alter RBC mobility, as of the 2006 Pb AQCD, the mechanism of this was not well understood. While the mechanism is still not fully understood, there has been some indication for a role of free Ca^{2+}. Occupational studies investigating highly Pb-exposed worker populations (mean blood Pb >28 µg/dL) observed increased intracellular free Ca^{2+} levels ($[Ca^{2+}]_i$) in RBCs, and decreased RBC membrane Ca^{2+}/Mg^{2+}ATPase activity in workers compared with unexposed controls (Abam et al., 2008; Quintanar-Escorza et al., 2007). $[Ca^{2+}]_i$ levels were highly correlated with blood Pb levels even among unexposed control populations with mean blood Pb levels of approximately 10 µg/dL (9.9 ± 2 µg/dL) (Quintanar-Escorza et al., 2007). Changes in $[Ca^{2+}]_i$ were associated with increased fragility of the RBCs and dramatic morphological alterations, including the increased presence of echinocytes (cells without normal biconcave shape) and crenocytes (speculated cells) in Pb-exposed workers.

Similar to the associations observed in Quintanar-Escorza et al. (2007), $[Ca^{2+}]_i$ increased in a concentration-dependent manner when RBCs from healthy human volunteers were

exposed (in vitro) to 0.2 or 0.4 µM Pb nitrate for 24 or 120 hours (0.4 µM Pb nitrate roughly approximates 10 µg/dL Pb, although concentrations in exposure media are not directly comparable to blood Pb levels) (Quintanar-Escorza et al., 2010). The increase in $[Ca^{2+}]_i$ levels was observed to be related to increased Ca^{2+} influx and decreased efflux. As was observed among highly Pb-exposed workers, changes in $[Ca^{2+}]_i$ were associated with increased fragility of the RBCs and dramatic morphological alterations following exposure to 0.4 µM Pb. Similarly, Ciubar et al. (2007) found that RBC morphology was disrupted, with ≥ 50% RBCs having lost the typical discocytic morphology and displaying moderate to severe echinocytosis following exposure to Pb nitrate concentrations of 0.5 µM or higher for 24 hours. Exposure of RBCs to higher concentrations (concentrations not stated) of Pb nitrate resulted in cell shrinkage. In rats exposed to 200 ppm Pb acetate via drinking water for three months (mean [SD] blood Pb level: 40.63 [9.21] µg/dL), the cholesterol/phospholipid ratio of RBC membranes was increased, indicating that RBC membrane fluidity was decreased.

Khaĭrullina et al. (2008) observed that the surface profiles of RBC membrane shadows incubated with 0.5–10 µM Pb acetate for three hours were much smoother than were untreated RBC membranes when examined by atomic force microscopy. The authors postulated that the observed smoothing in Pb-treated RBC membranes may be due to clusterization of band 3 protein. Band 3 (anion exchanger 1 [AE1]), is a chloride/bicarbonate (Cl^-/HCO_3^-) exchanger and is the most abundant protein in RBC membranes. AE1 is integral in carbon dioxide (CO_2) transport and linkage of the cellular membrane to the underlying cytoskeleton (Akel et al., 2007; Su et al., 2007). The observed smoothing of the RBC membrane may due to Pb interfering with how the membrane attaches to the cytoskeletal structure of the RBC through perturbation of the normal activity of AE1.

Eryptosis

Eryptosis is the suicidal death of RBCs. It is characterized by cell shrinkage, membrane blebbing, and cell membrane phospholipid scrambling associated with PS exposure on the cell membrane that leads to cell destruction via macrophages (Föller et al., 2008; Lang et al., 2008). As previously reported in the 2006 Pb AQCD (U.S. EPA, 2006b), Kempe et al. (2005) found that exposing human RBCs to Pb at concentrations ranging from 0.3 µM to 3 µM caused increased activation of K^+ channels that led to cell shrinkage and scramblase activation. The activation of scramblase increased the exposure to PS on the cell membrane, which causes an increase in the destruction of the RBCs by macrophages.

Consistent observations were made in recent studies that included in vitro and in vivo evidence. Shin et al. (2007) found that in vitro exposure of human RBCs to 1–5 µM Pb acetate increased PS expression in a time- and concentration-dependent manner. The maximum mean [SE] increase in expression of PS was 26.8% [3.15] (compared to deionized water), following exposure to 5 µM Pb for four hours. Scramblase activity was increased in Pb-exposed RBCs, and $[Ca^{2+}]_i$, which regulates scramblase activation, was also increased in exposed RBCs. Flippase, which translates PS exposure to inner membranes, is inhibited by high levels of $[Ca^{2+}]_i$ and was observed to exhibit reduced activity following Pb exposure. The inhibition of flippase is additionally influenced by the depletion of cellular adenosine triphosphate (ATP). ATP levels were decreased in a concentration-dependent manner following exposure to Pb. To corroborate these findings in vivo, Shin et al. (2007) treated male rats with Pb acetate (i.p. to 25, 50, or 100 mg/kg; blood Pb not reported). Expression of PS was observed to increase in a concentration-dependent manner at concentrations ≥ 50 mg/kg, confirming the in vitro results. No hemolysis or microvesicle formation was observed in the in vitro or in vivo experiments.

In a follow-up study, the same laboratory observed that in vitro exposure of human RBCs to much lower concentrations of Pb acetate (0.1, 0.25, and 0.5 µM) also induced PS expression. Most notably, exposure to 0.1 µM Pb for 24 hours increased PS expression on RBC membranes by approximately 20% (Jang et al., 2011). Accompanying the increased expression of PS (associated with Pb exposure) was the presence of abnormal echinocytic RBCs. Unlike the Shin et al. (2007) study described above, incubation of the RBCs with low concentrations of Pb (0.1 µM) induced the generation of microvesicles, which also expressed PS on their membranes in this (Jang et al., 2011) study. At 0.5 µM, Pb-exposed RBCs with externalized PS were observed to be targeted and engulfed by differentiated macrophages. Similar ex vivo effects were observed in rat erythrocytes four hours after oral exposure (0, 10 and 50 mg/kg) to Pb, although higher concentrations were generally required. PS expression on the rat erythrocytes was also observed. To corroborate these in vitro and ex vivo findings, rats were also exposed in vivo to 0, 50, 250, or 1,000 ppm Pb acetate in drinking water for 4 weeks. At 1,000 ppm, Hb and Hct were significantly decreased relative to control, and liver and spleen weights were increased. At the two highest doses, iron accumulation was observed in the spleen, a clear sign of increased RBC clearance via phagocytosis.

Ciubar et al. (2007) also found that exposure to Pb nitrate (0.5–2 µM) resulted in an increase in PS exposure in RBCs and cell shrinkage, which the authors stated were indicators of cell apoptosis. As reported above, Khaĭrullina et al. (2008) observed Pb-induced RBC membrane smoothing that may be due to alterations in AE1 activity. Disruptions in AE1 activity may also result in enhanced PS exposure and premature cell death. Akel et al. (2007) observed that in $AE1^{-/-}$ knockout mice, Pb-induced PS exposure was much greater than that in wild type mice. Decreased RBCs and increased reticulocytes were also observed, an indication of high cell turnover.

5.7.2.3 Red Blood Cell Hematopoiesis

Erythropoietin (EPO) is a glycoprotein hormone excreted by the kidney to promote the development of RBCs in the bone marrow. As reported in the 2006 Pb AQCD, analyses of the cohort of children in Yugoslavia observed that EPO was increased in children aged 4.5 and 6.5 years of age living in a town near Pb sources (blood Pb levels >30 µg/dL) compared to children living in more distant town (blood Pb levels <10 µg/dL), when stratified by Hb concentrations (Graziano et al., 2004; Factor-Litvak et al., 1999; Factor-Litvak et al., 1998). These differences were not observed in children aged 9.5 or 12 years. With adjustment for Hb concentrations, blood Pb levels were observed to be significantly associated with EPO levels at ages 4.5 and 6.5 years when considering all children together. No significant association was observed at ages 9.5 and 12 years. Hb was not observed to differ at any age between towns, thus possibly indicating that hyperproduction of EPO is necessary to maintain Hb levels in young children living near Pb sources. The authors postulated that increases in EPO in younger children reflect bone marrow hyperactivity to counteract RBC destruction, whereas the lack of EPO elevation in older children may reflect a transitional period where increasing renal and bone marrow toxicity leads to decreases in EPO observed later in life, as observed in anemic, pregnant women (Graziano et al., 1991). Decreased EPO concentrations were also observed in association with Pb exposure in adults in two cross-sectional studies cited in the 2006 Pb AQCD (Osterode et al., 1999; Romeo et al., 1996).

Consistent with findings that EPO is negatively associated with blood Pb levels in adults, Sakata et al. (2007) observed that non-anemic tricycle taxi drivers (n=27) working in Kathmandu, Nepal (blood Pb level: 6.4 µg/dL) had significantly lower levels of EPO (12.7 versus 18.8 mU/mL) compared to non-driver controls (blood Pb level: 2.4 µg/dL). In taxi drivers, there was an inverse relationship between the level of serum erythropoietin and blood Pb level ($r = -0.68$, $p < 0.001$). Blood Pb level was not associated with any other hematological effects.

Recent toxicology studies of cytotoxicity and genotoxicity in RBC precursor cells support the observations that Pb exposure disrupts normal hematopoiesis. Cytotoxicity and genotoxicity in RBC precursor cells are strong indications of altered hematopoiesis in bone marrow. Celik et al. (2005) observed that treatment of female rats with Pb acetate (140, 250, or 500 mg/kg via gavage once per week for 10 weeks; blood Pb not reported) resulted in decreased numbers of polychromatic RBCs (PCE) and increased numbers of micronucleated PCEs, compared to controls ($p < 0.001$). Alghazal et al. (2008b) exposed male and female rats to 100 mg/L Pb acetate daily in drinking water for 125 days (blood Pb not reported) and observed increases in micronucleated PCEs in female rats ($p = 0.02$) but no significant reduction in the ratio of PCEs to normochromic RBCs (NCE). In male rats, an increase in micronucleated PCEs was observed ($p < 0.001$) along with a decrease in the PCE/NCE ratio ($p = 0.02$). While the results from Alghazal et al. (2008b) indicate that Pb is cytotoxic in male rats only, but is genotoxic in both sexes, results from Celik et al. (2005) indicate that Pb is cytotoxic in female rats as well. Mice exposed to Pb acetate (1 g/L in drinking water for 90 days; blood Pb not reported) had statistically significant increases in micronucleated PCEs; a small, but statistically nonsignificant decrease in the PCE/NCE ratio was also observed (Marques et al., 2006).

5.7.2.4 Membrane Proteins

While there have been few studies, evidence included in the 2006 Pb AQCD indicated there are effects of Pb on changes in RBC proteins. Huel et al. (2008) found that newborn hair and cord blood Pb levels (mean [SD]: 1.22 [1.41] µg/g and 3.54 [1.72] µg/dL respectively) were negatively associated with Ca^{2+}ATPase activity in plasma membranes of RBCs isolated from cord blood after controlling for gestational age and maternal Ca pump activity. However, newborn hair Pb levels were more strongly associated with cord Ca^{2+}-pump activity than were cord blood Pb ($p < 0.0001$ versus $p < 0.05$). Maternal blood Pb levels were not correlated with Ca^{2+}-pump activity in maternal or newborn cord blood. Pb-induced disruptions in Ca^{2+} homeostasis in RBCs can lead to cytotoxicity and necrosis, and these effects may be representative of cellular dysfunction in other organ systems.

In RBC membranes from Pb-exposed workers, Fukumoto et al. (1983) used polyacrylamide electrophoresis analysis and found increased levels of polypeptides in bands 2, 4, 6, and 7 and decreased levels of polypeptides in band 3. Apostoli et al. (1988) found changes in RBC membrane polypeptides, including a significant decrease in band 3, in occupationally exposed workers with blood Pb levels greater than 50 µg/dL. Apostoli et al. (1988) suggested that band 3 may represent an anion channel protein, whereas, Fukumoto et al. (1983) suggested that the changes in the RBC membrane

polypeptides may cause changes in membrane permeability. Exposure to Pb acetate at concentrations above 0.1 µM for 60 minutes has also been found to increase the phosphorylation of proteins in human RBC membranes in vitro (Belloni-Olivi et al., 1996). Phosphorylation did not occur in cells depleted of protein kinase C (PKC), indicating a PKC-dependent mechanism.

5.7.2.5 Red Blood Cell Energy Metabolism Enzymes

RBCs use high energy purine nucleotides (i.e., ATP and guanine triphosphate [GTP]) to support basic metabolic functions. In mature RBCs, these nucleotides are synthesized via salvage reactions through either an adenine pathway, which requires adenine phosphoribosyltransferase (APRT), or an adenosine pathway, which requires adenosine kinase. The 2006 Pb AQCD (U.S. EPA, 2006b) reported that Pb significantly reduces the nucleotide pool (including NAD and NADP, as well as increases purine degradation products) resulting in altered RBC energetics. Since the 2006 Pb AQCD was published, there have been few studies examining Pb effects on energy metabolism. Baranowska-Bosiacka et al. (2009) examined the effects of Pb on RBC APRT and hypoxanthine-guanine phosphoribosyltransferase (HPRT). In an in vitro experiment, APRT and HPRT were measured in lysate of human RBCs after exposure to Pb at a concentration range from 0.1 to 100 µM for 5–30 minutes. Complementary in vivo tests measured APRT and HPRT in RBC lysate from rats exposed to Pb acetate (1,000 ppm) in drinking water for 9 months. Both the in vivo and vitro studies found a significant decrease in both HPRT and APRT levels. The levels in human RBCs were significantly decreased in vitro after only 5 minutes of exposure to the 0.1 µM concentration, but the decrease was also concentration-dependent. However, the study authors considered the inhibition moderate (30–35%) even with the highest Pb levels used in vitro. Shin et al. (2007) found a concentration-dependent decrease in intracellular ATP in human RBCs in vitro with significant decreases, found even with the lowest concentration (i.e., 1 µM).

5.7.2.6 Other Enzymes

The 2006 Pb AQCD (U.S. EPA, 2006b) reported that K^+ permeability was increased by Pb exposure due to altered sensitivity of the membrane Ca^{2+}-binding site that caused selective efflux of K^+ ions from the RBC membrane. However, inhibition of the RBC Na^+/K^+ATPase is more sensitive to Pb exposure than is the inhibition of Ca^{2+}/Mg^{2+}ATPase. Few recent studies were found that examined the effects of Pb exposure on other enzymes. Ekinci et al. (2007) tested the effects of Pb exposure on two carbonic anhydrase isozymes (I and II) isolated from human RBCs. Carbonic anhydrases

are metalloproteins that use Zn to catalyze the equilibrium between CO_2 and bicarbonate in the cells of higher invertebrates. Although investigators found that Pb nitrate inhibited both carbonic anhydrase isozymes in a concentration-dependent manner, the concentrations used (i.e., 200–1,000 µM) were above those that would be physiologically relevant. Inhibition of isozyme I was noncompetitive, while the inhibition for isozyme II was uncompetitive. Bitto et al. (2006) examined the mechanisms of action of Pb-induced inhibition of P5N, an enzyme important in the pyrimidine salvage pathway that requires Mn for normal activity. Pb was observed to bind directly to the active site of the enzyme in a different position than the Mn, thus possibly resulting in improper protein folding and inhibition of activity.

5.7.2.7 Red Blood Cell Oxidative Stress

It has been suggested that the Pb-associated decreases in ALAD activity result in increased oxidative stress, owing to the buildup of ALA. ALA can act as an electron donor in the formation of reactive oxygen species (ROS) (Nemsadze et al., 2009; Ahamed and Siddiqui, 2007). Many epidemiologic and toxicological studies have found an association between the level of blood Pb and lipid peroxidation, antioxidant levels, or indicators of ROS production. The same limitations regarding cross-sectional studies listed in Section 5.7.2.2 (including uncertainty in directionality of effects and specific information regarding exposure) apply to the epidemiologic studies investigating RBC oxidative stress. Additionally, potential confounders and co-exposures were not considered in the majority of these studies. However, in studies were confounders were considered, they are explicitly delineated in the text.

Oxidative Stress, Lipid Peroxidation, and Antioxidant Enzymes

Malondialdehyde (MDA) is an end product of lipid peroxidation and is commonly measured as an indicator of oxidative stress. Evidence of lipid peroxidation has been observed in children moderately exposed to Pb. Ahamed et al.(2008; 2006, 2005) investigated the relationship between blood Pb levels and antioxidant enzyme levels and lipid peroxidation in children in India. In children (n = 62) aged 4-12 years in Lucknow, India, children with mean blood Pb levels of 11.39 (SD: 1.39) µg/dL had increased measures of lipid peroxidation and decreased GSH levels compared to children with mean blood Pb levels of 3.93 (SD: 0.61) or 7.11 (SD: 1.25) µg/dL (Ahamed et al., 2005). Catalase activity was decreased in children with a mean 7.11 (SD: 1.25) µg/dL blood Pb level, compared to children with mean 3.93 (SD: 0.61) µg/dL blood Pb level. Additionally, blood Pb levels were found to be significantly positively correlated with

MDA and CAT, and negatively correlated with GSH. In a similar study, Ahamed et al. (2006) observed significantly higher levels of CAT and MDA in children with a mean 13.27 µg/dL blood Pb level compared to children with a mean 7.40 µg/dL blood Pb level; with other characteristics such as age, height, wieght, and BMI not differing between the two groups and thus, not considered as potential confounders. Examining all the study subjects together, investigators found a correlation between blood Pb level and blood MDA and RBC CAT levels, as well as an inverse relationship between ALAD activity and MDA and CAT levels. Among Indian children with neurological disorders, blood Pb levels were significantly increased compared to healthy control children (18.60 versus 10.37 µg/dL respectively) (Ahamed et al., 2008). Potential confounding characteristics such as age, sex, area of residence, and SES were not observed to be statistically different between the two groups, and therefore, were not included in statistical analyses. In addition, the following indicators of oxidative stress were elevated among case children: increased blood MDA, RBC SOD and CAT levels, and decreased blood GSH levels. GPx levels were similar between the two groups. Typical indicators of Pb exposure (active/nonactive ALAD ratio) were found to be correlated with lipid peroxidation and oxidative stress. Children aged 3–6 years old living near a steel refinery in China with blood Pb levels ≥ 10 µg/dL also had a significant increase in plasma MDA compared to children with blood Pb levels <10 µg/dL. However, levels of RBC SOD, GSH, and GPx were not different from those in controls (Jin et al., 2006).

Evidence of lipid peroxidation was also observed in occupational cohorts moderately exposed to Pb. In auto repair apprentices in Turkey (mean [SD]: 16.8 [1.2] years of age, 3.8 [1.8] years duration of exposure) with minimum blood Pb levels of 7.9 µg/dL (Ergurhan-Ilhan et al., 2008), increases in glutathione peroxidase (GPx) and MDA, as well as decreases in α-tocopherol and β-carotene were observed compared with controls (mean [SD] age: 16.3 [1.0] years, mean blood Pb level: 2.6 µg/dL). Decreases were observed in SOD and CAT, but the results did not attain statistical significance. Statistically significant alterations in measures of oxidative stress were also observed in other occupationally exposed populations. SOD, glutathione (GSH), and CAT were decreased; while oxidized GSH (i.e., GSSG) and thiobarbituric acid reactive species (TBARS, expressed in terms of MDA) were increased in painters in India (mean [SD] duration of exposure: 126.08 [49.53 months], mean blood Pb level: 21.92 µg/dL, compared to 3.06 µg/dL in controls) (Mohammad et al., 2008). Glutathione-S-transferase, GPx, and SOD were positively correlated with blood Pb levels (mean: 5.4 µg/dL, $r = 0.34$, 0.38, and 0.32, respectively; $p < 0.05$) in automotive painters in Brazil (Conterato et al., In Press).

Numerous cross-sectional, occupational studies have also demonstrated increased lipid peroxidation in highly-exposed worker populations (blood Pb levels ranging from 29.0 to 74.4 µg/dL) (Kasperczyk et al., 2009; Khan et al., 2008; Quintanar-Escorza et al., 2007; Patil et al., 2006a; Patil et al., 2006b). There was a correlation between MDA levels and blood Pb levels, even in the unexposed workers who had lower (i.e., <12 µg/dL) blood Pb levels, although the magnitude of correlation in exposed workers was greater (Quintanar-Escorza et al., 2007). Increases in C-reactive protein and decreases in RBC SOD, catalase, and plasma ceruloplasmin were also observed in these workers, further indicating increased RBC oxidative stress due to higher Pb exposure.

Oral administration of Pb (25 mg/kg) to rats once a week (i.e., bolus gavage) for 4 weeks, which produced a blood Pb level of about 6.5 µg/dL, caused a significant increase in RBC MDA levels (Lee et al., 2005). Other indications of Pb-induced oxidative stress included significant increases in RBC SOD and CAT levels accompanied by significant decreases in GSH and GPx. Exposure of rats to Pb acetate (750 mg/kg in drinking water for 11 weeks) resulted in decreased concentrations of plasma vitamin C, vitamin E, nonprotein thiol, and RBC-GSH, with simultaneous increased activity of SOD and GPx (Kharoubi et al., 2008b). CAT activity was also slightly elevated in RBCs from the Pb-exposed rats, but the increase failed to reach statistical significance. Exposure of male rats to 5,000 ppm Pb nitrate in drinking water (blood Pb not reported) for three weeks decreased GSH levels compared to that in controls (mean [SE]: 1.91 [0.02] versus 2.44 [0.09] mg/mL, respectively) (Gautam and Flora, 2010). SOD activity was significantly decreased in rats injected with Pb acetate (15 mg/kg, i.p. for seven days, but not rats injected with 5 mg/kg) (Berrahal et al., 2007). GPx activity and MDA concentrations were slightly elevated in the two exposed groups, but differences with the control (15 mg Na acetate/kg) group failed to reach statistical significance. Effects on indices of oxidative stress were also observed in in vitro studies: increased MDA and decreased SOD and CAT in RBCs exposed to 2 µM Pb (Ciubar et al., 2007), decreased glutathione reductase (GR) activity in human RBCs incubated with 5–18 µM Pb (Coban et al., 2007), and decreased GSH and increased GSSG and lipid peroxidation in RBCs from healthy volunteers (with no history of Pb exposure) incubated with 0.4 µM Pb for 24–120 hours (Quintanar-Escorza et al., 2010).

Antioxidant Defense

In addition to the studies listed above that examined lipid peroxidation and oxidative stress, there have been toxicological studies that indicate that the use of antioxidants and free radical reactions is protective against Pb-induced RBC oxidative stress. Rats treated with 500 ppm Pb acetate in drinking water for 15 or 30 days had a significant increase in free RBC protoporphyrin and TBARS levels that was related to length of exposure and

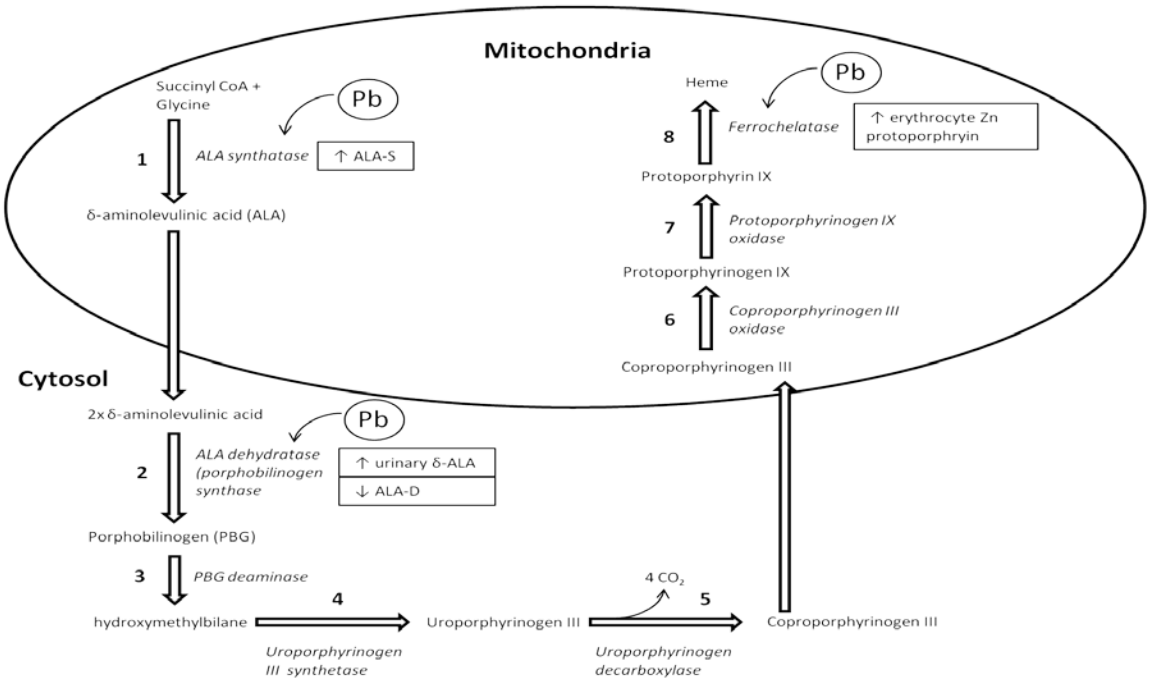
blood Pb levels (Rendón-Ramirez et al., 2007). Vitamin E administration after exposure to Pb significantly reduced the rat RBC TBARS levels and increased ALAD activity, compared to exposure to Pb alone. Co-exposure to vitamin E and Pb simultaneously and exposure to vitamin E before Pb exposure also prevented Pb-induced oxidative stress. In vitro studies by Casado et al. (2007) found that Pb-induced hemolysis using blood from non-occupationally exposed volunteers indicated that RBC membrane damage was mediated via oxidative stress. The in vitro studies demonstrated a concentration- and time-dependent formation in lipid peroxide that was inhibited with a number of antioxidants, including desferrioxamine (iron chelator), trolox (chain breaking antioxidant), and mannitol and Na formate (OH scavengers). Results suggested the role of singlet oxygen in Pb-mediated membrane damage and hemolysis of exposed RBCs. In rats exposed to 2,000 ppm Pb in drinking water for 5 weeks, MDA levels were significantly increased, whereas vitamin E concentrations were significantly decreased (Caylak et al., 2008). In the case of MDA, co-exposure to Pb and a number of sulfur-containing antioxidants (e.g., L-methionine, N-acetylcysteine, and L-homocysteine) reduced concentrations to a level not significantly different from that in controls, but were significantly smaller than concentrations observed with Pb alone. Exposure to L-methionine and N-acetylcysteine also reduced Pb-induced depletion of vitamin E.

5.7.2.8 Summary of Effects on RBC Survival and Function

In summary, Pb exposure has been shown to affect multiple hematological outcomes that are related to RBC survival and function, as demonstrated in both cross-sectional epidemiologic studies and toxicological studies. Pb exposure has been shown to decrease RBC survival, either through direct effects on RBC membranes leading to increased fragility, or through the induction of eryptosis and eventual phagocytosis by macrophages. Limited evidence that Pb can negatively affect hematopoiesis is also available. Consistent evidence also exists demonstrating that Pb exposure increases oxidative stress in exposed adults and children, as well as in laboratory animals. The epidemiologic studies demonstrating these effects are cross-sectional in design, therefore there is some uncertainty regarding the direction of effects and the magnitude, timing, frequency, and duration of Pb exposure that contributed to the observed observations. Also, the majority of epidemiologic studies did not account for potential confounding, although the effects observed in these studies are consistent with effects from studies that did consider potential confounding. The coherence with effects observed in animal toxicology studies supports the conclusion that Pb exposure affects both the survival and function of RBCs.

5.7.3 Red Blood Cell Heme Metabolism

Pb exposure has been found to inhibit several enzymes involved in heme synthesis, namely ALAD (a cytoplasmic enzyme catalyzing the second, rate-limiting, step of the heme biosynthesis pathway), coproporphyrinogen oxidase (catalyses the sixth step in heme biosynthesis converting coproporphyrinogen III into protoporphyrinogen IX), and ferrochelatase (catalyses the terminal [eighth] step in heme synthesis converting protoporphyrin IX into heme) (Figure 5-36). The observations of decreased Hb (measured as total Hb, MCH, or MCHC) in occupationally-exposed adults (Ukaejiofo et al., 2009; Khan et al., 2008; Patil et al., 2006b; Karita et al., 2005) and Pb-exposed experimental animal models (Sharma et al., 2010b; Baranowska-Bosiacka et al., 2009; Simsek et al., 2009; Marques et al., 2006; Lee et al., 2005) and associations with blood Pb levels in children (Queirolo et al., 2010; Shah et al., 2010; Olivero-Verbel et al., 2007; Riddell et al., 2007) are supporting lines of evidence for decreased heme synthesis due to Pb exposure.



Note: Steps in the pathway potentially affected by Pb are indicated with curved arrows pointing to the affected enzyme, and the directions of effects are represented by ↑ and ↓ arrows.

Figure 5-36 Schematic representation of the enzymatic steps involved in the heme synthetic pathway.

5.7.3.1 Red Blood Cell 5-Aminolevulinic Acid Dehydratase

Decreases in RBC 5-aminolevulinic acid dehydratase (ALAD) levels are strongly associated with Pb exposure in humans; to such an extent that RBC ALAD activity is used as a biomarker to assess Pb toxicity. Several epidemiologic studies published since the 2006 Pb AQCD evaluated the relationship between Pb exposure, blood Pb levels and ALAD activity in adults and children (see below). These studies were cross-sectional in nature. This limits their utility in assessing the direction of effects and the magnitude, timing, frequency, and duration of Pb exposure necessary to contribute to the observed associations. In studies which considered potential confounders, those confounding variables are listed in the test. However, potential confounding was not accounted for in the majority of these studies.

Wang et al. (2010f) found that, after controlling for sex, age, alcohol consumption and smoking (adults only), there was also a concentration-dependent decrease in ALAD activity in both children (4–13 years old) and adults (16–77 years old) (mean blood Pb levels: 7.1 and 6.4 µg/dL, respectively) in rural southwest China. Further, Wang et al. (2010f) observed that the relationship between blood Pb level and ALAD activity was nonlinear and exponential, with larger decreases in ALAD activity occurring with blood Pb levels >10 µg/dL. No correlation was observed between urinary ALA levels and blood Pb levels. Ahamed et al. (2006) studied male urban adolescents in India. The 39 adolescents were separated into two groups according to their blood Pb levels (Group 1: <10 µg/dL [mean 7.4 µg/dL], Group 2: >10 µg/dL [mean 13.27 µg/dL]). Although Groups 1 and 2 were similar in age (mean [SD]: 16.59 [0.91] versus 16.76 [0.90] years, respectively), height, weight, and BMI (therefore not considered potential confounders), Group 2 (with the higher blood Pb levels) had lower ALAD activity than did Group 1 ($p < 0.001$). When all 39 adolescents were examined together, an inverse relationship was found between blood Pb and ALAD activity. Similar decreases in ALAD activity were observed in other populations of children from India (aged 4–12 and 1–7 years) with elevated blood Pb levels (mean [SD]: 11.39 [1.39] and 21.86 [7.58] µg/dL respectively) compared to the two age ranges of the children with lower blood Pb levels (mean [SD]: 3.93 [0.61] and 6.89 [2.44] µg/dL respectively) (Ahamed et al., 2007; Ahamed et al., 2005). While Ahamed et al. (2005) did not address potential confounding, Ahamed et al. (2007) observed decreases in ALAD activity after controlling for age, sex, and area of residence. Decreases in ALAD activity were also observed in children 3–6 years of age with Pb blood levels >10 µg/dL, compared to children <10 µg/dL (mean blood Pb concentration for groups not reported) in northeastern China (Jin et al., 2006).

As was seen with epidemiologic studies investigating Pb-associated deficits in hematological parameters, most occupational studies investigating ALAD levels may not

be generalizable to the population as a whole; however, they are useful in demonstrating consistent and negative effects of Pb exposure on the activity of this enzyme (Quintanar-Escorza et al., 2007; Patil et al., 2006a; Patil et al., 2006b; Ademuyiwa et al., 2005b). Occupationally-exposed adults had levels of inhibition of ALAD that were as great as 90% relative to control (Quintanar-Escorza et al., 2007). There were few studies that investigated Pb-associated decrements in ALAD levels among moderately-exposed workers. Painters in India with a mean blood Pb level of 21.92 µg/dL (mean [SD] duration of exposure: 126.08 [49.53] months) had lower ALAD levels ($p < 0.01$) compared to controls whose mean blood Pb level was 3.06 µg/dL (Mohammad et al., 2008). Stoleski et al. (2008) observed that workers in a Pb smelter in Macedonia (mean [SD]: 16.4 [8.5] µg/dL blood Pb; 18.8 [7.5] years employment) had lower ALAD activity ($p < 0.001$) and higher ALA levels ($p < 0.0005$) compared to workers with no history of exposure to Pb (mean [SD] blood Pb: 7.0 [5.4] µg/dL). In automotive painters exposed to Pb in Brazil (mean [SD]: 5.4 [0.4] µg/dL blood Pb level; 133.9 [14.5] months duration of exposure), the ALAD reactivation index was increased over that in controls, although ALAD activity did not differ between groups (Conterato et al., In Press). However, ALAD activity was negatively correlated with blood Pb levels ($r = -0.59$, $p < 0.05$) but not blood Cd levels, whereas ALAD reactivation index was positively correlated with blood levels of both metals (Pb: $r = 0.84$, $p < 0.05$; Cd: $r = 0.27$, $p < 0.05$). In a benchmark dose (BMD)-based analysis (BMR = 5% using the hybrid approach and a 5% adversity cut-off value), Murata et al. (2009) calculated the BMD and 95% lower confidence limit of the BMD (BMDL) for decreased ALAD activity in RBCs of exposed Pb workers. The calculated BMD and BMDL values for Pb blood levels of 2.7 and 2.3 µg/dL, respectively, were substantially lower than the BMDs (28.7–44.2 µg/dL) and BMDLs (19.4–29.6 µg/dL) for decreased Hb, Hct, and RBC count in similarly exposed workers, indicating decreases in ALAD activity can occur at blood Pb levels that do not decrease RBC survival.

Decreased ALAD activity in response to Pb exposure has also been observed in toxicological studies. Rats administered 500 ppm Pb acetate in drinking water for 15 or 30 days had decreased blood ALAD activity, which was related to duration of exposure and blood Pb levels (Rendón-Ramirez et al., 2007). Oral administration of Pb (25 mg/kg) to rats once a week for 4 weeks achieved a blood Pb level of 6.5 µg/dL, which was associated with statistically significant decreases (approximately 50% lower than control levels) in RBC ALAD activity (Lee et al., 2005). Exposure of male Wistar rats to 5,000 ppm Pb acetate via drinking water for three weeks significantly decreased ALAD activity by 72% (mean [SD]: 7.35 [0.35] versus controls: 26.14 [2.19] nmol/min/mL RBCs [nanomoles of porphobilinogen (PBG) formed per minute, per 1 mL blood]) (Gautam and Flora, 2010).

5.7.3.2 Other Heme Metabolism Enzymes

The 2006 Pb AQCD (U.S. EPA, 2006b) indicated that Pb affects RBC PBG synthase (Simons, 1995; Farant and Wigfield, 1990, 1987), PBG deaminase (Tomokuni and Ichiba, 1990), and TF endocytosis and iron transport across membranes (Qian and Morgan, 1990), all of which are directly or indirectly involved in heme synthesis. Although there are no recent studies that examine the effect Pb has on the activities of other heme metabolism enzymes, a number of studies investigated associations of blood Pb level with concentrations of various intermediate products in the heme biosynthetic pathway.

Pb intoxication has been shown to inhibit the function of ferrochelatase, the enzyme that catalyzes the last (eighth) step in the heme biosynthetic pathway. Under normal conditions, ferrochelatase incorporates ferrous iron (Fe^{2+}) into protoporphyrin IX, converting it into a heme molecule (Figure 5-36). However, Pb has been shown to inhibit this insertion of Fe^{2+} into the protoporphyrin ring and instead, Zn is inserted into the ring creating ZPP. A number of recent studies have shown that blood Pb level is significantly associated with increased RBC ZPP levels in adults occupationally exposed to high levels of Pb (blood Pb levels: 27–54 µg/dL) (Patil et al., 2006b; Ademuyiwa et al., 2005b), workers exposed to moderate levels of Pb (blood Pb level = 21.92 µg/dL) (Mohammad et al., 2008), children aged 1–21 years (blood Pb levels: 18–23 µg/dL) (Counter et al., 2009, 2008; Counter et al., 2007), and animals exposed to 500 ppm Pb via drinking water for 15 or 30 days (Rendón-Ramirez et al., 2007). Interestingly, Wang et al. (2010f) found that in children and adults living in a rural area of Southwest China, ZPP levels were negatively correlated with blood Pb at blood Pb levels <10 µg/dL and were only positively correlated with blood Pb at higher blood Pb concentrations (i.e., >10 µg/dL). The authors suggested that this may be representative of ALAD activities at low blood Pb levels, which contributes to lower ZPP levels. Scinicariello et al. (2007) performed a meta-analysis and observed that Pb-exposed individuals who carried the ALAD2 allele had slightly lower concentrations of blood ZPP levels compared to carriers of the ALAD1 allele (overall pooled standardized mean estimate: -0.09 [units not specified]; 95% CI: -0.22, 0.03, p = 0.13).

5.7.3.3 Hematological Effects

In summary, Pb exposure has been shown in both cross-sectional epidemiologic studies and toxicological studies to alter heme synthesis. Pb exposure has been shown to inhibit the activities of two major enzymes in the heme biosynthetic pathway: ALAD and ferrochelatase. Evidence for the inhibition of ALAD comes from direct measurements of

its activity in exposed human populations, whereas evidence for inhibition of ferrochelatase comes from the observation of increased ZPP following exposure. Animal toxicology and ecotoxicology studies provide evidence of coherent effects in animals. The epidemiologic studies demonstrating these effects are cross-sectional in design, therefore there is some uncertainty regarding the direction of effects and the magnitude, timing, frequency, and duration of Pb exposure that contributed to the observed observations. Also, the majority of epidemiologic studies did not account for potential confounding, although the effects observed in these studies are consistent with effects from studies that did account for confounding. The coherency of effects observed in animal toxicology and ecotoxicology studies support the conclusion that Pb exposure alters the synthesis of heme in RBCs.

5.7.4 Summary and Causal Determination

Recent toxicological and epidemiologic evidence substantiates evidence presented in the 2006 Pb AQCD that exposure to Pb affects hematological endpoints, and supports a causal relationship between Pb exposure and decreased RBC survival and function and altered heme synthesis. Outcomes related to decreased RBC survival and function included alterations in multiple hematological parameters (e.g., Hb, Hct, PCV, MCV, MCH), oxidative stress (altered antioxidant enzyme activities [SOD, CAT, GPx], decreased cellular GSH, and increased lipid peroxidation), increased cytotoxicity in RBC precursor cells, and mode of action endpoints such as decreased intracellular calcium concentrations, decreased ATPase activity, and increased phosphatidylserine expression. Outcomes related to altered heme synthesis included decreased activities of ALAD and ferrochelatase, and decreased levels of Hb. The sections that follow describe the evaluation of evidence for decreased red blood cell (RBC) survival and function and heme synthesis, with respect to causal relationships with Pb exposure using the framework described in Table II of the Preamble. The application of the key supporting evidence to the causal framework is summarized in Table 5-35.

5.7.4.1 Evidence for Decreased RBC Survival and Function

The 2006 Pb AQCD (U.S. EPA, 2006b) reported that Pb exposure is associated with multiple measures of decreased RBC survival and function. Epidemiologic evidence included the observation of a 10% probability of anemia with blood Pb levels of approximately 20 µg/dL at age 1 year, and perturbed hematopoiesis in children and adults at blood Pb levels below 40 µg/dL. Oxidative stress was also identified by the 2006 Pb AQCD as a potential mode of action for Pb-induced effects in RBCs. A causal

relationship between Pb exposure and decreased RBC survival and function is strongly supported by the available, recent toxicological and epidemiological data. Among the strongest evidence for Pb-induced decreases in RBC survival and function is the consistent observation of alterations in hematological parameters (e.g., Hb, Hct, PCV, MCV, MCH), oxidative stress (altered antioxidant enzyme activities [SOD, CAT, GPx], decreased cellular GSH, and increased lipid peroxidation), and increased cytotoxicity in RBC precursor cells in rodents exposed to various forms of Pb via drinking water (Jang et al., 2011; Molina et al., 2011; Gautam and Flora, 2010; Baranowska-Bosiacka et al., 2009; Simsek et al., 2009; Alghazal et al., 2008b; Kharoubi et al., 2008b; Marques et al., 2006). Some of these effects have been observed in toxicological studies reporting blood Pb levels <10 µg/dL, and therefore occur at blood Pb levels that are relevant to humans. These effects at relevant blood Pb levels were found primarily in adult animals with Pb exposure durations of 4 weeks to 9 months. Although not as representative of potential human exposure pathways as exposure via drinking water, numerous toxicological studies utilizing oral gavage have also observed effects on hematological parameters, oxidative stress, and hematopoiesis (Sharma et al., 2010b; Celik et al., 2005; Lee et al., 2005). The animal toxicological evidence for decreased RBC survival and function is particularly important to the weight of evidence as it establishes clear temporality of exposure to Pb and induction of effects on red blood cells.

Associations between increased Pb blood levels and decreased RBC survival and function, are also evident in diverse populations of human adults and children. Cross-sectional studies in children measuring concurrent blood Pb levels are consistent regarding effects on hematological parameters (Queirolo et al., 2010; Shah et al., 2010; Ahamed et al., 2007; Huo et al., 2007; Olivero-Verbel et al., 2007; Riddell et al., 2007; Turgut et al., 2007; Ahamed et al., 2006; Jin et al., 2006; Rondo et al., 2006). Associations between altered indices of RBC oxidative stress and blood Pb levels were also seen in adolescents and children (Ahamed et al., 2008; Ahamed et al., 2006; Jin et al., 2006). The blood Pb levels observed in cross-sectional studies of children tended to be lower than those observed in adult populations (see below), with the majority of studies in children (ages 5 months to 5 years old) reporting mean blood Pb levels <15 µg/dL (range: 6.9 – 21.86 µg/dL). The difference in blood Pb levels may reflect the comparatively shorter duration and lower magnitude of Pb exposure experienced by children compared to adults.

For adult populations, the largest body of evidence consists of occupationally-exposed workers in which measures of RBC survival (e.g., Hb, Hct, PCV, MCV, MCH) are altered when compared with unexposed control populations in cross-sectional studies (Cabaravdic et al., 2010; Ukaejiofo et al., 2009; Khan et al., 2008; Patil et al., 2006a; Patil et al., 2006b; Karita et al., 2005; Conterato et al., In Press). Only one

non-occupational study was found investigating the association of Pb with hematological parameters; in pregnant women, concurrent blood Pb levels were found to be negatively correlated with Hb concentrations. Cross-sectional studies have also observed consistent increases in lipid peroxidation in occupationally-exposed adult populations (Ergurhan-Ilhan et al., 2008; Khan et al., 2008; Mohammad et al., 2008; Quintanar-Escorza et al., 2007; Patil et al., 2006a; Patil et al., 2006b), and have observed changes in oxidative stress parameters, including lowered activities of antioxidant enzymes such as SOD, GR, and CAT. Recent evidence of disrupted hematopoiesis, including the observation of decreased serum EPO in occupationally-exposed adults with a mean blood Pb level of 6.4 µg/dL (Sakata et al., 2007), was consistent with previous findings of decreased EPO in exposed adults reported in the 2006 Pb AQCD. Although the mean blood Pb level in most occupationally exposed populations was >20 µg/dL, multiple studies observed adverse effects in occupationally-exposed populations with mean blood Pb levels <10 µg/dL, including significant correlations PCV (7 µg/dL), significant correlations between RBC distribution width and MCHC (5.4 µg/dL), and decreased EPO (6.4 µg/dL). Any differences in the effects on specific hematological and oxidative stress parameters between adult populations and children may reflect differences in exposure durations or patterns of exposure, although there is greater uncertainty regarding the timing and duration of exposure associated with these effects in adults.

The evidence for Pb-associated decrements in RBC function and survival in adults and children comes from cross-sectional studies measuring concurrent blood Pb levels, and thus, the temporality of effects and the timing and duration of exposure associated with altered RBC survival and function in RBCs is unclear. This uncertainty is greatest in adults and older children as concurrent blood Pb levels also reflect higher past Pb exposures. Additional limitations of the epidemiologic database include the general lack of controlling for potential confounders or other possible co-exposures to contaminants that can affect the hematological system. Although most studies did not control for potential confounders, a few studies investigating effects in children did adjust for potential confounders such as age, sex, area of residence, breastfeeding, mouthing behavior, family structure, and SES-related variables, and still observed negative effects on RBC survival and function. However, no studies controlled for nutritional status, including iron intake. Further, while the epidemiologic database may be limited for the above reasons, the findings in these studies demonstrated coherence with findings from multiple toxicological studies that either reported blood Pb levels that are relevant to humans, i.e., <10 µg/dL (drinking water and gavage studies) or utilized a relevant route of exposure (drinking water), and reported clear evidence for decreased RBC survival and function.

The causal relationship between Pb exposure and decreased RBC survival and function is further supported by epidemiologic and toxicological evidence characterizing mode of action and biological plausibility. Pb was shown to reduce Ca^{2+}ATPase and Ca^{2+}/Mg^{2+}ATPase activities in RBC membranes, which leads to an increase in RBC $[Ca^{2+}]_i$, increased membrane fragility, and abnormal morphological changes in studies of occupationally exposed adults (Quintanar-Escorza et al., 2007) and in in vitro studies (Quintanar-Escorza et al., 2010; Ciubar et al., 2007). Heul et al. (2008) observed a reduction in plasma membrane Ca^{2+}ATPase pump activity in newborn children's RBC membranes in association with a concurrent group mean newborn cord blood Pb level of 3.54 µg/dL. Pb exposure has also been observed to increase PS expression on RBC membranes, leading to cell shrinkage, erythropoiesis, and destruction of the RBCs by macrophages (Jang et al., 2011; Ciubar et al., 2007; Shin et al., 2007).

Experimental animal studies demonstrate that Pb exposures via drinking water and gavage, resulting in blood Pb levels relevant to humans, alter several hematological parameters, increase measures of oxidative stress, and increase cytotoxicity in RBC precursor cells. These effects were found primarily in adult animals with Pb exposure durations of 4 weeks to 9 months. Support for these findings is provided by biologically plausible modes of action, including decreased intracellular calcium concentrations, decreased ATPase activity, and increased phosphatidylserine expression. Epidemiologic studies demonstrate evidence in both adults and children that concurrent blood Pb levels are associated with altered hematological endpoints and increased measures of oxidative stress, and altered hematopoiesis. However, the majority of these studies are limited by the lack of rigorous methodology and consideration for potential confounding. While some studies in children did control for or considered potential confounding and effects in adults and children are coherent with effects observed in exposed animals, there remains some uncertainty regarding the evidence for altered RBC survival and function in human populations. Because epidemiologic evidence is limited to associations with concurrent blood Pb levels, there is uncertainty regarding the timing, duration, magnitude, and frequency of Pb exposure associated with decreased RBC survival and function. Collectively, the strong evidence from toxicological studies that is supported by findings from mode of action and epidemiologic studies is sufficient to conclude that there is a causal relationship between Pb exposures and decreased RBC survival and function.

5.7.4.2 Evidence for Altered Heme Synthesis

The 2006 Pb AQCD (U.S. EPA, 2006b) reported that Pb exposure affects heme synthesis in humans and animals through the inhibition of multiple key enzymes in the heme biosynthetic pathway, including ALAD and ferrochelatase. A causal relationship between Pb exposure and altered heme synthesis is strongly supported by the available toxicological, ecotoxicological, and epidemiologic data (Table 5-35). The greatest weight of evidence for Pb-induced alterations in heme synthesis lies primarily in the toxicological and ecotoxicological literature. A small, but coherent, body of recent toxicological evidence demonstrates decreased ALAD activity (Gautam and Flora, 2010; Lee et al., 2005) and ferrochelatase (Rendón-Ramirez et al., 2007) in adult rats exposed to Pb via drinking water and oral gavage for 3-4 weeks. Lee et al. (2005) observed effects on ALAD activity at mean blood Pb levels of 6.5 µg/dL after Pb administration by oral gavage once per week for 4 weeks. Evidence from previous studies cited in the 2006 Pb AQCD consistently observed Pb-induced ALAD inhibition in multiple species, including birds, primates, and humans, further supporting the causal association between Pb exposure and altered heme synthesis.

Similar to the earlier and more recent toxicological studies that demonstrate an association between Pb exposure and hematological effects in humans and laboratory animals, the ecological literature has consistently reported on hematological responses in aquatic and terrestrial invertebrates and vertebrates (Sections 7.3.12.5, 7.4.12.5, and 7.4.21.5). The most consistently observed effect in metal impacted environments is decreased RBC ALAD activity. This effect has been observed across a wide range of taxa, including bivalves, fish, amphibians, birds, and mammals. More limited evidence exists regarding deleterious effects of Pb exposure on serum enzyme levels and white blood cell counts in birds and mammals.

Consistent associations between increased Pb blood levels and decreased activity of multiple enzymes involved in the heme synthetic pathway have also been observed in diverse populations of adults and children. The strongest evidence for altered heme synthesis in adults and children come from cross-sectional epidemiological studies measuring concurrent blood Pb and reporting decreases in RBC ALAD levels and activity (Wang et al., 2010f; Mohammad et al., 2008; Ahamed et al., 2007; Quintanar-Escorza et al., 2007; Ahamed et al., 2006; Patil et al., 2006a; Patil et al., 2006b; Ademuyiwa et al., 2005b; Ahamed et al., 2005; Conterato et al., In Press). In addition to ALAD inhibition, recent studies have also shown that Pb exposure inhibits the activity of ferrochelatase, leading to increased RBC ZPP levels in children and occupationally-exposed adults (Counter et al., 2009, 2008; Mohammad et al., 2008; Counter et al., 2007; Patil et al., 2006b; Ademuyiwa et al., 2005b). Although the mean blood Pb levels in most

of the studies investigating these effects in adults and children were >20 µg/dL, two studies did observe adverse effects in populations with mean blood Pb levels <10 µg/dL: increased ALAD reactivation index in exposed painters (5.4 µg/dL), and statistically significant, positive associations between ALAD and blood Pb level in children and the elderly (7.1 and 6.4 µg/dL, respectively).

The cross-sectional nature of the above epidemiologic studies in adults and children, and the measurement of concurrent blood Pb, introduces some uncertainty regarding the temporality of effects and the timing and duration of exposure associations with altered heme synthesis. Although most studies did not control for potential confounders, a few studies investigating effects in children, and one study investigating effects in adults, did adjust for confounders such as age, sex, urban/rural residence, height, weight, BMI, smoking status, and alcohol use, and still observed negative effects on heme synthesis. However, no studies controlled for nutritional status, including iron intake. Further, while the epidemiologic database may be limited for the above reasons, the findings in these studies demonstrated coherence with findings from multiple toxicological and ecotoxicological studies.

The causal relationship between Pb exposure and altered heme synthesis is further supported by cross-sectional studies observing decreased Hb (measured as total Hb, MCH, or MCHC) in occupationally-exposed adults (Ukaejiofo et al., 2009; Khan et al., 2008; Patil et al., 2006b; Karita et al., 2005) and in children (Queirolo et al., 2010; Shah et al., 2010; Olivero-Verbel et al., 2007; Riddell et al., 2007). Several recent toxicological studies also observed decreased Hb levels in laboratory animals exposed to Pb (Sharma et al., 2010b; Baranowska-Bosiacka et al., 2009; Simsek et al., 2009; Marques et al., 2006; Lee et al., 2005). Decreased Hb levels are a direct indicator of decreased heme synthesis due to Pb exposure.

In summary, altered heme synthesis is demonstrated by a small, but coherent, body of studies in adult animals reporting that Pb exposures via drinking water and gavage (resulting in blood Pb levels relevant to humans) for 15 days to 9 months decreased ALAD and ferrochelatase activities. Supporting this toxicological evidence is a larger body of ecotoxicological studies that demonstrate decreased ALAD activity across a wide range of taxa exposed to Pb. Epidemiologic studies demonstrate evidence in both adults and children that concurrent blood Pb levels are associated with decreased ALAD and ferrochelatase activities. However, the majority of these studies are limited by the lack of rigorous methodology and consideration for potential confounding. While some studies in children did control for or considered potential confounding and effects in adults and children are coherent with effects observed in exposed animals, there remains some uncertainty regarding the evidence for altered heme synthesis in human populations.

Because epidemiologic evidence is limited to associations with concurrent blood Pb levels, there is uncertainty regarding the timing, duration, magnitude, and frequency of Pb exposure associated with decreased RBC survival and function. Evidence for altered heme synthesis is also provided by a large body of toxicological and epidemiologic studies that report decreased Hb concentrations due to Pb exposure. Collectively, the strong evidence from toxicological and ecotoxicological studies, which is supported by findings from epidemiologic studies, is sufficient to conclude that there is a causal relationship between Pb exposures and altered heme synthesis.

Table 5-35 Summary of evidence supporting RBC survival and heme synthesis causal determinations.

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	Recent References[b]	Pb Exposure or Blood Pb Levels Associated with Effects[c]
Decreased RBC Survival and Function: Causal			
Consistent toxicological evidence with relevant exposures	Large body of studies with consistent findings for decreased RBC survival and function (decreased Hb, Hct, PVC, increased eryptosis, decreased hematopoiesis, increased oxidative stress) in rodents with relevant concentrations of Pb and routes of exposure	Baranowska-Bosiacka et al. (2009), Lee et al. (2005), Sharma et al. (2010b), Simsek et al. (2009), Marques et al. (2006), Molina et al. (2011), Jang et al (2011), Celik et al. (2005), Alghazal et al. (2008b), Kharoubi et al. (2008b), Gautam and Flora (2010)	Rodents: Blood Pb level: 1.7—7.1 µg/dL Exposures: Drinking water 50-2,000 ppm, 21—270 days as adults Oral gavage 25—500 mg/kg, 28—70 days
Associations consistently found in multiple epidemiologic studies with relevant blood Pb levels	Cross-sectional studies that considered potential confounding factors found blood Pb-associated decreases in Hb, increases in anemia prevalence, increased oxidative stress in children ages 6 mo-5 yr	Riddell et al. (2007), Queirolo et al. (2010), Ahamed et al. (2007), Ahamed et al. (2008)	Children: majority of concurrent blood Pb levels <15 µg/dL
	Association with Hb found in children with concurrent blood Pb levels with consideration for potential confounding by age, sex, mouthing behavior, anemia, dairy product consumption, maternal age, education, employment, marital status, family structure, SES-related variables	Queirolo et al. (2010)	
	Other studies of Hb, oxidative stress adjusted for factors such as age, sex, birthweight, breastfeeding history, urban/rural residence	Riddell et al. (2007), Ahamed et al. (2008), Ahamed et al. (2007)	

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	Recent References[b]	Pb Exposure or Blood Pb Levels Associated with Effects[c]
	Consistent evidence in large body of cross-sectional studies without consideration for potential confounding in occupationally-exposed adults and in children of associations of blood Pb levels with decreases RBC survival, interferes with hematopoiesis, and increases oxidative stress	Karita et al. (2005), Khan et al. (2008), Patil et al. (2006a), Patil et al. (2006b), Ukaejiofo et al. (2009), Conterato et al. (In Press), Cabaravdic et al. (2010), Ergurhan-Ilhan et al. (2008), Mohammad et al. (2008), Quintanar-Escorza et al. (2007), Sakata et al. (2007), Riddell et al. (2007), Queirolo et al. (2010), Olivero-Verbel et al. (2007), Ahamed et al. (2006), Ahamed et al. (2007), Ahamed et al. (2008), Turgut et al. (2007), Huo et al. (2007), Shah et al. (2010), Rondo et al. (2006), Jin et al. (2006)	Adults (occupational exposures): majority of blood Pb levels >20 µg/dL, some studies observed effects in the range of 5–7 µg/dL
Evidence clearly describes Mode of Action			
Altered RBC membrane ion transport	Evidence of increased $[Ca^{2+}]_I$ and decreased Ca^{2+}/Mg^{2+}ATPase activity in the RBCs of exposed workers. $[Ca^{2+}]_I$ levels highly correlated with blood Pb even among unexposed controls. $[Ca^{2+}]_I$ levels increased in RBCs from healthy volunteers when exposed in vitro to Pb $[Ca^{2+}]_I$ associated with increased RBC fragility and alterations in RBC morphology	See Section 5.7.2.2	
Phosphatidyl serine (PS) expression	Consistent evidence from in vivo and in vitro studies that Pb exposure increases PS expression on RBC membranes via modulation of $[Ca^{2+}]_I$ concentrations. Increased PS expression leads to eryptosis and phagocytosis by macrophages		

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	Recent References[b]	Pb Exposure or Blood Pb Levels Associated with Effects[c]
Altered Heme Synthesis: Causal			
Consistent toxicological evidence with relevant exposures	A small, but coherent toxicology database indicates decreased heme synthesis in rodents with relevant Pb concentrations and routes of exposure	Rendón-Ramirez et al. (2007), Lee et al. (2005), Gautam and Flora (2010)	Blood Pb levels 6.5 µg/dL Exposures: 500–5,000 ppm Drinking water, 15–30 days as adults
Consistent ecotoxicological evidence	Pb-induced decreased ALAD activity observed across many taxa (bivalves, fish, amphibians, birds, and mammals) in multiple ecotoxicity studies	Birds: Berglund et al. (2010), Gómez-Ramírez et al. (2011), Hansen et al. (2011a), Martinez-Haro et al. (2011)	Birds: 6 – >100 µg/dL
		Freshwater Invertebrates: Aisemberg et al. (2005)	Freshwater Invertebrates (48-h exposure in aquaria) 0.2-300 µg/g wet tissue
		Fish: Schmitt et al. (2005), Schmitt et al. (2007b), Heier et al. (2009),	Fish: 6–14 µg/g (gill or liver concentrations)
		Bivalves: Kalman et al. (2008), Company et al. (2011).	Bivalves: 0.38–3.50 µg/g dry weight
Associations found in epidemiologic studies with relevant blood Pb levels	Cross-sectional studies that considered potential confounding by age, sex, urban/rural residence, height, weight, BMI found associations with lower ALAD and ferrochelatase activities in children.	Ahamed et al. (2006), Ahamed et al. (2007)	Adults (occupational exposure) and children: Majority of concurrent blood Pb levels >20 µg/dL, Two studies observed associations in the range of concurrent blood Pb levels 5–7 µg/dL.
	Concurrent blood Pb level associated with lower ALAD and higher ZPP in adults with consideration for potential confounding by age, sex, smoking status, and alcohol use.	Wang et al. (2010f)	
	Associations found in several studies, mostly in occupationally-exposed adults, that did not consider potential confounding	Children: Ahamed et al. (2005) Occupational: Ademuyiwa et al. (2005b), Mohammad et al. (2008), Patil et al. (2006a), (2006b), Quintanar-Escorza et al. (2007), Conterato et al. (In Press)	

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	Recent References[b]	Pb Exposure or Blood Pb Levels Associated with Effects[c]
Epidemiologic and toxicological evidence for altered heme synthesis supported by consistent evidence of decreased Hb, a direct marker for decreased heme synthesis.	Consistent evidence in animals for decreases in Hb with relevant Pb exposures.	Animals: Baranowska-Bosiacka et al. (2009), Lee et al. (2005), Marques et al. (2006), Sharma et al. (2010b), Simsek et al. (2009)	Adult animals: Blood Pb levels 1.7–7.1 µg/dL after 15 day-9 month Pb exposure
	Association found in children with concurrent blood Pb levels with consideration for potential confounding by age, sex, mouthing behavior, anemia, dairy product consumption, maternal age, education, employment, marital status, family structure, SES-related variables	Queirolo et al. (2010)	Children: Majority of concurrent blood Pb <15 µg/dL
	Other studies in children had limited or no consideration for potential confounding.	Shah et al. (2010), Olivero-Verbel et al. (2007), Riddell et al. (2007)	
	Associations found in adults and, as well as coherent findings in animal toxicological studies, for decreased Hb.	Adults: Karita et al. (2005), Khan et al. (2008), Patil et al. (2006b), Ukaejiofo et al. (2009)	Adults (occupational exposure): Majority of blood Pb >20 µg/dL

[a]Described in detail in Table II of the Preamble.

[b]Describes the key evidence and references contributing most heavily to causal determination. Also noted are the sections where full body of evidence is described.

[c]Describes the blood Pb levels in humans with which the evidence is substantiated and blood Pb levels in animals most relevant to humans.

5.8 Reproductive and Developmental Effects

The effect of Pb on reproductive and developmental outcomes has been of interest for years, starting in cohorts of occupationally-exposed individuals. More recently, researchers have begun to focus on reproductive and developmental effects in populations without occupational exposures, with more environmentally-relevant levels of Pb exposure. The toxicological and epidemiologic literature on reproductive effects of Pb include research on female and male reproductive function such as hormone levels, fertility, spontaneous abortions, effects on sperm, estrus, and effects on reproductive organs. Evaluation of effects on the developing organism includes effects on puberty, postnatal growth, and effects on the development of the teeth, sensory organs, and other systems. Research on birth outcomes includes birth defects, infant mortality, preterm birth, and low birth weight. A few studies of pregnancy-induced hypertension and eclampsia have been conducted and are reported on in the section on hypertension (Section 5.4.2.1). Briefly, the relatively small number of studies found consistently positive associations between blood Pb levels and pregnancy-induced hypertension. Biomarkers of Pb exposure, including blood Pb and bone Pb, are used in the epidemiologic studies reviewed in this section. Bone Pb typically indicates cumulative exposure to Pb, whereas, blood Pb may indicate more recent exposure. However, Pb can also be remobilized from the bone during times of active bone remodeling, such as pregnancy or lactation. Toxicological studies typically report exposure using blood Pb. More detailed discussion of these measures and Pb transfer via umbilical cord blood Pb across the placenta, and via lactation is given in Section 4.2.2.4 on Pb Toxicokinetics.

Overall, the recent literature on reproductive effects of Pb exposure continues to support associations reported in earlier Pb AQCDs between Pb exposure and effects on various parameters of sperm (function, motility, count, integrity, histology). The toxicological and epidemiologic literature of developmental effects of Pb exposure also indicates that Pb exposure is associated with delayed onset of puberty in both males and females. Associations between Pb exposure and other reproductive and developmental effects have less consistent findings. The recent information from epidemiologic and toxicological studies is integrated with conclusions from previous Pb AQCDs below.

5.8.1 Effects on Development

The 2006 Pb AQCD (U.S. EPA, 2006b) reported Pb-associated developmental effects on teeth, sensory organs, the GI system, the liver, and postnatal growth as well as delayed puberty (U.S. EPA, 2006b). There was recognition that Pb is transferred across the placenta and through the breast milk, contributing to exposure during development. The

2006 Pb AQCD reported delayed puberty in both male and female populations in animal toxicology studies showing associations with dam blood Pb levels of ~40 µg/dL and pup blood Pb levels of 26 µg/dL. The research reported in this ISA continues to find delayed puberty with Pb exposure at even lower Pb doses in animal toxicology studies as is detailed below. Mechanistic understanding of delayed puberty is also reported in this ISA. Lower dose Pb exposure studies in animal toxicology are also reported in studies of sensory organ function and postnatal growth in this ISA. Studies included in this ISA expand upon evidence reported in previous Pb AQCDs for the aforementioned systems sensitive to developmental effects with recent studies showing effects at lower doses of Pb.

5.8.1.1 Effects on Puberty among Females

Recent toxicological studies of rodents have examined the effects of Pb on pubertal and reproductive organ development and on biomarkers of pubertal development among females. There have also been recent epidemiologic studies examining associations between blood Pb levels and onset of puberty among girls, which are summarized in Table 5-36 and in the text below. All of the epidemiologic studies examined concurrently measured blood Pb and puberty and are reported below. Additionally, while there was a longitudinal investigation by Naicker et al. (2010), who followed girls to determine their age of menarche, blood Pb levels were measured once at 13 years of age.

Table 5-36 Summary of recent epidemiologic studies of associations between Pb levels and puberty for females.

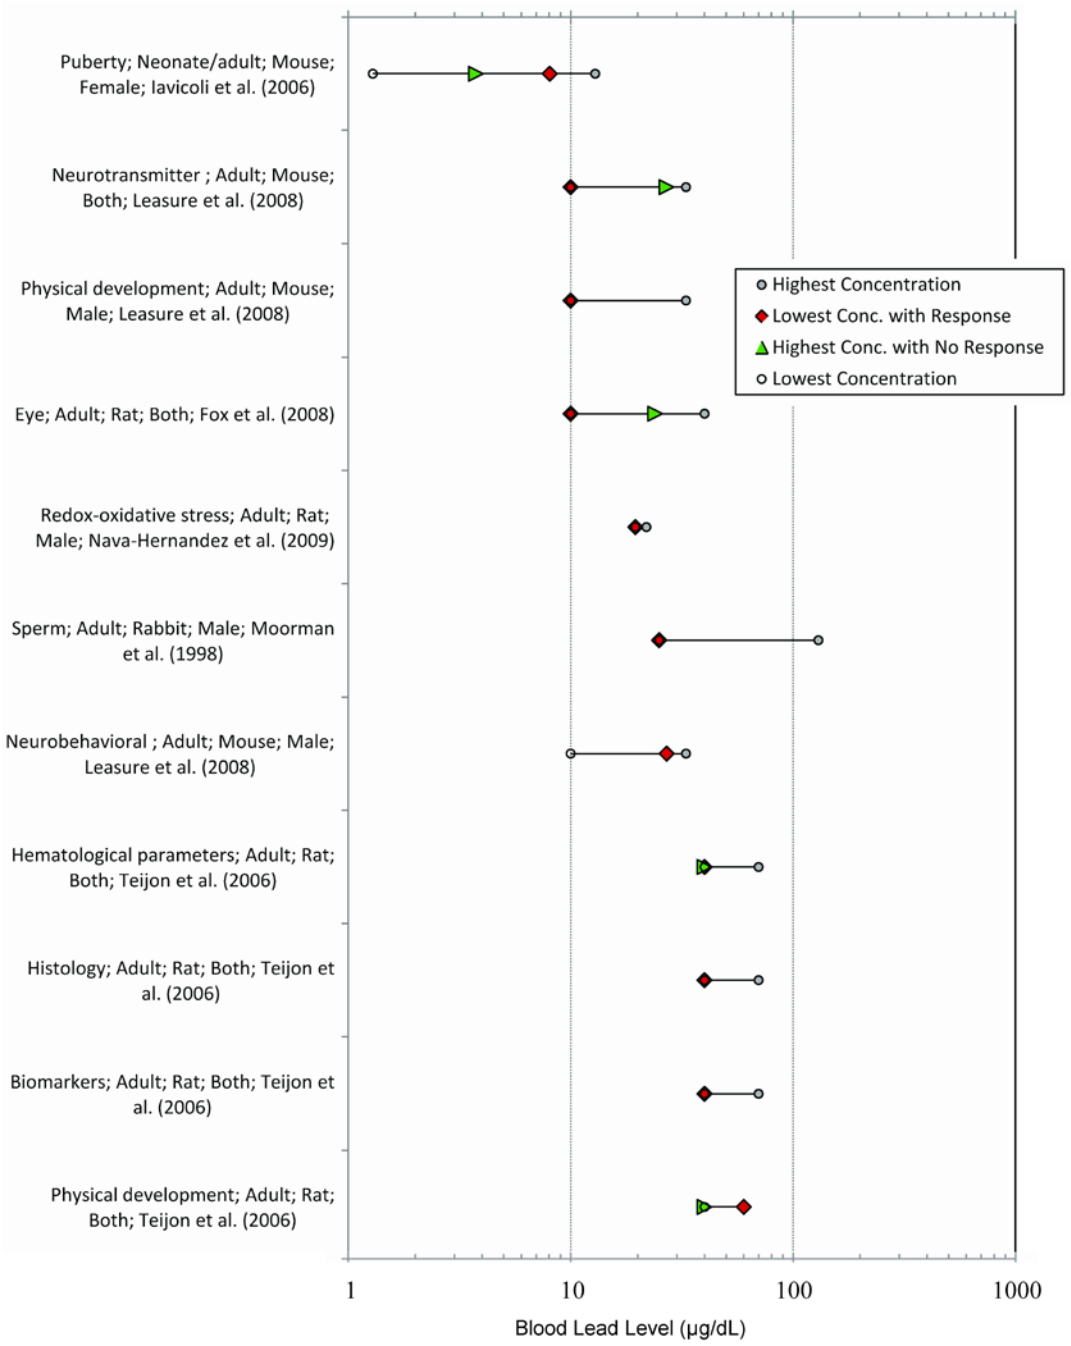
Multiple studies have been performed examining blood Pb levels and puberty using NHANES III data (Gollenberg et al., 2010; Selevan et al., 2003; Wu et al., 2003b). A study that included girls aged 8-16 years reported an association between increased blood Pb and delayed attainment of menarche and pubic hair development, but not for breast development (Wu et al., 2003b). The associations were observed even at blood Pb levels of 2.1-4.9 µg/dL compared to girls with blood Pb levels <2.1 µg/dL. Another NHANES III study included girls 8-18 years of age and reported the results stratified by race (Selevan et al., 2003). This study also included many important potential confounders, such as nutritional information. Higher blood Pb levels were associated with lower Tanner stage of breast and pubic hair development and later age at menarche among African Americans and with lower stage of breast and pubic hair development among Mexican Americans. For whites, the associations were in the same directions, but none reached statistical significance. In a study of girls aged 6-11 years old from NHANES III data, higher blood Pb levels were associated with lower inhibin B, a protein that inhibits FSH production, but no association was observed for LH. (Gollenberg et al., 2010). The inverse association between blood Pb and inhibin B was greater among girls with iron deficiency compared to those with high Pb but sufficient iron levels. Inhibin B and LH were chosen for this study because, as the authors indicated, these hormones are, "believed to be relevant for younger girls… near the onset of puberty and…serve as markers for hypothalamic-pituitary-gonadal functioning."

A study of girls aged 10-16.9 years of age in the Akwesasne Mohawk Nation reported a nonlinear association between higher blood Pb and greater age at menarche (Denham et al., 2005). No association was observed below blood Pb of 0.49 µg/dL in a nonlinear model of the Pb-menarche relationship. A study conducted in South Africa reported an association between increased blood Pb levels and older age at first menarche and pubertal development (Naicker et al., 2010). Another study reporting on girls with low blood Pb concentrations observed an association between higher blood Pb and less pubic hair development but not breast development (Den Hond E, 2011). The association was no longer statistically significant when a marker for polychlorinated biphenyl exposure was included in the model. A study among girls aged 10-13 years (median: 12 years) reported lower levels of FSH and LH levels in the group with blood Pb of at least 10 µg/dL compared to the group with blood Pb less than 10 µg/dL (Tomoum et al., 2010). In addition, there were some indications of lower Tanner stages of breast development associated with Pb levels of at least 10 µg/dL, but this relationship was not present for stages of pubic hair development and there was no control for potential confounders. A study performed in NYC among 9-year old girls reported no association between Pb levels and pubertal development (Wolff et al., 2008), but this age group may be too young to study when investigating delayed puberty as the outcome.



Note: This figure illustrates reproductive and developmental effects associated with Pb exposure in studies that examined multiple exposure concentrations. Dosimetric representation reported by blood Pb level. (Studies are described in Table 5-37).

Earlier studies showed that prenatal and lactational exposures to Pb can cause a delay in the onset of female puberty in rodents. Recent studies corroborate these findings and show that puberty onset is one of the more sensitive markers of effects of Pb exposure as is demonstrated in the exposure response array (Figure 5-37 and Table 5-37; including outcomes described in sections that follow). Dumitrescu et al. (2008c) exposed adult Wistar female rats to varying doses of Pb acetate (50-150 ppb) in drinking water for 3 months before mating and during pregnancy. Vaginal opening, an indicator of sexual maturation, was statistically significantly delayed in pups from all Pb treated groups when compared to pups from non-treated dams. The age at vaginal opening in female pups from the Pb treated groups increased, in a concentration-dependent manner, from 39 days to 43-47 days. The authors also observed a correlation between body weight and age at vaginal opening meaning that as body weight decreased the age at vaginal opening increased. This effect also exhibited a concentration-dependent relationship.

In another recent study, Iavicoli et al. (2006a) reported a statistically significant delay in several indicators of sexual maturity in offspring (Swiss mice, F_1 generation) born to dams that ingested 3.5-40 ppm Pb in their daily diet; offspring had continuous dietary exposure until the termination of the experiment at puberty. Maternal ingestion of Pb at the various doses resulted in female pup blood Pb levels of 3.5-13 µg/dL. For all diet groups in this range (3.5-13 µg/dL), there was a delay in age at vaginal opening, age of first estrus, age of vaginal plug formation, and age of first parturition when compared to the group at background Pb concentration (2 µg/dL). A novel finding in the Iavicoli study was that very low dose Pb (blood Pb of 0.7 µg/dL, food concentration of 0.02 ppm continuous through gestation, lactation and until the termination of the experiment) induced statistically significant acceleration of markers of sexual maturation in female offspring versus background Pb level animals (blood Pb of 2 µg/dL). There were statistically significant increases in time of vaginal opening (30% earlier), first estrous, first vaginal plug formation, and first parturition at the very low Pb exposure versus 2 µg/dL animals. Thus, the timing of puberty is delayed in a concentration-dependent fashion with very low dose Pb having a statistically significant earlier onset of puberty than the background Pb animals (2 µg/dL). Also, the animals exposed to the higher dose of Pb (blood Pb up to 13 µg/dL) had statistically significant delays in onset of puberty when compared to the other dose groups.

In addition, Pb-induced shifts in sexual maturity were observed in the subsequent generation (F_2 generation) across that dose range. These F_2 animals continued to be exposed to same concentrations of Pb over multiple generations through the diet. Results in the F_2 generation closely resembled those of the F_1 generation, as both generations received Pb exposure. The authors concluded that a modest elevation in blood Pb level (13 µg/dL) over background (2-3 µg/dL) can result in a profound delay in the onset of puberty (15-20%). In the F_2 generation, reduction in blood Pb (0.7 µg/dL) below background (2-3 µg/dL) was associated with an earlier onset of sexual maturity (30% increase) above background.

In the 2006 Pb AQCD (U.S. EPA, 2006b), it was reported that a statistically significant reduction in the circulating levels of insulin-like growth factor 1 (IGF-1), LH, and estradiol (E2) was associated with Pb-induced delayed puberty in Fischer 344 pups. Subsequently, Pine et al. (2006) evaluated whether IGF-1 replacement could reverse the effects of Pb on delayed female puberty onset. The authors reported that offspring from dams exposed to Pb during gestation and lactation (daily oral gavage of dam with 1.0 mL solution of Pb acetate 12 mg/mL; mean maternal blood Pb level 40 µg/dL) exhibited a marked increase in LH and luteinizing hormone releasing hormone (LHRH) secretion after IGF-1 administration (200 ng^3/µL i.p. injection twice daily from PND23 until the appearance of vaginal opening which appears in control animals at ~PND40) resulting in

restored timing of vaginal to that of control animals. It should be noted that, IGF-1 replacement in Pb-exposed animals did not cause advanced puberty over non-Pb-exposed controls. The results of this study provide support to the theory that Pb-induced delayed onset of puberty may be due to disruption of pulsatile release of sex hormones (U.S. EPA, 2006b) and not necessarily due to a direct toxic effect on the hypothalamic-pituitary-gonadal axis (Salawu et al., 2009), and IGF-1 may play a prominent role in the process.

In summary, epidemiologic studies consistently show an association between higher concurrent blood Pb and delayed pubertal development in girls. This association is apparent even at low blood Pb levels. Most of the studies had good sample sizes and controlled for some potential confounders. Nutritional information was rarely controlled for although this could be important, especially in populations where malnutrition is prevalent. These epidemiologic studies are cross-sectional, which does not allow for the study of temporality between Pb levels and pubertal onset nor does it consider the influence of past blood Pb levels. New evidence from the toxicology literature continues to indicate Pb-induced delays in the onset of puberty. Further, the biological plausibility of delayed puberty is expanded with the toxicological literature that shows this pathway is mediated by IGF-1.

5.8.1.2 Effects on Puberty among Males

Recent epidemiologic studies examining the association between blood Pb and onset of puberty in males are summarized in Table 5-38. The majority of studies used concurrent measures of blood Pb and puberty (Den Hond E, 2011; Tomoum et al., 2010; Hauser et al., 2008), but Williams et al. (2010) performed a longitudinal analysis of blood Pb levels measured at ages 8-9 years and pubertal onset, following the participants for 3 years. Little epidemiologic information was available regarding pubertal onset in the 2006 Pb AQCD (U.S. EPA, 2006b).

Table 5-38 Summary of recent epidemiologic studies of associations between Pb levels and puberty for males.

Den Hond et al. (2011)	Flanders 2003-2004	Tanner staging and gynecomastia	Boys ages 14 and 15, in their 3rd year of secondary education and living in the same study areas for at least 5 years N=887	Cross-sectional study using logistic regression	Blood Pb	Median: 2.50 10th percentile: 1.20 90th percentile: 5.12	OR (95% CI) for gynecomastia with doubling of exposure 1.84 (1.11, 3.05) No association between Pb and pubic hair or genital development (results not given)	Parental education, age, BMI, smoking status Considered but not included: food intake, lifestyle parameters NOTE: results were the same when hexachlorobenzene was included in the model

Studies were performed among a cohort of Russian boys enrolled between ages 8-9 years (Williams et al., 2010; Hauser et al., 2008). The area where these studies were performed had various environmental contaminants, such as dioxin, polychlorinated biphenyls, and other metals, present but these were not included in the analyses (although preliminary analyses found no correlation between blood Pb levels and serum dioxin levels). Both the cross-sectional study (Hauser et al., 2008) and the prospective study with annual follow-ups (Williams et al., 2010) demonstrated an association; higher blood Pb levels at 8-9 years of age was associated with later onset of puberty. In a study of boys in Egypt, boys with higher blood Pb had delayed pubertal onset compared to those with lower levels (Tomoum et al., 2010). In addition, compared to the low blood Pb group, those boys with higher blood Pb had lower testosterone, FSH, and LH levels but there was no control for confounding. A study in Flanders reported no associations between blood Pb concentration and pubertal development among 14- and 15-year old boys (Den Hond E, 2011). However, higher blood Pb levels were associated with an increased odds of gynecomastia.

No recent toxicological studies address Pb-induced male sexual maturation and development, but earlier studies do provide support to findings in epidemiologic cohorts. Pb exposure resulted in delayed sexual maturity as measured by prostate weight in male Sprague-Dawley pups at PND35. These pups were exposed chronically to 1,500 or 4,500 ppm Pb acetate in dam or their own drinking water from GD5 until PND85 and had blood Pb ranges from low to high of 88-196 and 120-379 µg/dL, respectively (Ronis et al., 1998b). Cynomolgus monkeys exposed to Pb over a lifetime (an oral capsule of 1,500 µg/kg body weight/day for 10 years, blood Pb levels ranging from 30–60 µg/dL) had altered pituitary and Sertoli cell function along with decreases in inhibin/FSH ratio and reduced gonadotropin-releasing hormone (GnRH) stimulation of LH release in adulthood (Foster et al., 1993), all indicators that are important in proper sexual maturation. Further mechanistic understanding of the effect of Pb can be gleaned from studies in adult male Wistar rats exposed to Pb for 1 month (starting at PND56, 1,000 or 3,000 ppm Pb acetate in drinking water, respective blood Pb levels of 34 or 60 µg/dL) that showed significant decreases in FSH, ventral prostate weight and serum testosterone but no change in serum LH (Sokol et al., 1985). These Pb-exposed adult male rats (3,000 ppm Pb acetate in drinking water starting at PND56 for 30 days) demonstrated an impaired pituitary release of LH in response to challenge of the hypothalamic–pituitary–adrenal (HPA) axis with the opiate antagonist naloxone, an enhanced release of LH from the pituitary in response to direct stimulation of the pituitary with luteinizing hormone-releasing hormone (LHRH), an enhanced response to human chorionic gonadotropin (hCG) by the testes, increased pituitary LH stores, and increased GnRH mRNA levels in the hypothalamus (Klein et al., 1994; Sokol, 1987). Thus, Pb likely interferes with the male HPA axis, contributing to its reproductive toxicity.

In summary, recent epidemiologic studies have demonstrated an inverse effect of Pb on pubertal development among boys at low concurrent blood Pb levels. These studies were mostly cross-sectional, but associations were observed between Pb levels and delayed puberty in a longitudinal study as well (Williams et al., 2010). The larger studies controlled for some potential confounders, with a few studies at least considering the inclusion of dietary factors, which may be an important confounder, especially in populations with high prevalence of malnutrition. Some populations, such as the Russian boys cohorts, had potential exposures to dioxins and polychlorinated biphenyls, but these were not considered in the analyses. No recent toxicological studies were found that addressed the effect of Pb on male sexual development and maturation; however, the 2006 Pb AQCD (U.S. EPA, 2006b) supported earlier findings that Pb exposure may result in delayed onset of male puberty and altered reproductive function later in life in experimental animals.

5.8.1.3 Effects on Postnatal Stature and Body Weight

Findings from previous toxicological studies of rodents and primates have demonstrated Pb induced impairment of postnatal growth (U.S. EPA, 2006b). Little epidemiologic evidence was available in the 2006 Pb AQCD on postnatal growth. Several recent epidemiologic studies examining the association of various biomarkers of Pb exposure with stature and body weight have been conducted and the evidence reported is mixed.

Table 5-39 Summary of recent epidemiologic studies of associations between Pb levels and postnatal growth.

Results from recent epidemiologic studies of postnatal growth are summarized in Table 5-39. Longitudinal epidemiologic studies have had inconsistent findings regarding the association between Pb levels and post-natal growth. Afeiche et al. (2011) conducted a longitudinal study of children in Mexico City, born between 1994 and 2005. Maternal bone Pb during pregnancy was associated with a statistically significant decrease in weight at age 5 years in girls but not in boys. The findings were robust to additional adjustment for child's concurrent blood Pb level. A study in New York reported an inverse association between maternal blood Pb during the second trimester of pregnancy and various measures of growth, especially among those mothers with blood Pb levels of at least 3 µg/dL (Schell et al., 2009). These associations did not persist for those with maternal blood Pb levels less than 3 µg/dL. Among infants, 6 month blood Pb levels were not associated with measures of growth at 12 months. In comparisons of changes in blood Pb levels over time, high maternal blood Pb combined with low 12 month blood Pb among infants (indicating a decrease in blood Pb over time) resulted in the greatest growth, even compared to those with both low or both high maternal and infant blood Pb measures. In a prospective study of 309 mother-child pairs from Yugoslavia, the relationship between maternal blood Pb measured mid-pregnancy and attained height in children was investigated in those living in a highly exposed town with a smelter and battery plant and those living in a relatively lower exposed town (Lamb et al., 2008). In multivariate adjusted regression models, neither attained height (at birth, 1, 4, 6.6, or 10 years age) nor rate of height change per month (at birth-1 year, 1-4 years, 4-6.5 years, 6.5-10 years age) was associated in a consistent direction with maternal pregnancy blood Pb levels in either the industrial or less exposed town. Weight was also not associated with maternal blood Pb in this study.

Multiple cross-sectional studies reported an association between Pb levels and impaired growth. Ignasiak et al. (2006) studied school children aged 7-15 years living close to Cu smelters and refineries in Poland to assess the impact of Pb exposure on their growth status. There was a statistically significant linear relationship between concurrent blood Pb and reduced weight, height, trunk, leg and arm lengths. This decrease in height was more influenced by decreases in leg length than trunk length. These results also indicated that there was attenuation in osteoblast activity associated with higher blood Pb levels, consistent with animal toxicological studies (Long et al., 1990). Hauser et al. (2008) investigated the relationship between blood Pb and height in boys living in Chapaevsk, Russia, an area contaminated with multiple pollutants including dioxins and metals. In a multivariate adjusted regression analysis, height significantly decreased with increasing blood Pb. Statistically nonsignificant decreases in weight and BMI were also observed. The association of blood Pb with height, weight, and BMI was examined among two cohorts of children living near Pb smelters in Texas (Little et al., 2009). The first cohort included children 2-12 years old in 1980 and the second cohort included children of the

same age in 2002 when blood Pb levels were substantially lower. Decreases in height, weight, and BMI with increasing blood Pb levels were observed among children in both cohorts and increases in height and weight were observed comparing children from the 2002 cohort to those from the 1980 cohort. In a study with Korean children, Min et al. (2008b) observed that height and total arm length decreased significantly with increasing blood Pb in multivariate adjusted regression models. A statistically nonsignificant decrease in body weight was observed with increasing blood Pb while no effect on BMI was reported. In a study of children in Sardinia Italy, Sanna and Vallascas (2011) measured Pb in hair at three points in time (1997, 2002, and 2007) and reported cross-sectional results from regression analyses for each of these time periods. Pb in hair decreased over time and significant associations of Pb in hair with height were observed only in earlier time periods when hair Pb levels were relatively high. However, Pb in hair samples is not a well-characterized biomarker (see Chapter 4 and Section 4.3.4.2).

Contrary to the results summarized above, several cross-sectional studies do not observe associations between blood Pb levels and impaired growth. In a study with a similar design, Zailina et al. (2008) studied the relationship of blood Pb and height in 7 year-old Malaysian school children comparing those attending two schools in an urban setting to those attending a school near an industrial area. After adjustment for age no statistically significant associations between concurrent blood Pb and physical development were observed. Tomoum et al. (2010) investigated the association between blood Pb and height in pubertal children in Cairo, Egypt. Neither boys nor girls with concurrent blood Pb levels >10 µg/dL differed significantly in height or weight when compared to those with blood Pb <10 µg/dL. In a simple correlation analysis of children aged 5-9 years in Colombia, Olivero-Verbel et al. (2007) reported that concurrent blood Pb levels were negatively associated with body size ($r = -0.224$, $p < 0.002$). However, when a partial correlation analysis was performed controlling for age, the association between blood Pb and body size was no longer statistically significant. In a study of school children in China, chest and head circumference were found to differ between high (>10µg/dL) and low concurrent blood Pb level groups; however, the direction of the difference was not consistent (Liu et al., 2011b). Among girls, in comparison of those with high and low blood Pb levels, a reduction in head circumference was observed. Among children greater than 6 years of age, those with higher blood Pb levels were reported to have greater head and chest circumferences. In a study of children aged 7-11 years and living in an area of Iran with or without Pb smelters, age-standardized weight and height did not vary by study area (Mahram et al., 2007).

Evidence from previous toxicological studies has shown an association between gestational Pb exposure and impaired postnatal growth (U.S. EPA, 2006b). Recent toxicological studies report significant changes in postnatal or adult body weight after Pb

exposure during different developmental windows. Masso-Gonzalez and Antonio-Garcia (2009) found Pb-induced decreased body weights at weaning (PND21) in rat pups from dams exposed to Pb during pregnancy and lactation (drinking water, 300 mg/L). Blood Pb level in the control group was 1.43 µg/dL, in the Pb group it was 22.8 µg/dL. Dong et al. (2009) reported decreased body weight in adult Kunming mice after exposure to 6,000 ppm Pb acetate in drinking water for 8 weeks. In contrast, Leasure et al. (2008) reported a statistically significant inverse relationship between Pb exposure and body weight for male mice exposed to lower (27 ppm), moderate (55 ppm) and higher levels (109 ppm) levels of Pb during gestation and lactation (dam drinking water, 2 weeks before mating, through gestation and to PND10) with those exposed to the lowest dose having the highest adult body weight among the overweight Pb-exposed animals. Male mice exposed to the lower and higher Pb concentrations during gestation were 26% and 13% heavier than were controls at 1 year of age, respectively. In this study, dams were administered 27 ppm (low), 55 ppm (moderate), and 109 ppm (high) Pb in drinking water beginning which resulted in respective blood Pb levels from 10 µg/dL or less in the low-exposure offspring to 42 µg/dL in the high-exposure offspring at PND10. Leasure et al. (2008) also exposed a separate group of mice to Pb only during the postnatal period (PND0-PND21, lactation only exposure) and mice exposed to the same aforementioned low or high dose of Pb did not exhibit a difference in body weight when compared to control offspring. Wang et al. (2009e) observed a statistically significant decrease in fetal body weight and body length of Wistar rats at GD20 after maternal exposure to 250 ppm Pb acetate during gestation days 1-10, 11-20, or 1-20. Also, associations were reported between elevated maternal blood Pb levels (0.6, 1.3, or 1.74 µM, respectively or ~12.4, 26.9, or 36.0 µg/dL, respectively) compared to control (0.04 µM or ~0.83 µg/dL) decreased pup body length, and placental weight in Wistar rats at GD20. The greatest decrease in fetal body weight and length was observed in the group exposed to Pb during gestation days 1-20 followed by the group exposed to Pb during gestation days 11-20. Teijón et al. (2006) observed reductions in birthweight of litters administered 200 ppm or 400 ppm Pb acetate in drinking water (Wistar rats, Pb to dams from GD1 through lactation to 1 and 3 months postweaning to pups), but found that this effect did not persist in the postnatal growth of the rats.

Notably, previous toxicological studies observed reductions in postnatal weight as well as birth weight after exposure to Pb, albeit often at higher concentrations of Pb exposure. Ronis et al. (2001; 1998a; 1998b; 1996) have published a series of papers exposing rats to Pb over different developmental windows, showing associations between Pb exposure and deficits in growth. Sprague-Dawley rats with lifetime Pb exposure to 6,000 ppm Pb acetate in drinking water (gestational-termination of experiment Pb exposure, maximum blood Pb of 316 µg/dL in males and 264 µg/dL in females) had sex-independent pre-pubertal growth suppression, male-specific suppression of pubertal

growth and loss of growth effects postnatally but still maintained an overall decreased body size out to PND60 due to earlier deficits. In a follow up study using the same exposure duration with a dose of 4,500 ppm Pb acetate (resulting in blood Pb of 263 µg/dL at PND85) yielded the same results (Ronis et al., 1996) with mechanistic insight showing decrements in insulin-like growth factor 1 (IGF1) accompanying the decreases in growth rates.

In summary, the body of toxicological literature on postnatal growth with Pb exposure indicates that Pb exposure can induce decrements in both height/body length and BW that may be persistent and differ by sex. However, findings from epidemiologic studies of postnatal growth are not consistent. Many of these studies were limited by their cross-sectional design. A few studies used longitudinal cohorts and controlled for multiple potential confounders, such as parity, but the results of these studies are inconsistent. Animal toxicology studies give insight to mechanistic changes that may contribute to this Pb-induced decrement and to the windows of exposure that may contribute greatest to these decrements.

5.8.2 Toxicological Studies of Other Developmental Effects

5.8.2.1 Developmental Effects on Blood and Liver

The 1986 and 2006 Pb AQCDs [(U.S. EPA, 1986b) and (U.S. EPA, 2006b)] reported studies that suggest Pb may alter hematopoietic and hepatic function during development. Some recent studies provide evidence that support these findings; however recent results are not consistent among the studies.

Massó et al. (2007) reported a decrease in liver weights of pups born to dams that consumed 300 mg/L Pb in drinking water during gestation and lactation. They also reported an increase in the number of erythrocytes; however the erythrocyte size was diminished by 62%. Pb produced microcytic anemia as evidenced by decreased hemoglobin content and hematocrit values without changes in mean corpuscular hemoglobin (MCH) concentration. Alkaline phosphatase (ALP) activity, CAT activity, or thiobarbituric acid reactive substances (TBARS) production did not change in pups at postnatal 0, but increased statistically significantly by PND21 indicating reactive oxygen generation. No change in acid phosphatase (ACP) activity was observed in the livers of pups at PND0 or PND21.

Massó-González and Antonia-García (2009) reported normochromic and microcytic anemia and a significant decrease in hematocrit values and blood δ-aminolevulinic acid dehydratase (ALAD) activity (90% reduction) in pups from dams administered 300 mg/L Pb acetate in drinking water during gestation. The authors also reported that erythrocyte osmotic fragility was four times greater in Pb-exposed pups than in control pups. Massó-González and Antonia-García (2009) reported increases in TBARS and CAT activity in the liver after Pb exposure. Intoxication with Pb also resulted in decreased liver protein concentrations and Mn-dependent SOD activity. Abnormalities in liver function were further exemplified by increases in liver concentrations of ALP and ACP.

Teijón et al. (2006) observed that gestational exposure to Pb caused a decrease in erythrocytes, hemoglobin, and MCH at weaning; however, by 1 and 3 months postweaning, these parameters had returned to normal values. The authors observed a slight increase in serum ALP, alanine aminotransferase (ALT), and aspartate aminotransferase (AST) levels after Pb exposure in the absence of liver histological changes.

Pb-induced effects on SOD activity in the liver of fetuses after Pb intoxication was supported by a study by Uzbekov et al. (2007). The authors reported an initial increase in SOD activity in livers of pups exposed to 0.3 mg/L and 3.0 mg/L Pb nitrate in drinking water during gestation for 1 month (mean daily consumption 27 µg/kg). In contrast, long-term exposure (5 months) to the same concentrations of Pb nitrate concentration during gestation resulted in decreased hepatic SOD activity.

Effects on hepatic Phase I and Phase II enzymes after early developmental exposure of offspring to Pb during gestation and lactation was evaluated by Pillai et al. (2009). In the study, pregnant Charles Foster rats were administered 0.05 mg/kg body weight Pb subcutaneously throughout gestation until PND21. Pups were evaluated on PND56. Results of the study show that Phase I xenobiotic-metabolizing enzymes (NADPH- and NADH cytochrome c reductase) and Phase II xenobiotic- and steroid-metabolizing enzymes (δ-glutamyl transpeptidase, UDPGT, glutathione-s-transferase, and 17β-hydroxysteroid oxidoreductase) were reduced in both male and female pups by PND56. Only inhibition in glutathione-s-transferase and 17β-hydroxysteroid oxidoreductase activities demonstrated a sex-specific pattern (glutathione-s-transferase inhibition in males; 17β-hydroxysteroid oxidoreductase inhibition greater in females). Observed Pb-induced histological changes included massive fatty degeneration in hepatocytes, large vacuoles in cytoplasm, appearance of pyknotic nuclei, and infiltration of lymphocytes in the liver. Activities of antioxidant enzymes (SOD, CAT, glutathione peroxidase, and glutathione reductase) were also reduced after Pb intoxication. Alterations in biochemical parameters included decreased DNA, RNA, and cholesterol

content, although it was not clear whether these changes were related to genetic expression of xenobiotic-metabolizing enzymes or changes in steroid hormone homeostasis.

5.8.2.2 Developmental Effects on Skin

The 2006 Pb AQCD (U.S. EPA, 2006b) reported a study that demonstrated Pb-induced abnormalities in skin development. No current studies were identified that addressed Pb-induced skin alterations.

5.8.2.3 Developmental Effects on the Retina

The 2006 Pb AQCD (U.S. EPA, 2006b) concluded that Pb exposure during early postnatal development (resulting in blood Pb levels ~20 µg/dL) impaired retinal development in female Long-Evans hooded rats. A more recent study (Fox et al., 2008) exposed female Long-Evans hooded rats to low (27 ppm), moderate (55 ppm), and high (109 ppm) levels of Pb acetate in drinking water beginning 2 weeks before mating, throughout gestation, and until PND10. Blood Pb levels measured in these pups on postnatal days 0-10 were 10-12 µg/dL (low), 21-24 µg/dL (moderate), and 40-46 µg/dL (high). Results of the study demonstrated supernormal persistent rod photoreceptor-mediated (scotopic) electroretinograms (ERGs) [(Fox et al., 2008), and Table 5-13] in adult rats similar to ERG findings in male and female children in association with maternal first trimester blood Pb levels 10.5-32 µg/dL [(Rothenberg et al., 2002b), and Table 5-13]. In rats, low- and moderate-levels of Pb increased neurogenesis of rod photoreceptors and rod bipolar cells without affecting Müller glial cells and statistically significantly increased the number of rods in central and peripheral retina. High-level Pb exposure (109 ppm) statistically significantly decreased the number of rods in central and peripheral retina. Pb-exposure induced concentration-dependent decreases in adult rat retinal dopamine synthesis and utilization/release.

5.8.2.4 Developmental Effects on Teeth

Pb has been associated with multiple health effects including dental caries, however, there is very limited information available on the temporal and spatial incorporation of Pb in dental tissue (Arora et al., 2005). Arora et al. (2005) demonstrated that Wistar rat pups exposed to Pb during gestation and lactation (40 mg/L of Pb nitrate in drinking water of pregnant dams) had higher concentrations of Pb on the surface of enamel and in the

dentine immediately adjacent to the pulp. The authors concluded that additional research is needed on the intracellular uptake of Pb during tooth development to fully understand the spatial distribution of Pb in teeth.

5.8.3 Effects on Birth Outcomes

The 2006 Pb AQCD reported on multiple studies of adverse birth outcomes such as, fetal mortality, birth defects, preterm birth, and low birth weight/fetal growth (U.S. EPA, 2006b). The toxicological studies reviewed in the 2006 Pb AQCD concluded that Pb exposure can increase fetal mortality and produce sublethal effects, smaller litters, and fewer implantation sites. Epidemiologic studies using occupational histories reported the possibility of small associations between increased Pb exposure and birth defects, and toxicological studies demonstrated associations between exposure to high doses of Pb and increased incidences of teratogenic effects in experimental animals. Epidemiologic studies on preterm birth and low birth weight/fetal growth included in the 2006 Pb AQCD reported inconsistent findings. Evidence from previous toxicological studies has shown an association between gestational Pb exposure and reduced birth weight and decreased litter size or number of pups. Continued research on adverse birth outcomes is described in the sections that follow.

5.8.3.1 Infant Mortality and Embryogenesis

No recent epidemiologic or toxicological studies have reported on the relationship between Pb levels and infant mortality. The 2006 Pb AQCD (U.S. EPA, 2006b) concluded that Pb exposure can increase fetal mortality and produce sublethal effects (disrupt growth and development) in offspring of Pb exposed dams at concentrations that do not result in clinical toxicity to the dams by disrupting implantation and pregnancy, particularly at the blastocyst stage of development. In rodent studies gestational exposure to Pb (blood Pb levels 32 to >70 μg/dL) resulted in smaller litters and fewer implantation sites and in non-human primates pre- and perinatal mortality was reported in squirrel monkeys exposed to Pb (mean dam blood Pb level of 54 μg/dL) in the last two-thirds of gestation (U.S. EPA, 2006b). There is substantial evidence to show that there is no apparent maternal-fetal barrier to Pb and it can easily cross the placenta and accumulate in fetal tissue during gestation (Pillai et al., 2009; Wang et al., 2009e; Uzbekov et al., 2007).

5.8.3.2 Birth Defects

The 2006 Pb AQCD (U.S. EPA, 2006b) reported the possibility of small associations between high Pb exposure and birth defects, but many of the epidemiologic studies used occupational histories instead of actual measures of blood Pb levels. Among the studies included in the 2006 Pb AQCD, a couple reported associations between parental exposure to Pb and neural tube defects (Irgens et al., 1998; Bound et al., 1997). Recent studies also examined indicators of Pb exposure and neural tube defects (Table 5-40). No other recent epidemiologic studies of Pb exposure and birth defects were identified in the literature. No recent toxicological studies were found that investigated Pb-induced changes in morphology, teratology effects, or skeletal malformations of developing fetuses as a result of maternal Pb exposure; however, in the 2006 Pb AQCD toxicological studies demonstrated associations between exposure to high doses of Pb and increased incidences of teratogenic effect in experimental animals.

Table 5-40 Summary of recent epidemiologic studies of associations between Pb levels and neural tube defects.

Reference (Presented in order of appearance in the text)	Study Location	Study Population	Methodological Details	Pb Biomarkers and Exposure Measurement	Mean Pb (SD) in µg/dL	Adjusted Effect Estimates	Potential Confounders Adjusted for in Analysis
Zeyrek et al. (2009)	Turkey NS	Infants with gestational age of at least 20 weeks N_{NTD}=74 $N_{controls}$=70	Case-control study using Student's t-test and Mann-Whitney U-test	Maternal and umbilical cord blood Pb taken 0.5h after birth	Cases: Maternal: 15.5 (15.0) Umbilical cord: 18.2 (17.8) Controls: Maternal: 12.5 (12.7) Umbilical cord: 16.5 (16.1)	P-values for differences of Student's t-test or Mann-Whitney U test (dependent on distribution) were 0.35 for maternal blood Pb and 0.63 for umbilical cord blood Pb	N/A
Brender et al. (2006)	Texas 1995-2000	Infants of Mexican-American women N_{NTD}=184 $N_{controls}$=225	Case-control study using logistic regression	Maternal blood Pb taken 5-6 weeks post-partum	Cases: 2.4 (1.9) Controls: 2.5 (1.6)	OR (95% CI): Blood Pb<6.0 µg/dL: 1.0 (Ref) Blood Pb≥ 6.0 µg/dL: 1.5 (0.6, 4.3)	Inclusion of breast feeding in the model changed the OR (95% CI) to 3.8 (0.8, 19.5)
Huang et al. (2011b)	China 2002-2004	Live and still births of women living in the study area (villages in the Lvliang region of Shanxi province) N=112 villages	Ecologic	2 soil samples from each village	56.14 µg/g (11.43 µg/g)	N/A	

Among the recent epidemiologic studies (described in Table 5-40), a study of women in Turkey detected no difference between the blood Pb of mothers or the umbilical cord blood Pb of the newborns for healthy infants compared with infants with neural tube defects (cases of spina bifida occulta were excluded, but other forms of spina bifida were included) (Zeyrek et al., 2009). Brender et al. (2006) performed a study of Mexican-American women living in Texas. Measurements were taken 5-6 weeks postpartum, which is a limitation of this study because the blood Pb levels may be different from those during the developmental period of gestation. The OR comparing women with at least 6 µg/dL blood Pb to those with less than 6 µg/dL blood Pb was 1.5 (95% CI: 0.6, 4.3). This increased after adjusting for breast feeding, although this variable was not a confounder because it cannot be associated with neural tube defects. For these women, neither occupational exposure to Pb nor proximity of residence to a facility with Pb air emissions at the time of conception was associated with increased odds of neural tube

defects. A study with an ecologic design was performed in China and did not use individual-level biomarkers to determine Pb levels (Huang et al., 2011b). A positive association between Pb levels in soil samples and neural tube defects was reported. Exposure to multiple other trace elements also demonstrated a positive association but no control for co-exposures was included in the models for Pb.

In summary, previous studies included in the 2006 Pb AQCD observed associations between Pb and neural tube defects but were limited due to the lack of biologically measured Pb [Pb was measured in drinking water (Bound et al., 1997) and estimated from occupational reports (Irgens et al., 1998)]. A recent ecologic study reported an association between Pb in the soil and neural tube defects but was also limited by its lack of biological samples, as well as a lack of individual-level data and the prevalence of several other metals (Huang et al., 2011b). Other recent epidemiologic studies of maternal blood Pb levels and neural tube defects observed no statistically significant associations (Zeyrek et al., 2009; Brender et al., 2006). These studies also have limitations, including the timing of Pb measurements and lack of control for potential confounders.

5.8.3.3 Preterm Birth

Epidemiologic studies on preterm birth included in the 2006 Pb AQCD (U.S. EPA, 2006b) reported inconsistent findings regarding the relationship between Pb and gestational age. Recent studies examined this potential association and again mixed results were reported (Table 5-41). Of these studies, the ones that categorized births as preterm or term all defined preterm birth as less than 37 weeks of gestation. One limitation to note for these studies is that if Pb affects spontaneous abortion and length of gestation via a similar pathway, then the studies that only collect data at delivery and not at earlier stages of pregnancy would be biased toward the null.

Table 5-41 Summary of recent epidemiologic studies of associations between Pb levels and preterm birth.

In a study taking place in California, women with information on blood Pb levels during pregnancy based on their participation in a surveillance program (reason for participation in the surveillance program was unknown but the authors speculate it was likely because of potential Pb exposure due to occupational or environmental exposures or a family member was identified as exposed to Pb) were matched with the birth certificates of their infants (Jelliffe-Pawlowski et al., 2006). Almost 70% of women had maximum blood Pb measurements <10 µg/dL with the majority being <5 µg/dL. Preterm birth was associated with higher blood Pb when comparing women with maximum pregnancy blood Pb levels ≥ 10 µg/dL to women with blood Pb levels <10 µg/dL in adjusted analyses. In analyses of maximum Pb levels further refined into additional categories, the odds of preterm birth were elevated among women with maximum blood Pb measurement ≥ 20 µg/dL compared with women with maximum blood Pb levels ≤ 5 µg/dL. A study in Iran also reported higher maternal blood Pb for preterm births than for term births (Vigeh et al., 2011). The women in this study had lower blood Pb levels than did those observed in the Jelliffe-Pawlowski et al. (2006). Higher maternal blood Pb level was associated with higher odds of preterm birth. Another study examining blood Pb and gestational age among women with lower blood Pb levels reported an inverse association between maternal blood Pb concentration and gestational age, especially for blood Pb levels early in pregnancy (Cantonwine et al., 2010a). However, a study conducted in New York among women with lower blood Pb levels (inclusion criteria mandated that blood Pb levels be less than 10 µg/dL), no association was observed between blood Pb levels and preterm birth (Zhu et al., 2010). Similarly, a study of maternal and paternal blood Pb concentrations reported no association between maternal or paternal blood Pb levels and preterm birth (Chen et al., 2006a).

In another study, measurements of umbilical cord blood were taken after birth at a hospital in Nagpur, India (Patel and Prabhu, 2009). A sample of women had their blood Pb measured and among this sample, maternal blood Pb was correlated with the umbilical cord Pb levels. Mean gestational age differed between infants with >5 µg/dL cord blood Pb and infants with ≤ 5 µg/dL cord blood Pb. In a linear regression model, gestational age was found to decrease with increasing umbilical cord Pb levels. A study of women in Tennessee consisted primarily of African American women living in an urban setting (Jones et al., 2010). The mean level of umbilical cord blood Pb was slightly higher among infants born preterm but the difference was not statistically significant. Using umbilical cord blood Pb measures, a study reported no association between cord blood Pb levels and gestational age. The concentrations of cord blood Pb among study participants were overall low (99.3% had umbilical cord blood Pb ≤ 5 µg/dL) (Wells et al., 2011a).

A study of preterm birth included women living in two different residential areas over three different time periods (Berkowitz et al., 2006). One residential area had consistently lower exposures but the other had a period of high Pb emissions due to damage at a local factory (Pb measured in ambient air was up to 30 μg/m^3). Preterm birth rates were examined during three time periods: before, during, and after the time of higher Pb exposure. No association was observed between women living in the high exposure area compared to those in the low exposure area during any of the exposure time periods, but the number of preterm infants born during the period of higher exposure was small.

A study of breast milk in the second month postpartum reported no difference in breast milk Pb levels for those infants born preterm or term; however, a limitation of this study is that Pb levels were not measured until two months after the birth (Örün et al., 2011).

In summary, as in the 2006 Pb AQCD, (U.S. EPA, 2006b) recent epidemiologic studies report inconsistent findings for a relationship between indicators of Pb exposure and preterm birth. No patterns were apparent within type of exposure measurement or Pb level. Many of these studies are limited by the small number of preterm births and their cross-sectional design (i.e., studies of umbilical cord blood may not adequately characterized blood Pb levels earlier in pregnancy).A few studies utilized a longitudinal cohort design (Vigeh et al., 2011; Cantonwine et al., 2010a; Chen et al., 2006a; Jelliffe-Pawlowski et al., 2006), and although results among these studies were mixed some did report an association between maternal blood Pb during pregnancy and preterm birth. Most studies controlled for important confounders, such as maternal age and smoking.

5.8.3.4 Low Birth Weight/Fetal Growth

The 2006 Pb AQCD reported inconsistent epidemiologic study results for the associations between Pb and birth weight/fetal growth but concluded that there could be a small effect of Pb exposure on birth weight and fetal growth (U.S. EPA, 2006b). Since then, multiple epidemiologic studies on the relationship between Pb exposure and birth weight and fetal growth have been published using various measures of exposure, such as air levels, umbilical cord blood, and maternal blood and bone. These studies are summarized in Table 5-42 below (organized in the text and table by the type of Pb measurement and then by study design). Additionally, there have been a few recent toxicological studies evaluating the effect of Pb exposure during gestation on birth weight.

Table 5-42 Summary of recent epidemiologic studies of associations between Pb levels and low birth weight and fetal growth.

Multiple studies were conducted that examined the association between maternal blood Pb and birth weight/fetal growth. A study in Vienna, Austria reported an inverse association between maternal blood Pb levels and birth weight but no associations for birth length or head circumference (Gundacker et al., 2010). Similarly, increased maternal blood Pb was associated with decreased birth weight among infants in a study performed in New York (Zhu et al., 2010). No association was observed between maternal blood Pb levels and SGA. A study in Taiwan examined both maternal and paternal blood Pb levels among those occupationally exposed to Pb and their associations with birth weight and SGA (Chen et al., 2006a). Paternal blood Pb levels were not associated with increased risk of low birth weight or SGA. Higher maternal blood Pb concentration was associated with higher risk of low birth weight and SGA, although not all of the associations were statistically significant. There were small numbers of infants with low birth weight or SGA, especially at the highest blood Pb levels (≥ 20 µg/dL). In California, blood Pb measurements of women during pregnancy were matched with the corresponding birth certificates (Jelliffe-Pawlowski et al., 2006). The adjusted OR for low birth weight that compared women with blood Pb levels ≥ 10 µg/dL to women with levels <10 µg/dL was elevated. However, it was difficult to draw conclusions about the relationship between blood Pb and birth weight due to small numbers (n = 9 for low birth weight) and the subsequently wide 95% CI. An association was detected for increased blood Pb and having an infant who was small for his/her gestational age (SGA). Women residing in two different towns in Yugoslavia (one with a Pb smelter and one without a Pb smelter) were recruited during their first prenatal visit (Lamb et al., 2008) (study based on previous work by Factor-Litvak et al. (1991)). The mid-pregnancy blood Pb levels were greater in women from the town with a Pb smelter. No association was reported between maternal blood Pb and height or BMI at birth for the infants of these women despite the differences in maternal blood Pb between the two towns. A study of term births in Iran reported no difference in blood Pb levels of women giving birth to a normal weight infant and women giving birth to an infant with low birth weight (Iranpour et al., 2007).

A study examining the association between Pb biomarker levels and birth weight used tibia bone measurements one month post-partum from mothers living in Mexico City (Kordas et al., 2009). Tibia Pb levels were inversely associated with birth weight but not with birth length. This association between Pb and birth weight was not modified by maternal folate consumption or maternal or infant MTHFR genotype, although the association between tibia Pb levels and birth weight was greater in magnitude among women with certain MTHFR SNPs (statistical tests not reported). Another study in Mexico City reported no association between maternal tibia Pb levels and birth weight among girls but reported a positive association for boys (Afeiche et al., 2011). No associations were observed with maternal patella Pb concentration, although among boys,

the relationship was positive but not statistically significant. One of the cohorts used by Afeiche et al. (2011) was also evaluated in another study (Cantonwine et al., 2010b). An inverse association was observed between tibia Pb and birth weight, especially at higher levels (over 15.4 µg/dL). This association was stronger among those mothers with variants of the hemochromatosis iron gene (HFE).

Multiple studies examined the relationship between Pb level and birth weight using Pb measured from the placenta or umbilical cord. A study performed in Baltimore, MD reported no association between umbilical cord blood Pb concentration and birth weight (Wells et al., 2011a). This study had low blood Pb levels, with only 0.7% of participants having umbilical cord blood Pb measuring >5 µg/dL. In Saudi Arabia, a study was conducted among non-occupationally exposed women (Al-Saleh et al., 2008b). Umbilical cord blood Pb concentrations were low and an association was observed between umbilical cord Pb and head circumference. A study with high Pb concentrations in umbilical cord blood reported an inverse association between Pb levels and birth weight (Atabek et al., 2007). However, no correlation was detected in an analysis restricted to umbilical cord Pb less than 10 µg/dL. No associations with other measures of growth, such as birth length and mid-arm circumference, were detected. Researchers in Chile collected the placentas from term births and compared the Pb levels for those born with normal birth weights to those with low birth weights (Llanos and Ronco, 2009). Pb levels were greater in the placentas of infants with low birth weights. In addition, the authors note that 3 low birth weight infants had extremely high Pb levels in the placentas (>1.5 µg/g) and were excluded from these analyses. A study in Brazil examined Pb levels in umbilical cord blood from term births of women residing within 5 km of a Pb smelter (Zentner et al., 2006). The cord blood Pb level was found to be inversely correlated with length and weight of the infants. Another study recruited women in Pakistan (Janjua et al., 2009). Umbilical cord blood Pb levels were not associated with low birth weight. The study by Iranpour et al. (2007) discussed above investigated the association with umbilical cord blood Pb levels in addition to their examination of maternal whole blood Pb. They again report no difference in levels between term infants of normal and low birth weight. A study comparing geometric mean umbilical cord blood Pb levels reported no difference in the levels for normal and low birth weight infants born to women living primarily in urban areas of Memphis, TN (Jones et al., 2010). A study previously mentioned that observed an inverse association between maternal tibia Pb and birth weight in Mexico City reported no association between umbilical cord blood Pb concentration and birth weight (Cantonwine et al., 2010b). Finally, a study in Vienna measured Pb in the placenta (Gundacker et al., 2010). A positive correlation was observed between placenta Pb and birth length and weight; however, in the same study, maternal blood Pb was inversely related to birth weight.

A study performed in Turkey examined the relationship between Pb levels in breast milk two months postpartum and size at birth (Örün et al., 2011). No association was observed between breast milk Pb concentration and birth weight or head circumference.

A few studies examined air exposures and reported inverse associations between air Pb concentrations and birth weight. However, a limitation of these studies is the difficulty in assessing if the measured concentrations represent population exposures (see Section 3.5.3). Williams et al. (2007) examined Pb concentrations in the air during the first trimester. The purpose of their study was to demonstrate the use of hierarchical linear models and they used the example of air pollution and birth weight in Tennessee. The model results showed an association between ambient Pb concentration and birth weight, with an estimated decrease in birth weight of 38 grams for every 0.04 $\mu g/m^3$ (i.e., one standard deviation) increase in Pb concentration. Another study of air Pb levels was conducted in Idaho and included two areas over three time periods. One study area was affected by damage to a local factory that led to high Pb emissions during one of the time periods under study (Berkowitz et al., 2006). During the time of the fire, estimates of Pb in ambient air were as high as 30 $\mu g/m^3$. Mean birth weight for term births was decreased among infants born to women living in the high exposure area during the period of high exposure compared to those living in the lower exposure area. The difference in birth weight of term births remained, but was reduced, between the two areas during the time period after the exposure ended. During the period of higher exposure, the odds of low birth weight among term births was increased among those living in the higher exposed area compared to those in the lower exposed area, but the odds were not different between the two study areas during the time periods before or after the high level of exposure. An increase in SGA infants (defined as infants with weights less than or equal to the lowest 5th percentile of birth weight for their sex and age) was also associated with living in the higher exposed area during the time period of higher exposure. The odds of SGA infants decreased during the time period after the exposure but the odds were still elevated compared to those residing in the lower exposed area.

Evidence from previous toxicological studies has shown an association between gestational Pb exposure and reduced birth weight (U.S. EPA, 2006b). More recent studies have reported conflicting results. Wang et al. (2009e) demonstrated a statistically significant decrease in fetal body weight and body length of Wistar rats after maternal exposure to 250 ppm Pb acetate during gestation days 1-10, 11-20, or 1-20. The greatest decrease in fetal body weight and length was observed in the group exposed to Pb during gestation days 1-20 followed by the group exposed to Pb during gestation days 11-20. Teijón et al. (2006) observed that when pregnant dams were administered 200 ppm or 400 ppm Pb acetate in drinking water, litter weight was significantly decreased (400 ppm

Pb only) versus controls due to significant decrements in female pup birth weight; male birth weight was unaffected. The results of these studies indicate that as Pb exposure increases, the body weight of exposed offspring decreases. Massó-González and Antonia-García (2009) also observed an 8-20% decrease in body weight of pups from rat dams given 300 mg/L Pb acetate in drinking water (exposure during gestation and lactation resulting in mean blood Pb level of 22.8 µg/dL), but no changes in body length were reported.

In summary, associations were observed between Pb and low birth weight in epidemiologic studies of maternal bone Pb and studies of Pb air exposures and birth weight. The associations were less consistent when using maternal blood Pb or umbilical cord and placenta Pb as the exposure measurement although some studies did demonstrate associations. Epidemiologic studies of Pb and fetal growth face multiple limitations. One limitation is the cross-sectional nature of many studies. These do not allow an understanding of the temporality for Pb and fetal growth. In addition, some studies suffer from small sample size. The studies of air Pb levels and birth weight demonstrate positive associations but are limited in that individual exposure levels are unknown. Also, many of the studies controlled for important confounders, such as parity and gestational age, but adjustment in some studies was lacking. Previous toxicological studies observed an association between gestational Pb exposure and reduced birth weight with moderate to high dose Pb.

5.8.4 Effects on Male Reproductive Function

The 2006 Pb AQCD (U.S. EPA, 2006b) reported on male Pb exposure or biomarker levels and reproductive functions in males as measured by sperm count/motility/morphology, time to pregnancy, reproductive history, and chromosomal aberrations. Despite limitations, most of the studies found slight associations between high blood Pb levels (i.e., ≥ 45 µg/dL) and reduced male fecundity or fertility (U.S. EPA, 2006b). Evidence reviewed in the 1986 Pb AQCD (U.S. EPA, 1986a) also demonstrated that Pb exposure affects male reproductive function in humans and experimental animals. Recently published research has continued to support an association between Pb and sperm/semen production, quality, and function. Studies of Pb and male reproductive function are described in the sections below.

5.8.4.1 Effects on Sperm/Semen Production, Quality, and Function

Multiple epidemiologic and toxicological studies have examined the relationship between Pb and sperm and semen production, quality, and function. These studies are summarized in the text below. In addition, recent epidemiologic studies are included in Table 5-43. All epidemiologic studies were cross-sectional with concurrent measurements of Pb levels in biological samples and sperm-related outcomes.

Table 5-43 Summary of recent epidemiologic studies of associations between Pb levels and effects on sperm and semen.

Mendiola et al. (2011)	Spain 2005-2007	Men attending infertility clinics and classified as either normal sperm (controls) or oligo-astheno-teratozoospermia (cases) based on WHO semen quality criteria $N_{controls}$=31 N_{cases}=30	Case-control study using multiple linear regression	Seminal plasma Pb Blood Pb	Seminal plasma: 2.90 (IQR 2.70, 3.20) Whole blood: 9.50 (IQR 7.50, 11.90) Blood plasma: 2.90 (IQR 2.70, 3.10) Cases: Seminal plasma: 3.0 (0.3) Whole blood: 9.8 (2.3) Blood plasma: 2.9 (0.2) Controls: Seminal plasma: 2.9 (0.3) Whole blood: 9.7 (2.3) Blood plasma: 2.9 (0.3)	β (95% CI) Sperm concentration Seminal plasma: -1.0 (-3.1, 2.3) Whole blood: -0.2 (-1.7, 1.6) Blood plasma: 0.08 (-4.1, 5.2) % Immotile sperm Seminal plasma: 1.5 (0.37, 1.9) Whole blood: 0.05 (-0.32, 0.43) Blood plasma: -0.49 (-1.8, 0.62) % Morphologically normal sperm Seminal plasma: -0.54 (-3.1, 2.0) Whole blood: -0.31 (-1.5, 0.89) Blood plasma: -0.08 (-3.5, 3.4) *Units not given (assume 1 µg/dL) Note: No correlation in Pb levels among bloods or seminal plasma. There was correlation between Pb and other metals (Cd and Hg) within each body fluid. Other metals were not controlled for in models	Age, BMI, number of cigarettes/day

International epidemiologic studies of men occupationally exposed to Pb have reported on associations between Pb exposure or biomarker levels and sperm count and quality and semen quality. In most of these occupational studies, mean blood Pb levels over 40 µg/dL have been reported for individuals occupationally exposed to Pb. In addition, they did not control for other potential occupational exposures. A study performed in Taiwan among men with high levels of blood Pb reported that men with higher blood Pb levels had increased sperm head abnormalities, increased sperm DNA denaturation, and increased sensitivity to denaturation compared to men with lower blood Pb levels (Hsu et al., 2009b). No difference was detected between three Pb exposure groups and semen volume, sperm count, motility, velocity, and reactive oxygen species production. A similar study in Poland included employees exposed to Pb and compared them with a group of male office workers (Kasperczyk et al., 2008). Pb levels measured in seminal fluid were slightly higher among those in the exposed groups although they were not statistically different from the levels in the control group. No difference was observed for semen volume, sperm count, or sperm morphology among the groups. Sperm motility was lower in the highest exposure group compared to both the control and moderate exposure groups. Lipid peroxidation, which can induce tissue damage in sperm via reactive oxygen species, was greater in the highest exposure group compared to the controls. Studies performed in India (Naha and Manna, 2007; Naha and Chowdhury, 2006) reported that men in the highest exposure group (men working in battery or paint manufacturing plants for 10-15 years for 8 hours/day) had mean blood Pb levels of 77.22 µg/dL (Naha and Chowdhury, 2006) and 68.26 µg/dL (Naha and Manna, 2007). Control groups in these studies (those without occupational Pb exposure) had mean blood Pb levels below 15 µg/dL. Increases in levels of Pb in semen were also noted across exposure groups. Both studies report decreases in sperm count and in sperm velocity and motility with increasing Pb exposure. Higher Pb exposure was also associated with greater hyploidy of sperm DNA and morphologic abnormalities (Naha and Manna, 2007; Naha and Chowdhury, 2006). Decreased viability and increased lipid peroxidation were detected (Naha and Chowdhury, 2006).

A few studies examined blood or seminal plasma Pb levels and semen quality of men at infertility clinics (Mendiola et al., 2011; Slivkova et al., 2009; Meeker et al., 2008) (Telisman et al., 2007). In general, these men had lower levels of Pb biomarkers than men who were occupationally exposed, but the studies are limited by the strong possibility of selection bias related to the recruitment of men attending infertility clinics. A study performed in Croatia recruited men attending a clinic for infertility examination or to donate semen for use in artificial inseminations, who had never been occupationally exposed to metals and therefore had lower blood Pb levels than the occupational studies (although leaded gasoline was still sold during the study period) (Telisman et al., 2007). Increased blood Pb was associated with increased percentages of pathologic sperm, wide

sperm, and round sperm. There was also a slight increase in immature sperm although it was not statistically significant. Similar results were seen when other biomarkers for Pb (erythrocyte protoporphyrin and δ-aminolevulinic acid dehydratase [ALAD]) were used instead. This study controlled for multiple potential confounders, including other metals. Meeker et al. (2008) detected no associations between higher blood Pb and semen concentration, morphology, or motility (although a slight positive trend was observed between higher Pb levels and motility in unadjusted models). In models that include multiple metals, blood Pb was associated with being below the WHO limit of sperm concentration levels (less than 20 million sperm/mL), although the 95% CI: was wide for the 4th quartile of Pb levels and included the null. The precision of estimates in this study was extremely low. Slivkova et al. (2009) reported a negative correlation between semen Pb and pathological changes in sperm (specifically, flagellum ball), but no correlations were observed for other alterations in the sperm. Another study reported a positive association between seminal plasma Pb concentration and percentage of immotile sperm, but this analysis did not adjust for exposure to other metals reported to be correlated with Pb concentration in the seminal plasma (Mendiola et al., 2011). No association was observed for seminal plasma Pb concentration and sperm concentration or percentage of morphologically normal sperm. Additionally, neither Pb levels in whole blood nor plasma were associated with sperm concentration, percentage of immotile sperm, or percentage of morphologically normal sperm.

Extensive evidence in the toxicological literature demonstrates that Pb exposure is detrimental to the quality and overall health of testicular germ cells, affecting sperm and semen quality and production. Earlier Pb AQCDs contained studies of Pb-induced decreased sperm counts, decreased sperm production rate, and dose-dependent suppression of spermatogenesis in adult rodents with 30 day drinking water Pb exposure [(Sokol and Berman, 1991), blood Pb level 35 and 37 µg/dL; (Sokol et al., 1985), blood Pb level 34 µg/dL; (Sokol, 1989), blood Pb levels <43 µg/dL]. Chronic Pb exposure (15 weeks) in adult male rabbits, resulting in blood Pb of 24 µg/dL, induced statistically significant decrements in semen quality and greater testicular pathology (Moorman et al., 1998) with dosing by subcutaneous injection, loading dose of 0.2-3.85 mg/kg BW Monday (M), Wednesday (W) and Fridays (F) weeks 6-10, followed by maintenance dose of 0.13-2.0 mg/kg BW Pb acetate MWF over weeks 11-20 of the study. The 2006 Pb AQCD also cited studies in which sperm from Pb exposed rats yielded lower rates of fertilization when used for in vitro fertilization of eggs harvested from unexposed females [(Sokol et al., 1994), blood Pb level 33-46 µg/dL].

Recent studies corroborate earlier findings that Pb alters sperm parameters such as sperm count, viability, motility, and morphology. Anjum et al. (2010) exposed 50 day old male albino Wistar/NIN rats to Pb acetate (273 or 819 mg/L in drinking water, 500 or

1,500 ppm, respectively) for 45 days. Affected endpoints included reduced epididymal sperm count, motile sperm, and viable sperm, indicating decreased sperm production and quality. Anjum did not report blood Pb values. Wistar/NIN rats (1,500 ppm Pb acetate in drinking water for 70 days) supplemented with the herb Centella asiatica (Sainath et al., 2011) had significant attenuation of the Pb-induced changes observed by Anjum et al. (2010). Pillai et al. (2012) found gestational and lactational treatment with Pb acetate in Charles Foster rats (subcutaneous injection of 0.05 mg/kg BW/day) induced effects on sperm in adults (PND65) including significant decreases in testicular sperm count, epididymal sperm count, and sperm motility. These findings are consistent with Pb-associated effects on sperm and male reproductive organs in wildlife from the ecological literature including deer, Asian earthworms, rainbow trout, marine worms, and the fathead minnow (see Sections 7.3.12.1 and 7.4.12.1 from the ecology terrestrial and aquatic reproduction sperm sections).

Pb exposure has been shown to affect the male reproductive organs, as is seen with histological or morphological changes. Studies included in previous Pb AQCDs showed that histological and ultrastructural damage to the testes or seminiferous tubules was seen in non-human primates with chronic oral Pb exposure (daily Pb exposure, gelatin capsule; control plus 3 treatment groups: (1) infancy exposure group [PND0-PND400, resulting in maximum blood Pb level of 36 µg/dL], (2) post-infancy exposure group [PND300 up to 10 years of age, resulting in maximum blood Pb level of 33 µg/dL], and (3) lifetime exposure group [PND0 up to 10 years of age, resulting in maximum blood Pb level of 32 µg/dL]) (Foster et al., 1998; Singh et al., 1993a). Rodent studies using i.p. injections of Pb also showed ultrastructural damage to structures involved in spermatogenesis (blood Pb level after i.p. injection treatment for 16 days: 7.4 µg/dL) (Murthy et al., 1995). More recently, Salawu et al. (2009) observed a decrease in absolute testicular weight after Pb exposure (adult male SD rats, 10,000 ppm Pb acetate in drinking water for 8 weeks). Anjum et al. (2010) reported decreased testicular and epididymal weights of male rats exposed to Pb acetate (500 or 1,500 ppm Pb acetate in drinking water for 45 days) which were significantly attenuated with Pb co-exposure to the herb *Centella asiatica* (Sainath et al., 2011). Pb induced morphological abnormalities in sperm in a concentration-dependent manner (Allouche et al., 2009; Oliveira et al., 2009; Salawu et al., 2009; Shan et al., 2009; Tapisso et al., 2009; Massanyi et al., 2007; Wang et al., 2006a). Sperm abnormalities reported after Pb exposures were amorphous sperm head, abnormal tail, and abnormal neck. Dong et al. (2009) reported decreased epididymis and body weights in mice after an eight-week exposure to 6,000 ppm Pb acetate in drinking water (adult male Kunming mice, 8-week exposure). Oliveira et al. (2009) observed a negative correlation between Pb dose and intact acrosomes (8 week old ICR-CD1 mice, subcutaneous injection of 74 and 100 mg $PbCl_2$/kg body weight for four consecutive days). Rubio et al. (2006) (adult mice treated with i.p. injections of 8, 16

or 24 mg/kg of Pb acetate for 35 days), Biswas and Ghosh (2006) (adult male Wistar rats, i.p. injection of 8 mg/kg body weight Pb acetate for 21 days). Rubio et al. (2006) and Biswas and Ghosh (2006) also observed a Pb-induced decrease in seminal vesicle and ventral prostate weights. Rubio et al. (2006) reported that Pb acetate, in an exposure concentration-dependent manner (8-24 mg/kg body weight), reduced the length of certain stages of the spermatogenic cycle of rat seminiferous tubules and thus affected spermatogenesis. Oral Pb acetate exposure (25 mg/kg bw in drinking water for 3 months, resulting in blood Pb level of 5.3 µg/dL) to adult male albino rats produced significant histological seminiferous tubule damage (epithelium, spermatocytes, acrosomes) that was attenuated with ascorbic acid treatment (Pb exposure + 100 mg/kg bw/day ascorbic acid, resulting in blood Pb level of 4.7 µg/dL) (El Shafai et al., 2011). However, the majority of studies did not observe a statistically significant difference in body weight or reproductive organ weights after Pb exposure at the doses used in the studies. Not all of the aforementioned studies observed changes in every parameter. This may be due to the use of different strains or species, chemical form of the Pb compound administered, dosage schedule, duration of exposure, and age of animals at the time of the study (Oliveira et al., 2009).Data from recent studies suggested that the generation of reactive oxygen species (ROS) in the male reproductive tissues, which can then affect antioxidant defense systems of cells (Pandya et al., 2010) (adult male Charles Foster rats, Pb acetate 0.025 mg/kg body weight/day i.p. for 8 weeks) contributes to the MOA of Pb damage to the male reproductive organs and sperm or semen. Salawu et al. (2009) observed a statistically significant increase in malondialdehyde (MDA, oxidative stress marker) and a significant decrease in the activity of antioxidant enzymes superoxide dismutase (SOD) and catalase (CAT) in plasma and testes of adult male Sprague Dawley rats after administration of 10,000 ppm Pb acetate in drinking water for 8 weeks. Supplementation with tomato paste (used as a source of antioxidants) reduced Pb-induced ROS production and prevented the Pb-induced increase in MDA formation and decrease in SOD and CAT activity. Furthermore, co-treatment of Pb with substances that are known to have antioxidant properties [i.e., tomato paste, Maca (*Lepidium meyenii*), and ascorbic acid] prevented the Pb-induced reduction in sperm count, sperm motility, and sperm viability (Salawu et al., 2009; Shan et al., 2009; Madhavi et al., 2007; Rubio et al., 2006; Wang et al., 2006a).

Recent studies continue to demonstrate that Pb may be directly toxic to mature spermatozoa (adult Algerian mice, Pb acetate 21.5 mg/kg BW/every other day i.p. for 11 or 21 days) (Tapisso et al., 2009; Hernandez-Ochoa et al., 2006) (adult NMRI mice, 6,000 ppm Pb chloride in drinking water for 16 weeks) as well as primary spermatocytes (adult male Wistar rats were treated with drinking water containing 250mg/L Pb acetate for) (Nava-Hernandez et al., 2009; Rafique et al., 2009) (adult albino rats, 10 mg/kg BW Pb chloride i.p. once daily for 8 weeks). Nava-Hernandez et al. (2009) exposed two

groups of adult male rodent to Pb via drinking water (L1 and L2, 250mg/L or 500 mg/L Pb acetate starting at PND60 for 90 days). They found significant increases in spermatid DNA damage with Pb exposure. In their study, all Pb-treated animals had blood Pb levels statistically significantly higher than controls (L1:19.54 µg/dL and L2:21.90 µg/dL); no statistically significant difference in blood Pb levels existed between the two Pb exposure groups likely because the L2 group drank less water than did the L1 group. Piao et al. (2007) reported that Pb exposure caused DNA damage to sperm; the Pb exposed group had a blood Pb of 67 µg/l. Piao et al. (2007) also examined the effect of Zn supplementation on Pb-induced sperm aberrations and found that the proportion of abnormal sperm was statistically significantly higher in the Pb group and the Pb+Zn group than in controls (25 mg/kg Pb acetate i.p., 4 mg/kg Zn acetate i.p., both Pb acetate and Zn acetate, once every two days, for 2 weeks). However, the proportion of abnormal sperm in Pb+Zn group was statistically significantly lower than in Pb alone group. Hernandez-Ochoa et al. (2006) reported that Pb reaches the sperm nucleus in the epididymis of mice chronically exposed (16 weeks in adult animals) to Pb (resulting in mean blood Pb of 75.6 µg/dL) by binding to nuclear sulfhydryl groups from the DNA-protamine complex, increasing sperm chromatin condensation, and thereby interfering with the sperm maturation process without altering sperm quality parameters. Tapisso et al. (2009) observed a statistically significant increase in the number of micronuclei and frequency of sister chromatid exchange with increasing treatment duration in adult male mice administered 21.5 mg/kg body weight Pb acetate by i.p. injection (adult Algerian mice, Pb acetate 21.5 mg/kg BW/every other day for 11 or 21 days). Nava-Hernandez (2009) reported a concentration-dependent increase in DNA damage in rat primary spermatocytes after a 13-week exposure period to Pb acetate in drinking water (resulting in mean blood Pb levels between 19.5 and 21.9 µg/dL). Rafique et al. (2009) reported degenerative changes from pyknosis to apoptosis in primary spermatocytes (adult albino rats, 10 mg/kg BW Pb chloride i.p. once daily for 8 weeks). Hepatic expression of spermatogenic genes was transiently down-regulated in 8 week old male Wistar-Kyoto (WKY) rats in response to Pb nitrate (100 µmol single i.v. injection) 3 hours after injection and recovered to baseline by 12 hours (Nemoto et al., 2011); this effect was not seen in the stroke-prone spontaneously hypertensive rats, which are from a WKY background, or in Sprague-Dawley rats, demonstrating strain specificity.

Pb-induced apoptosis in germ cells within the seminiferous tubules is another suggested mechanism by which Pb exerts its toxic effects on sperm production and function (Wang et al., 2006a) (Kunming mice, 2,000 ppm Pb acetate in drinking water for 14-42 days). Dong et al. (2009) reported a exposure concentration-related increase in apoptosis in spermatogonia and spermatocytes of Kunming mice after exposure to 1,500–6,000 ppm Pb acetate in drinking water. Pb-induced testicular germ cell apoptosis was associated with up-regulation of genes involved in the signal pathway of MAPK and death receptor

signaling pathway of FAS. For instance, up-regulation of K-ras and Fas expressions was concomitant with activation of c-fos and active caspase-3 proteins. Wang et al. (2006a) observed an exposure concentration-dependent increase in the expression of apoptotic markers TGFβ1 and caspase-3 in spermatogenic cells, Sertoli cells, and Leydig cells. Shan et al. (2009) (20 mg/kg BW intragastric Pb acetate for 6 weeks) also reported a statistically significant increase in mRNA expression and protein levels of Fas, Fas-L and caspase-3 after Pb exposure. Supplementation with ascorbic acid inhibited or reduced the Pb-induced apoptosis in germ cells and protected testicular structure and function (El Shafai et al., 2011; Shan et al., 2009; Wang et al., 2006a) suggesting ROS generation is a major contributing factor in decreased male fertility observed after chronic Pb exposure.

Similar to the results summarized in previous Pb AQCDs, recent epidemiologic and toxicological studies indicate that Pb exposure has effects on sperm, semen, and male reproductive organs. Consistent toxicological evidence from multiple labs with multiple species of animals showed decrements in sperm or semen quality with Pb exposure including decreased sperm counts, decreased sperm production rate, and a dose-dependent suppression of spermatogenesis. Histological damage to rodent sperm and ultrastructural damage to rodent and non-human primate seminiferous tubules has been reported. Sperm from Pb-exposed male rodents used for in vitro fertilization of eggs from unexposed females yielded a lower rate of fertilization. Also, direct effects of Pb on rodent sperm DNA have been reported in rodents with drinking water exposure. The toxicological findings cross species and are seen in wildlife including deer, earthworms, rainbow trout, marine worms and fathead minnow. In studies of men exposed to Pb in occupational settings, associations were observed between blood Pb levels of at least 25 µg/dL and sperm count and quality. Multiple epidemiologic studies of occupational cohorts included control populations with high blood Pb levels (close to or greater than 10 µg/dL), which makes identification of effects at lower levels difficult. Occupational studies had limited consideration for potential confounding factors, such as other workplace exposures. An epidemiologic study of men attending a clinic for purposes of infertility exam or semen donation demonstrated an inverse relationship between Pb levels and sperm and semen quality (Telisman et al., 2007). This study also controlled for other metals in the analyses. Other studies of men at infertility clinics had greater imprecision in their estimates, less control for confounding (such as other metals), and/or small sample sizes. Additionally, studies limited to men at infertility clinics may suffer from selection bias and are not generalizable. Future epidemiologic studies are warranted to determine whether this association is observed at lower Pb levels.

5.8.4.2 Effects on Hormone Levels

The 2006 Pb AQCD (U.S. EPA, 2006b) provided evidence that Pb acts as an endocrine disruptor in males at various points along the hypothalamic-pituitary-gonadal axis. The 2006 Pb AQCD also reported inconsistencies in the effects of Pb exposure on circulating testosterone levels. Recent epidemiologic and toxicological studies are reported below. Epidemiologic studies are summarized in Table 5-44. Epidemiologic studies were cross-sectional; biological samples used for the measurement of Pb were measured concurrently with hormone levels. One study estimated cumulative blood Pb.

Table 5-44 Summary of recent epidemiologic studies of associations between Pb levels and hormones for males.

Hormone levels were measured in a few recent epidemiologic studies. In a study of men non-occupationally exposed to Pb in Croatia, increased blood Pb level was associated with increasing serum testosterone and estradiol but decreasing serum prolactin (Telisman et al., 2007). In addition, the analysis of an interaction term for blood Pb and blood Cd levels demonstrated a synergistic effect on increasing serum testosterone levels. No association was observed between blood Pb and FSH or LH. This study controlled for multiple potential confounders, including other metals. Among men recruited from infertility clinics in Michigan, median blood Pb levels were much lower than those observed in the other studies of Pb and hormone levels among men (Meeker et al., 2010). No association was detected between blood Pb and levels of FSH, LH, inhibin B, sex hormone-binding globulin (SHBG), free androgen index (FAI), or a measure of Leydig cell function (T/LH). A positive association between the highest quartile of blood Pb and testosterone was present, but this association did not persist when other metals were included in the model. Similarly, another study of men recruited from infertility clinics observed no association between Pb concentrations from seminal plasma, whole blood, or blood plasma and FSH, LH, or testosterone (Mendiola et al., 2011).

A study of occupationally-exposed men in Taiwan reported an association between measures of cumulative blood Pb levels and inhibin B levels, but no association was detected when using current blood Pb levels (Hsieh et al., 2009a). A correlation between cumulative blood Pb measures and LH levels was detected but correlations were not present when examining FSH or testosterone levels. No correlations were apparent between FSH, LH, or testosterone and current blood Pb levels. Another study of men with high blood Pb levels reported no difference in serum FSH, LH, and testosterone among the three groups (controls: mean blood Pb 10.25 µg/dL, low exposure: mean blood Pb 50.29 µg/dL, high exposure: mean blood Pb 68.26 µg/dL) (Naha and Manna, 2007). This study did not assess any potential confounding factors.

In a recent toxicological study, Rubio et al. (2006) observed a decrease in testosterone levels in Pb acetate-treated rats in a exposure concentration-related fashion (8-24 mg/kg body weight), and this decrease correlated with reduced lengths of spermatogenic cycle stages VII-VIII (spermiation) and IX-XI (onset of spermatogenesis). Anjum et al. (2010), who dosed 50 day old male rats with 273 or 819 mg/L Pb acetate in drinking water (500 or 1,500 ppm, respectively; blood Pb not reported), found significant decreases in serum testosterone and testicular 3β-HSD and 17β-HSD levels in Pb-exposed animals versus controls. Pandya et al. (2010) reported altered hepatic steroidogenic enzyme activity. Pillai et al. (2012) found gestational and lactational exposure to Pb acetate in Charles Foster rats (subcutaneous injection of 0.05 mg/kg BW/day, blood Pb not reported) induced significant decreases in testicular 17β-HSD and serum testosterone. Biswas and Ghosh (2006) reported a Pb-induced decrease in serum testosterone and gonadotropins

(FSH, LH) with inhibition of spermatogenesis, however, there was a statistically significant increase in adrenal steroidogenic enzyme, Δ5-3β-HSD, activity and serum corticosterone levels indicating disruption of the adrenocortical process. Exposure concentration-dependent decreases in serum testosterone were reported in Pb-exposed male rats (Anjum et al., 2010). In contrast, Salawu et al. (2009) did not observe a decrease in serum testosterone between control animals and animals administered 10,000 ppm Pb acetate in drinking water for 8 weeks. Allouche et al. (2009) not only did not observe any statistically significant changes in serum FSH or LH, but reported an increase in serum testosterone levels after 500–3,000 ppm Pb acetate treatment in drinking water (only statistically significant in animals administered 500 ppm Pb acetate). The results of these recent studies further support the theory that compensatory mechanisms in the hypothalamic-pituitary-gonadal axis may allow for the adaptation of exposed animals to the toxic endocrine effects of Pb (Rubio et al., 2006; U.S. EPA, 2006b).

Overall, recent epidemiologic and toxicological studies report mixed findings regarding hormone aberrations in males associated with Pb exposure or Pb biomarker levels. These results are similar to those from the 2006 Pb AQCD (U.S. EPA, 2006b)on the effects of Pb exposure on circulating testosterone levels. Epidemiologic studies are limited by their sample populations, often occupational cohorts or men at infertility clinics, which may not be generalizable. Occupational cohorts may have other exposures that confound the associations, and studies at infertility clinics are subject to selection bias. A few of the recent epidemiologic studies include important confounding factors, such as smoking, but other factors, such as exposure to other metals, were often absent. Additionally, most studies examine concurrent Pb and hormone levels which may not reflect changes resulting from long-term exposures, as demonstrated by the longitudinal occupational cohort study. Further, in cross-sectional studies, the temporality of effects cannot be established.

5.8.4.3 Fertility

Epidemiologic studies have been performed comparing Pb and infertility in men. The SMART study is a longitudinal study that examined the success of IVF treatment for women and their partners starting their first round of treatment (Bloom et al., 2011b; Bloom et al., 2010). A small number of the male partners participated (n=16). Their mean (SD) blood Pb level was 1.50 (0.80) µg/dL. Higher blood Pb levels were associated with greater oocyte fertilization (OR 1.08 [95% CI: 0.97, 1.21] per 1 µg/dL increase in blood Pb when adjusted for Cd, Hg, age, cigarette smoking, race/ethnicity, and creatinine), which is not the expected direction (Bloom et al., 2010). However, higher blood Pb was

associated with lower embryo cell number, a predictor of IVF success, and with higher embryo fragmentation score, an inverse predictor of IVF success (OR for embryo cell number: 0.58 [95% CI: 0.37, 0.91]; OR for embryo fragmentation score: 1.47 [95% CI: 1.11, 1.94] per 1 µg/dL, controlled for age, race/ethnicity, cigarette smoking, creatinine, Cd, and Hg, plus day of embryo transfer for embryo cell number) (Bloom et al., 2011b). A case-control study conducted in Turkey reported that blood and seminal plasma Pb levels were different in fertile (n=45; mean [SD] blood Pb: 23.16 [5.59] µg/dL) and infertile men (n=50; mean [SD] blood Pb: 36.82 [12.30] µg/dL) (p <0.001, ANOVA) (Kiziler et al., 2007). There was no control for potential confounding factors although the relationship persisted when limited to non-smokers. Another case-control study examined occupational Pb exposure (determined by self-report of occupational exposure in the past month) and detected no difference in reported exposure for infertile (n=650) versus fertile men (n=698) (unadjusted OR 0.95 [95% CI: 0.6, 1.6]) (Gracia et al., 2005). Blood Pb was not measured but approximately 5.0% of infertile men and 5.3% fertile men reported occupational exposure to Pb. A limitation present in these studies is that the cases included are men who are seeking help at fertility clinics; the study populations are not a sample of the general population regarding fertility. The results could be biased due to the recruitment of individuals going to an infertility clinic, who may be different than individuals suffering from infertility without knowing it or without going to a clinic.

Recent animal toxicology studies assessed paternal-mediated reproductive fitness by examining the reproductive success of Pb-exposed males with non-exposed control females. Anjum et al. (2010) found that adult male rats who were exposed to 273 or 819 mg/L Pb acetate in drinking water (500 or 1,500 ppm, respectively; blood Pb not reported) spent a significantly longer time copulating than did their control littermates. The Pb-exposed males were less successful copulators with only 73% of the 0.05% Pb acetate exposed males, and 53% of the 1,500 ppm exposed males generating copulatory plugs in the unexposed female mates. While the number of pregnant females did not significantly differ from controls, Pb exposed males contributed to the formation of significantly fewer implantations/dam, and significantly fewer fetuses/dam. Pb-exposed males were able to sire offspring, but produced fewer offspring per litter. In a group of males rats with co-exposure to Pb and the herb Centella asiatica, these reproductive decrements were attenuated relative to rats exposed to Pb alone (adult albino male rats, 1,500 ppm Pb acetate in drinking water for 70 days) (Sainath et al., 2011).

Overall, large, well-conducted epidemiologic studies of Pb exposure and fertility in males are lacking. The few available studies reported inconsistent findings. Toxicological studies demonstrated paternal associated subfecundity (fewer pups sired per pregnancy) with altered mating behavior (longer time spent copulating), albeit in studies with no blood Pb levels reported. Supplementation with antioxidants in a separate study showed restoration of this subfecundity, possibly contributing MOA support to this decreased fertility in male rodents.

5.8.4.4 Effects on Morphology and Histology of Male Sex Organs

Recent toxicological studies further support historical findings that showed an association between Pb exposure and changes in the sex organs as well as germ cells. Histological changes of testes in Pb nitrate-treated adult animals (a single i.p. dose of 12.5, 25, or 50 mg/kg of BW and were sacrificed 48 hours later) included seminiferous tubule atrophy, Sertoli cell and Leydig cell shrinkage with pyknotic nuclei (Shan et al., 2009; Wang et al., 2006a), dilatation of blood capillaries in the interstitium, undulation of basal membrane, and occurrence of empty spaces in seminiferous epithelium (adult male Wistar rats, single i.p. dose of 12, 25 or 50 mg/kg BW Pb acetate) (Massanyi et al., 2007). Pillai et al. (2010) found gestational and lactational exposure to Pb acetate in Charles Foster rats (subcutaneous injection of 0.05 mg/kg BW/day) induced significant decreases in absolute organ weight (testes and epididymis) and significant decreases in relative epididymal weight. Anjum et al. (2010), who exposed 50 day old male albino Wistar/NIN rats to Pb acetate (273 or 819 mg/L in drinking water, 500 or 1,500 ppm, respectively, blood Pb levels not reported) for 45 days, reported significant decreases in relative reproductive organ weight (epididymis, testis, vas deferens, and seminal vesicle) in Pb-exposed animals.

5.8.4.5 Summary of Effects on Male Reproductive Function

Evidence of associations between Pb exposure and male reproductive function vary by outcome. The strongest evidence of an association is the relationship observed between Pb and negative effects on sperm and semen in both recent epidemiologic and toxicological studies and studies reviewed in previous Pb AQCDs. Decrements in sperm count, sperm production rate and semen quality were reported in animal toxicological studies in rodents with drinking water Pb exposure rodents [(Sokol and Berman, 1991; Sokol et al., 1985), (blood Pb level 34-37 µg/dL)] and rabbits exposed to subcutaneous Pb [blood Pb levels of 25 µg/dL, (Moorman et al., 1998)]. Rodents exposed to Pb had direct effects of Pb on sperm DNA, i.e., elevated levels of DNA damage [(Nava-

Hernandez et al., 2009), blood Pb levels 19 and 22 µg/dL]. Histological or ultrastructural damage to the male reproductive organs were reported in studies from rodents [(El Shafai et al., 2011), blood Pb level 5.1 µg/dL] and non-human primates [(Singh et al., 1993a), blood Pb level 43 µg/dL]. Subfecundity has been reported in unexposed females mated to Pb exposed males (decreased number of pups born/litter). Also, sperm from Pb-exposed rats (blood Pb 33 to 46 µg/dL) used for in vitro fertilization of eggs harvested from unexposed females yielded lower rates of fertilization (Sokol et al., 1994). Many of the epidemiologic studies included occupational cohorts, which had high blood Pb levels (≥ 25µg/dL), or men attending infertility clinics, which have potential selection bias. Additionally, control for confounding factors, such as other workplace exposures, was not often performed. A study of men (who were attending a clinic for an infertility exam or to donate semen for use in artificial insemination) did control for multiple factors, including other metals and smoking status, and reported an association between blood Pb levels and some indicators of poor sperm quality (Telisman et al., 2007). Recent toxicological studies also reported an association between Pb exposure and decreases in reproductive organ weight, organ histological changes in the testes and germ cells. Male rats exposed to Pb also showed subfecundity, in that they produced smaller litters when mated with unexposed females (Anjum et al., 2010). Further coherence for these findings in laboratory animal models is found in with findings in the ecological literature for the effects of Pb exposure on reduced fecundity in terrestrial and aquatic animal species (Sections 7.4.5.2, 7.3.4.2, and 7.4.5.3). Similar to the 2006 Pb AQCD (U.S. EPA, 2006b), recent epidemiologic and toxicological studies reported inconsistent results regarding hormone aberrations associated with Pb exposure. Mixed findings were also apparent among epidemiologic studies of fertility among men.

5.8.5 Effects on Female Reproductive Function

The epidemiologic studies on Pb and female reproductive function presented in the 2006 Pb AQCD (U.S. EPA, 2006b) provided little evidence for an association between Pb biomarkers and effects on female reproduction and fertility. However, the 1986 and 2006 Pb AQCDs (U.S. EPA, 2006b, 1986a) reported toxicological findings that Pb exposure was associated with effects on female reproductive function that can be classified as alterations in female sexual maturation, effects on fertility and menstrual cycle, endocrine disruption, and changes in morphology or histology of female reproductive organs including the placenta. Since the 2006 Pb AQCD, many epidemiologic studies have been published regarding Pb biomarker levels in women and reproductive effects. In addition, recent toxicological studies add further knowledge of Pb-related effects on the female reproductive system.

5.8.5.1 Effects on Female Sex Endocrine System and Estrus Cycle

Multiple epidemiologic studies have examined the association between blood Pb levels and hormone levels and the estrus cycle. Epidemiologic studies (characterized in Table 5-45) were cross-sectional in design, analyzing measures of Pb and hormones that were collected either concurrently or close in time. These studies support the toxicological findings, which are the major body of evidence on endocrine effects of Pb.

Table 5-45 Summary of recent epidemiologic studies of associations between Pb levels and hormones for females.

An epidemiologic study using the NHANES III data and including women aged 35-60 years old examined the relationship between blood Pb levels (mean 2.8 µg/dL) and serum follicle stimulating hormone (FSH) and luteinizing hormone (LH) (Krieg, 2007). Deviation from normal FSH and LH levels may indicate endocrine disruption related to ovary functioning. Researchers found that higher blood Pb levels were associated with higher levels of serum FSH and LH among both postmenopausal women and women with both ovaries removed. There was also a trend of increasing serum FSH with blood Pb levels for pre-menopausal women who were not menstruating at the time of the exam or pregnant, although the association was not statistically significant for LH. A limitation of this portion of the study is that FSH and LH were measured without attention to day of a woman's menstrual cycle and LH and FSH are known to vary throughout the cycle of non-menopausal, cycling women who are not taking birth control pills. Higher blood Pb levels were associated with lower levels of serum FSH among women taking birth control pills. The inverse association was also present for LH, but it was not statistically significant. No associations between blood Pb and FSH or LH were apparent for women who were menstruating at the time of the exam or were pregnant. Further analysis indicated that the lowest level of blood Pb for which a statistically significant association between blood Pb and FSH could be observed was 1.7 µg/dL among women with their ovaries removed. For LH, the lowest level of blood Pb for which a statistically significant association between blood Pb and LH could be observed was 2.8 µg/dL among postmenopausal women. Associations between hormones and blood Pb level were also investigated using the BioCycle study cohort (Jackson et al., 2011; Pollack et al., 2011). These women were premenopausal with normal cycles and not on birth control. Blood Pb was measured at enrollment and hormones were measured multiple times throughout the menstrual cycle. Neither study detected an association between unit change in blood Pb and hormone levels. However, when examining tertiles of Pb, women in the highest tertile blood Pb (1.11-6.20 µg/dL) had higher mean progesterone and longer length of a phase shift compared to women in the lowest tertile (0.30-0.72 µg/dL) (Pollack et al., 2011). Other associations were observed but were not statistically significant (Pollack et al., 2011). No associations were detected for anovulation (Pollack et al., 2011) or for cycle length (Jackson et al., 2011). Another epidemiologic study was performed in Kaohsiung City, Taiwan among two groups of women aged 23-44 years: those who were seeking help at a fertility clinic after one year of trying to conceive, and those who had previously delivered an infant and were identified from medical records of a postpartum care unit (Chang et al., 2006). The mean (SD) concurrent blood Pb level in this study was 3.12 (0.19) µg/dL. The study reported a positive association between blood Pb levels and serum estradiol concentrations during the early follicular phase, which reflects ovary activity.

The effect of Pb exposure on the female endocrine system was demonstrated in toxicological studies reviewed in the 1986 and 2006 Pb AQCD (U.S. EPA, 2006b, 1986a). However, the mechanism by which Pb affects the endocrine system has not been fully elucidated. Several recent articles continue to demonstrate that Pb alters the concentration of circulating hormones in female experimental animals. As mentioned in the previous AQCD, Pine et al. (2006) observed that maternal Pb exposure (during gestation and lactation) caused a decrease in basal LH levels in pre-pubertal female Fischer 344 rat pups as compared to control, non-Pb exposed pups. Dumitrescu et al. (2008a) observed alteration of hormone levels in adult female Wistar rats after ingesting Pb acetate (50, 100, 150 ppb) in drinking water for 6 months; measurements were made during the pro-estrous stage of the estrous cycle to allow for consistent timing for comparison of cyclic hormonal variation. The authors reported decreases in FSH, estradiol, and progesterone levels with increases in LH and testosterone levels. Nampoothiri and Gupta (2008) administered Pb acetate at a concentration that did not affect reproductive performance, implantation or pregnancy outcome (0.05 mg/kg body weight) to Charles Foster female rats 5 days before mating and during the gestational period. They observed a decrease in steroidogenic enzymes, 3β- hydroxysteroid dehydrogenase (HSD) and 17β-HSD, activity in reproductive organs, as well as a decrease in steroid hormones (progesterone and estradiol), suggesting that chronic exposure to low levels of Pb may affect reproductive function of mothers and their offspring. Similarly, Pillai et al. (2010) reported impaired ovarian steroidogenesis in Charles Foster adult female rats (PND56) from dams exposed gestationally and lactationally to Pb acetate (subcutaneous daily injections of 0.05 µg/kg BW). Pillai observed a decrease in steroidogenic enzymes, 3β-HSD and 17β-HSD, but saw no changes in ovarian steroidogenic acute regulatory protein (StAR) or CYP11 mRNA levels indicating Pb-induced inhibition of ovarian steroidogenesis.

Kolesarova et al. (2010) conducted an in vitro study to examine the secretory activity of porcine ovarian granulose cells after Pb administration for 18 hours. The results of the study showed that Pb acetate concentrations of 0.046 mg/mL and 0.063 mg/mL statistically significantly inhibited insulin-like growth factor-1 (IGF-1) release, but concentrations of 0.25 mg/mL and 0.5 mg/mL did not influence IGF-1 release. Progesterone release was not affected by Pb treatment; however, Pb caused a reduction in LH and FSH binding in granulose cells and increased apoptosis as evidenced by increased expression of caspase-3 and cyclin B1, suggesting a Pb-induced alteration in the pathways of proliferation and apoptosis of porcine ovarian granulose cells. Decreased gonadotropin binding was also observed in rats after Pb exposure subcutaneously administered Pb (0.05 mg/kg body weight daily before mating and during pregnancy) with a resulting blood Pb of 2.49 µg/mL) (Nampoothiri and Gupta, 2006).

No recent toxicological studies were found that examined Pb-induced effects on the estrus cycle.

Overall, toxicological studies report alterations in hormone levels related to blood Pb concentration. Similarly, epidemiologic studies reported associations between concurrent/closely timed blood Pb levels and hormone levels in female adults. Although Pb-associated changes in hormone levels are observed, there are discrepancies and the hormones examined vary by study. One explanation for the inconsistent findings is that changes could vary based on current hormonal and reproductive status of the participants. Also, the covariates included in statistical models as potential confounders varied among studies, which could contribute to between study heterogeneity. This is also a limitation of the epidemiologic studies; not all of the studies investigated important confounders, such as other metal exposures or smoking. Additionally, the cross-sectional design of these studies leaves uncertainty regarding Pb exposure timing, duration, and frequency that contributed to the observed associations.

5.8.5.2 Effects on Fertility

Previous studies indicated that Pb exposure does not produce total sterility, but it can disrupt female fertility (U.S. EPA, 2006b). Recent epidemiologic studies and studies in experimental animals have inconsistent results. The epidemiologic studies are summarized in Table 5-46. Most of these studies examining biological measures of Pb collected at or during the period of possible fertilization or start of fertility treatment, although Bloom et al. (2011a) measured blood Pb at baseline and followed women for at least 12 menstrual cycles (or until pregnancy).

Table 5-46 Summary of recent epidemiologic studies of associations between Pb levels and fertility for females.

Reference (Presented in order of appearance in the text)	**Study Location, and Years**	**Outcome**	**Study Population**	**Methodological Details**	**Pb Biomarker**	**Mean Pb (SD) in µg/dL**	**Adjusted Effect Estimates**	**Potential Confounders Adjusted for in Analysis**
Silberstein et al. (2006)	Providence, RI NS	Achieving pregnancy	Women undergoing IVF at the study hospital N: pregnancy =4 N: No pregnancy =5	Longitudinal cohort study using Mann-Whitney U-test	Follicular fluid Pb	Not given quantitatively From a figure in the paper: Median Pb in follicular fluid of pregnant women: ~1.3 Median Pb in follicular fluid of non-pregnant women: ~2.2	P-value for difference in medians by Mann-Whitney U test: 0.0059 *Note, This study only included 9 women	None

A prospective cohort study enrolled women who previously participated in a study of fish consumption for a length of up to 12 menstrual cycles and investigated the relationship between blood Pb levels at baseline and having a positive pregnancy test at some point during the next 12 menstrual cycles (Bloom et al., 2011a). No association was observed between blood Pb and achieving pregnancy.

Among women aged 23-44 years, a difference in blood Pb was reported between women who were seeking help at a fertility clinic after one year of trying to conceive and women who had previously delivered an infant and were identified from medical records of a postpartum care unit at a medical center (Chang et al., 2006). Higher odds of infertility were observed when comparing women with blood Pb levels >2.5 µg/dL to those with blood Pb levels ≤ 2.5 µg/dL although this study is limited by its case-control design.

Epidemiologic studies have also examined women having difficulty conceiving by performing studies among patients of fertility clinics or undergoing *in vitro* fertilization (IVF). The Study of Metals and Assisted Reproductive Technologies (SMART) enrolled women undergoing their first round of IVF and investigated multiple steps before pregnancy as the outcomes (Bloom et al., 2011b; Bloom et al., 2010). Higher blood Pb levels were associated with lower oocyte maturity although the lack of power made interpretation of models controlling for Cd difficult. No association was observed between blood Pb and oocyte fertilization (Bloom et al., 2010). In the examination of markers of IVF success, inconsistent results were observed. Embryo cell number was lower in association with higher blood Pb levels but no association was observed for embryo fragmentation score (Bloom et al., 2011b). Another study examining fertility reported on women in Saudi Arabia aged 19-50 years who were undergoing IVF treatment (Al-Saleh et al., 2008a). Women were categorized as having achieved a pregnancy versus not having achieved a pregnancy and achieved fertilization versus not achieving fertilization. The majority of women had follicular Pb levels that were below the limit of detection, whereas less than 2% of women had blood Pb levels below the limit of detection. In addition, less than 2% of women had blood Pb levels that were above 10 µg/dL. Follicular Pb levels were not correlated with the blood Pb. No association was observed between blood or follicular Pb and pregnancy outcomes in either crude or adjusted models. An association was not detected between follicular Pb and fertilization, but higher blood Pb was associated with lower rates of fertilization. Finally, a study that included nine women undergoing IVF treatment in Rhode Island (Silberstein et al., 2006) found that median follicular Pb levels in women who achieved pregnancy were lower than the follicular Pb levels among nonpregnant women.

Overall, these epidemiologic studies examine a variety of fertility-related endpoints and although some studies demonstrate an association between higher Pb levels and fertility/pregnancy, as a whole the results are inconsistent across studies. One limitation present in most of these studies is that the participants are women who are seeking help for fertility problems. The participants are not samples of the general population and therefore cannot be generalized to all women of childbearing age. This may also have introduced substantial selection bias into the study.

Animal toxicology studies following female fertility looked at various outcomes. Several studies observed a decrease in litter size when females were exposed to Pb before mating or during pregnancy (Dumitrescu et al., 2008c; Iavicoli et al., 2006a; Teijón et al., 2006). Pups in a study by Teijon et al. (2006) receiving 400 ppm Pb acetate in drinking water had blood Pb of 97 µg Pb/dL blood at 1 week post-weaning and 18.2 µg Pb/dL blood at 2 week post-weaning. Dumitrescu et al. (2008c) observed a modification in sex ratio of pups born to dams exposed to Pb before mating and during the entirety of pregnancy. As the dose of Pb increased, the number of females per litter also increased (i.e., 1 male to 0.8 female in non-Pb exposed group; 1 male to 0.66 female in 50 ppb Pb acetate group; 1 male to 2.25 females in 100 ppb group; and 1 male to 2.5 females in 150 ppb group). These results are not consistent with earlier results of Ronis et al. (1998b), who did not observe differences in sex ratio dams and offspring were exposed only during pregnancy. Thus, Pb exposure in animal studies during or before pregnancy have shown effects on litter size and mixed effects on sex ratio.

Nandi et al. (2010) demonstrated a concentration-dependent decline in viability rate, maturation, fertilization, and cleavage rates of buffalo oocytes cultured in medium containing 1-10 µg/mL Pb acetate (24 hour culture). Karaca and Şimşek (2007) observed an increase in the number of mast cells in ovary tissue after Pb exposure (2,000 µg/mL in drinking water for 6 weeks prior to estrous monitoring then for 1 additional month during which estrous cyclicity was monitored) suggesting that Pb may stimulate an inflammatory response in the ovaries which may contribute to Pb-induced female infertility.

In contrast, Nampoothiri and Gupta (2008) did not observe any statistically significant change in fertility rate or litter size in female rats subcutaneously administered Pb (0.05 mg/kg body weight daily before mating and during pregnancy) with a resulting blood Pb of 2.49 µg/mL. Although reproductive performance was not affected in this study, the authors did report an alteration in implantation enzymes. Cathepsin-D activity decreased and alkaline phosphatase activity increased after Pb exposure.

In summary, recent epidemiologic and toxicological studies on the effect of Pb on fertility outcomes have generated inconsistent results. Most of the epidemiologic studies are limited by their small sample sizes and selection bias and lack of generalizability due to a focus on women seeking help for infertility. Most of the studies control for multiple potential confounders, such as smoking status and age. The studies from the toxicological literature show that Pb exposure to females affects litter size (decreased litter size), sex ratio (ratio of male to female offspring in a litter) and ovarian viability, albeit often at higher dose of Pb. However, the bulk of the evidence including the current and historical Pb literature (U.S. EPA, 2006b) indicate that increased Pb exposure may decrease female fertility.

5.8.5.3 Ovaries, Embryo Development, Placental function, and Spontaneous Abortions

The 2006 Pb AQCD included studies of Pb exposure among men and women and their associations with spontaneous abortions. The 2006 Pb AQCD concluded that overall there was little evidence to support an association between Pb exposure among women and spontaneous abortion (U.S. EPA, 2006b). Most of the studies examined in the 2006 Pb AQCD assigned exposure based on living near a smelter or working in occupations that often result in Pb exposure and the results of these studies were inconsistent. Little evidence was available in the 2006 Pb AQCD to suggest an association with paternal Pb levels, and no recent studies have been performed to examine paternal Pb levels and spontaneous abortion. Since the 2006 Pb AQCD, multiple epidemiologic studies have been published that examine Pb levels in women and their possible association with spontaneous abortion. Table 5-47 provides information on these longitudinal and cross-sectional studies. Additionally, toxicological studies have studied the effects of Pb on fetal loss and the contribution of the ovaries and placenta to fetal loss.

Table 5-47 Summary of recent epidemiologic studies of associations between Pb levels and spontaneous abortions.

(2007)	Mexico City, Mexico 1997-1999, 2001-2004	Previous miscarriage	Women who had a previous pregnancy and were currently pregnant with gestational age of ≤ 14 weeks N: ≥ 1 previous miscarriages =71 N: No previous miscarriages =136	Cross-sectional study using Poisson regression	Maternal and umbilical cord blood Pb, maternal bone Pb	Overall: Blood Pb: 6.2 (4.5) Plasma Pb: 0.014 (0.013) Cases: Blood Pb: 5.8 (3.4) Plasma Pb: 0.014 (0.013) Controls: Blood Pb: 6.5 (4.9) Plasma Pb: 0.013 (0.013)	Categorized Plasma Blood Pb ratio: 1st tertile: 1.00 (Ref) 2nd tertile: 1.16 (p-value 0.61) 3rd tertile: 1.90 (p-value 0.015) **IRR** (95%CI) Per 1 SD increase: Plasma Pb 1.12 (p-value 0.22) Blood Pb 0.93 (p-value 0.56) Plasma/Blood Pb ratio 1.18 (p-value 0.02) Patella Pb 1.15 (p-value 0.39) Tibia Pb 1.07 (p-value 0.56)	Age, education
Gundacker et al. (2010)	Vienna, Austria 2005	Previous miscarriage	Women recruited during the second trimester of pregnancy N: ≥ 1 previous miscarriages =8 N: No previous miscarriages =22	Cross-sectional study using non-parametric tests	Whole placentas shortly after birth	Median (IQR): 25.8 (21.0, 36.8)	Median Placenta Pb: Women who had not previously miscarried: 27 µg/kg Women who had previously miscarried: 39 µg/kg (p-value for difference: 0.039)	N/A

A longitudinal study examining spontaneous abortions occurring early in the pregnancy was conducted in Iran (Vigeh et al., 2010). Mean blood Pb concentrations, measured at 8-12 weeks of pregnancy, were similar in women who did and did not have spontaneous abortions. Higher blood Pb levels were not associated with greater odds of spontaneous abortions before 20 weeks of pregnancy. Yin et al. (2008) performed a study in the Shanxi Province of China to examine if plasma Pb levels were associated with anembryonic pregnancies (spontaneous abortions during the first trimester, which account for 15% of all spontaneous abortions). Women were enrolled at 8-12 weeks of gestation. Women who delivered a term pregnancy had mean plasma Pb levels that were lower than those of women who had an anembryonic pregnancy (plasma Pb measured at the time of miscarriage for cases and at 8-12 weeks for controls). Of note, among cases plasma Pb level was inversely correlated with folate and vitamin B12, but this correlation was not observed among those who delivered at term; no models examining plasma Pb levels adjusted for nutrient status. A study in Mexico City examined a group of pregnant women (maximum gestational period at enrollment was 14 weeks) who had previously been pregnant and either given birth or had a spontaneous abortion (Lamadrid-Figueroa et al., 2007). Women in the highest tertile of plasma/blood Pb ratio had higher rates of previous spontaneous abortions than did women in the lowest tertile. The authors state that the plasma/whole blood ratio represents the bioavailability of Pb, which is capable of crossing the placental barrier for a given blood concentration. No association was observed when examining the relationship between Pb and spontaneous abortions using whole blood, plasma, or bone Pb alone. Similarly, a study of placental Pb levels among pregnant women in Austria observed higher placenta Pb levels among women who had miscarried a previous pregnancy compared to women who had not miscarried a previous pregnancy (Gundacker et al., 2010). It is important to note that the number of women included in the study was small (only 8 women reported previously having a miscarriage)

In toxicological studies, isolated embryo cultures are often used to understand the mechanisms responsible for aberrant embryo development as it may contribute to teratogenesis, fetal loss or negative postnatal pup outcomes. Nandi et al. (2010) demonstrated an exposure concentration-dependent decline in embryo development of fertilized buffalo oocytes cultured for 24 hours in medium containing 0.05-10 µg/mL Pb acetate as evidenced by reduced morula/blastocyst yield and increased four-to eight-cell arrest, embryo degeneration, and asynchronous division. This study provides evidence of the negative effect of Pb on embryo development and contributes mechanistic understanding to Pb-dependent pregnancy loss.

A possible explanation for reduced fertility and impaired female reproductive success as a result of Pb exposure is changes in morphology or histology in female sex organs and the placenta (Dumitrescu et al., 2007; U.S. EPA, 2006b). Wang et al. (2009e) observed

that elevated maternal blood Pb (0.6-1.74 µM, ~12.4-36.0 µg/dL) compared to control (0.04 µM, ~0.83 µg/dL) were associated with decreased fetal body weight, pup body length, and placental weight in Wistar rats. The authors reported that placentae from Pb-exposed groups showed concentration-dependent increasing pathology of cytoarchitecture and cytoplasmic organelles. The authors also reported a positive expression of NF-κB, a transcription factor that controls the expression of genes involved in immune responses, apoptosis, and cell cycle, in the cytotrophoblasts, decidual cells, and small vascular endothelial cells in rat placenta under a low-level Pb exposure condition which correlated with low blood Pb levels.

Pb-exposed (273 mg/L or 819 mg/L in drinking water, 500 or 1,500 ppm Pb acetate, respectively) male rats from Anjum et al. (2010) that had an exposure concentration-dependent decreases in serum testosterone, decreased male reproductive organ weight and decreased sperm were mated to untreated females. These untreated dams bred to the Pb exposed males had male related exposure concentration-dependent decreased implantation rate and higher pre- and post-implantation loss, indicating paternally mediated fetal loss. The magnitude of these effects in dams was dependent on the concentration of Pb exposure in their male mating partners.

As observed in sperm cells, Pb stimulates changes in antioxidant enzyme activity in rat ovaries indicating that oxidative stress may be a contributing factor in Pb-induced ovarian dysfunction. Nampoothiri et al. (2007) observed a reduction in SOD activity and an increase in CAT activity along with a decrease in glutathione content and an increase in lipid peroxidation in rat granulosa cells after 15 days of Pb treatment (subcutaneously administered Pb (0.05 mg/kg body weight daily before mating and during pregnancy) with a resulting blood Pb of 2.49 µg/mL).

Previous studies demonstrated that Pb accumulates in the ovaries and causes histological changes, thus contributing to Pb-induced effects on female fertility (U.S. EPA, 2006b). In support of historical studies, recent studies demonstrate Pb-induced histological changes in ovarian cells of pigs (Kolesarova et al., 2010) and rats (Nampoothiri et al., 2007; Nampoothiri and Gupta, 2006). Kolesarova et al. (2010) observed a reduction of the monolayer of granulosa cells after Pb addition (0.5 mg/mL, 18 hours culture). Nampoothiri and Gupta (2006) reported that Pb exposure caused a decrease in cholesterol and total phospholipid content in the membranes of granulosa cells which resulted in increased membrane fluidity (subcutaneously administered Pb, 0.05 mg/kg body weight daily before mating and during pregnancy with a resulting blood Pb of 2.49 µg/mL).

Overall, the recent studies support the conclusions of the 2006 Pb AQCD (U.S. EPA, 2006b) that there is mixed evidence among epidemiologic studies to suggest an association between Pb and spontaneous abortions. It is important to note that studies of

spontaneous abortions are difficult to conduct. The majority of spontaneous abortions are during the first trimester, which makes them difficult to capture. Women may miscarry before being enrolled in a study and many women may not have known they were pregnant when they miscarried. This limits the ability to detect subtle effects, especially if higher Pb levels do lead to increased risk of early spontaneous abortions. In addition, some studies are limited by their retrospective examination of current Pb levels in relation to previous miscarriages. Sample size is another limitation of the available epidemiologic studies. The epidemiologic studies also had little control for potential confounding factors, with some studies including no potential confounders in their analyses. Toxicological data provide mechanistic understanding of the contribution of Pb exposure to spontaneous abortions. These laboratory data show that Pb exposure impaired placental function, induced oxidative stress and histological changes in the ovaries, and affected embryo development. The toxicological and epidemiologic data provide inconsistent findings for the role of Pb in spontaneous abortions.

5.8.5.4 Effects on Breast Milk

Experiments in laboratory animals have shown that dietary manipulation of maternal fatty acid (FA) levels in diet can worsen Pb-related behavioral effects of offspring after lactational Pb exposure (Lim et al., 2005). To determine if components of dam milk contributed to this change, dam milk fatty acids were altered via diet. Diets deficient in n-3 fatty acids can lead to a deficiency of DHA, which is essential for proper nervous system development. Lim et al. (2005) found that dam Pb exposure (Long-Evans rats, 2,000 ppm Pb acetate trihydrate/BW) during lactation (PND0-PND21) led to a decrement in non-essential fatty acids in the maternal organs at PND25 (mean [SD] blood Pb levels in dams: 308 [56] µg/dL). In animals with a diet deficient in n-3 FAs, there was a Pb-diet interaction with a specific size PUFA (i.e., a 20-carbon n-6 PUFA). In general, Pb exposure caused a decrement in shorter chain monounsaturated and saturated FAs in maternal organs.

Dietary supplementation with calcium can be an especially important contributor to Pb mobilization during periods of high calcium demand including pregnancy/lactation. For example, mothers with elevated blood Pb levels given calcium phosphate and ascorbic acid supplementation during lactation had a 90% decrease in placental Pb content and a 15% decrease in the concentration of Pb in breast milk (Altmann et al., 1981) versus the control group that did not receive dietary treatment. Another study (Gulson et al., 2004a) has shown that calcium supplementation during the lactation is less beneficial in modulating maternal blood Pb levels (mean blood Pb at first sampling was 2.4 µg/dL); the Gulson cohort (Gulson et al., 2004a) was limited by power (n=10 women). In a

cohort of women from Mexico City, daily calcium supplementation during lactation reduced maternal blood Pb by 15–20% and Pb in breast milk by 5–10% (Ettinger et al., 2004a). Another study by the same investigators showed that using calcium supplements daily during pregnancy also reduced blood Pb levels during pregnancy (Ettinger et al., 2009) with the effect strongest in women with higher biomarkers of Pb exposure (elevated baseline bone Pb or >5 µg/dL blood Pb) or in women with higher Pb exposure (self-reported use of Pb-glazed ceramics). Thus, dietary modulation with calcium supplementation during pregnancy and lactation may decrease the amount of Pb to which the developing fetus of infant is exposed. The evidence for this seems especially strong for protection during pregnancy and more mixed for protective effects of calcium during lactation.

5.8.5.5 Summary of Effects on Female Reproductive Function

In summary, Pb exposure was found to affect female reproductive function as demonstrated by both epidemiologic and toxicological studies. Some evidence is also available regarding blood Pb levels and altered hormone levels in adults, but varied among studies. The differences may have been due to the different hormones examined and the different timing in the menstrual and life cycles of the women. Although studies reported inconsistent findings for the association between Pb and fertility, there is some evidence of a potential relationship. Adjustment for potential confounders varies from study to study, with some potentially important confounders, such as BMI, not included in all studies. Also, many epidemiologic studies are limited by small samples sizes and are generally of women attending infertility clinics, which presents the possibility of selection bias and lack of generalizability. Toxicological studies found effects on female reproductive function after prenatal or early postnatal exposures. Further coherence for these findings in laboratory animal models is found in with findings in the ecological literature for the effects of Pb exposure on reduced fecundity in terrestrial and aquatic animal species (Sections 7.4.5.2, 7.3.4.2, 7.3.4.3, and 7.4.5.3). Although epidemiologic and toxicological studies provide information on different exposure periods, both types of studies support the conclusion that Pb affects at least some aspects of female reproductive function.

5.8.6 Summary and Causal Determination

Many epidemiologic and toxicological studies of the effects of Pb on reproductive and developmental outcomes have been conducted since the 2006 Pb AQCD. The evaluation of causal relationships with Pb exposure focuses on four areas: developmental effects, birth outcomes, reproductive function among males, and reproductive function among females. The sections that follow describe the evaluation of evidence for these outcomes with respect to causal relationships with Pb exposure using the framework described in Table II of the Preamble. The application of the key supporting evidence to the causal framework is summarized in Table 5-48.

5.8.6.1 Effects on Development

The 2006 Pb AQCD (U.S. EPA, 2006b) reported Pb-associated effects on development in toxicological studies. Multiple recent epidemiologic studies of Pb and puberty have shown associations between concurrent blood Pb levels and delayed pubertal onset for girls and boys. Delayed puberty has been linked to decreased peak bone mass and increased risk of osteoporotic fractures (Gilsanz et al., 2011; Naves et al., 2005). In cross-sectional epidemiologic studies of girls (ages 6-18 years) with mean and/or median concurrent blood Pb levels less than 5 µg/dL consistent associations with delayed pubertal onset (measured by age at menarche, pubic hair development, and breast development) were observed. In boys (ages 8-15 years), fewer epidemiologic studies were conducted but associations were observed, including associations among boys in a longitudinal study. These associations are consistently observed in populations with concurrent blood Pb levels <10µg/dL. Potential confounders considered in the epidemiologic studies of both boys and girls that performed regression analyses varied. Most studies controlled for age and BMI. Other variables, such as measures of diet, SES, and race/ethnicity, were included in some of the studies. Adjustment for nutritional factors was done less often and this could be an important confounder. A study using a cohort of girls from the NHANES analysis controlled for various dietary factors as well as other potential confounders and reported an association between increased concurrent blood Pb levels and delayed pubertal onset (Selevan et al., 2003). A limitation across most of the epidemiologic studies of blood Pb levels and delayed puberty is their cross-sectional design, which does not allow for an understanding of temporality. There is uncertainty with regard to the exposure frequency, timing, duration, and level that contributed to the associations observed in these studies.

Recent toxicological studies show that pubertal onset is one of the more sensitive markers of Pb exposure with effects observed after gestational exposures leading to blood Pb

levels in the female pup of 3.5-13 µg/dL (Iavicoli et al., 2006a; Iavicoli et al., 2004). Toxicological studies have reported delayed male sexual maturity as measured with sex organ weight, among other outcomes, seeing significant decrements at blood Pb levels of 34 µg/dL (Sokol et al., 1985). Thus, data from the toxicological literature and from epidemiologic findings demonstrate that puberty onset in both males and females is delayed with Pb exposure.

Findings from epidemiologic studies of postnatal growth are inconsistent and findings from the toxicological literature are mixed with recent growth findings showing adult onset obesity. Toxicological studies demonstrated that the effects of Pb exposure during early development include impairment of retinal development and alterations in the developing hematopoietic and hepatic systems. Affected developmental outcomes with Pb exposure also included effects on the eyes and teeth.

The collective body of evidence integrated across epidemiologic and toxicological studies, based on the findings of delayed pubertal onset among males and females, is sufficient to conclude that there is a causal relationship between Pb exposure and developmental effects.

5.8.6.2 Effects on Birth Outcomes

Overall, results of pregnancy outcomes were similar to those of the 2006 Pb AQCD; (U.S. EPA, 2006b) inconsistent evidence of a relationship with Pb was available for preterm birth. The 2006 Pb AQCD included a few studies that reported potential associations between Pb and neural tube defects, but the recent epidemiologic studies found no association. Some associations were observed between Pb and low birth weight when epidemiologic studies used measures of postpartum maternal bone Pb or air exposures. The associations were less consistent when using maternal blood Pb measured during pregnancy or at delivery or umbilical cord and placenta Pb (maternal blood Pb or umbilical cord and placenta Pb were the biomarkers most commonly used in studies of low birth weight) but some associations between increased Pb levels and decreased low birth weight/fetal growth were observed. The effects of Pb exposure during gestation in animal toxicological studies included mixed findings with some studies showing reduction in litter size, implantation, and birth weight, and some showing no effect. Based on the mix of inconsistent results of studies on various birth outcomes but some associations observed in well-conducted epidemiologic studies of preterm birth and low birth weight/fetal growth, the evidence is suggestive of a relationship between Pb exposure and birth outcomes.

5.8.6.3 Effects on Male Reproductive Function

Toxicological evidence and supporting epidemiologic evidence indicate that a causal relationship exists between Pb exposure and effects on male reproductive function. Key evidence is provided by toxicological studies in rodents, non-human primates, and rabbits showing detrimental effects on semen quality, sperm and fecundity/fertility with supporting evidence in epidemiologic studies of associations between Pb exposure and detrimental effects on sperm. This is consistent with studies reported in the 2006 Pb AQCD (U.S. EPA, 2006b).

Toxicological studies with relevant Pb exposure routes reported effects on rodent sperm quality and sperm production rate [(Sokol and Berman, 1991; Sokol et al., 1985), blood Pb level 34-37 µg/dL], sperm DNA damage [(Nava-Hernandez et al., 2009), blood Pb levels 19 and 22 µg/dL], and histological or ultrastructural damage to the male reproductive organs in studies from rodents [(El Shafai et al., 2011), blood Pb level 5.1 µg/dL] and non-human primates [(Cullen et al., 1993), blood Pb level 43 µg/dL]. These effects were found in animals exposed to Pb during peripuberty or adults for 1 week to 3 months. The toxicological studies reported an association between Pb exposure and decreases in reproductive organ weight and organ histological changes in the testes and germ cells. Subfecundity (decreased number of pups born/litter) was reported in unexposed females mated to Pb exposed males. Also, sperm from Pb-exposed rats (blood Pb level: 33 to 46 µg/dL) used for in vitro fertilization of eggs harvested from unexposed females yielded lower rates of fertilization. (Sokol et al., 1994). Supporting evidence was provided by decrements in sperm quality from rabbits administered Pb subcutaneously (blood Pb levels of 25 µg/dL) (Moorman et al., 1998).

The detrimental effects of Pb on sperm were observed in epidemiologic studies with concurrent blood Pb levels of 25 µg/dL and greater among men occupationally exposed (Hsu et al., 2009b; Kasperczyk et al., 2008; Naha and Manna, 2007; Naha and Chowdhury, 2006). The epidemiologic studies were limited due to these high exposure levels among the occupational cohorts and the lack of consideration for potential confounding factors, including other occupational exposures. Studies among men with lower Pb levels were limited to infertility clinic studies, which may be a biased sample and lack generalizability. However, a well-conducted epidemiologic study that enrolled men going to a clinic for either infertility issues or to make a semen donation and controlled for other metals as well as smoking reported a positive association with various detrimental effects in sperm (Telisman et al., 2007). The median concurrent blood Pb levels in this study were 4.92 µg/dL (range: 1.13-14.91). A similar study (Meeker et al., 2008) also reported possible associations between concurrent blood Pb

and various semen parameters, but the results were extremely imprecise, making it difficult to draw conclusions.

Similar to the 2006 Pb AQCD (U.S. EPA, 2006b), recent epidemiologic and toxicological studies reported inconsistent results regarding hormone aberrations associated with Pb exposure. Due to the complexity of the reproductive system, uncertainty exists as to whether Pb exerts its toxic effects on the reproductive system by affecting the responsiveness of the hypothalamic-pituitary-gonad axis, by suppressing circulating hormone levels or by some other pathway. Mixed findings were also apparent among epidemiologic studies of fertility among men.

More recent toxicological studies suggest that oxidative stress is a major contributor to the effects of Pb exposure on the male reproductive system, providing mode of action support. The effects of ROS may involve interference with cellular defense systems leading to increased lipid peroxidation and free radical attack on lipids, proteins, and DNA. Several recent studies showed that Pb induced an increased generation of ROS within the male sex organs, and germ cell injury, as evidenced by aberrant germ cell structure and function. Co-administration of Pb with various antioxidant compounds either eliminated Pb-induced injury or greatly attenuated its effects. In addition, many studies that observed increased oxidative stress also observed increased apoptosis which is likely a critical underlying mechanism in Pb-induced germ cell DNA damage and dysfunction.

Based on the consistency and coherence of findings for the detrimental effects of Pb exposure on sperm and semen in the toxicological literature, the support from epidemiologic studies, and biological plausibility provided by mode of action evidence, the evidence is sufficient to conclude that there is a causal relationship between Pb exposures and male reproductive function.

5.8.6.4 Effects on Female Reproductive Function

Epidemiologic and toxicological studies of reproductive function among females investigated whether Pb biomarker levels were associated with hormone levels, fertility, estrus cycle changes, and morphology or histology of female reproductive organs including the placenta. Toxicological studies reported in the 2006 Pb AQCD (U.S. EPA, 2006b) reported associations between Pb exposure and female reproductive function, although little evidence was provided by epidemiologic studies. Some epidemiologic studies have shown associations with concurrent blood Pb levels and altered hormone levels in adults, but varied among studies, likely due to the different hormones examined and the different timing in the menstrual and life cycles. There is some evidence of a

potential relationship between Pb exposure and female fertility, but findings are mixed. The majority of the epidemiologic studies are cross-sectional, and adjustment for potential confounders varies from study to study, with some potentially important confounders, such as BMI, not included in all studies. Also, most of the studies have small samples sizes and are generally of women attending infertility clinics. Toxicological study design often employs prenatal or early postnatal Pb exposures with Pb contributing to placental pathology and inflammation, decreased ovarian antioxidant capacity, altered ovarian steriodogenesis and aberrant gestational hormone levels. Although epidemiologic and toxicological studies provide information on different exposure periods, both types of studies support the conclusion that Pb possibly affects at least some aspects of female reproductive function. Overall, the relationship observed with female reproductive outcomes is sufficient to conclude that there is a suggestive relationship between Pb exposure and female reproductive function.

Table 5-48 Summary of evidence supporting reproductive and developmental causal determinations.

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	Recent References[b]	Pb Exposure or Blood Pb Levels Associated with Effects[c]
Effects on Development – Causal			
Delayed Puberty Onset			
Consistent associations between higher blood Pb levels in high-quality epidemiologic studies	Consistent evidence in multiple large cross-sectional epidemiologic studies for females and males plus a longitudinal study for males. Most of these studies have large sample sizes and controlled for potential confounding by covariates such as age, BMI, and education/SES.	Tomoum et al. (2010), Hauser et al. (2008), Williams et al. (2010), Denham et al .(2005), Naicker et al. (2010), Wu et al. (2003b), Gollenberg et al. (2010) Sections 5.8.1.1 and 5.8.1.2	Concurrent blood Pb levels: <10 µg/dL
	A large study using females aged 8-18 years from the NHANES III study also controlled for various dietary factors and reported associations between blood Pb levels and delayed puberty onset	Selevan et al. (2003)	
Epidemiologic evidence supported by consistent toxicological findings with relevant Pb exposure	Consistent toxicological evidence from multiple laboratories of delayed male and female puberty onset with Pb exposure via diet or oral gavage in rodents	Dumitrescu et al. (2008c), Iavicoli et al. (2006a), Pine et al. (2006) Sections 5.8.1.1 and 5.8.1.2	Blood Pb level after dietary exposure from gestation to estrus: 3.5-13 µg/dL
Evidence clearly describes Mode of Action.	Toxicological evidence describes HPG axis dysfunction providing mechanism of action support for delayed puberty findings. MOA further supported by IGF-1 changes contributing to Pb-induced delay in puberty onset.	Section 5.8.1.1	

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	Recent References[b]	Pb Exposure or Blood Pb Levels Associated with Effects[c]
Postnatal Growth			
Available toxicological studies reported mixed findings of effects of Pb on postnatal growth	There are mixed findings in the toxicological literature on Pb exposure and postnatal growth with some studies showing stunted growth in animals exposed to Pb and some showing no effects. Recent toxicological evidence of effect of Pb on postnatal growth: obesity in adult male offspring after gestational + lactational Pb exposure	Section 5.8.1.3	
Available epidemiologic findings of associations between higher blood Pb levels and postnatal growth are inconsistent	Multiple studies, mostly cross-sectional, for children of varying ages have reported inconsistent results for the association between blood Pb levels and various measures of growth	Section 5.8.1.3	
Impaired Organ Systems			
Consistent toxicological findings of effects on sensory organ systems, bone, teeth, and GI system but not always at relevant Pb exposure levels.	Relevant gestational and lactational Pb exposure of rats resulted in retinal ERG aberrations and increased retinal cell layer thickness.	Fox et al. (2008)	Blood Pb level after gestational-lactational exposure: 10-12 µg/dL
Effects on Birth Outcomes - Suggestive			
Inconsistent findings in epidemiologic studies of various birth outcomes	Inconsistent findings for studies for birth defects, preterm birth, and low birth weight/fetal growth.	See Section 5.8.3 (and all subsections): 5.8.3.1, 5.8.3.2, 5.8.3.3, 5.8.3.4	
	A few well-conducted epidemiologic studies of preterm birth and low birth weight/fetal growth using measures of maternal blood Pb at the time of pregnancy reported associations.	Jelliffe-Pawlowski et al. (2006), Vigeh et al.(2011), Zhu et al. (2010), Chen et al. (2006a), Gundacker et al. (2010)	Maternal pregnancy blood Pb levels: >10 µg/dL
Inconsistent findings in toxicological literature for birth outcomes	The toxicological literature reported mixed findings with some studies showing smaller litter size (fewer pups born) or decreased birth weight with Pb exposure and some studies showing no effect.	See Section 5.8.3.4 and 5.8.3.1	

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	Recent References[b]	Pb Exposure or Blood Pb Levels Associated with Effects[c]
Effects on Male Reproductive Function – Causal			
High-quality and consistent findings in toxicological studies of detrimental effects of Pb exposure on sperm or semen in multiple species.	Decreased sperm counts, decreased sperm production rate, dose-dependent suppression of spermatiogenesis in rodents with drinking water Pb exposure.	All results: Section 5.8.4.1 Sokol et al. (1985)	Blood Pb level after adult drinking water exposure for 30 days: 34 µg/dL
		Sokol and Berman (1991)	Blood Pb level after peripubertal or adult drinking water exposure for 30 days: 35 and 37 µg/dL.
	Ultrastructural damage and histological to non-human primates testis and seminiferous tubules.	Singh et al. (1993a) Foster et al. (1998)	Maximum blood Pb levels after daily oral Pb exposure (gelatin capsule) during infancy, post infancy, or over a lifetime (up to 10 yr): 32 to 36 µg/dL
	Histologic damage to rodent seminiferous tubules including spermatids and developing sperm.	El Shafai et al. (2011)	Blood Pb level after adult exposure (oral gavage) for 3 months: 5.31 µg/dL
	Ultrastructural abnormalities to rat spermatogenesis.	Murthy et al.(1995)	Blood Pb level after i.p. injection for 16 days: 7.4 µg/dL
	Direct effects on rodent sperm DNA after drinking water Pb exposure.	Nava-Hernández et al. (2009)	Blood Pb level after adult exposure for 13 weeks: 19 and 22 µg/dL
	Sperm from Pb exposed rats used for in vitro fertilization of eggs harvested from unexposed females yielded lower rates of fertilization.	Sokol et al.(1994)	Blood Pb level after adult exposure for 14-60 days: 33-46 µg/dL
	Semen and sperm quality in rabbits with subcutaneous Pb treatment; ultrastructural damage to spermatids with i.p. injection of Pb.	Moorman et al.(1998),	Blood Pb level after adult exposure for 15 weeks: 16-24 µg/dL
	Findings of detrimental effects of Pb exposure on sperm from multiple species (Deer, Asian earthworm, rainbow trout, marine worm, *H. elegans*,Fathead minnow)	See Ecological Effects; Sections 7.4.12.1 and 7.4.21.1)	
Toxicological evidence is supported by consistent findings in epidemiologic studies of associations between higher blood Pb levels and decrements in sperm count and quality in occupational cohorts	Consistent evidence from studies of occupational cohorts with high blood Pb levels. Results from occupational cohorts may have been confounded by other workplace exposures, which were not adjusted for in the epidemiologic studies. Potential confounding by smoking was considered in one study.	Naha and Manna (2007), Naha and Chowdhury (2006), Hsu et al. (2009b), Kasperczyk et al. (2008)	Concurrent blood Pb levels: ≥ 25 µg/dL
	Results less consistent at lower blood Pb level. A well-conducted epidemiologic study at an infertility clinic reported associations between detrimental effects in sperm and blood Pb levels after controlling for smoking and other metal exposure. A similar study also reported some elevated effect estimates but the results were too imprecise to draw definitive conclusions.	Telisman et al. (2007), Meeker et al. (2008)	Concurrent blood Pb level: <10 µg/dL

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	Recent References[b]	Pb Exposure or Blood Pb Levels Associated with Effects[c]
Evidence describes mode of action for effects on sperm.	Consistent MOA evidence in reproductive organs of Pb-exposed male animals of increased apoptosis, decreased antioxidant activity (SOD and CAT),and increased oxidative stress (MDA).	Sections 5.8.4.1 and 5.8.4.2	
Inconsistent findings of associations between Pb levels and hormone levels in epidemiologic studies; few studies available	There are a small number of studies examining hormone levels and the results are inconsistent.	Telisman et al. (2007), Naha and Manna (2007), Hsieh et al. (2009a), Meeker et al. (2010), Mendiola et al. (2011) Section 5.8.4.2	
Lack of large, well-conducted epidemiologic studies examining associations between Pb levels and fertility	The few epidemiologic studies examining this outcome generally have small samples sizes and are drawn from men attending infertility clinics.	Kiziler et al. (2007), Bloom et al. (2011b), Bloom et al. (2010), Gracia et al. (2005) Section 5.8.4.3	
Limited toxicological findings of Pb exposure inducing effects on fertility	Paternal Pb exposure resulted in less successful copulation, fewer implantations, and longer periods of time copulating for successful matings. Unexposed females with Pb-exposed male partners did not have fewer pregnancies, but did produce smaller litters.	Anjum et al. (2010) Sainatha et al. (2011) Pace et al. (2005) Section 5.8.4.3	45-day exposure of adult male rats to 500 or 1,500 ppm Pb acetate exposure in drinking water, followed by behavioral mating studies with unexposed females.
Effects on Female Reproductive Function - Suggestive			
Epidemiologic studies of Pb levels and hormones demonstrate associations but are inconsistent overall	Evidence in some high-quality cross-sectional epidemiologic studies demonstrates associations with hormone levels but results are mixed and vary by hormone examined and timing in a woman's menstrual and life cycles. In addition, the potential confounders vary from study to study, with some potentially important confounders, such as BMI, not included in all studies.	Jackson et al. (2011), Pollack et al. (2011), Chang et al. (2006), Krieg (2007) Section 5.8.5.1	Concurrent mean blood Pb levels: <5 µg/dL
Lack of large, well-conducted epidemiologic studies examining associations between Pb levels and fertility	Epidemiologic studies of this association are limited by the small sample sizes included in those studies. In addition, most of the study populations were drawn from women undergoing IVF and/or attending infertility clinics.	Section 5.8.5.2	
Toxicological studies of Pb and effects on female reproduction demonstrate effects in some studies.	Evidence in the toxicological literature of Pb contributing to placental pathology and inflammation, decreased ovarian antioxidant capacity, altered ovarian steriodogenesis and aberrant gestational hormone levels. [a]Described in detail in Table II of the Preamble.

[b]Describes the key evidence and references contributing the most heavily to causal determination. References to earlier sections indicate where full body of evidence is described.

[c]Describes the blood Pb level in humans with which evidence is substantiated or the blood Pb levels or Pb exposure concentrations in animals relevant to humans.

5.9 Effects on Other Organ Systems

The 2006 Pb AQCD described limited evidence for the effects of Pb exposure on various organ systems including the liver, GI tract, endocrine system, bone and teeth, eyes, and respiratory tract. These lines of evidence largely are supported by recent toxicological and epidemiologic studies, although the collective evidence remains relatively limited in terms of the quantity and design of studies and/or the populations examined.

5.9.1 Effects on the Hepatic System

Hepatotoxic effects of Pb exposure indicated in various animal models and/or human populations include alterations in hepatic metabolism, hepatic cell proliferation, changes in cholesterol metabolism, as well as oxidative stress-related injury.

5.9.1.1 Summary of Key Findings of the Effects on the Hepatic System (2006 Pb AQCD)

The 2006 Pb AQCD (U.S. EPA, 2006b) stated that the experimental animal database indicated hepatotoxic effects, including liver hyperplasia, at very high dose Pb exposures. Other effects noted in the liver following exposure to Pb included altered cholesterol synthesis, DNA synthesis, and glucose-6-phosphotase dehydrogenase (G6DP) activity. The 2006 Pb AQCD reported that cytochrome (CYP) P450 levels decreased following single doses of Pb nitrate. Induced and constitutive expression of microsomal CYP1A1 and CYP1A2 was inhibited by Pb exposure. Inhibition of these (Phase I) xenobiotic metabolizing enzymes was accompanied by an increase in Phase II enzymes following exposure to Pb nitrate and other Pb compounds, suggesting that Pb is capable of inducing a biochemical phenotype similar to hepatic nodules. Studies related to Pb-induced hepatic hyperplasia suggested alterations in the gluconeogenic mechanism, DNA hypomethylation, changes in proto-oncogene expression, as well as cholesterol synthesis. Cholesterol metabolism changes following exposure to Pb were reportedly mediated by induction of several enzymes related to cholesterol metabolism as well as a decrease in the cholesterol catabolizing enzyme, 7 α-hydroxylase. Tumor necrosis factor alpha (TNF-α) was reported to be one of the major mitogenic signals that mediated Pb nitrate-induced hepatic hyperplasia, based on findings showing that inhibitors blocking TNF-α activity also blocked Pb-induced hyperplasia. Other Pb-related effects presented in the 2006 Pb AQCD included liver cell apoptosis mediated by Kupffer cell derived signals and Pb-induced oxidative stress in vitro cell cultures. The 2006 Pb AQCD further suggested that alterations in liver heme metabolism may involve changes in

5-aminolevulinic acid dehydrogenase (ALAD) activity, porphyrin metabolism, transferrin gene expression and changes in iron metabolism.

With regard to human studies, the 2006 Pb AQCD stated that increases in serum liver enzymes suggest that Pb exposure results in nonspecific liver injury in occupationally-exposed adults. However, studies did not adjust for potential confounding factors, including other occupational exposures or establish explicit associations between Pb exposure and hepatic injury (i.e., observation of histopathological effects). In addition, similar to effects were noted in animal studies, and decreased cytochrome P450 activity was associated with higher blood Pb levels in a few studies of children or adults (drawn from the general population). The 2006 Pb AQCD reported that hepatic effects in humans were associated only with high blood Pb levels, i.e., >30 µg/dL.

5.9.1.2 Recent Epidemiologic Studies

A few epidemiologic studies examined antioxidant status and oxidative stress effects, as measured by liver biochemical parameters, associated with occupational exposure to Pb. However, all of these occupationally-exposed cohorts represented populations highly exposed to Pb, with mean or median blood Pb levels ranging from 29 to 53 µg/dL. Although the hepatic effects observed within these cohorts may not be generalizable to the general population as a whole, they are useful in demonstrating consistent effects on a number of liver outcomes, including altered liver function (i.e., changes in the level of liver function enzymes), oxidative stress, and antioxidant status (Can et al., 2008; Khan et al., 2008; Patil et al., 2007). However, these studies were cross-sectional in design with concurrent blood Pb measurement. Thus, there is uncertainty regarding the directionality of effects and the magnitude, timing, frequency, and duration of Pb exposure that contributed to the observed associations. Further, analyses did not consider potential confounding by factors such as age, diet, BMI, smoking, or other occupational exposures.

In spray painters from Kolhapur City in western Maharashtra, India, exposed to Pb for >6 hours/day for 2 to 20 years examined by Patil et al. (2007), mean concurrent (SD) blood Pb levels in 30 workers (mean [SD]: 22.32 [8.87] µg/dL) were significantly higher ($p < 0.001$, t-test) than those in the 35 concurrent controls (mean [SD]: 12.52 [4.08] µg/dL), who had no history of Pb exposure and lived in rural areas. Levels of liver function enzymes, including the two serum transaminase enzymes SGOT (also known as AST; serum glutamic oxaloacetic transaminase/aspartate aminotransferase) and SGPT (also known as ALT; serum glutamic pyruvic transaminase/alanine aminotransferase), were increased in spray painters compared to those in controls, whereas total serum protein levels were decreased compared to controls ($p < 0.01$, t-test). In another

occupational study, Conterato et al. (In Press) investigated liver function parameters in automotive painters exposed to Pb in Brazil. Mean (SD) concurrent blood Pb levels were 5.4 (0.4) µg/dL in the 50 exposed painters and 1.5 (0.1) µg/dL in the 36 unexposed controls. The mean (SD) duration of exposure to Pb in painters was 133.9 (14.5) months. In exposed workers, the levels of AST, but not γ-glutamyltransferase, were increased approximately 2-fold compared to levels in controls ($p < 0.05$). The activity of AST was positively correlated with blood Pb levels ($r = 0.26$, $p < 0.05$). The authors suggested that confounding exposures to toxic constituents of the paints regularly used by painters, and not Pb, may be the etiological cause of decrements in AST function as these effects were not also seen in battery workers with much higher blood Pb levels (49.8 µg/dL) (Conterato et al., In Press). Co-exposure to other environmental contaminants may also explain the effects that were previously reported in occupationally-exposed spray-painters in Patil et al. (2007).

5.9.1.3 Recent Toxicological Studies

Hepatic Metabolism

As stated in the 2006 Pb AQCD (U.S. EPA, 2006b), acute (e.g., single dose) treatment of rodents with Pb nitrate and other Pb compounds was found to result in a decrease in Phase I enzymes and a simultaneous increase in Phase II enzymes. The conclusions presented in the 2006 Pb AQCD were also reviewed by Mudipalli (2007).

Recent studies found changes in biochemical parameters, suggestive of liver damage, in animals exposed to Pb; however, the relevance to humans is uncertain because of the high blood Pb levels used in animal studies and the exposure routes of Pb administration. Undernourished male Wistar rats (fed low-protein diet without mineral supplements) exposed to 500 ppm Pb acetate in drinking water over a 10 month period had decreases in serum protein and albumin levels as well as increases in AST, ALT, serum alkaline phosphatase (ALP), and gamma glutamyl transpeptidase (GGT) levels (Herman et al., 2009). In Pb-treated animals, the blood Pb levels steadily increased throughout the initial portion of the study period, reaching a maximum of approximately 30 µg/dL after 2 months. After this time, blood Pb levels rapidly increased to approximately 110 µg/dL by six months time, and remained at this level until the termination of exposure at 10 months. Similar biochemical changes were not observed in animals treated with Pb acetate maintained on protein-adequate, mineral rich diet.

Similarly, mice gavaged with Pb nitrate (50 mg/kg for 40 days) also demonstrated increased activities of AST, ALT, ALP, and acid phosphatase (ACP) compared to

controls (Sharma et al., 2010a). Upadhyay et al. (2009) reported that treatment of Sprague-Dawley rats with Pb acetate (35 mg/kg via i.p. injection for 3 days, blood Pb not reported) significantly increased the activities of ALT, AST, serum ALP, and acid phosphatase over those in controls but decreased liver ALP activity. Concomitant treatment with Zn and varying levels of vitamin C were observed to ameliorate the toxic effects of Pb. The serum activities of glutamic pyruvic transaminase (GPT) and lactate dehydrogenase (LDH) were similarly significantly increased over those in controls in mice subcutaneously injected with Pb acetate (50 mg/kg daily for 15 days, blood Pb not reported) (Wang et al., 2010g). Swarup et al. (2007) investigated serum biochemical changes in cows living in Pb-contaminated environments. Serum levels of ALT, AST, ALP, total protein, albumin, globulin, and A/G ratio were significantly altered in cows living near Pb-Zn smelters (mean [SD] blood Pb level: 86 [6] µg/dL) compared to control cows (mean [SD] blood Pb level: 7 [1] µg/dL). Significant positive correlations were found between blood Pb level and ALT and AST, whereas a negative correlation was observed between blood Pb level and total lipids, protein, and albumin.

Pillai et al. (2009) investigated hepatic Phase I and II enzymes in male and female rats born to dams that were treated with Pb acetate (50 µg/kg, via s.c. injection daily throughout gestation and continuing until PND21). Thus, the offspring of treated dams were exposed to Pb via placental and lactational transfer. The female and male pups were then allowed to reach sexual maturity (PND55-PND56) to assess continuing exposure to bioaccumulated Pb. The activities of hepatic Phase I enzymes NADPH- and NADH-cytochrome *c* reductase were significantly reduced in Pb-exposed male and female rats on PND56 (blood Pb not reported), compared to controls. In rats treated with 25 µg/kg Pb and Cd, the effect on Phase I enzymes was increased. Pb treatment additionally decreased the activities of Phase II enzymes uridine diphosphate-glucoronyl transferase and GST in males and females, but no effect was observed on GGT or 17β-hydroxysteroid oxidoreductase. Additionally, no effect was observed on serum glutamate pyruvate dehydrogenase or ALP activities in Pb-treated males or females. Histological observations demonstrated fatty degeneration of the liver, vacuolization, and pycnotic nuclei, indicating general hepatotoxicity following Pb treatment in both male and female rats.

In a similar study, Teijon et al. (2006) exposed Wistar rats to Pb acetate (200 or 400 ppm drinking water) throughout gestation, lactation, and 3 months postweaning, or only 1 month postweaning. In the animals exposed continuously throughout gestation and lactation, the concentrations of Pb in the liver were elevated in the 200- and 400-ppm groups 1 and 3 months postweaning. Liver concentrations of Pb were greater in the 200 ppm animals compared to the 400 ppm animals at one month postweaning (mean [SE]: 1.19 [0.30] µg Pb/g tissue versus 0.76 [0.06] µg Pb/g tissue, respectively), but were

similar between the 2 dosing regimens (200 ppm versus 400 ppm) at 3 months postweaning (mean [SE]: 0.54 [0.06] versus 0.55 [0.07] µg Pb/g tissue, respectively). ALP activity was increased at 2 weeks postweaning in animals continuously exposed to Pb throughout gestation and lactation, whereas ALT activity was decreased only at 2 and 3 months postweaning. In animals exposed for 1 month postweaning alone, only serum ALP activity was significantly increased, although not in a concentration-dependent manner. ALT and AST activities did not show significant changes.

Cheng et al. (2006) studied the mechanism of Pb effects on bacterial lipopolysaccharide (LPS)-induced TNF-α expression. A/J mice were injected with Pb acetate (100 µmol/kg via i.p.), with or without LPS (5 mg/kg). Pb alone did not affect AST or ALT activity or the level of TNF-α in the serum of the mice. In comparison, treatment of mice with low doses of Pb and LPS together caused a statistically significant increase in TNF-α induction as well as enhanced liver injury, suggesting that Pb potentiated LPS-induced inflammation. In a complementary in vitro experiment, co-exposure of Pb and LPS stimulated the phosphorylation of p42/44 mitogen-activated protein kinase (MAPK) and increased TNF-α expression in mouse whole blood cells, peritoneal macrophages, and RAW264.7 cells (a macrophage cell line). These results indicated that Pb increased LPS-induced TNF-α levels via the protein kinase C (PKC)/MAPK pathway in monocytes/macrophages rather than hepatocytes. Similarly, Pb chloride potentiated bovine serum albumin (BSA)-induced inflammation in the livers of mice subcutaneously injected with Pb (Sá et al., 2012).

Lipid Metabolism

Several recent toxicological studies indicated Pb-induced impaired lipid metabolism, as evidenced by increases in liver cholesterol. There was some evidence in animals exposed to Pb in diet, albeit at relatively high exposure concentrations or measured blood Pb. Ademuyiwa et al. (2009) reported that male albino Sprague Dawley rats exposed to 200, 300 and 400 ppm Pb acetate in drinking water had mean (SD) blood Pb levels of 40.63 (9.21), 61.44 (4.63), and 39.00 (7.90) µg/dL, respectively. Animals exposed to 200 ppm Pb had mean (SD) liver Pb concentrations of 10.04 (1.14) µg/g, compared to 3.24 (1.19) µg/g and 2.41 (0.31) µg/g in animals exposed to 300 or 400 ppm Pb, respectively. Animals exposed to Pb exhibited increased hepatic cholesterogenesis at all doses tested compared to controls. Additionally, a decrease in triglyceride levels was observed at 300 and 400 ppm Pb; a decrease in phospholipid levels was observed at 400 ppm Pb. The authors also reported positive correlations between tissue cholesterol and phospholipids and Pb accumulation in liver across all doses. In contrast, the association between tissue triglyceride levels and Pb accumulation was negative. In related studies, Khotimchenko and Kolenchenko (2007) reported that adult male albino rats treated with Pb acetate

(100 mg/kg for 14 days, blood Pb not reported) exhibited disorders in lipid metabolism that were accompanied by increased levels of total cholesterol and triglycerides in the liver tissue. Sharma et al. (2010a) reported increased liver cholesterol in mice gavaged with Pb nitrate, 50 mg/kg for 40 days. Pillai et al. (2009) observed decreases in total liver cholesterol in PND56 male and female rats that had been treated with Pb acetate (via s.c. injection, 50 µg/kg, continuously throughout gestation and lactation). These results suggest that Pb induction of cholesterogenesis and phospholipidosis in the liver may cause subtle effects at the cellular level that may lead to hepatotoxicity.

Kojima and Degawa (2006) examined sex-related differences in Pb-induced gene expression of a rate limiting hepatic cholesterol biosynthesis enzyme, 3-hydroxy-3-methylglutaryl-CoA reductase (HMGR) and its transcription factor, sterol regulatory element binding protein-2 (SREBP-2). Male and female Sprague Dawley rats were injected with Pb nitrate (100 µmol/kg body weight, intravenously, blood Pb not reported). SREBP-2 expression was significantly increased in males and females with the increase occurring earlier in male rats (6-12 hours, compared to 24-36 hours in females). In contrast, expression of HMGR was significantly increased in both Pb-exposed males and females at earlier time frames and greater range of onset (3-48 hours in males; 12-48 hours in females) compared to that of SREBP-2. Significant increases in total liver cholesterol were also observed in Pb-exposed males and females at 3-48 and 24-48 hours, respectively. These results suggest that the SREBP-2 and HMGR gene expressions and increase in total cholesterol levels in the liver in response to Pb exposure occur earlier in males compared to females and also suggest that the HMGR gene expression and increase in total cholesterol levels in the liver occur before an increase in the SREBP-2 gene expression in each sex.

Hepatic Oxidative Stress

A number of studies demonstrated increased hepatic oxidative stress as a result of exposure to various Pb compounds, demonstrated by increases in reactive oxygen species (ROS) or decreases in antioxidant levels or enzyme activity. ROS can potentially result in damage to hepatic function and structure. Several of these observations were made in animals exposed to Pb in drinking water that produced blood Pb levels relevant to humans. In a study examining the effects of Pb exposure to fetuses, Massó et al. (2007) exposed pregnant Wistar rats to 300 ppm Pb in drinking water from GD1 to parturition, or to weaning. Blood Pb levels were higher at parturition (mean [SD]: 31.5 [0.80] µg/dL) than at weaning (mean [SD]: 22.8 [0.50] µg/dL). Pups exhibited liver damage that was accompanied by an increased production of thiobarbituric acid-reactive species (TBARS, an indicator of lipid peroxidation) and increased CAT activity compared to controls. In addition, increased ALP and acid phosphatase activity was observed. Uzbekov et al.

(2007) showed differential effects by duration of maternal exposure before mating. Female Wistar rats were exposed to 0.3 and 3.0 ppm Pb nitrate in drinking water, for 1 month or 5 months prior to pregnancy, and also continuing during pregnancy; then the livers from both groups of GD20 fetuses were examined for hepatic SOD activity. The pregnant control rats had a mean (SD) blood Pb level of 16.1 (0.63) µg/dL, whereas the dams exposed to 0.3 and 3.0 ppm Pb had mean blood Pb levels of 20.4 µg/dL and 24.4 µg/dL, respectively. In the GD20 fetuses from dams exposed for 1 month prior to pregnancy, a concentration-dependent increase in liver SOD activity was observed, whereas SOD activity was decreased in the GD20 fetuses from dams exposed for 5 months prior to pregnancy. The increase in SOD activity in the livers of fetuses from dams exposed to 0.3 or 3.0 ppm Pb nitrate for one month suggests an initial activation of SOD in response to increased free radical production, while the decrease in SOD production in fetal livers from dams exposed to the same concentrations for 5 months suggests that longer durations of Pb exposure impairs the antioxidant defense mechanism.

Increased oxidative stress also was found in animals with postnatal Pb exposure in drinking water. Jurczuk et al. (2007) reported that male Wistar rats treated with 500 ppm Pb in drinking water (blood Pb not reported) exhibited decreases in liver vitamin E and GSH levels along with an increase in lipid peroxidation. The correlation between vitamin E and lipid peroxidation suggested that vitamin E is involved in the mechanism of peroxidative action of Pb in the liver. In a study examining the role of low molecular weight thiols on peroxidative mechanisms, Jurczuk et al. (2006) found that male Wistar rats treated with 500 ppm Pb acetate in drinking water exhibited a decrease in blood ALAD as well as decreases in GSH and nonprotein sulfhydryl levels in the liver. Metallothionein levels were also reported to be higher in the liver following exposure to Pb. Yu et al. (2008) reported concentration-dependent increases in lipid peroxide levels and decreases in GSH levels and CAT, SOD and GPx activities in livers from castrated male pigs that received a diet mixed with 0, 5, 10, or 20 mg/kg Pb nitrate exposure, during ages 55-100 days. The level of hepatic CuZnSOD mRNA was also reduced in Pb-treated animals. The study authors suggested that this decrease in SOD mRNA expression and activity of antioxidant enzymes may lead to a reduction in free radical scavenging capability and increased lipid peroxidation.

Studies administering Pb by bolus doses had similar findings. Adegbesan and Adenuga (2007) reported that lipid peroxidation was increased and SOD activity was decreased in protein undernourished male Wistar rats compared to well-fed rats, and that these effects were further exacerbated in protein undernourished rats injected with Pb nitrate (100 µmol/kg, blood Pb not reported). Protein undernourishment also decreased GSH levels and CAT activity compared to normal diet; however, co-treatment with Pb mitigated the severity of these effects. GSH levels and CAT activity were still lower in

undernourished rats with Pb exposure compared to well-fed rats, but greater than undernourished rats with no Pb exposure. The results indicated Pb treatment exacerbated the effects of malnutrition on liver lipid peroxidation and altered the involvement of free radicals. Male Charles-Foster rats treated with Pb acetate (0.025 mg/kg via i.p. injection, blood Pb not reported) also exhibited statistically significant increases in lipid peroxidation levels and decreases in SOD, CAT, and glucose-6-phosphatase dehydrogenase levels in liver mitochondrial and postmitochondrial fractions (Pandya et al., 2010). Statistically nonsignificant decreases were observed in GSH levels, and in GPx and GR activities in Pb-treated animals. In mice gavaged with Pb nitrate (50 mg/kg for 40 days), lipid peroxidation was increased, and SOD, CAT, and GSH were decreased compared to controls (Sharma et al., 2010a). Additionally, Pb nitrate treatment resulted in histopathological changes in the structure of the liver: hepatocytes were damaged and were marked by cytoplasmic vacuolization and pycnotic nuclei.

Khotimchenko and Kolinchenko (2007) also reported an increase in lipid peroxidation and development of hepatitis in male albino rat liver parenchyma following intragastric treatment with Pb acetate (100 mg/kg for 14 days). Lipid peroxidation was demonstrated by increases in malondialdehyde (MDA) levels along with decreases in GSH and thiol groups; indicating injury in the liver antioxidant system. Levels of hepatic lipid peroxidation were observed to be significantly increased in rats treated with Pb acetate (35 mg/kg via i.p. injection daily for 3 days, blood Pb not reported), whereas hepatic GSH was significantly decreased (Upadhyay et al., 2009). A study examining male and female rat pups that were continuously exposed to Pb during gestation and lactation (pregnant dams were injected [s.c.] with Pb acetate, 50 µg/kg per day [GD0 to PND21], blood Pb not reported), did not find effects on GSH or MDA levels at PND56 (Pillai et al., 2009). In vitro exposure of cells from a hepatic human embryonic epithelial cell line (WRL-68) to 5 µM Pb acetate for 30 days resulted in increased production of ROS throughout the incubation period (Hernández-Franco et al., 2011). Concurrent with this increase in ROS generation, the activities of SOD and the levels of membrane lipid peroxidative damage increased throughout the first 24 days of exposure but returned to normal levels by day 30.

Hepatic Apoptosis

Fan et al. (2009b) reported that a single i.v. injection (tail vein) of Pb nitrate (200 µmol/kg in 0.5 mL) in rats resulted in an increase in the percentage of apoptotic hepatocytes (mean: 2.5 [SD: 1.4]% of total hepatocytes) compared with controls (mean: 0.31 [SD: 0.31]%). Expression of ferritin light-chain (FTL) protein also increased (mean [SD]: 3.5 [1.0]-fold increase) over that in controls. Immunohistochemical analysis revealed that hepatocytes around the central vein were heavily stained by anti-FTL

antibodies, as were nonparenchymal cells identified as Kupffer cells. The authors hypothesized that the expression of FTL in Kupffer cells may have resulted from the phagocytosis of apoptotic cells. Treatment of rats with clofibrate, a lipid lowering agent, did not increase FTL expression in Kupffer cells and induced hepatocellular proliferation but not apoptosis.

5.9.1.4 Summary of Effects on the Hepatic System

While explicit associations between hepatic injury (i.e., histopathological effects) and Pb exposure have not established, evidence from epidemiologic and toxicological studies have indicated that exposure to Pb can result in altered liver function and hepatic oxidative stress. A few studies have reported associations of higher blood Pb levels with decreased cytochrome P450 enzymes (Phase I xenobiotic metabolism) in children and nonoccupationally-exposed adults. However, most evidence indicates decreases in serum protein and albumin levels and increased AST, ALT, ALP, and GGT activities (indicators of decreased liver function), increased oxidative stress, and decreased antioxidant status in Pb-exposed workers with blood Pb levels >29 µg/dL (Can et al., 2008; Khan et al., 2008; Patil et al., 2007; Conterato et al., In Press). The implications of the epidemiologic evidence is limited because of its cross-sectional study design nature, the high blood Pb levels examined, and lack of consideration for potential confounding by factors such as age, diet, BMI, smoking, or other occupational exposures.

Similar changes in liver function enzymes have been found in mature animals exposed to high levels of Pb during adulthood (Sharma et al., 2010a; Wang et al., 2010; Herman et al., 2009; Cheng et al., 2006), and animals exposed during gestation and lactation (Pillai et al., 2009; Teijón et al., 2006). Pb exposure has been shown to impair lipid metabolism in animals, as evidenced by increased hepatic cholesterogenesis, and in altered triglyceride and phospholipid levels (Ademuyiwa et al., 2009; Khotimchenko and Kolenchenko, 2007). Multiple studies in humans and animals have observed Pb-associated hepatic oxidative stress, generally indicated by an increase in lipid peroxidation along with a decrease in GSH levels and CAT, SOD, and GPx activities (Pandya et al., 2010; Sharma et al., 2010a; Khan et al., 2008; Yu et al., 2008; Adegbesan and Adenuga, 2007; Jurczuk et al., 2007; Khotimchenko and Kolenchenko, 2007; Jurczuk et al., 2006). Indices of increased oxidative stress were also observed in the livers of fetuses exposed to Pb throughout gestation (Massó et al., 2007). The relevance of the toxicological evidence is uncertain as many studies administered Pb as bolus doses. Because of the insufficient quality of studies, the evidence is inadequate to determine if there is a causal relationship between Pb exposure and hepatic effects.

5.9.2 Effects on the Gastrointestinal System

Gastrointestinal effects examined in relation to Pb exposure include abdominal pain, constipation, and internal paralysis in humans and degeneration of the intestinal epithelial mucosa and a decrease in duodenal motility in animals.

5.9.2.1 Summary of Key Findings on the Effects on the Gastrointestinal System (2006 Pb AQCD)

The 2006 Pb AQCD (U.S. EPA, 2006b) stated that a number of factors influence the gastrointestinal absorption of Pb; including the chemical and physical form of Pb, the age at Pb intake, as well as various nutritional factors. Rats exposed to Pb acetate in drinking water had degeneration of the intestinal epithelial mucosa, potentially leading to malabsorption of nutrients. In suckling rat pups, increased casein micelles incidences were reported as a result of Pb present in bovine and rat milk and in infant milk formula. Pb ingestion through water was more toxic compared to Pb ingestion via milk. Pb ingested in milk was reported to be taken up by the ileal tissue, whereas Pb administered intragastrically as a soluble salt was primarily accumulated in the duodenum irrespective of vehicle used for administration. Decreases in duodenal motility and the amplitude of contractility in the intestinal tract were observed in rats following Pb exposure. Nutritional studies examining different dietary levels of Pb, Ca^{2+}, and vitamin D in rats indicated competition in absorption between Pb and calcium. Dietary supplementation with vitamin D led to an increase in intestinal absorption of Pb and calcium. In instances where severe calcium deficiency was noted, ingestion of Pb caused a clear decrease in 1,25-dihydroxy vitamin D (1,25-(OH)2D3) levels. Overall, the 2006 Pb AQCD stated that studies in rat intestine have shown that the largest amount of Pb absorption occurs in the duodenum with the mechanisms of absorption involving active transport and diffusion via the intestinal epithelial cells. Absorption has been reported to occur, through both saturable and nonsaturable pathways, based on results from various animal studies. The 2006 Pb AQCD reported evidence that symptoms associated with gastrointestinal colic (abdominal pain, constipation, intestinal paralysis) were more prevalent in occupationally-exposed adults with blood Pb levels $\geq$ 50 µg/dL.

5.9.2.2 Recent Epidemiologic Studies

Consistent with previous findings, Kuruvilla et al. (2006) reported gastrointestinal effects including stomach pain and gastritis along with other non-gastrointestinal effects in 53 Pb-exposed painters (mean [SD] blood Pb: 8.04 [5.04] µg/dL) in India compared with 50

controls (mean [SD] blood Pb level: 5.76 [4.45] µg/dL) matched by sex, age, education, income, smoking, and alcohol consumption. Prevalence of symptoms in painters did not differ from that in battery workers with higher blood Pb levels (mean [SD] blood Pb level of 42.40 ([25.53] µg/dL). Despite the consistent evidence among occupational studies, the implications of gastrointestinal findings in Pb-exposed workers are limited by the cross-sectional study designs, high blood Pb levels associated with effects (mostly ≥ 50 µg/dL), and limited consideration for potential confounding by factors such as age, smoking, alcohol use, nutrition, or other occupational exposures.

5.9.2.3 Recent Toxicological Studies

A few recent studies pertaining to gastrointestinal effects of Pb exposure were identified that provide evidence for additional mechanisms underlying gastrointestinal damage and impaired function. Santos et al. (2006) examined the impact of Pb exposure on nonadrenergic noncholinergic (NANC) relaxations in rat gastric fundus. Male Wistar rats treated with 80 ppm Pb acetate via drinking water for 15, 30, and 120 days (blood Pb not reported) exhibited a significant difference in NANC relaxations in the gastric fundus following electrical field stimulus. While frequency-dependent relaxations were observed in all groups, including the control group, the relaxations were significantly inhibited in rats treated with Pb acetate for all three durations. When gastric fundus strips from rats were incubated with L-nitroarginine, a nitric oxide (NO) synthase inhibiter, no additional inhibition in relaxations was observed. In contrast, incubation with sodium nitroprusside and 8-Br-GMPc (a cyclic guanosine monophosphate [cGMP] analog), resulted in a concentration-dependent relaxation in strips in the control group and in the group exposed to Pb acetate for 120 days. The results suggested that long-term exposure to Pb causes inhibition in NANC relaxation probably due to the modulated release of NO from the NANC nerves or due to interaction with the intracellular transducer mechanism in the rat gastric fundus.

In another study examining Pb-induced oxidative stress in the gastric mucosa, Olaleye et al. (2007) treated Albino Wistar rats with 100 or 5,000 ppm Pb acetate in drinking water for 15 weeks (blood Pb not reported). Exposure to Pb acetate caused a significant increase in gastric mucosal damage caused by pretreatment with acidified ethanol. While the basal gastric acid secretory rate was not altered, stomach response to histamine was significantly higher in animals treated with Pb acetate compared to that in the controls. Additionally, there was a significant increase in gastric lipid peroxidation at both the 100 and 5,000 ppm dose levels. In contrast, CAT, and SOD activities and nitrite levels were significantly decreased in the gastric mucosa. The results indicated that Pb-induced gastric damage may be mediated via increases in oxidative stress.

5.9.2.4 Summary of Gastrointestinal Effects

Relatively few human studies have been conducted on the gastrointestinal toxicity of Pb. The evidence points to more prevalent symptoms, such as stomach pain, gastritis, constipation, and intestinal paralysis, in Pb-exposed workers (Kuruvilla et al., 2006). However, the implications of gastrointestinal findings in Pb-exposed workers are limited by the cross-sectional study designs, high blood Pb levels associated with effects (mostly ≥ 40 µg/dL), and limited consideration of potential confounding by factors such as age, smoking, alcohol use, nutrition, or other occupational exposures. Toxicological evidence indicates that Pb is absorbed primarily in the duodenum by active transport and diffusion, although variability is observed by Pb compound, age of intake, and nutritional factors. There is some coherence between the evidence in Pb-exposed workers and observations in animals that Pb induces damage to the intestinal mucosal epithelium, decreases duodenum contractility and motility, reduces absorption of Ca^{2+}, inhibits NANC relaxations in the gastric fundus, and induces oxidative stress (lipid peroxidation, decreased SOD and CAT) in the gastric mucosa (Olaleye et al., 2007; Santos et al., 2006). The observation of oxidative stress was accompanied by gastric mucosal damage. Because of the insufficient quantity and quality of studies, the evidence is inadequate to determine if there is a causal relationship between Pb exposure and gastrointestinal effects.

5.9.3 Effects on the Endocrine System

A summary of key findings pertaining to reproductive hormones in males and females is presented in the section on Reproductive and Developmental Effects (Sections 5.8.1 and 5.8.2). Collective epidemiologic and toxicological evidence is inconsistent in demonstrating the effects of Pb exposure on male and female sex hormone levels. Other endocrine processes that are most commonly found to be impacted by Pb exposure include changes in thyroid hormones, including thyroid stimulating hormone (TSH), triiodothyronine (T3), and thyroxine (T4). A few studies have examined calcium and cortisol.

5.9.3.1 Summary of Key Findings of the Effects on the Endocrine System (2006 Pb AQCD)

The 2006 Pb AQCD (U.S. EPA, 2006b) reported that endocrine processes impacted by occupational Pb exposure include thyroid hormone levels, changes in male sex hormone levels, as well as changes in the production of vitamin D (1,25-(OH)2D3). However,

these effects were observed only with blood Pb levels exceeding 30–40 µg/dL and in studies with little or no consideration for potential confounding by factors such as sex, SES, nutritional status, BMI, smoking, comorbid conditions, and other occupational exposures. In addition, alterations in calcitropic hormones were found in children with blood Pb levels ranging from 10-120 µg/dL and in an opposite direction than that in Pb-exposed workers.

5.9.3.2 Recent Epidemiologic Studies

Recent epidemiologic studies have reported associations between indicators of exposure to Pb and thyroid hormone levels, in populations of children and in adults with and without occupational Pb exposure; although results have not been consistent for a particular hormone. Further, the implications of these findings are limited because of the use of cross-sectional study design, lack of rigorous statistical analysis, and limited consideration for potential confounding factors. Inconsistent associations were found in a study that considered potential confounding factors. Abdelouahab et al. (2008) examined a Canadian population characterized by high consumption of freshwater fish contaminated with Pb and other environmental pollutants. The median concurrent blood Pb level was 3.1 µg/dL for men and 1.7 µg/dL for women. The median blood Pb level for women was lower than the limit of detection (2.1 µg/dL), resulting in measurement error of blood Pb level and greater uncertainty in the results. In an analysis stratified by sex, TSH levels were negatively correlated with blood Pb in women with adjustment for age, smoking status, estro-progestative intake, total plasma lipids, and Se. No associations with T3 and T4 levels were found in women. TSH, T3 and T4 levels were not correlated with blood Pb level in males, after adjustment for the same covariates (excluding hormone intake) plus pesticide exposure, corticoid medication, concurrent alcohol consumption, and occupational exposure to metals. Overall, the inconsistent associations and potential influence of other exposures did not strongly demonstrate an effect of Pb exposure.

Studies with less rigorous methods also did not clearly indicate an association between blood Pb level and a particular thyroid hormone. In a Kosovo, Yugoslavia population, higher pregnancy blood Pb levels were associated with lower pregnancy free T4 level among the 156 women living in a highly exposed town with a smelter and battery plant, but not among the 153 women living in a relatively unexposed nearby town (Lamb et al., 2008). The mid-pregnancy blood Pb levels were highly elevated in the industrial town compared to the unexposed town (mean [SD]: 20.56 [7.38] versus 5.60 [1.99] µg/dL). In 24 newborns delivered in Tokyo, Japan, neither TSH nor free T4 (sampled 4-6 days postpartum) was correlated with cord blood Pb level (mean: 0.67 µg/dL) (Iijima et al.,

2007). Neither of these studies considered potential confounding. Croes et al. (2009) examined the hormone levels in 1,679 adolescents residing in nine study areas in Belgium with varying exposures to multiple industrial pollutants including Pb. The median concurrent blood Pb level of the participants from the nine different regions ranged from 1.6 to 2.8 µg/dL. Analyses only indicated differences in free T3, at the region or neighborhood level with adjustment for age, sex, recent disease, and BMI. No direct associations with blood Pb level were analyzed, thus the results could be attributed to other factors that varied by location.

Contrasting results were found for free T4 in Pb-exposed workers. Dundar et al. (2006) examined associations between blood Pb levels and thyroid function in 42 male adolescent auto repair apprentice workers, with no history of prior disease, exposed long term to Pb (in the auto repair apprenticeship at least 1 year). Mean blood Pb level was higher in the auto repair workers compared to the 55 healthy unexposed control subjects (mean [SD]: 7.3 [2.92] versus 2.08 [1.24] µg/dL). Free T4 levels were significantly lower in the auto workers compared to the control group, which had no abnormal free T4 levels reported. In contrast, free T3 and TSH levels were comparable between auto workers and controls. Blood Pb level was negatively correlated with free T4 levels. In contrast, another study (Pekcici et al., 2010) found higher free T4 and TSH in adult auto mechanic or battery factory workers who were highly exposed to Pb (mean blood Pb: 71.1 µg/dL) compared to controls (mean blood Pb level: 0.2 µg/dL). Free T3 levels were similar between the two groups. The results from this study are likely not generalizable to the general public due to the high blood Pb levels of the exposed workers.

Previous findings for blood Pb-associated changes in serum vitamin D (1,25-(OH)2D3) in children were mixed. A recent study in New Jersey examined winter (December to March) and summer (July to September) seasonal changes in the associations between blood Pb level and serum 1,25-(OH)2D3 status, in 142 young, U.S. urban African-American or Hispanic children (ages 1-8 years, grouped by age [1-3 year-olds and 4-8 year-olds] and race/ethnicity) using a repeated measures design (Kemp et al., 2007). The percentage of 1-3 year-old African-American children (n = 49) with blood Pb levels $\geq$ 10 µg/dL increased from 12.2% in winter to 22.5% in summer. This large seasonal increase in blood Pb levels in these 1–3 year-old children was not accompanied by a significant increase in serum 1,25-(OH)2D3 concentrations. There was also a larger seasonal increase in blood Pb levels in 1-3 year-old children from both races combined (n = 78) (mean [SE]: 4.94 [0.45] µg/dL winter, 6.54 [0.82] µg/dL summer) than in 4-8 year-old children from both races combined (n = 64) (mean [SE]: 3.68 [0.31] µg/dL winter, 4.16 [0.36] µg/dL summer). However, no difference in seasonal 1,25-(OH)2D3 was observed in the 1-3 year-old children from both races combined. A larger winter to summer increase in blood Pb level was correlated with a larger seasonal increase in

serum 1,25-(OH)2D3 in the 4-8 year-old children from both races combined and in the 4-8 year-old African American children (n = 42). In the 4-8 year-old children from both races combined, there was a winter to summer increase in 1,25-(OH)2D3 (mean [SE]: 25.3 [1.2] µg/L in winter versus 33.8 [1.1] µg/L in summer.), which may account for the results in this older age group. Based on these results, the study authors concluded that higher summertime increase in serum 1,25-(OH)2D3 levels in children between 4 and 8 years is most likely due to increased sunlight-induced vitamin D synthesis and may be a contributing factor to seasonal changes in blood Pb levels via changes in gastrointestinal absorption or release of Pb from bone.

HPA function was examined in a prospective analysis of associations between prenatal maternal blood Pb levels (cord blood collected at delivery) or postnatal blood Pb levels (at mean [SD] age: 2.62 [1.2] years, data obtained from family physicians or state records), and saliva cortisol levels during a stress protocol in the children at age 9.5 years (Gump et al., 2008). For prenatal blood Pb, the children were divided into the following quartiles: ≤ 1, 1.1-1.4, 1.5-1.9, and 2.0-6.3 µg/dL. For postnatal blood Pb, the quartiles were: 1.5-2.8, 2.9-4.1, 4.2-5.4, and 5.5-13.1 µg/dL. With adjustment for potential confounding (by SES-related factors, HOME score, pregnancy health, maternal substance abuse), blood Pb level was not associated with initial salivary cortisol levels. However, following an acute stressor, which comprised submerging the dominant arm for a minute in a gallon of one part ice to one part water, increasing prenatal and postnatal blood Pb levels were associated with statistically significant increases in salivary cortisol responses. Children in the 2nd, 3rd, and 4th prenatal blood Pb quartiles and in the 4th postnatal quartile had increased salivary cortisol responses compared to children in the 1st quartile. When blood Pb was treated as a continuous variable, regression analysis showed that both prenatal and postnatal blood Pb levels were associated salivary cortisol reactivity. While associations were found in children with blood Pb levels below 10 µg/dL, they could have been attributed to higher earlier childhood blood Pb levels of these children who were born in 1980-1990s.

5.9.3.3 Recent Toxicological Studies

Pb-associated changes in thyroid hormones also were found in animal studies. In a study examining the effects of Pb and Cd in adult cows reared in a polluted environment in India, Swarup et al. (2007) found significantly higher mean plasma T3 and T4 levels in cows living near Pb/Zn smelters (mean [SD] blood Pb: 86 [6] µg/dL) and near closed Pb/operational Zn smelters (mean [SD] blood Pb: 51 [9] µg/dL) when compared to cows in unpolluted areas (mean [SD] blood Pb: 7 [1] µg/dL). Regression analyses of the 269 cows showed a significant positive correlation between blood Pb levels and plasma T3

and T4 levels, whereas the correlation between blood Pb levels and plasma cortisol was not statistically significant. Mean plasma estradiol level was significantly higher in cows near closed Pb/operational Zn smelters compared to the control group of cows. Because of the Pb-Zn co-exposure, the effects cannot be attributed specifically to Pb.

Biswas and Ghosh (2006) investigated the effect of Pb treatment on adrenal and male gonadal functions in Wistar rats treated with Pb acetate (8.0 mg/kg via i.p. injection for 21 days, blood Pb not reported). Pb treatment significantly increased adrenal steroidogenic enzyme activity and serum corticosterone levels. Accessory sex organ (prostate and seminal vesicle) weights were decreased in Pb-treated animals, whereas adrenal weights were increased. These effects were accompanied by a decrease in spermatogenesis and serum concentrations of testosterone, FSH, and LH and by an increase in the percent of spermatid degeneration. Supplementation with testosterone during the last 14 days of Pb treatment was observed to ameliorate these effects.

5.9.3.4 Summary of Endocrine Effects

Collective epidemiologic and toxicological evidence is inconsistent in demonstrating the effects of Pb exposure on male and female sex hormone levels (Sections 5.8.1 and 5.8.2) and vitamin D levels. Several epidemiologic studies have reported associations between indicators of Pb exposure and thyroid hormone levels in populations of children and adults without (Lamb et al., 2008) and with occupational Pb exposure (Dundar et al., 2006), although results have not been consistent for a particular hormone. Further, the implications of these findings are limited because of the cross-sectional study design, high blood Pb levels associated with effects (>30 µg/dL), lack of rigorous statistical analysis, and limited consideration for potential confounding factors. Blood Pb level was positively correlated with plasma T3 and T4 levels in adult cows living near Pb-Zn smelters; however, the effects could not be attributed specifically to Pb exposure (Swarup et al., 2007).

In a prospective study of children in New York, who were challenged with an acute stressor, higher cord blood levels (as a reflection of prenatal maternal Pb blood level), or 2-year-old blood Pb levels, were associated with significant higher salivary cortisol in response to a stress challenge at age 9 years (Gump et al., 2008). While these associations were found with blood Pb levels <10 µg/dL, they could have been attributed to higher earlier childhood blood Pb levels of these children who were born in the 1980s and 1990s. Biswas and Ghosh (2006) found a Pb-induced increase in corticosterone in rats, albeit by i.p. Pb treatment. Cortisol and corticosterone are the major glucocorticoids in humans and rodent, respectively.

In conclusion, epidemiologic and toxicological evidence indicates Pb-associated endocrine effects such as thyroid hormones, cortisol, and vitamin D, although results are not consistent. Because of the lack of insufficient quantity and quality of studies, the evidence is inadequate to determine if there is a causal relationship between Pb exposure and endocrine effects related to thyroid hormones, cortisol, and vitamin D.

5.9.4 Effects on Bone and Teeth

Primary effects on bone associated with Pb exposure or biomarker levels have included an increase in osteoporosis, increased frequencies of falls and fractures, changes in bone cell function as a result of replacement of bone calcium with Pb, and depression in early bone growth. Other effects include tooth loss and periodontitis. Mechanistic evidence from toxicological studies includes effects on cell proliferation, procollagen type I production, intracellular protein, and osteocalcin in human dental pulp cell cultures.

5.9.4.1 Summary of Key Findings of the Effects on Bone and Teeth (2006 Pb AQCD)

The 2006 Pb AQCD reported many effects on bone and some in teeth in animals following Pb exposure. Exposure of animals to Pb during gestation and the immediate postnatal period was reported to significantly depress early bone growth with the effects showing concentration-dependent trends. In mature animals, long-term Pb exposure (up to one year), along with poor nutrition (low calcium) reduced bone growth as well as bone density. Systemic effects of Pb exposure included disruption in bone mineralization during growth, alteration in bone cell differentiation and function due to alterations in plasma levels of growth hormones and calcitropic hormones such as 1,25-[OH]2D3 and impact on Ca^{2+}- binding proteins and increases in Ca^{2+} and phosphorus concentrations in the bloodstream. Bone cell cultures exposed to Pb had altered vitamin D-stimulated production of osteocalcin accompanied by inhibited secretion of bone-related proteins such as osteonectin and collagen. In addition, Pb exposure caused suppression in bone cell proliferation most likely due to interference from factors such as growth hormone (GH), epidermal growth factor (EGF), transforming growth factor-beta 1 (TGF-β1), and parathyroid hormone-related protein (PTHrP).

As in bone, Pb exposure was found to easily substitute for Ca^{2+} in the teeth and was taken up and incorporated into developing teeth in experimental animals. Since teeth do not undergo remodeling like bone does during growth, most of the Pb in the teeth remains in a state of permanent storage. High dose Pb exposure to animals (30 mg/kg body weight)

was found to induce the formation of a "Pb line" that is visible in both the enamel and dentin and is localized in areas of recently formed tooth structure. Areas of mineralization were easily evident in the enamel and the dentin within these "Pb lines." Pb has also been shown to decrease cell proliferation, procollagen type I production, intracellular protein, and osteocalcin in human dental pulp cell cultures. Adult rats exposed to Pb have exhibited an inhibition of the posteruptive enamel proteinases, delayed teeth eruption times, as well as a decrease in microhardness of surface enamel. Pb was reported to be widely dispersed and incorporated into developing apatite crystal during enamel formation process; however, post formation, Pb was reported to be capable of entering and concentrating in specific enamel areas which were Ca^{2+}-deficient. The 2006 Pb AQCD (U.S. EPA, 2006b) also reported that a number of animal studies and a few epidemiologic studies each suggested that Pb is a caries-promoting element. The strongest epidemiologic evidence comprised associations between concurrent blood Pb level and dental caries in an NHANES analysis of thousands of children that adjusted for age, sex, race/ethnicity, poverty to income ratio, exposure to cigarette smoke, geographic region, head of household education, carbohydrate and calcium intake, and frequency of dental visits. Other effects found in humans included bone disease (e.g., Paget's disease); however, the evidence was provided by occupational or case-control studies.

5.9.4.2 Recent Toxicological and Epidemiologic Studies

Consistent with evidence reported in the 2006 Pb AQCD, recent studies have found associations between Pb exposure or biomarker levels and effects in bones of humans and animals. The association between blood Pb levels and lower bone mineral density was examined in several epidemiologic studies. Prospective evidence was provided by Khalil et al. (2008) in 533 older women aged 65-87 years with a mean (SD) blood Pb of 5.3 (2.3) µg/dL. Bone mineral density was measured in 1986-1988 (calcaneus), again in 1988-1990 (total hip and femoral neck), and again in 1993-1994 (calcaneus, total hip and femoral neck), while blood Pb levels were measured in between the 2nd and last bone analyses (during 1990-1991; and categorized as low [n = 122], medium [n = 332], and high [n = 79] Pb blood levels [range: 1-21 µg/dL]). Information on falls and fractures was collected every 4 months, starting after the initial enrollment (1986-1988) and continuing for more than 10 years. The bone mineral density at the last measurement (1993-1994) was 7% lower in the total hip ($p < 0.02$) and 5% lower in the femoral neck ($p < 0.03$) in the high blood Pb group (≥ 8 µg/dL) compared to the low blood Pb group (≤ 3 µg/dL). A concentration-dependent relationship was found for total hip and femoral neck bone mineral density across the three blood Pb level groups. In addition, total hip, femoral neck, and calcaneus bone loss was observed to be greater in the medium (blood Pb:

4-7 µg/dL) and high Pb groups compared to the low Pb group, with a statistically significant trend found for calcaneus bone loss. Compared to the low blood Pb level group, women in the high blood Pb level group had an increased risk of non-spine fracture (10.5 year interview follow-up), and women with medium or high blood Pb levels had a higher risk of falls (4 year follow-up) with adjustment for age, clinic, BMI, weight change between visits, smoking, chair stands (were able to stand up five times from a chair, without using the arms of the chair), fracture history, estrogen use, and baseline (1986-1988) bone mineral density. Nutritional factors were not considered. The increased risk of lower bone density and falls leading to osteoporosis-related fractures associated with blood Pb levels >4 µg/dL are likely influenced by higher past Pb exposures of these women.

Supporting evidence was provided by cross-sectional epidemiologic studies, although the direction of the association and the magnitude, timing, frequency, and duration of Pb exposure that contributed to the observed associations are uncertain. Further, most studies did not consider potential confounding by nutritional factors. A large NHANES II analysis of 8,654 adults ≥ 50 years of age (Campbell and Auinger, 2007), which was stratified by non-Hispanic white men (mean blood Pb: 4.9 [range: 0.7 to 48.1] µg/dL), non-Hispanic white women (mean blood Pb: 3.6 [range: 0.7 to 28.7] µg/dL), African-American men (mean blood Pb: 7.7 [range: 0.7 to 52.9] µg/dL), and African-American women (mean blood Pb: 4.5 [range: 0.7 to 23.3] µg/dL). In analyses of covariance that considered potential confounding (by age, race, sex, BMI, menopausal status, tobacco use, alcohol use, physical activity, Ca^{2+} intake, chronic medical conditions, certain medication use, and SES), non-Hispanic white men ($n = 1,693$, $p < 0.05$) and women ($n = 1,754$, $p < 0.10$) in the highest tertile of concurrent blood Pb level had lower mean total hip bone mineral density than non-Hispanic white men and women in the lowest tertile of blood Pb levels (actual concentration not reported). Smaller differences were observed in African-American men and women (possibly due to the smaller sample sizes ($n = 613$, and 629, respectively). No association was observed between blood Pb levels and osteoporotic fractures in any sex or race/ethnicity group.

Similar observations were made by Sun et al. (2008a) in 155 males and 37 females in China who were occupationally-exposed to Pb (mean blood Pb: 20.22 and 15.5 µg/dL, respectively). In analyses (including all workers, plus 36 male and 21 female unexposed controls stratified into groups according to blood Pb and urinary Pb levels), groups with urinary Pb levels ≥ 5 µg/g creatinine had lower ($p < 0.01$) bone mineral density compared to groups with lower urinary Pb in each sex. Prevalence of osteoporosis increased with increasing blood Pb in a linear manner. In contrast, a significant difference was observed between blood Pb level and bone mineral density, but only in men with blood Pb levels >30 µg/dL. Prevalence of osteoporosis increased significantly with increasing blood Pb

in a linear manner. Results were not adjusted for potential confounding factors, including other occupational exposures.

Cross-sectional epidemiologic studies also found associations between concurrent blood Pb level and biological markers of bone turnover. Among 329 male (mean age: 65 years, median blood Pb level: 2.2 µg/dL) and 342 female (mean age: 62 years, median blood Pb level: 1.9 µg/dL) adults in North Carolina, Nelson et al. (2011) found in women that higher blood Pb level was associated with higher uN-telopeptide cross-linked collagen type I (uNTX-I, a marker of bone resorption/turnover) and uCTX-II (a marker associated with the progression of radiographic knee and hip osteoarthritis) after adjusting for age, BMI, race, and smoking status. In adjusted analyses of men, higher blood Pb level was associated with higher uCTX-II, COMP, and C2C:CPII ratio (an indication of the balance between cartilage collagen degradation and synthesis). In women, a weaker association was found for COMP, a cartilage biomarker related to osteroarthritis. The results indicated that blood Pb level is associated with bone turnover and mineralized cartilage turnover in women, and with non-mineralized cartilage turnover in men.

Similarly, Machida et al. (2009) investigated bone matrix turnover in Japanese women farmers, and how it is related to age-related menopause status and blood Pb level. Perimenopausal women (n = 319 [age range: 49 to 55 years]) had higher geometric mean blood Pb level (2.0 µg/dL) than the other 3 groups did: premenopausal women (n = 261 [age range: 35 to 48 years], blood Pb level: 1.6 µg/dL), younger postmenopausal women (n = 397 [age range: 56 to 65 years], blood Pb level: 1.8 µg/dL), or older postmenopausal women (n = 248 [age range: 66 to 75 years], blood Pb level: 1.7 µg/dL). In a model that simultaneously included bone-mineral density, NTx, osteocalcin, and age, higher blood Pb levels were positively associated with bone mineral density, NTx, and osteocalcin (all $p < 0.01$). In perimenopausal women, higher blood Pb level was predicted most strongly by higher osteocalcin levels. Age was positively associated with higher blood Pb levels in perimenopausal women only. Associations also were reported for bone-specific ALP in unadjusted analyses.

To characterize mechanisms underlying the effects of Pb on bone, Jang et al. (2008) studied the effect of Pb exposure on Ca^{2+}-release activated Ca^{2+}-influx (CRACI) using cultures of human fetal osteoblast-like hFOB 1.19 cells (OLCs) in vitro. When cells were incubated with 1,000 or 3,000 µM Pb in the culture medium, a concentration-dependent decrease on CRACI was observed, as was a concentration-dependent increase in the influx of Pb into human OLC. These results suggest that Pb inhibits the measurable influx of Ca^{2+} upon re-addition of Ca^{2+}, which in turn, results in an influx of Pb into the OLCs.

Studies have found inconsistent associations between higher blood Pb level and reduced growth in children; however, Zuscik et al. (2007) hypothesized that Pb may alter growth by altering chondrogenic commitment of mesenchymal cells and by affecting various signaling pathways. Exposure of stage E11.5 murine limb bud mesenchymal cells (MSCs) to 1 µM Pb in vitro caused increased basal and TGF-β/BMP induction of chondrogenesis, which was accompanied by nodule formation and upregulation of Sox-9, type 2 collagen, and aggrecan, which are all key markers of chondrogenesis. Enhanced chondrogenesis during induced ectopic bone formation also was found in mice that had been pre-exposed to Pb acetate for six weeks via drinking water (55 or 233 ppm, [previously shown to correspond to 14 or 40 µg/dL blood Pb level, respectively]). MSCs exposed to Pb in vitro exhibited an increase in TGF-β, but BMP-2 signaling was inhibited. Pb also induced NF-κB and inhibited AP-1 signaling. These results suggested that the chondrogenesis induced by Pb exposure most likely involved modulation and integration of multiple signaling pathways including TGF-β, BMP, AP-1, and NF-κB.

Effects of Pb exposure on teeth were examined in a few recent cross-sectional epidemiologic studies. A subset of the U.S. NHANES III (1988-1994) population was selected for a large periodontitis versus Pb blood level study of both men (n = 2,500) and women (n = 2,399), 30-55 years-old, that considered potential confounding by a large set of factors, including nutritional status (Saraiva et al., 2007). Compared to individuals with a concurrent blood Pb level of <3 µg/dL, the prevalence ratios of periodontitis were 1.70 (95% CI: 1.02, 2.85) for men with concurrent blood Pb level of >7 µg/dL and 3.80 (95% CI: 1.66, 8.73) for women with concurrent blood Pb level >7 µg/dL. These results were adjusted for age, NHANES III phase, cotinine levels, poverty to income ratio, race/ethnicity, education, bone mineral density, diabetes, calcium intake, dental visits, and menopause status in women.

Arora et al. (2009) examined the association between blood and bone Pb level and the loss of natural teeth, in 333 men (age range: 50 to 94 years) from a subset of the Veterans Affairs Normative Aging Study (NAS). Tooth loss was ascertained as the number of teeth present during a dental assessment, and was categorized into three groups: 0 missing teeth (n = 44), 1-8 missing teeth (n = 164), or ≥ 9 missing teeth (n = 125). Men with ≥ 9 teeth missing had significantly higher tibia and patella Pb concentrations (measured within 3 years of dental assessment) compared to those with no tooth loss. Men with the highest tibia Pb concentrations (>23 µg/g) had higher odds of tooth loss (OR: 3.03 [95% CI: 1.60, 5.75]) compared to men with tibia Pb levels ≤ 15 µg/g. Men with the highest patella Pb levels (>36 µg/g) also had higher odds of tooth loss (≥ 9 missing teeth versus 0-8 missing teeth; or ≥ 1 missing teeth versus 0 missing teeth: OR: 2.41 [95% CI: 1.30, 4.49]) compared to men with patella Pb levels ≤ 22.0 µg/g. Men with tibia Pb levels 16-23 µg/g, and men with patella Pb levels 23-36 µg/g also had elevated odds of tooth

loss. Results were adjusted for age, education, smoking status, pack-years of smoking, and diabetes, but nutritional factors were not considered. Tooth loss was not associated with higher blood Pb levels [also measured within 3 years of dental assessment (Hu et al., 1996b)], indicating that long-term cumulative exposure to Pb is associated with increased odds of tooth loss. However, because the timing of tooth loss was not ascertained and bone Pb levels may represent exposures after tooth loss occurred, the directionality of effects is uncertain.

5.9.4.3 Summary of Effects on Bone and Teeth

A few studies have indicated associations of Pb exposure or Pb biomarker levels with bone disease (e.g., Paget's disease); however, the implications are limited by examination of Pb-exposed workers or individuals with bone disease (i.e., case-control). Numerous epidemiologic studies indicated an association between higher Pb biomarker levels and lower bone density in adults. Prospective evidence was provided by a study of elderly women (65-87 years-old), in which higher blood Pb levels were associated with lower bone density measured after 2-4 years and greater risk of falls and osteoporosis-related fractures (Khalil et al., 2008). Cross-sectional epidemiologic associations between higher blood Pb levels and lower bone mineral density were found in adults without (Campbell and Auinger, 2007) and with occupational Pb exposure (Sun et al., 2008a). Cross-sectional studies also indicated associations between higher blood Pb levels and higher markers of bone turnover in elderly populations (Nelson et al., 2011; Machida et al., 2009). In the cross-sectional epidemiologic evidence, it is difficult to determine whether an increase in blood Pb level results from lower bone density or from higher bone turnover, and whether these effects lead to a greater release of Pb from bone into the bloodstream. Except for Sun et al. (2008a), studies adjusted for several potentially important confounding factors, including age, BMI, and smoking. However, studies did not consider nutritional status, which could affect the release of Pb from bone to blood. To support the direction and independent effects of Pb on bone, toxicological studies have found Pb-induced (gestational and postnatal) decreases in bone growth in juvenile animals. Further, these toxicological studies have characterized potential modes of action, by showing Pb-induced decreases in bone mineralization and bone cell differentiation, inhibition of CRACI, and alterations in signaling pathways involved in skeletal development (Jang et al., 2008; Zuscik et al., 2007).

Epidemiologic studies have found associations between blood Pb levels and effects on teeth. Large NHANES analyses adjusted for several potentially important confounding factors (including age, SES-related factors, and nutritional factors), and found associations between concurrent blood Pb level and dental caries in children (Moss et al.,

1999) and periodontitis in adults (Saraiva et al., 2007). Higher patella and tibia Pb levels were associated with tooth loss in NAS men (Arora et al., 2009). The results for blood Pb and bone Pb levels in adults indicate that long-term, cumulative exposure to Pb exposure is associated with negative effect on teeth. This epidemiologic evidence was based on cross-sectional study design analyses, which precludes conclusions about the directionality of effects. However, these findings are supported by toxicological evidence in animals for Pb-induced increases in Pb uptake into teeth; and decreases in cell proliferation, procollagen type I production, intracellular protein, and osteocalcin in cells exposed to Pb in vitro.

The small body of epidemiologic evidence showing associations between Pb biomarker levels and various bone and teeth effects (after adjusting for potential confounding by age, SES-related factors, and nutritional factors), plus the supporting toxicological evidence, is sufficient to conclude that there is a likely causal relationship between Pb exposure and effects on bone and teeth.

5.9.5 Effects on Ocular Health

Ocular effects most commonly associated with exposure to Pb include formation of cataracts, impaired vision, edema and retinal stippling.

5.9.5.1 Summary of Key Findings of the Effects on Ocular Health (2006 Pb AQCD)

The 2006 Pb AQCD stated that various changes in the visual system were observed with Pb poisoning including retinal stippling and edema, cataracts, ocular muscle paralysis and impaired vision. Maternal prenatal blood Pb levels in the range of 10.5 to 32.5 µg/dL were associated with supernormal retinal ERGs in children at age 5-7 years. Cataracts were noted in middle-aged men with tibia bone Pb levels of 31-126 µg/g.

5.9.5.2 Recent Toxicological and Epidemiologic Studies

The recent cross-sectional epidemiologic studies of ocular effects in adults did not produce clear evidence, and each was limited by the lack of rigorous statistical analysis and lack of consideration for potential confounding. Erie et al. (2009) measured Pb and Cd in retinal tissue from 36 eye donors with age-related macular degeneration (cases) and 25 normal control donors. Pb, but not Cd, concentration was significantly elevated in the neural retina tissue of the 36 donors with macular degeneration (72 eyes; median [IQR]:

12.0 [8-18] ng/g Pb) versus normal control donors (50 eyes; median [IQR]: 8.0 [0-11] ng/g Pb). Neither of these heavy metals were significantly elevated in the retinal pigment epithelium (RPE)/choroid complex in donors with macular degeneration over normal controls. Mosad et al. (2010) compared Pb, Cd, vitamin C, vitamin E, and beta carotene blood levels between 45 middle-aged male smokers and nonsmokers with cataracts. Blood Pb levels were elevated ($p < 0.0001$) in 15 light (mean [SD]: 14.5 [0.41] µg/dL), 15 moderate (14.5 [0.41] µg/dL), and 15 heavy smokers (18.7 [1.24] µg/dL) compared to 15 nonsmokers (12.2 [0.21] µg/dL). Similar associations were observed for Cd blood levels and lens concentrations. There was no direct analysis of the association between Pb blood level or lens Pb concentration and the severity of cataracts.

Recent animal studies have observed Pb-induced retinal progenitor cell proliferation and neurogenesis (Section 5.3.7.3). An in vitro study found increased opacity of rat (age 4-6 weeks) lens exposed to 1 µM Pb nitrate with or without secondary oxidative challenge after 5-8 days but not after 3 days (Neal et al., 2010b). Thus, short-term Pb exposure did not induce osmotic swelling or lens shrinkage. With a 5-day exposure, 30% of the Pb-exposed lenses displayed "definite cataracts" compared to only 2.5% of control lenses. By culture day 8, 100% of the exposed lenses were described either as clearly opaque or definite cataracts, while only 7% of control lenses displayed these characteristics, indicating that prolonged exposure of lenses to Pb induced an accelerated formation of opacity/cataract compared to unexposed lenses. Pb-exposed lenses cleared the media of hydrogen peroxide more rapidly than did control lenses, potentially due to increased CAT activity. Exposure to hydrogen peroxide resulted in total (100%) opacity in Pb-exposed lenses at culture day 7, compared to less than 20% in control cells. Exposure to Pb additionally altered epithelial nutrient transport and lens histology, relative to that in controls.

In summary, prospective epidemiologic evidence indicates associations between prenatal maternal blood Pb levels of 10.5-32.5 µg/dL and supernormal retinal ERGs in children ages 5-7 years after adjusting for age, sex, and head circumference. However, the relevance of supernormal ERGs is uncertain. Evidence in adults for associations between eye tissue Pb levels and macular degeneration (Mosad et al., 2010) and cataracts in adults (Erie et al., 2009) is limited by weak statistical methods and lack of consideration for potential confounding to warrant conclusions. Toxicology studies have reported Pb-induced retinal progenitor cell proliferation, retinal ERGs, and lens opacity (Section 5.3.7.3). Because of the insufficient quantity and quality of studies in the cumulative body of evidence, the evidence is inadequate to determine a causal relationship between Pb exposure and ocular effects.

5.9.6 Effects on the Respiratory System

Blood Pb level has been associated with asthma and allergy in children in prospective and cross-sectional epidemiologic studies (Section 5.6.5.2). As described in Section 5.2.4, Pb exposure has been shown to induce the generation of ROS. ROS are implicated in mediating increases in bronchial responsiveness and activating neural reflexes, leading to decrements in lung function. Collectively, studies investigating these airway responses in asthma-free populations are limited in number, lack rigorous statistical analysis, and collectively do not provide strong evidence of an association with blood Pb level (Section 5.6.5.3). Collectively, panel and time-series epidemiologic studies demonstrate associations between short-term increases in ambient air Pb (measured in $PM_{2.5}$ or PM_{10} air samples), and decreases in lung function and increases in respiratory symptoms, and asthma hospitalizations in children but not adults (Section 5.6.5.3). Toxicological studies have found pulmonary inflammation induced by concentrated ambient air particles (CAPs) in which Pb was one of the numerous components (Wei et al., 2011; Duvall et al., 2008; Godleski et al., 2002; Saldiva et al., 2002). Despite this evidence for respiratory effects related to air-Pb concentrations, the limitations of air-Pb studies, including the limited data on the size distribution of Pb-PM (Section 3.5.3), the uncertain relationships of Pb-PM_{10} and Pb-$PM_{2.5}$ with blood Pb levels, and the lack of adjustment for other correlated PM chemical components preclude firm conclusions about air Pb-associated respiratory effects. Because of the insufficient quantity and quality of studies in the cumulative body of evidence, the evidence is inadequate to determine a causal relationship between Pb exposure and respiratory effects in populations without asthma.

5.10 Cancer

Previous AQCDs have demonstrated that Pb is a well-established animal carcinogen. Oral Pb acetate exposure to male and female rodents has consistently been shown to be a kidney carcinogen in multiple separate studies, inducing adenocarcinomas and adenomas after chronic exposure. Developmental Pb acetate exposure also induced kidney tumors in offspring whose dams received Pb acetate in drinking water during pregnancy and lactation. Gliomas of the brain have also been reported after oral Pb exposure. These rodent toxicological studies have been conducted at high doses of Pb and have shown that Pb is an animal carcinogen. Because of this strong body of historical data, the 2006 Pb AQCD states, “limited tumorigenesis studies have been conducted in animal models and the focus has been more on the mechanism of neoplasia…and possible immunomodulatory effects of Pb in the promotion of cancer.” More recent studies have

focused on administration of Pb with known carcinogens or modifiers such that lifestage, diet, and mechanism of action can be better understood.

The previous epidemiologic studies included in the 2006 Pb AQCD (U.S. EPA, 2006b) "provide[d] only very limited evidence suggestive of Pb exposure associations with carcinogenic or genotoxic effects in humans," and the studies were summarized as follows:

> "The epidemiologic data …suggest a relationship between Pb exposure and cancers of the lung and the stomach… Studies of genotoxicity consistently link Pb-exposed populations with DNA damage and micronuclei formation, although less consistently with chromosomal aberrations."

The International Agency for Research on Cancer (IARC) classified inorganic Pb compounds as probable human carcinogens (Group 2A of IARC classification) based on sufficient evidence in animal studies (evidence in human studies was limited), and organic Pb compounds as not classifiable (Group 3 of IARC classifications) (IARC, 2006a; Rousseau et al., 2005). Additionally, the National Toxicology Program (NTP) listed Pb and Pb compounds as "reasonably anticipated to be human carcinogens" (NTP, 2011). The typical cancer bioassays employed by IARC or NTP as evidence of Pb-induced carcinogenicity used rodents that were continuously exposed to Pb acetate in chow or drinking water for 18 months to two years in duration. These two year cancer bioassays and the doses administered are typical of cancer bioassays used with other chemicals.

In the following sections, recent epidemiologic and toxicological studies published since the 2006 Pb AQCD, regarding Pb and cancer mortality and incidence are examined. In addition, recent studies of Pb exposure associated with DNA and cellular damage, as well as epigenetic effects, are summarized. When the information is available, the form of the Pb compound under study (e.g., inorganic, organic) is indicated. In epidemiologic studies, various biological indicators of Pb exposure are used including Pb measured in blood and bone. The biological indicators of Pb associated with cancer-related endpoints are considered in drawing conclusions about potentially important levels and timing of Pb exposure. Bone Pb is indicative of cumulative Pb exposure. Blood Pb can represent more recent exposure, but because it can also represent remobilized Pb occurring during times of bone remodeling, blood Pb level may also be an indicator of long-term Pb exposure in adults. Toxicological studies only report exposure by blood Pb or exposure dose. More detailed discussion of these measures is given in Section 4.3.5. Details of the recent epidemiologic and toxicological studies follow.

5.10.1 Cancer Incidence and Mortality

Recent studies have included epidemiologic evaluations of the associations between Pb exposure and both specific cancers (such as lung cancer and brain cancer), and overall cancer (cancer of any type). Table 5-49 provides an overview of the study characteristics and results for the epidemiologic studies that reported effect estimates. This section also evaluates toxicological evidence on the potential carcinogenicity of Pb.

Table 5-49 Summary of recent epidemiologic studies of cancer incidence and overall cancer mortality.

5.10.1.1 Overall Cancer Mortality

Several recent cohort studies examined the association between Pb levels and cancer mortality, including multiple analyses of the NHANES III population. In one NHANES III analysis, the cohort of 13,946 (N for cancer mortality=411) was followed for 12 years and individuals with blood Pb levels greater than 10 µg/dL were excluded from the study (mean baseline blood Pb level was 2.58 µg/dL). No association was observed between blood Pb and cancer mortality (HR of highest tertile [≥ 3.63 µg/dL] compared to lowest tertile [<1.93 µg/dL]: 1.10 [95% CI: 0.82, 1.47]) (Menke et al., 2006). Another analysis of the NHANES III population, which was restricted to individuals 40 years and older at the time of blood Pb collection and included 9,757 (N for cancer mortality=543) individuals with all blood Pb levels (including those greater than 10 µg/dL), reported associations between blood Pb and cancer mortality (Schober et al., 2006). In this study, median follow-up time was 8.6 years. The RRs were 1.69 (95% CI: 1.14, 2.52) for individuals with blood Pb levels of at least 10 µg/dL and 1.44 (95% CI: 1.12, 1.86) for blood Pb levels of 5-9 µg/dL compared to individuals with blood Pb levels less than 5 µg/dL. When stratified by age, point estimates comparing blood Pb levels of 5-9 versus less than 5 µg/dL were similar across all age groups but only statistically significant among 75-84 year olds. The risks of mortality associated with blood Pb levels ≥ 10 µg/dL in the groups aged 40-74 years and 85 years and older were elevated.

A study of men (primarily white) from the greater Boston, MA area enrolled in the Normative Aging Study (NAS) found no association between blood or bone Pb and cancer mortality in adjusted analyses (N=1,038, N for cancer mortality=85 when using blood Pb measures; N=727, N for cancer mortality=57 when using bone Pb measures). At baseline, the mean (SD) blood Pb level for this population was 5.6 (3.4) µg/dL and blood Pb was poorly correlated with measured bone Pb (Weisskopf et al., 2009). As part of the Study of Osteoporotic Fractures , 533 white women aged 65-87 (N for cancer mortality=38) were included in a sub-study of blood Pb level and cancer mortality and were followed for approximately 12 years (Khalil et al., 2009b). The mean (SD) blood Pb level at baseline was 5.3 (2.3) µg/dL and no association was detected between blood Pb and cancer mortality in the study population.

Overall, epidemiologic studies of blood Pb levels and cancer mortality reported inconsistent results. An epidemiologic study using NHANES III data demonstrated the strongest association between blood Pb and increased cancer mortality; however, other studies reported weak or no associations. These cohort studies were well-conducted longitudinal studies with control for potential confounders, such as age, smoking, and

education (see list of the potential confounders addressed in each study in Table 5-49). One limitation is that the studies in populations other than NHANES cohorts each had a small number of cancer mortality cases.

5.10.1.2 Overall Cancer Incidence

Studies of overall cancer incidence have also been performed (Table 5-49). An ecologic analysis compared Pb-related air pollution over 5 year increments from 1990 to 2005 with incidence rates of cancer during this time period (cancer sites not specified) among children (N not specified) (Absalon and Slesak, 2010). The highest Pb air pollution levels were measured in 1990 when over 50% of the study area exceeded the limit of 1 $\mu g/m^2 \cdot$year. No correlation was observed both overall and in sex-specific analyses. Another study (N=1,940) examined correlations between Pb concentrations in soil, water, vegetation, and hair samples with incidence of neoplasms (Obhodas et al., 2007). The Pb concentrations were not correlated with incidence of neoplasms. A recent study using the 2007-2008 NHANES cohort reported no association between higher creatinine-adjusted urine Pb levels and elevated odds of having ever had cancer or a malignancy (N=1,857) (Mendy et al., 2012). The timing of cancer diagnosis in relation to the urine sample collection was not identified.

Overall, epidemiologic studies reported no positive associations between various measures of Pb exposure and overall cancer incidence. These studies are limited by their ecologic and cross-sectional designs. Absalon and Slesak (2010) and Obhodas (2007) did not collect biological measurements, and no control for potential confounding was mentioned.

5.10.1.3 Lung Cancer

Most of the recent evidence regarding lung cancer incidence is provided by a few studies of occupationally-exposed adults. These are described in Table 5-49. Some studies in the 2006 Pb AQCD (U.S. EPA, 2006b) reported associations between Pb exposure and lung cancer in occupational cohorts, although the studies were limited due to possible confounding by smoking or other workplace exposures. In a more recently published study of smelter workers (N=187, N for lung cancer=46), no association was observed between several metrics of Pb exposure (peak blood Pb values, number of years Pb samples were obtained, and cumulative blood Pb index) and lung cancer incidence and mortality combined (Lundstrom et al., 2006). The median follow-up in the study was about 30 years, and the median peak blood Pb values during employment were

49.7 µg/dL for lung cancer cases and 55.9 µg/dL for controls. In a study of 1,462 tin smelter workers, no association was observed between Pb exposure and lung cancer mortality in unweighted analyses, but when the analyses were weighted by age and time since exposure, positive associations were apparent (Jones et al., 2007). In this study, cumulative Pb exposure was calculated by combining historical air sampling data and personnel record cards, which specified work histories. The median cumulative Pb exposure was estimated to be approximately y 2 mg/m^3•yr. It is important to note that the tin smelter workers were exposed to other metals as well, such as As and antimony and the study did not specify if additional potential confounders were evaluated (beyond the weighting for age and time since exposure). A population-based case-control study performed among men in Montreal, Canada in the 1980s assessed occupational Pb exposure via interviews regarding job histories and determined the likely Pb exposures associated with the job activities (Rousseau et al., 2007). No association was apparent between organic Pb, inorganic Pb, or Pb from gasoline emissions and lung cancer (N ranged from 271 to 1,203 depending on the exposure of interest).

Studies were also conducted that compared lung tissue Pb measurements for individuals with lung cancer to those without lung cancer. The controls for these studies were individuals with metastases in the lung from other primary cancers (De Palma et al., 2008) and individuals with non-cancerous lung diseases (De Palma et al., 2008; Kuo et al., 2006). Limitations in these studies include their cross-sectional; design, the measurement of Pb in cancerous tissue, which may have altered Pb distribution, and the use of controls with other cancers and lung diseases. Findings are mixed among the studies. De Palma et al. (2008) reported higher Pb concentrations in the cancerous and non-cancerous lung tissue of individuals with non-small cell lung cancer compared to control groups, although the authors report these results may be confounded by smoking. Kuo et al. (2006) found no statistical difference in Pb levels for lung tissue of individuals with lung cancer compared to controls.

Some studies in the 2006 Pb AQCD reported associations between Pb exposure and lung cancer among occupational cohorts; however, recent epidemiologic studies of lung cancer reported no associations. Overall, these recent epidemiologic studies included only men, limiting the generalizability. The studies by Jones et al. (2007) and Rousseau et al. (2007) also have the disadvantage of not obtaining actual measures of Pb exposure or biomarker levels. In addition, these studies, as well as those in the 2006 Pb AQCD, are of occupational cohorts, and the relationships with Pb exposures may be confounded by other workplace exposures and covariates that were not considered, such as smoking.

5.10.1.4 Brain Cancer

A few studies of brain cancer examined the association between cancer and occupational Pb exposure using exposures determined via exposure databases and patient interviews about past jobs and known exposures (Table 5-49). The National Longitudinal Mortality Study, a study that included a national sample of the U.S. population (N=317,968), estimated occupational Pb exposure based on current/most recent employment among individuals (van Wijngaarden and Dosemeci, 2006). Although not all estimates using various statistical techniques and measures of Pb exposure/intensity are statistically significant, a pattern of increased associations between Pb exposure and brain cancer mortality was observed in the study population. In a case-control study of brain tumors (N for controls=799, N for glioma=489, n for meningioma =197), glioma was reported to have no association with any Pb exposure metric. However, positive associations were observed between high cumulative occupational Pb exposure and meningioma among individuals with *ALAD2* genotypes (OR 2.4 [95% CI: 0.7, 8.8] comparing individuals ever exposed to Pb with those not exposed to Pb; OR 12.8 [95% CI: 1.4, 120.8] comparing individuals with cumulative Pb exposure $\geq$ 100 µg-year/m^3 to those not exposed to Pb) (Rajaraman et al., 2006). This association was not present among individuals with the *ALAD1* genotypes (OR 0.5 [95% CI: 0.3, 1.0] comparing individuals ever exposed to Pb with those not exposed to Pb; OR 0.7 [95% CI: 0.2, 1.8] comparing individuals with cumulative Pb exposure $\geq$ 100 µg-year/m^3 to those not exposed to Pb). Another study of the association between occupational Pb exposure (measured using self-reported occupational exposure history) and brain tumors reported none or slight overall associations with types of brain tumors; however, positive associations were observed among individuals with certain genetic single nucleotide polymorphisms (SNPs) (N for controls=494, N for glioma=362, n for meningioma =134) (Bhatti et al., 2009). After control for multiple comparisons, individuals with *GPX1* variants (rs1050450) had positive associations between cumulative Pb exposure and glioblastoma multiforme and meningioma. Individuals without *RAC2* variants (rs2239774) showed a positive association between Pb and glioblastoma multiforme. Also, individuals without *XDH* variants (rs7574920) displayed a positive association between Pb and meningioma.

Overall, associations between occupational Pb exposure and brain cancer incidence and mortality were found to vary according to several genetic variants. Studies of the association between Pb exposure and brain cancer were not reported in the 2006 Pb AQCD. These studies were limited in their methods because they do not have individual level biological or exposure Pb measurements and the potential for confounding by other workplace exposures exist. Additional research is needed to characterize these associations and the modification by various genetic variants.

5.10.1.5 Breast Cancer

The association between proximity to a Pb smelter and breast cancer was evaluated in a non-occupational cohort. A population-based case-control study in Canada (N for controls=2,467, N for cases=2,343) examined the proximity to a Pb smelter based on residential addresses (Pan et al., 2011) (Table 5-49). No association was reported between proximity of a Pb smelter and breast cancer incidence, but the study was limited by the small number of women who resided near a Pb smelter (n=13 lived ≤ 3.2 km from Pb smelter). No biological samples to determine Pb levels in the body were used in the study, nor were Pb biomarker or exposure data were available.

A few case-control studies examined Pb levels in biological samples among individuals with and without breast tumor and/or cancer. A study of newly diagnosed breast cancer patients and controls examined Pb levels in blood and hair samples and reported higher Pb levels in both for cancer cases, although the difference in the Pb content in hair samples was not statistically significant (Alatise and Schrauzer, 2010). Siddiqui et al. (2006) observed higher blood Pb levels in women with benign and malignant tumors compared to controls. Additionally, although blood Pb levels were higher among those with malignant breast tumors compared to those with benign tumors, both had similar levels of Pb detected in breast tissues. Another study of Pb levels present in breast tissue reported no statistical difference in Pb levels (Pasha et al., 2008b). However, a study of breast tissue did observe a statistically significant difference between Pb levels in the breast tissue of cancer cases and controls (Ionescu et al., 2007). Finally, a study of Pb levels in urine reported a positive association between urine Pb and breast cancer, but this association became null when women taking nonsteroidal aromatase inhibitors but not taking bisphostphonates (a combination responsible for bone loss) were excluded from the analysis (McElroy et al., 2008).

The 2006 Pb AQCD (U.S. EPA, 2006b) did not report any studies examining Pb levels and breast cancer. Overall, recent studies suggest that women with breast cancer may have higher blood Pb levels than those without breast cancer. However, results are mixed in studies that compared breast tissue Pb concentrations between breast tumor and control samples. These studies are limited by their study design. The samples are taken after cancer is already present in the cases, thus, the directionality between tissue or blood Pb levels and cancer development cannot be established. Additionally, the sample sizes are often small and the studies may be underpowered (most of the studies had less than 25 cases (Alatise and Schrauzer, 2010; Ionescu et al., 2007; Siddiqui et al., 2006). A case-control study, also limited by its method of exposure measurement, reported no association between living near a Pb smelter and breast cancer (Pan et al., 2011).

5.10.1.6 Other Cancers

There have been a few studies of cancer types other than those listed above. The 2006 Pb AQCD reported evidence of an association between Pb exposure and stomach cancer in several occupational cohorts. A study performed among men in Montreal, Canada in the 1980s evaluated multiple cancer outcomes and estimated occupational exposures to organic Pb, inorganic Pb, and Pb from gasoline emissions via interviews regarding job histories and subsequent exposure approximations by chemists and hygienists (N for cases and controls varied from 60 to 2,250 based on the cancer type and exposure) (Rousseau et al., 2007). Adults with occupational exposure to organic Pb exposure had greater odds of having stomach cancer compared to adults without occupational exposure to organic Pb. A positive association was also observed for rectal cancer when population-based controls were used but was null when the control population was limited to individuals with other types of cancers. No association was detected for cancers of the esophagus, colon, pancreas, prostate, bladder, kidney, melanoma, or non-Hodgkin's lymphoma. None of the cancers were associated with occupational exposure to inorganic Pb. When occupational exposure to Pb in gasoline emissions was categorized as "unexposed," "nonsubstantial level," or "substantial level," a positive association with stomach cancer was observed when cancer controls were used as the comparison group; however, the association was not present when population controls were utilized as the control group). Another case-control study using participant interviews and a job exposure matrix, including only men, (N for controls=285, N for cancer=185) reported no association between occupational Pb exposure and esophageal squamous cell carcinomas, but an association was present between high occupational Pb exposure and adenocarcinoma of the esophagus (Santibanez et al., 2008). However, neither of these studies quantified Pb levels in biological or exposure samples.

Several studies compared Pb levels in blood, tissue, and urine of individuals who have cancer with Pb-levels in individuals who are cancer-free. Compared to control groups, higher Pb levels were observed in the blood and bladder tissue of individuals with bladder cancer (Golabek et al., 2009), the kidney tissue of individuals with renal cell carcinoma (with highest levels among those with the highest stage tumors) (Calvo et al., 2009), the tissue (but not serum) of individuals with laryngeal cancer (Olszewski et al., 2006), the blood of individuals with gastric cancer (Khorasani et al., 2008), the plasma and hair of individuals with gastrointestinal cancer (Pasha et al., 2010), the blood and hair of individuals with non-specified types of cancer (Pasha et al., 2008c; Pasha et al., 2007), and the hair of individuals with benign tumors (Pasha et al., 2008a). No statistical difference in Pb levels was reported for colon tissue of individuals with colorectal polyps (Alimonti et al., 2008) or urine of individuals with bladder cancer (Lin et al., 2009) compared to control groups. A study examining Pb levels in kidney tissue reported the

highest levels of Pb in normal kidney tissue samples that were adjacent to neoplastic tumors. The Pb levels reported in the kidney tissue of neoplastic tumors were elevated compared to those detected in corpses without neoplastic tumors of the kidney (Cerulli et al., 2006). All of these comparison studies are limited by the inability to determine temporality as Pb biomarkers were measured after the cancer diagnosis; the level of Pb may be due to changes that result from having cancer, not changes that result in cancer. Many of these studies attempted to control for this by including only cases who have not undergone certain treatments. Additionally, studies are limited by their small sample sizes and the selection of the control populations. Control populations are supposed to represent the general population from which the cases are drawn; some of the control subjects in these studies are individuals with diseases/conditions warranting tissue resections, which are not prevalent in the general population.

In summary, epidemiologic studies examining the potential for associations of Pb exposure with the incidence of specific cancers reported varying associations with occupational Pb exposure. Associations were null for occupational Pb exposure and most cancer sites examined. However, a positive association was observed between occupational Pb exposure and adenocarcinoma of the esophagus as well as exposure to occupational organic Pb and stomach cancer, which is supported by evidence of a relationship between Pb exposure and stomach cancer in occupational cohorts reported in the 2006 Pb AQCD. Associations between occupational organic Pb exposure and rectal cancer and occupational exposure to Pb in gasoline emissions and stomach cancer were inconsistent. These studies of various cancer sites have limited generalizability due to the study populations comprising only men. In addition, there are no personal biological or exposure samples used in the epidemiologic analyses and confounding by other occupational exposures is possible. In other studies, biological samples were used in biomarker comparisons of cancer and cancer-free individuals but as stated above, these studies have multiple other limitations.

5.10.1.7 Animal Models of Carcinogenicity

Previous AQCDs have established that Pb has been shown to act as a carcinogen in animal toxicology models, albeit at relatively high concentrations. Chronic oral Pb acetate exposure to male and female rodents has consistently been shown to be a kidney carcinogen in multiple separate studies, inducing adenocarcinomas and adenomas after chronic exposure. Gliomas of the brain have also been reported after oral Pb exposure. The kidneys are the most common target of Pb-dependent carcinogenicity (Kasprzak et al., 1985; Koller et al., 1985; Azar et al., 1973; Van Esch and Kroes, 1969) but the testes, brain, adrenals, prostate, pituitary, and mammary gland have also been

affected (IARC, 2006a). The typical cancer bioassays used by IARC or NTP as evidence of Pb-induced carcinogenicity were designed using rodents, typically males but sometimes animals of both sexes, that were continuously exposed to Pb acetate in chow (i.e., 1,000 or 10,000 ppm Pb acetate) or drinking water (i.e., 26 or 2,600 ppm Pb acetate) for 18 months to two years in duration, the typical lifespan of a rodent (Kasprzak et al., 1985; Koller et al., 1985; Azar et al., 1973; Van Esch and Kroes, 1969). These two-year cancer bioassays and the doses employed are typical of cancer bioassays employed for other chemicals, albeit at doses that are higher than Pb doses cited in other toxicological sections of the ISA. In cancer bioassays, to obtain statistically valid data from small groups of animals, doses are selected such that any dose-related effects will occur frequently enough to be detected. The 2006 Pb AQCD (U.S. EPA, 2006b) pointed out that because Pb is a "well-established animal carcinogen…., focus has been more on the mechanism of neoplasia and possible immunomodulatory effects of Pb in the promotion of cancer." This focus continues to date. More recent studies have focused on administration of Pb with known carcinogens or antioxidants such that lifestage, diet, and mode of action can be better understood. Developmental Pb acetate exposure also induced kidney tumors in offspring whose dams received Pb acetate in drinking water during pregnancy and lactation.

Recognition of the importance of windows of exposure in Pb-induced cancer bioassays is a focus of more recent studies. In one study, gestational and lactational exposure of laboratory rodents to inorganic Pb (500, 750 or 1,000 ppm Pb acetate in drinking water) induced carcinogenicity in adult offspring (Waalkes et al., 1995). Another recent study considered Pb-induced carcinogenesis in laboratory animals with early life Pb exposure (gestation and lactation) in which Tokar et al. (2010) examined tumorigenesis in homozygous metallothionein I/II knockout mice and their corresponding wild type controls (groups of ten mice each). The dams/mothers were exposed by drinking water to 2,000 or 4,000 ppm Pb acetate during gestation and lactation and compared to untreated controls. Study animals were exposed in utero, through birth and lactation, and then postnatally to drinking water until 8 weeks old. The Pb-exposed metallothionein I/II knockout mice had increased testicular teratomas and renal and urinary bladder preneoplasia. The tumor burden of Pb-exposed wild-type mice were not statistically significantly different than controls. The data suggest that metallothionein can protect against Pb-induced tumorigenesis. Concerns with the study are that the doses are at levels of Pb to which humans would not likely be exposed and there is no metallothionein null condition in humans, though there is variability in the expression of metallothionein. The data do not address whether this variability would have any impact on Pb-induced carcinogenesis in humans. Thus, the animal toxicology data demonstrate that Pb is a well-established animal carcinogen in studies employing high-dose Pb exposure over a continuous extended duration of exposure (i.e., 2 years), which is typical of cancer

bioassays. Newer studies are showing early-life maternal Pb exposure can contribute to carcinogenicity in offspring and have shown that metallothionein is protective against cancer in this pathway.

5.10.2 Cancer Biomarkers

A cross-sectional study of men aged 21-40 years without occupational history of exposure to metals examined prostate specific antigen (PSA), a biomarker for prostate cancer (N=57). Studies of Pb exposure and PSA were not reported in the 2006 Pb AQCD (U.S. EPA, 2006b). This recent study reported a positive association between Pb levels and PSA levels (measured in the same blood samples) in regression models adjusted for the following potential confounders: age, smoking, alcohol consumption, and other metals (Cd, Zn, Se, and Cu) (Pizent et al., 2009). The median concurrent blood Pb level was 2.6 µg/dL (range 1.0-10.8 µg/dL). The authors note that the study population was young and at lower risk of prostate cancer than are older men.

5.10.3 Modes of Action for Pb-induced Carcinogenicity

The carcinogenic mode of action of Pb is poorly understood. It is unclear whether the mode of action of Pb is best understood within the framework of multistage carcinogenesis, genomic instability or epigenetic modification. For example, multistage carcinogenesis involves a series of cellular and molecular changes that result from the progressive accumulation of mutations that induce alterations in cancer-related genes. Pb does not appear to follow this paradigm, and the literature suggests it is weakly mutagenic. Pb does appear to have some ability to induce DNA damage (Section 5.10.3.2). However, the ability of Pb to alter gene expression through epigenetic mechanism (Section 5.10.3.3) and to interact with proteins may be a means by which Pb induces carcinogenicity. It is known that Pb can replace Zn in Zn-binding (Zn-finger) proteins (Section 5.2), which include hormone receptors, cell-cycle regulatory proteins, the Ah receptor, estrogen receptor, p53, DNA repair proteins, protamines, and histones. These Zn-finger proteins all bind to specific recognition elements in DNA. Thus, Pb may act at a post-translational stage to alter protein structure of Zn-finger proteins, which can in turn alter gene expression, DNA repair and other cellular functions. To recapitulate, cancer develops from one or a combination of multiple mechanisms including modification of DNA via epigenetics or enzyme dysfunction and genetic instability or mutation. These modifications then provide the cancer cells with a selective growth advantage. In this schematic, Pb may contribute to epigenetic changes and chromosomal aberrations.

The genomic instability paradigm requires a cascade of genome-wide changes caused by impaired DNA repair, kinetochore assembly, cellular checkpoints, centrosome duplication, microtubule dynamics or a number of cell maintenance processes. These processes have been rarely studied for Pb, thus there are few data that suggest Pb may interfere with some of these processes. Furthermore, the bulk of the literature in this area involves Pb chromate and it is unclear if the effects are due to Pb or chromate. Epigenetic modifications may lead to cancer by altering cellular functions without altering the DNA sequence. The most commonly studied epigenetic change is methylation alterations. A small number of studies show that Pb can induce epigenetic changes (Section 5.10.3.3), but studies are still missing to clearly tie these effects to Pb-induced carcinogenesis and genotoxicity. Thus, either genomic instability or epigenetic modification paradigms or some combination of the two may underlie Pb-induced carcinogenicity.

Exposure to mixtures can also contribute to understanding of modes of action. No recent studies of the protective role of Ca^{2+} or Zn in Pb-induced carcinogenesis or genotoxicity were found. Pb can displace these and other divalent cations, affecting physiological processes. There were some data suggesting that metallothionein (Section 5.10.4), which sequesters Pb and makes it less bioavailable, protects rodents from Pb-induced cancers. Boron, melatonin, N-acetylcysteine, turmeric and myrrh protected cells against Pb-induced genotoxicity (Section 5.10.3.2) and affected antioxidant status, especially the glutathione pathway. There were some data suggesting that Pb mimics or antagonizes the essential micronutrient Se in rodents. These data are discussed in more detail elsewhere (Section 5.10.4) and point to the relevance of mixtures in assessing toxicity.

5.10.3.1 Neoplastic Transformation Studies, Human Cell Cultures

Carcinogenesis can be measured in cell culture systems through neoplastic transformation models that monitor change by following morphological transformation of cells, i.e., formation of a focus (or foci) of cell growth. Xie et al. (2007) treated BEP2D cells (human papilloma virus- immortalized human bronchial cells) with 0, 1, 5, or 10 µg/cm^2 $PbCrO_4$ for 120 hours. $PbCrO_4$ induced foci formation in a concentration-dependent manner. Xie et al. (2008) treated BJhTERT cells (hTERT-immortalized human skin fibroblasts) and ATLD-2 cells (hTERT-immortalized human skin fibroblasts deficient in Mre11) with 0, 0.1, 0.5, and 1 µg/cm^2 $PbCrO_4$ for 120 hours. $PbCrO_4$ induced foci formation in a concentration-dependent manner in the Mre11 deficient cells. Mre11 was required to prevent $PbCrO_4$-induced neoplastic transformation.

Immune Modulation of Tumorigenesis by Pb

As described in the 2006 Pb AQCD (U.S. EPA, 2006b), Pb-induced immunotoxicity can contribute to increased risk of cancer, primarily as the result of suppressed Th1 responses and misregulated inflammation. First, Pb-induced misregulation of inflammation involving innate immune cells has been shown to result in chronic insult to tissues. These insults, excessive lipid and DNA oxidation production by overproduction of ROS and weakened antioxidant defenses, can increase the likelihood of mutagenesis, cellular instability, and tumor cell formation. For example, results from Xu et al. (2008) support the association with Pb exposure and DNA damage, and investigators concluded that it is a possible route to increased Pb-induced tumorigenesis. The second component of increased risk of cancer involves Pb-induced suppression of Th1-dependent anti-tumor immunity as acquired immunity shifts statistically significantly toward Th2 responses. With cytotoxic T lymphocytes and other cell-mediated defenses dramatically lessened, the capacity to resist cancer may be compromised.

5.10.3.2 DNA and Cellular Damage

Multiple studies have been performed examining the relationship between Pb and DNA and cellular damage. Details of the recent epidemiologic and toxicological studies follow.

Epidemiologic Evidence for DNA and Cellular Damage

Multiple studies examined the relationship between Pb and sister chromatid exchange (SCE). SCEs are exchanges of homologous DNA material between chromatids on a chromosome and are a test for mutagenicity or DNA damage. A study of male policemen reported mean blood Pb levels for the study population of 43.5 µg/dL (Wiwanitkit et al., 2008). In analyses dichotomized as high or low blood Pb levels (cut-off at 49.7 µg/dL), the higher blood Pb group was observed to have higher mean SCE. Another study of adult males compared the SCE of storage battery manufacturing workers (mean blood Pb levels of 40.14 µg/dL) and office workers (mean blood Pb levels of 9.77 µg/dL) (Duydu et al., 2005). The exposed workers had higher SCE levels and also a greater number of cells in which the SCEs per cell were higher than the 95th percentile of the population. Finally, a study of children aged 5-14 years old (mean [SD] blood Pb levels of 7.69 [4.29] µg/dL) reported no correlation between blood Pb levels and SCE (Mielzyńska et al., 2006). However, the study did report a positive association between blood Pb and micronuclei (MN) levels.

Other studies of DNA damage have reported mixed results. A study of children ages 6-11 years old and environmentally-exposed to Pb reported no association between blood Pb and baseline DNA damage or repair ability after a peroxide challenge (children attending a school far from a Pb smelter: median blood Pb level 4.6 µg/dL; children attending a school near a Pb smelter: median blood Pb level 28.6 µg/dL) (Méndez-Gómez et al., 2008). Another study included adult participants aged 50-65 years and reported an association between blood Pb and carcinoembryonic antigen (CEA) but not with DNA-strand breaks, MN frequency, or oxidative DNA damage (median blood Pb level of the study population: 3.92 µg/dL) (De Coster et al., 2008). A study conducted among workers exposed to Pb (mean blood Pb level: 30.3 µg/dL) and unexposed controls (mean blood Pb level: 3.2 µg/dL) reported greater cytogenetic damage (measured by MN frequency), chromosomal aberrations, and DNA damage in the Pb-exposed group (although this was not statistically significant in linear regression models controlling for age) (Grover et al., 2010). A study of painters in India, where Pb concentrations in paint are high, reported a mean (SD) blood Pb level of 21.56 (6.43) µg/dL among painters who reported painting houses for 8-9 hours/day for 5-10 years (Khan et al., 2010b); the mean (SD) blood Pb level was 2.84 (0.96) µg/dL for healthy workers who had not been occupationally exposed to Pb. Cytogenetic damage was higher among the painters compared to the healthy controls. Another study compared the blood Pb of metal workers and office workers and reported higher blood Pb levels (both current and 2 year average) among the metal workers (blood Pb level ≥ 20 µg/dL) compared to the office workers (blood Pb level <10 µg/dL) (Olewińska et al., 2010). Overall, the workers had increased DNA strand breaks versus the office workers (this held true at various blood Pb levels). Finally, a study of Pb battery workers with symptoms of Pb toxicity and a group of controls were examined (Shaik and Jamil, 2009). Higher chromosomal aberrations, MN frequency, and DNA damage were reported for the battery workers as compared to the controls. These workplace studies are limited by the lack of consideration for potential confounding factors, including other occupational exposures.

Toxicological Evidence for DNA and Cellular Damage

Sister Chromatid Exchanges

Pb has been shown to induce SCEs both in vivo and in vitro. Tapisso et al. (2009), considered SCEs in adult Algerian mice (groups of six mice each) that were treated by i.p. injection with 5 or 10 doses of 0.46 mg/kg Pb acetate. The SCE in bone marrow were elevated after Pb exposure alone and increased with time. Co-exposure with Cd or Zn further increased SCE levels.

SCE was also followed in cultured human cells. Ustundag and Duydu (2007) considered the ability of N-acetylcysteine and melatonin to reduce Pb nitrate-induced SCE in a single human donor. Cells were treated with 0, 1, 5, 10, or 50 µM Pb nitrate. SCE statistically significantly increased at every Pb concentration in a concentration dependent manner. Both 1 and 2 mM N-acetylcysteine and melatonin were able to statistically significantly reduce SCE levels in Pb-exposed cells. In another study, Turkez et al. (2011) considered the ability of boron compounds, essential micronutrients, to prevent Pb chloride-induced SCE in human lymphocytes. Cells were obtained from 4 non-smoking donors. Both 3 and 5 ppm Pb chloride induced a statistically significant increase in SCE levels over controls. Boron was able to statistically significantly diminish these levels. For both studies, exposure times were not provided, and the full interpretation of these data is limited by the limited number of donors and the absence of an exposure time for the SCE assay.

Micronuclei Formation

The 2006 Pb AQCD stated "studies of genotoxicity consistently find associations of Pb exposure with DNA damage and MN formation" and recent studies continue to report these associations. Alghazal et al. (2008b) considered the ability of Pb acetate trihydrate to induce MN in bone marrow of adult Wistar rats. Animals were given a daily dose of 100 mg/L in their drinking water for 125 days. The mean number of MN in male and female rats was statistically significantly higher in Pb-exposed animals than in unexposed controls. Tapisso et al. (2009) considered Pb-induced MN in rodents. Algerian mice were treated by i.p. injection with 5 or 10 doses of 0.46 mg/kg Pb acetate and compared to untreated controls. The MN in bone marrow were elevated after Pb exposure and increased with time

MN formation has also been followed in cultured human cells. Ustundag and Duydu (2007) considered the ability of N-acetylcysteine and melatonin to reduce Pb nitrate-induced MN in a single human donor. Cells were treated with 0, 1, 5, 10, or 50 µM Pb nitrate. MN formation statistically significantly increased at the two highest Pb concentrations in a concentration-dependent manner. Both 1 and 2 mM N-acetylcysteine and melatonin were not able to statistically significantly reduce MN levels. In another study, Turkez et al. considered the ability of boron compounds to prevent Pb chloride-induced MN in human lymphocytes. Cells were obtained from 4 non-smoking donors. Both 3 and 5 ppm Pb chloride induced a statistically significant increase in MN levels over controls. Boron induced a statistically significant attenuation of these Pb-induced levels. For both studies, exposure times were not provided, and the full interpretation of these data is limited by the limited number of donors and the absence of an exposure time for the MN assay. Gastaldo et al. (2007) evaluated the ability of Pb to induce MN.

Human endothelial HMEC cell line was treated with 1–1,000 µM Pb nitrate for 24 hours. MN increased in a statistically significant, concentration-dependent manner.

Hypoxanthine-guanine phosphoribosyltransferase Mutations

The potential mutagenicity of Pb in human or animal cells has been evaluated by monitoring mutations at the hypoxanthine-guanine phosphoribosytransferase (HPRT) locus. Li et al. (2008a) evaluated Pb acetate-induced HPRT in the non-small-cell lung carcinoma tumor cell line, CL3, and in normal human diploid fibroblasts (specific tissue source not reported). All cells were exposed to 0, 100, 300 or 500 µM Pb acetate for 24 hours in serum-free medium ± a 1-hour pretreatment with a MKK1/2 inhibitor or a PKC-alpha inhibitor. Pb alone did not induce HPRT mutations. Inhibiting the ERK pathway via either inhibitor statistically significantly increased Pb-induced mutagenesis. Wang et al. (2008c), investigated Pb acetate -induced HPRT mutations in CL3 cells. All cells were exposed to 0, 100, 300 or 500 µM Pb acetate for 24 hours in serum-free medium ± a 1-hour pretreatment with a PKC-alpha inhibitor or siRNA for PKC-alpha. Pb alone did not induce HPRT mutations. Inhibiting PKC-alpha via either inhibitor statistically significantly increased Pb-induced mutagenesis. McNeill et al. (2007) examined Pb acetate induced HPRT mutations in Chinese hamster ovary AA8 cells and AA8 cells overexpressing human Ape1. Cells were treated with 5 µM Pb acetate for 6 hours. No increases in HPRT mutations were observed after Pb exposure in either cell line but with specific pathway perturbations (PKC-alpha or ERK), Pb was able to induce HPRT mutations.

Chromosomal Aberrations

Chromosomal aberrations, an indicator of cancer risk, were followed in Pb-exposed rodents (El-Ashmawy et al., 2006). Dietary exposure to Pb acetate administered as a single dose of 5,000 ppm w/w to adult male Swiss albino mice caused statistically significant increased levels of chromosomal aberrations in the Pb treatment alone group, particularly with respect to fragments, deletions, ring chromosomes, gaps, and end-to-end associations. In addition, the authors found turmeric and myrrh powders were protective. Concerns with the study include the use of only a single dose of Pb acetate along with the high levels of unusual aberrations such as ring chromosomes and end-to-end associations. Typically, these aberrations are rare after metal exposure, but were the most commonly observed aberration in this study raising questions about the quality of the metaphase preparations. An additional concern was that only 50 metaphases per dose were analyzed instead of the more common 100 metaphases per dose. The authors did not explain why their spectrum of aberrations was so different, why they only used one dose, or analyzed fewer metaphases per dose.

Multiple studies considered the ability of Pb to induce chromosomal aberrations in cultured human cells. The ability of Pb nitrate to induce chromosomal aberrations was examined in primary human peripheral blood lymphocytes obtained from healthy, nonsmoking donors (Pasha Shaik et al., 2006). Cells were treated with 0, 1.2 or 2 mM Pb nitrate for 2 hours. No increase in chromosomal aberrations was reported. Some aneuploidy was observed. Concerns with the study are that only a 2-hour exposure was used, which may not be long enough for DNA damage to be expressed as a chromosomal aberration. It also appears from the data presentation that only three subjects were used; one for a control, one for the low dose and one for the high dose. Experiments were not repeated, thus given the small number of subjects, this study may not have had sufficient power to detect any effects. Holmes et al. (2006a), treated WHTBF-6 cells (hTERT-immortalized human lung cells) with 0, 0.1, 0.5, or 1 μg/cm^2 Pb chromate for 24-120 hours or with 0, 0.1, 0.5, 1, 5 or 10 μg/cm^2 Pb oxide for 24 or 120 hours. Pb chromate induced statistically significant, concentration-dependent increases in centrosome abnormalities and aneuploidy. Wise et al. (2006a) treated BEP2D cells with 0, 0.5, 1, 5, or 10 μg/cm^2 Pb chromate for 24 hours. Pb chromate induced statistically significant concentration-dependent increases in chromosomal aberrations. Holmes et al. (2006b), treated WHTBF-6 cells with 0, 0.1, 0.5, or 1 μg/cm^2 Pb chromate for 24-72 hours. Pb chromate induced statistically significant, concentration-dependent increases in chromosomal aberrations. The effects of the chromate anion cannot be ruled out as causative in inducing these chromosomal aberrations. Wise et al. (2006b), treated WHTBF-6 cells with 0, 0.1, 0.5, or 1 μg/cm^2 Pb chromate for 24-120 hours. Pb chromate induced statistically significant, concentration-dependent increases in spindle assembly and checkpoint disruption, effects of mitosis and aneuploidy. By contrast, chromate-free Pb oxide did not induce centrosome amplification. The effects were likely attributable to the chromate anion. Xie et al. (2007) treated BEP2D cells with 0, 1, 5, or 10 μg/cm^2 Pb chromate for 24 hours. Pb chromate induced statistically significant, concentration-dependent increases in chromosomal aberrations and aneuploidy. Wise et al. (2010) treated WHTBF-6 cells with 0, 0.1, 0.5, or 1 μg/cm^2 Pb chromate for 24 hours in a study comparing 4 chromate compounds. Pb chromate induced statistically significant, concentration-dependent increases in chromosomal aberrations.

Multiple investigators considered the ability of Pb chromate to induce chromosome aberrations in rodent cell cultures. Grlickova-Duzevik et al. (2006) treated Chinese hamster ovary (CHO) cells with 0, 0.1, 0.5, or 1 μg/cm^2 Pb chromate for 24 hours. Specific CHO lines used included AA8 (wildtype) EM9 (XRCC1-deficient), and H9T3 (EM9 complemented with human XRCC1 gene). Pb chromate induced statistically significant, concentration-dependent increases in chromosomal aberrations that were statistically significantly increased by XRCC1 deficiency. Nestmann and Zhang (2007) treated Chinese hamster ovary cells (clone WB(L)) with 0, 0.1, 0.5, 1, 5, or 10 μg/cm^2

Pb chromate (as pigment yellow) for 18 hours. No increases in chromosomal aberrations were observed. Savery et al. (2007) treated CHO cells with 0, 0.1, 0.5, 1, or 5 µg/cm^2 Pb chromate for 24 hours. Specific CHO lines used included AA8 (wildtype), KO40 (*Fancg*-deficient), and 40BP6 (*Fancg*-complemented). The *Fancg* gene plays an important role in cellular resistance to DNA interstrand crosslinks, protecting against genetic instability. Pb chromate induced statistically significant, concentration-dependent increases in chromosomal aberrations that were increased by *Fancg*-deficiency. Camyre et al. (2007) treated CHO cells with 0, 0.1, 0.5, 1, 5, or 10 µg/cm^2 Pb chromate for 24 hours. Specific CHO lines used included CHO-K1 (parental), xrs-6 (Ku80 deficient), and 2E (xrs-6 complemented with Ku80 gene). Pb chromate induced statistically significant, concentration-dependent increases in chromosomal aberrations that were not affected by Ku80 deficiency. Ku80 is a gene involved in nonhomologous end-joining repair and its absence can contribute to genetic instability. Stackpole et al. (2007) treated CHO and Chinese hamster lung (CHL) cells with 0, 0.1, 0.5, or 1 µg/cm^2 Pb chromate for 24 hours. Specific CHO lines used included AA8 (wildtype), irs1SF (XRCC3-deficient), and 1SFwt8 (XRCC3 complemented). XRCC3 is DNA repair enzyme involved in homologous recombination. CHL lines used included V79 (wildtype), irs3 (Rad51C deficient) and irs3#6 (Rad51C complemented). Rad51C is a gene that encodes strand-transfer proteins that are thought to be involved in recombinational repair of damaged DNA and in meiotic recombination. Pb chromate induced statistically significant, concentration-dependent increases in chromosomal aberrations that were statistically significantly increased by both XRCC3 and Rad51C deficiency.

Multiple studies considered the ability of Pb chromate to induce chromosome aberrations in marine mammal cell cultures. Li Chen et al. (2009) treated primary North Atlantic right whale lung and skin fibroblasts with 0, 0.5, 1.0, 2.0, and 4.0 µg/cm^2 Pb chromate for 24 hours. Wise et al. (2009) treated primary Steller sea lion lung fibroblasts with 0, 0.1, 0.5, 1 and 5 µg/cm^2 Pb chromate for 24 hours. Wise et al. (2011) treated primary sperm whale skin fibroblasts with 0, 0.5, 1, 3, 5, and 10 µg/cm^2 Pb chromate for 24 hours. In all three studies, Pb chromate induced statistically significant, concentration-dependent increases in chromosomal aberrations.

In summary, exposure of various cell models and an in vivo model to Pb (acetate, chromate, or nitrate) induced significant increases in chromosomal aberration that often responded in a concentration dependent manner. The use of various cell lines deficient in specific DNA repair enzymes helped to elucidate which pathways may be most sensitive to Pb-dependent chromosomal aberration. However, a number of studies used Pb chromate exposures and the effects of the chromate anion cannot be ruled out as causative in inducing these chromosomal aberrations.

COMET Assay

Multiple studies considered the ability of Pb to induce DNA single strand breaks in laboratory animals and human and animal cells using the comet assays. The COMET assay measures DNA damage assessed by single cell electrophoresis of a lysed cell and measurement of the fragmented DNA or tail length. Xu et al. (2008) examined DNA damage in male ICR mice treated with Pb acetate. Animals (5 per group) were given Pb acetate by gavage at doses of 0, 10, 50, or 100 mg/kg body weight every other day for 4 weeks. Pb exposure statistically significantly increased both tail length and tail moment in a dose-dependent manner. Nava-Hernandez et al. (2009) considered the ability of Pb acetate to induce DNA damage in primary spermatocyte DNA of male Wistar rats. Animals (3 per group) were treated for 13 weeks with 0, 250, or 500 mg/L Pb in their drinking water. There was statistically significantly less DNA damage in the controls compared to the two treatment groups. Narayana and Al-Bader (2011) examined DNA damage in liver tissue of adult male Wistar rats exposed to Pb nitrate. Animals (8 per group) were treated for 60 days with doses of 0, 5,000, or 10,000 ppm Pb nitrate in their drinking water. There were no statistical differences between treated groups and controls. Drosophila melanogaster larvae (72 hours old) exposed to Pb nitrate (2,000, 4,000, and 8,000 µM in culture media for 24 hours) yielded haemocytes that tested positive in the comet assay; Pb chloride (8,000 µM) did not cause DNA damage with the comet assay (Carmona et al., 2011).

Other studies used the COMET assay in cultured human cells. Pasha Shaik et al. (2006) treated primary human peripheral blood lymphocytes obtained from healthy, nonsmoking donors with 0, 2.1, 2.4, 2.7, 3.0, $3.3*10^3$ µM Pb nitrate for 2 hours and found dose-dependent increases in Comet tail length. Concerns with the study are that apparently no negative control was used. It also appears from the data presentation that only five subjects were used; one for each dose. Experiments were not repeated. Thus, given the small number of subjects and the absence of a negative control, this study may only be detecting background levels of DNA damage. Xie et al. (2008) treated BJhTERT cells (hTERT-immortalized human skin fibroblasts) and ATLD-2 cells (hTERT-immortalized human skin fibroblasts deficient in Mre11) with 0, 0.1, 0.5, and 1 µg/cm^2 Pb chromate for 24 hours. Mre11 is a component of the MRN complex and plays a role in telomere maintenance and double-strand break repair. Pb chromate induced a concentration-dependent increase in DNA double strand breaks measured by the comet assay. Pb chromate exposure and the effects of the chromate anion cannot be ruled out as causative in inducing these aberrations. In another study, Pb nitrate exposure (30 µg/mL) induced statistically significant increased DNA damage in human liver HepG2 cells that was attenuated with co-exposure with the antioxidant NAC (500 µM) (Yedjou et al., 2010).

Other studies used the comet assay to examine Pb-induced DNA single strand breaks in rodent cell cultures. Xu et al. (2006), treated PC12 cells with 0, 0.1, 1 or 10 µM Pb acetate. Both tail length and tail moment statistically significantly increased in a concentration-dependent manner. Kermani et al. (2008) exposed mouse bone marrow-mesenchymal stem cells to 60 µM Pb acetate for 48 hours. There was an increase in several comet assay measurements including tail length.

The COMET assay showed multiple positive findings after Pb exposure in rodents, flies, primary human cells, and cell lines. In vivo studies with rodents exposed to Pb acetate yielded significant increases in tail length and moment via COMET assays in separate studies that used lymphocytes and sperm. In drosophila, Pb nitrate but not Pb chloride produced significant increases with the COMET assay. Human cell culture from primary cells (lymphocytes) and from cell lines (fibroblasts and liver) produced positive COMET assays with separate Pb nitrate and Pb chromate exposures. Thus, the COMET assay showed multiple positive findings of DNA damage after in vitro and in vivo Pb exposure.

Other Indicators of DNA Damage

Other studies considered the ability of Pb to induce DNA double strand breaks by measuring gamma-H2A.X foci formation in cultured human cells. Xie et al. (2008) treated BJhTERT cells (hTERT-immortalized human skin fibroblasts) and ATLD-2 cells (hTERT-immortalized human skin fibroblasts deficient in Mre11) with 0, 0.1, 0.5, and 1 µg/cm^2 Pb chromate for 24 hours. Pb chromate induced a concentration-dependent increase in DNA double strand breaks measured by gamma-H2A.X foci formation. Pb chromate exposure and the effects of the chromate anion cannot be ruled out as contributory. Gastaldo et al. (2007) evaluated the ability of Pb to induce DNA double strand breaks with both gamma-H2A.X foci formation and pulse-field gel electrophoresis in cultured human cells. The human endothelial HMEC cell line was treated with 1 to 1,000 µM Pb nitrate for 24 hours. DNA double strand breaks increased in a concentration-dependent manner. Wise et al. (2010) treated WHTBF-6 cells with 0, 0.1, 0.5, or 1 µg/cm^2 Pb chromate for 24 hours in a study comparing four chromate compounds. Pb chromate induced statistically significant, concentration-dependent increases in DNA double strand breaks measured by gamma-H2A.X foci formation, at a similar level to the three other compounds. A few studies demonstrated the ability of Pb to destabilize DNA by forming DNA-histone cross links, which can lead to histone aggregation (Rabbani-Chadegani et al., 2011; Rabbani-Chadegani et al., 2009). In extracts of rat liver, Pb nitrate (<300 µM) was shown to react with chromatin components and induce chromatin aggregation via histone-DNA cross links.

Genotoxicity testing of *Drosophila melanogaster* larvae (72 hours old) using the Wing Spot test showed that neither Pb chloride nor Pb nitrate (at concentrations of 2,000, 4,000

and 8,000 µM in culture media with exposure until pupation) was able to induce significant increases in the frequency of wing spots (Carmona et al., 2011). The wing spot test can detect mitotic recombination and multiple mutational events such as point mutations, deletions, and certain types of chromosome aberrations (Graf and Würgler, 1986). Further, wing spot assays employing Pb co-exposure with gamma radiation showed no effect of Pb on gamma radiation induced spotting frequency.

Multiple studies examined the effects of Pb on DNA repair. Most were conducted in cultured cells, and one was done in an animal model. El-Ghor et al. (2011) followed microsatellite instability (MSI) in Pb acetate trihydrate exposed adult male rats. MSI reflects impaired DNA mismatch repair and contributes to an increased risk of cancer. DNA from leukocytes of adult male albino rats exposed to Pb acetate (acute: single oral dose of 467 mg/kg BW or sub-chronic: 47 mg/kg BW six days/week for 4 week) showed increased MSI at three microsatellite loci (D6mit3, D9mit2, and D15Mgh1). This study is limited by its small sample size (n=2 to 3 rodents per treatment group). Li et al. (2008a) evaluated Pb acetate-induced effects on nucleotide excision repair efficiency in CL3 cells. All cells were exposed to 0, 100, 300 or 500 µM Pb acetate for 24 hours in serum-free medium. Pb increased nucleotide excision repair efficiency. Gastaldo et al. (2007) evaluated the ability of Pb to affect DNA repair in cultured human cells. The human endothelial HMEC cell line was treated with 100 µM Pb nitrate for 24 hours. Pb inhibited non-homologous end joining repair, over activated MRE11-dependent repair, and increased Rad51-related repair. Xie et al. (2008) treated BJhTERT cells (hTERT-immortalized human skin fibroblasts) and ATLD-2 cells (hTERT-immortalized human skin fibroblasts deficient in Mre11) with 0, 0.1, 0.5, and 1 µg/cm^2 Pb chromate for 24 or 120 hours. Mre11 was required to prevent Pb chromate-induced DNA double strand breaks. In this finding, Pb chromate exposure and the effects of the chromate anion cannot be ruled out as causative. McNeill et al, (2007) considered Pb acetate effects on Ape1. Chinese hamster ovary cells (AA8) were treated with 0, 0.5, 5, 50, or 500 µM Pb acetate and then whole cell extracts were used to determine AP site incision activity. The data show that Pb reduced AP endonuclease function. Finally, studies considered Pb-induced cellular proliferation in laboratory animals. Kermani et al. (2008) exposed mouse bone marrow-mesenchymal stem cells to 0-100 µM Pb acetate for 48 hours. As measured by the MTT assay, Pb decreased cell proliferation at all concentrations tested. An earlier study in rats showed Pb nitrate-induced increased proliferation of liver cells after a partial hepatectomy, with more prominent effects found in males than females (sexual dimorphism) (Tessitore et al., 1995). Recent studies showed similar trends in males. Fortoul et al. (2005) exposed adult male CD1 mice (24 animals per group) to 1*10^4 µM Pb acetate, 0.006 M Cd chloride or a mixture of the two chemicals for 1 h twice a week for 4 weeks by inhalation. Electron microscopy indicated Pb-induced cellular proliferation in the lungs.

5.10.3.3 Epigenetics

Air pollution exposure is being linked increasingly with epigenetic changes in humans and toxicological models (Pavanello et al., 2010; Baccarelli and Bollati, 2009; Tarantini et al., 2009; Bollati et al., 2007). Epigenetic changes are changes in DNA expression that occur without actual changes in the DNA sequence, and these changes may be heritable. Epigenetic changes are mediated by histone modification, DNA methylation, miRNA changes, or pathways that affect these three mediators. Differential epigenetic modification has the possibility to contribute to disease. Epigenetic studies have been conducted to examine the associations between Pb biomarker levels and global DNA methylation markers [Alu and long interspersed nuclear element-1 (LINE-1)] in humans (Wright et al., 2010; Pilsner et al., 2009). Wright et al. (2010) examined men from the Normative Aging Study (N=517) with mean (SD) Pb levels of 20.5(14.8)g/g in tibia, 27.4 (19.7)g/g in patella, and 4.1 (2.4) µg/dL in blood. In both crude and adjusted analyses, patella Pb levels were inversely associated with LINE-1 methylation but not with Alu. The adjusted models all included age, BMI, percent lymphocytes, with some adjusted models also controlling for education, smoking, and blood Pb levels. In examination of the relationship between patella Pb and LINE-1 more closely, a non-linear trend was observed with a smaller magnitude of effect estimated for higher patella Pb (≥ 40 µg/g). No associations were observed for tibia or blood Pb and either LINE-1 or Alu. Another study included maternal-infant pairs from the Early Life Exposures in Mexico to Environmental Toxicants study (N=103) and measured LINE-1 and Alu methylation in umbilical cord blood samples (Pilsner et al., 2009). In unadjusted models, maternal tibia Pb levels one month postpartum (mean [SD]: 10.5 [8.4] µg/g) were inversely associated with Alu methylation in the cord blood. Maternal patella Pb levels one month postpartum (mean [SD]: 12.9 [14.3] µg/g) were inversely associated with LINE-1 methylation. The associations persisted in models adjusted for maternal age, maternal education, infant sex, smoking during pregnancy, and umbilical cord blood Pb levels (the results were no longer statistically significant when umbilical cord blood was removed from the model). No association was detected between umbilical cord Pb levels and the DNA methylation markers. Overall, the studies consistently demonstrate an association between higher patella Pb levels and lower LINE-1 methylation. Lower DNA methylation is associated with increased gene expression; however, the link between global DNA methylation and risk of disease, has not been established.

Toxicological studies have examined Pb-induced epigenetic changes and gene expression, DNA repair, and mitogenesis. Glahn et al., (2008) performed a gene array study in primary normal human bronchial epithelial cells from four donors after in vitro treatment of the cells with 55 µg/dL Pb chloride, 15 µg/L Cd sulfate, 25 µg/L Co chloride or all three combined for 72 hours. The authors describe a pattern of RNA expression

changes indicating "…coordinated stress-response and cell-survival signaling, deregulation of cell proliferation, increased steroid metabolism, and increased expression of xenobiotic metabolizing enzymes." These are all known targets of possible epigenetic changes, but attributing the results to epigenetic changes is complicated. In a recent publication (Li et al., 2011), exposure of HepG2 cells to a high dose of Pb (100 µM Pb acetate) resulted in ALAD gene promoter hypermethylation and decreased ALAD transcription. This was in agreement with findings in battery plant workers who showed ALAD hypermethylation (versus non-occupationally exposed controls) and an association of this hypermethylation with elevated risk of Pb poisoning (Li et al., 2011). These latter results have implications for Pb toxicokinetics or disposition of Pb as modified by ALAD.

5.10.4 Effects of Pb within Mixtures

Several studies considered the impact of Pb as part of a mixture on mixtures genotoxicity and mutagenesis. Mendez-Gomez et al. (2008) evaluated 65 children in Mexico with high environmental exposures to both As and Pb. DNA damage and decreased DNA repair were seen using the comet assay and other assays but did not correlate with urinary As or blood Pb levels. Tapisso et al. (2009) examined Pb alone, Pb plus Zn and Pb plus Cd-induced MN in rodents. Algerian mice (groups of six mice each) were treated i.p. with 5 or 10 doses of 0.46 mg/kg Pb acetate and compared to untreated controls. The MN in bone marrow were elevated after Pb treatment alone and increased with time. Co-exposure with Cd or Zn did not further increase MN levels but did increase SCE levels. Glahn et al. (2008) performed a gene array study in primary normal human bronchial epithelial cells from four donors treated with 55 µg/dL Pb chloride, 15 µg/L Cd sulfate, 25 µg/L Co chloride or all three combined for 72 hours. There was a clear interaction of all three metals impacting RNA expression.

Studies in the 2006 Pb AQCD (U.S. EPA, 2006b) found a protective role for calcium in genotoxic and mutagenic assays with Pb co-exposure. No recent studies of the protective role of calcium in Pb-induced carcinogenesis or genotoxicity were found. There were some data suggesting that boron, melatonin, N-acetylcysteine, turmeric and myrrh protect cells against Pb-induced genotoxicity (Section 5.10.3.2).

A recent study details Pb and Se interactions in virus-dependent carcinogenesis in laboratory animals. Schrauzer (2008) considered the impact of Se on carcinogenesis by studying four groups of weanling virgin female C3H/St mice infected with murine mammary tumor virus (groups of 20-30 mice), which induces mammary tumor formation. One set of two groups were fed a diet containing 0.15 ppm Se and then were

exposed via drinking water to acetic acid (control group) or 0.5 ppm Pb acetate. The second set of two groups were fed a diet containing 0.65 ppm Se and then similarly exposed to acetic acid or 0.5 ppm Pb acetate. The study was primarily focused on the general effects of a low Se diet. The data suggest that Se is anticarcinogenic as in the groups without Pb exposure, the animals exposed to the higher Se levels had fewer mammary tumors and these tumors had a delayed onset of appearance. Pb exposure with low Se caused the same delayed onset as did the higher dose of Se and also caused some reduction in the tumor frequency. Pb exposure with higher Se increased the tumor frequency and the onset of the tumors. Pb also induced weight loss at 14 months in both exposed groups. The data suggest that there may be interactions of Pb and Se, but they suggest that Pb mimics or antagonizes Se. They do not suggest that Se is protective of Pb-induced toxicity or carcinogenesis.

In summary, the new data on Pb exposure as part of a mixture is derived from studies designed with co-exposure to metals or antioxidants. Children in Mexico with co-exposure to high levels of Pb and As showed elevated DNA damage and impaired DNA repair. Pb and Cd co-exposure in mice elevated SCE levels but did not further exacerbate MN levels above Pb exposure alone. Primary lung cells exposed to a metals mixture showed an interaction at the mRNA level among the three metals tested. In other genotoxicity assays, various antioxidants (melatonin, NAC, turmeric and myrrh) and metals (boron) were protective against Pb-induced genotoxicity. In an animal model of breast cancer, Se modified the onset and multiplicity of murine mammary tumor virus-induced tumorogenicity in Pb-exposed animals. These data show that co-exposure of Pb with antioxidants or metals, modifies the effect of Pb on DNA damage, DNA repair, mutagenicity, genotoxicity, or tumorogenicity.

5.10.5 Summary and Causal Determination

Toxicological and epidemiologic studies of the association between Pb exposure and cancer and cancer-related outcomes have been reviewed in the preceding sections. Evaluation of the relationship between Pb exposure and cancer with respect to causality was based on evidence for tumor incidence in experimental animals, associations of Pb exposure with cancer incidence and mortality in humans, and evidence describing potential modes of action including mutagenesis, clastogenesis, and epigenetic changes. The application of the key supporting evidence from these studies to the causal framework is summarized in Table 5-50 and the following text.

The toxicological literature provides consistent evidence of the carcinogenic potential of Pb and possible contributing modes of action, including genotoxic, mutagenic and epigenetic effects. In laboratory studies, chronic Pb exposure for 18 months or two years to high concentrations such as 10,000 ppm Pb acetate in diet or 2,600 ppm Pb acetate in drinking water has been demonstrated to be an animal carcinogen. Chronic Pb exposure to male and female rodents has consistently induced kidney and brain carcinogenesis in multiple separate studies, inducing various tumors, (i.e., adenocarcinomas, adenomas, and gliomas. Pb has also been shown to cause mammary gland, prostate, adrenal, and testicular tumors in animals. Developmental Pb acetate exposure also induced tumors in offspring whose dams received Pb acetate in drinking water during pregnancy and lactation. Multiple toxicological studies showed neoplastic transformation in cultured cells providing an additional potential mode of action, but most used Pb chromate, and it is possible that the chromate ion contributed to these findings. The toxicological and epidemiologic literature provides evidence for potential carcinogenic modes of action from genotoxic, mutagenic and epigenetic assays. Multiple longitudinal epidemiologic studies have been performed examining the association between cancer incidence and mortality and Pb exposures, estimated with biological measures and exposure databases. Mixed results have been reported for cancer mortality studies; a large NHANES epidemiologic study demonstrated a positive association between blood Pb and cancer mortality with median 8.6 years of follow up on subjects (Schober et al., 2006), but the other studies reported null results (Khalil et al., 2009b; Weisskopf et al., 2009; Menke et al., 2006). These were well-conducted epidemiologic studies with control for important potential confounders such as age, smoking, and education. Although the 2006 Pb AQCD (U.S. EPA, 2006b) reported some studies that found an association between Pb exposure indicators and lung cancer, recent studies mostly included occupationally-exposed adults and observed no associations. Most studies of Pb and brain cancer were null among the overall study population, but positive associations were observed among individuals with certain genetic variants. However, the studies of Pb and brain cancer were all limited by the use of occupational cohorts and interviews instead of biological measurements to represent Pb exposure, and by possible confounding by several factors, including other workplace exposures. A limited amount of research has been performed on other types of cancer. The 2006 Pb AQCD reported evidence that suggested an association between Pb exposure and stomach cancer, but in a recent study of stomach cancer the results were inconsistent, reporting a positive association between organic Pb exposure and stomach cancer but null findings for exposure to inorganic Pb or Pb from gasoline emissions and stomach cancer.

Among epidemiologic studies, high Pb levels (over 40 µg/dL in adults) were associated with SCEs among adults. This association was not observed among children (mean blood Pb 7.69 µg/dL). Other epidemiologic studies of DNA damage reported inconsistent

results. Consistent with previous toxicological findings, Pb does appear to have genotoxic activity in animal and in vitro models, inducing SCE, MN and DNA strand breaks. The majority of the chromosomal aberration studies with Pb-induced significant finding used Pb chromate exposure and the aberrations are likely due to the chromate. Pb does not appear to be very mutagenic as the HPRT assays were typically negative unless a cell signaling pathway was disturbed.

Mechanistic understanding of the carcinogenicity of Pb in toxicological models is expanding with work on the antioxidant Se and metallothionein, a protein that binds Pb and reduces its bioavailability. Low Se diet affects tumorigenesis and tumor multiplicity with Pb exposure. Metallothionein has been shown to be protective against the effect of Pb on carcinogenicity. Pb is clastogenic and mutagenic in some but not all models. Clastogenicity and mutagenicity may be possible mechanisms contributing to cancer but are not absolutely associated with the induction of cancer. Because Pb has a higher atomic weight than does Zn, Pb replaces Zn at many Zn binding sites or Zn finger proteins. This substitution has the potential to induce effects that can indirectly contribute to carcinogenicity via interactions with hormone receptors, cell-cycle regulatory proteins, tumor suppressor genes like p53, DNA repair enzymes, histones, etc. These indirect effects may act at a post-translational level to negatively alter protein structure and DNA repair.

Epigenetic changes associated with Pb exposure or biological markers, particularly, methylation and effects on DNA repair, are beginning to appear in the literature. Epigenetic modifications may contribute to carcinogenicity by altering DNA repair or changing the expression of a tumor suppressor gene or oncogene. A small number of epidemiologic studies examining Pb and global epigenetic changes demonstrated an inverse association between bone Pb and LINE-1 or Alu methylation. Lower DNA methylation is associated with increased gene expression, but epigenetic contributions to cancer are not yet fully characterized in this emerging area of research. Toxicological studies show that Pb can activate or interfere with a number of signaling and repair pathways, though it is unclear whether these are due to epigenetic responses or genotoxicity. Thus, an underlying mechanism is still uncertain, but likely involves genomic instability, epigenetic modifications, or both.

In conclusion, the toxicological literature provides the strong evidence for long-term exposure (i.e., 18 months or 2 years) to high concentrations of Pb (> 2,600 ppm) and cancer. The consistent evidence indicating Pb-induced carcinogenicity in animal models is substantiated by the mode of action findings from multiple high-quality toxicological studies in animal and in vitro models from different laboratories. This is substantiated by the findings of other agencies including IARC, which has classified inorganic Pb

compounds as a probable human carcinogen and the National Toxicology Program, which has listed Pb and Pb compounds as "reasonably anticipated to be human carcinogens." Strong evidence from animal toxicological studies demonstrates an association between Pb and cancer, genotoxicity, mutagenicity or epigenetic modification. Carcinogenicity in animal toxicology studies with relevant routes of Pb exposure has been reported in the kidneys, testes, brain, adrenals, prostate, pituitary, and mammary gland, albeit at high doses of Pb. Epidemiologic studies of cancer incidence and mortality reported inconsistent results; one strong epidemiologic study demonstrated an association between blood Pb and increased cancer mortality, but the other studies reported weak or no associations. In the 2006 Pb AQCD, indicators of Pb exposure were found to be associated with stomach cancer, and a recent study on stomach cancer and occupational Pb exposure, reported mixed findings depending on the type of Pb exposure (organic Pb, inorganic Pb, or Pb from gasoline emissions). Similarly, some studies in the 2006 Pb AQCD reported associations between Pb exposure indicators and lung cancer. Recent epidemiologic studies of lung cancer focused on occupational exposures and reported inconsistent associations. The majority of epidemiologic studies of brain cancer had null results overall, but positive associations between Pb exposure indicators and brain cancer were observed among individuals with certain genotypes. Overall, the consistent and strong body of evidence from toxicological studies but inconsistent epidemiologic evidence is sufficient to conclude that a causal relationship is likely to exist between Pb exposure and cancer.

Table 5-50 Summary of evidence supporting cancer and genotoxicity causal determinations.

Attribute in Causal Framework[a]	Key Supporting Evidence[b]	References[b]	Pb Exposure or Blood Levels Associated with Effects
Cancer - Likely Causal			
Consistent toxicological results of tumors in laboratory animals with chronic Pb exposure	Consistent findings across multiple toxicology studies using 18 month or two year cancer bioassays in rats wherein rodents are fed chow or received drinking water enriched with Pb acetate, showing tumor development.	Azar et al. (1973), Kasprzak et al. (1985), Koller et al. (1985), Van Esch and Kroes (1969)	Chronic 10,000 ppm Pb acetate diet or 2,600 ppm drinking water Pb acetate, no blood Pb measurement available.
Toxicological studies of early life Pb exposure induced tumor formation in adulthood	Gestational and lactational Pb exposure induced carcinogenicity in adult offspring	Waalkes et al., (1995)	500, 750 and 1,000 ppm Pb in drinking water, no blood Pb measurement available.
Limited and inconsistent epidemiologic studies	Epidemiologic studies of overall cancer mortality have inconsistent findings. These are high-quality, longitudinal studies with control for confounders, such as age, smoking, and education. Epidemiologic studies of specific cancer sites were limited. Recent studies were not consistent with previous findings of possible associations for lung and stomach cancers reported in the 2006 Pb AQCD. Many of the epidemiologic studies examining specific cancer sites were case-control studies and not all included potentially important confounders, such as smoking.	Menke et al. (2006) Schober et al. (2006) Weisskopf et al. (2009), Khalil (2009b) Overall Cancer Mortality: See Section 5.10.1.1 Specific Cancer: See Sections: 5.10.1.3 (Lung), 5.10.1.4 (Brain), 5.10.1.5 (Breast); and Section 5.10.1.6 (Other cancers).	
Evidence clearly supports mode of action			
Mutagenic, carcinogenic and genotoxic assays provide consistent support to the MOA	Consistent evidence of toxicological findings of mutagenicity, carcinogenicity, and genotoxicity has been reported by multiple laboratories in animals and in vitro models using multiple assays (MN, SCE, COMET).	Epidemiology evidence of DNA and cellular damage: See Section 5.10.3.2 Toxicology evidence of DNA and cellular damage: See Section 5.10.3.2	
Clastogenic assays provide inconsistent support to the MOA	Toxicological studies of the clastogenic effects of Pb often employ Pb chromate. The effect of the chromate ion in contributing to the clastogenic effects cannot be ruled out.	See Section 5.10.3.2 (Toxicological Evidence for DNA and Cellular Damage)	
Epigenetic evidence provides support to the MOA	Bone Pb levels were inversely associated with LINE-1 methylation in adult men. Maternal pregnancy bone Pb levels were inversely associated with Alu and LINE-1 methylation in child cord blood. Occupational battery workers had ALAD hypermethylation compared with controls; cell culture study of high dose Pb exposure caused ALAD hypermethylation.	See Section 5.10.3.3	

[a]Described in detail in Table II of the Preamble.

[b]Describes the key evidence and references contributing the most heavily to causal determination. References to earlier sections indicate where full body of evidence is described.

6 POTENTIALLY AT-RISK POPULATIONS

The NAAQS are intended to protect public health with an adequate margin of safety. In so doing, protection is provided for both the population as a whole and those groups potentially at increased risk for health effects from exposure to the air pollutant for which each NAAQS is set (Preface to this ISA). To facilitate the identification of populations at increased risk for Pb-related health effects, studies have evaluated various factors that may contribute to susceptibility and/or vulnerability to Pb. The definitions of susceptibility and vulnerability vary across studies, but in most instances "susceptibility" refers to biological or intrinsic factors (e.g., age, sex) while "vulnerability" refers to nonbiological or extrinsic factors (e.g., socioeconomic status [SES]) (U.S. EPA, 2010, 2009a). Additionally, in some cases, the terms "at-risk" and "sensitive" populations have been used to encompass these concepts more generally. In this ISA, "at-risk" groups are defined as those with characteristics that increase the risk of Pb-related health effects in a population. These characteristics include various factors, such as genetic background, race and ethnicity, sex, age, diet, pre-existing disease, SES, and characteristics that may modify exposure or the response to Pb.

Individuals, and ultimately populations, could experience increased risk for air pollutant induced health effects via multiple avenues. A group with intrinsically increased risk would have one or more factors that increase risk for an effect through a biological mechanism. In general, people in this category would have a steeper concentration-risk relationship, compared to those not in the category. Potential factors that are often considered intrinsic include genetic background and sex. A group of people could also have extrinsically increased risk, which would be through an external, non-biological factor. Examples of extrinsic factors include SES and diet. Some groups are at risk of increased internal dose at a given exposure concentration. In addition, some groups could have greater exposure (concentration x time), regardless of the delivered dose. Finally, there are those who might be placed at increased risk for experiencing a greater exposure by being exposed at a higher concentration. For example, groups of people living near Pb smelters.

Some factors described above are multifaceted and may influence the risk of an air pollutant related health effect through a combination of avenues. For example, SES may affect access to medical care, which itself may contribute to the presence of preexisting diseases and conditions considered as intrinsic factors. Additionally, children's outdoor activities can lead to more hand-to-mouth contact with contaminated soil than adults, which leads to increased intake dose and exposure. At the same time, children have

biological (i.e., intrinsic) differences from adults that may influence their uptake, metabolism, storage, and excretion.

The emphasis of this chapter is to identify and understand the factors that potentially increase the risk of Pb-related health effects, regardless of whether the increased risk is due to intrinsic factors, extrinsic factors, increased dose/exposure, or a combination due to the often interconnectedness of factors. The following sections examine factors that potentially lead to increased risk of Pb-related health effects and characterize the overall weight of evidence for each factor.

Approach to Classifying Potential At-Risk Factors

To identify factors that potentially lead to some populations being at greater risk of Pb-related health effects, the evidence across relevant scientific disciplines (i.e., exposure sciences, dosimetry, toxicology, and epidemiology) was evaluated. In this systematic approach, the collective evidence is used to examine coherence of effects across disciplines and determine biological plausibility. The collective results across the scientific disciplines comprise the overall weight of evidence that is used to determine whether a specific factor results in a population being at increased risk of an air pollutant related health effect. The first section of this chapter (Section 6.1) summarizes physiological factors that influence Pb levels in the body. The second section of this chapter (Section 6.2) summarizes information on factors potentially related to differential Pb exposure. The studies presented in this section supplement the material provided in Chapter 3 and Chapter 4 by examining how factors such as age, sex, race and ethnicity, SES, proximity to Pb sources, and residential factors may affect Pb exposure or blood Pb levels. The third section of this chapter (Section 6.3) discusses the epidemiologic and toxicological studies evaluated in Chapter 5 that provide information on factors potentially related to increased risk of Pb-induced health effects. To examine whether Pb differentially affects certain populations, epidemiologic studies conduct stratified analyses to identify the presence or absence of effect measure modification. A thorough evaluation of potential effect measure modifiers may help identify populations that are at increased risk for Pb-related health effects. Highlighted studies include only those where the population was stratified into subgroups (e.g., males versus females or smokers versus nonsmokers) for comparative analysis. In the case of many biomarker studies and the epidemiologic studies considered, this approach allowed for a comparison between populations exposed to similar Pb concentrations and within the same study design. Toxicological studies also provide evidence of Pb effects and biological plausibility for factors that may lead to increased risk for Pb-related health effects. Included toxicological studies may have categorized the study populations by different factors, such as age, sex, diet/nutrition status, and genetics, or are those that examined animal

models of disease. These epidemiologic and toxicological studies provide the scientific basis for an overall weight of the evidence evaluation for the identification of specific populations potentially at risk of Pb-related health effects. Details on the magnitude of effects for studies in this third section (Section 6.3) are included in summaries of the studies presented in Chapter 5.

Numerous studies that focused on only one potentially at-risk population were described in previous chapters (Chapter 5) but are not discussed in detail in this chapter because they lacked stratified analysis with adequate comparison groups. For example, pregnancy is a lifestage with potentially increased risk for mothers and fetuses, but because there are no comparison groups for stratified analyses, these studies were presented in Chapter 5 but are not included here. Additionally, it is understood that some of the stratified variables/factors discussed in this third section (Section 6.3) may not be effect measure modifiers but instead may be mediators of Pb-related health effects. Mediators are factors that fall on the causal pathway between Pb exposure and health outcomes, whereas effect measure modifiers are factors that result in changes in the measured associations between Pb exposure and health effects. Because mediators are caused by Pb exposure and are also intermediates in the disease pathway that is studied, mediators are not correctly termed "at-risk" factors. Some of the factors discussed in this third section could be mediators and/or modifiers. These are noted in Table 6-5.

Building on the causal framework discussed in detail in the Preamble and used throughout the ISA, conclusions are made regarding the strength of evidence for each factor that may contribute to increased risk of a Pb-related health effect based on the evaluation and synthesis of evidence across scientific disciplines. The conclusions drawn considered the "Aspects to Aid in Judging Causality" discussed in Table I of the Preamble. The categories considered for evaluating the potential increased risk of an air pollutant-related health effect are "adequate evidence," "suggestive evidence," "inadequate evidence," and "evidence of no effect." They are described in more detail in Table 6-1.

Table 6-1 Classification of evidence for potential at-risk factors.

	Health Effects
Adequate evidence	There is substantial, consistent evidence within a discipline to conclude that a factor results in a population or lifestage being at increased risk of air pollutant-related health effect(s) relative to some reference population or lifestage. Where applicable this includes coherence across disciplines. Evidence includes multiple high-quality studies.
Suggestive evidence	The collective evidence suggests that a factor results in a population or lifestage being at increased risk of an air pollutant-related health effect relative to some reference population or lifestage, but the evidence is limited due to some inconsistency within a discipline or, where applicable, a lack of coherence across disciplines.
Inadequate evidence	The collective evidence is inadequate to determine if a factor results in a population or lifestage being at increased risk of an air pollutant-related health effect relative to some reference population or lifestage. The available studies are of insufficient quantity, quality, consistency, and/or statistical power to permit a conclusion to be drawn.
Evidence of no effect	There is substantial, consistent evidence within a discipline to conclude that a factor does not result in a population or lifestage being at increased risk of air pollutant-related health effect(s) relative to some reference population or lifestage. Where applicable this includes coherence across disciplines. Evidence includes multiple high-quality studies.

6.1 Physiological Factors that Influence the Internal Distribution of Pb

Blood and bone Pb measures are influenced to varying degrees by biokinetic processes (e.g., absorption, distribution, metabolism, excretion), which are discussed in detail in Chapter 4. These processes can be affected by multiple factors, such as age, genetics, diet, and co-exposure with other metals and non-metals.

Age influences the biokinetic response to Pb within the body. Infants may be considered an at-risk population because Pb easily crosses the placental barrier and accumulates in fetal tissue during gestation (Pillai et al., 2009; Wang et al., 2009e; Uzbekov et al., 2007). This transfer of Pb from mother to fetus is partly due to the remobilization of the mother's bone stores (O'Flaherty, 1998; Franklin et al., 1997). This also results in increased maternal blood Pb levels (Lamadrid-Figueroa et al., 2006; Gulson et al., 2004a; Hertz-Picciotto et al., 2000; Gulson et al., 1997; Lagerkvist et al., 1996; Schuhmacher et al., 1996; Rothenberg et al., 1994a). Bone growth rate is high during childhood. The majority of a child's Pb body burden is not permanently incorporated in the bone, but some Pb does remain in the bone until older age (McNeill et al., 2000; O'Flaherty, 1995; Leggett, 1993). Older adults are more likely to have age-related degeneration of bones and organ systems and a possible redistribution of Pb stored in the bones into the blood stream (Popovic et al., 2005; Garrido Latorre et al., 2003; Gulson et al., 2002).

Various genes can also affect Pb biomarker concentrations. Genetic variants of the vitamin D receptor (VDR) in humans have been associated with varied bone and plasma Pb levels (Rezende et al., 2008; Theppeang et al., 2004; Schwartz et al., 2000a). Multiple studies have also examined the association between the aminolevulinate dehydratase (ALAD) polymorphism and blood Pb levels and found that the ALAD-2 polymorphism may be biologically related to varying Pb levels, although some studies report no difference for ALAD alleles (see also Section 5.2.3) (Miyaki et al., 2009; Shaik and Jamil, 2009; Sobin et al., 2009; Chen et al., 2008c; Rabstein et al., 2008; Scinicariello et al., 2007; Zhao et al., 2007; Montenegro et al., 2006; Wananukul et al., 2006).

It is well established that diets sufficient in minerals such as calcium, iron, and zinc offer some protection from Pb exposure by preventing or competing with Pb for absorption in the GI tract. A study in China reported that children who regularly consumed breakfast had lower blood Pb levels than those children that did not eat breakfast (Liu et al., 2011a). Diets designed to limit or reduce caloric intake and induce weight loss have been associated with increased blood Pb levels in adult animals (Han et al., 1999). A toxicological study reported negative effects of Pb on osmotic fragility, TBARS production, catalase activity, and other oxidative parameters, but most of these effects were reduced to the levels observed in the control group when the rats were given supplementation of zinc and vitamins (Massó-González and Antonio-García, 2009). Toxicological studies by Jamieson et al. (2008; 2006) also reported that a zinc-deficient diet increases bone and renal Pb content and impairs skeletal growth and mineralization. A zinc-supplemented diet attenuated bone and renal Pb content. Toxicological studies have shown that dietary deficiency of calcium induces increased Pb absorption and retention (Fullmer, 1992; Mykkanen and Wasserman, 1981; Six and Goyer, 1970). Increased calcium intake reduces accumulation of Pb in bone and mobilization of Pb during pregnancy and lactation (Bogden et al., 1995). Additionally, studies have reported that iron deficiencies may result in higher Pb absorption or altered biokinetics (Schell et al., 2004; Marcus and Schwartz, 1987; Mahaffey and Annest, 1986).

In summary, age, genetics, and diet affect the biokinetics of Pb, which in turn affects the internal distribution of Pb. These factors were discussed in greater detail in Chapter 4 where more information on overall biokinetic and physiological factors affecting Pb distribution is provided.

6.2 Population Characteristics Potentially Related to Differential Pb Exposure

Elevated or differential Pb exposure and related biomarker levels (such as blood Pb), have been shown to be statistically related to several population characteristics, including age, sex, race and ethnicity, SES, proximity to Pb sources, and residential factors (U.S. EPA, 2006b). In most cases, exposure, absorption, and biokinetics of Pb are all influenced to varying degrees by such characteristics. Additionally, the relative importance of such population characteristics in affecting exposure, absorption, and biokinetics varies among individuals in a population and is difficult to quantify. This section presents recent studies demonstrating a relationship between each population characteristic and exposure status. The studies presented in this section build upon the current body of literature suggesting that population characteristics differentially influence Pb exposure; the new literature does not alter previous understanding of the differential influence of population characteristics on Pb exposure. Differential response to given Pb exposures is discussed in Section 6.3.

6.2.1 Age

6.2.1.1 Early Childhood

Typically, children have increased exposure to Pb compared with adults because children's behaviors and activities include increased hand-to-mouth contact, crawling, and poor hand-washing that typically result in increased ingestion compared with adults (U.S. EPA, 2006b). Children can also have increased Pb exposure because outdoor activities can lead to hand-to-mouth contact with contaminated soil. For example, Zahran et al. (2010) observed that a 1% reduction in soil Pb concentration led to a 1.55 µg/dL reduction in median blood Pb levels ($p < 0.05$) among New Orleans children.

Age of the children may influence blood Pb levels through a combination of behavioral and biokinetic factors. The 2009-2010 NHANES data are presented in Table 6-2 by age and sex. Among children, highest blood Pb levels occurred in the 1-5 year age group (children under age 1 were not included), and within this subgroup (not shown on the table), 1-year old children had the highest blood Pb levels (99th percentile: 9.47 µg/dL) (NCHS, 2010). It is possible that high blood Pb levels among these young children may also be related to in utero exposures resulting from maternal Pb remobilization from bone stores from historic exposures (Miranda et al., 2010) or from contemporaneous Pb exposures if the mothers had appreciable current Pb exposure. Jones et al. (2009a)

analyzed the NHANES datasets for the years 1999-2004 to study trends in blood Pb among two different age groups of children over time (see Table 6-3). They observed greater percentages of children aged 1-2 years having blood Pb levels of 2.5 to <5 µg/dL, 5 to <7.5 µg/dL, and ≥ 10 µg/dL, compared with 3-5 year-old children, but no age difference was noted for the 7.5 to <10 µg/dL bracket. At the same time, 1-2 year-old children had lower percentages of blood Pb levels <1 µg/dL and 1 to <2.5 µg/dL compared with children ages 3-5 years old. This implies that there is a shift in the distribution of blood Pb levels as children age, even during early childhood. These distribution differences may be attributable to differences in exposure (including behavioral influences, such as hand-to-mouth contact and crawling in proximity to contaminated surfaces), residual contributions from the mother's Pb burden, age-dependent variability in biokinetics or diet (e.g., milk versus solid diets). Yapici et al. (2006) studied the relationship between blood Pb level and age among a cohort of children between 6 and 73 months of age with elevated blood Pb levels (87.6% of study group with blood Pb greater than 20 µg/dL) living near a Turkish coal mine. They observed a low but statistically significant negative correlation between blood Pb and age ($r = -0.38$, $p < 0.001$).

Fetal and child Pb biomarkers have been demonstrated to relate to maternal Pb biomarkers as reported in the 2006 Pb AQCD (U.S. EPA, 2006b). Kordas et al. (2010) observed that maternal hair Pb concentration was a statistically significant predictor of child hair Pb concentration ($\beta = 0.37 \pm 0.07$, $p < 0.01$). Elevated blood Pb levels among mothers present a potential exposure route to their children in utero or through breast milk; see Miranda et al. (2010).

6.2.1.2 Older Adulthood

Blood Pb levels tend to be higher in older adults compared with the general adult population, as described in the 2006 Pb AQCD (U.S. EPA, 2006b). Table 6-2 presents 2009-2010 NHANES data broken down by age group and shows that blood Pb levels were highest in the among participants 65 years old or older, in comparison with adults aged 20-64 years and with adolescents. In a study of blood Pb and saliva Pb in a mostly female population in Detroit, Nriagu et al. (2006) found that age was a statistically significant positive predictor of blood Pb ($p < 0.001$). Average blood Pb levels among 14- to 24-year-old subjects was 2.60 ± 0.16 μg/dL compared with 4.29 ± 0.56 μg/dL among subjects aged 55 years or older. Higher average and median levels among older adults could potentially be due to a shared experience of higher historical Pb exposures stored in bone in conjunction with remobilization of stored Pb during bone loss (Section 4.2).

Theppeang et al. (2008b) studied Pb concentrations in the blood, tibia, and patella of subjects age 50-70 as part of the Baltimore Memory Study. They found a statistically significant relationship between age and tibia Pb ($\beta = 0.37$, $p < 0.01$ in a model including age, race/ethnicity, Yale energy index, and 2 diet variables; $\beta = 0.57$, $p < 0.01$ in a model including age, sex, and an interaction term for sex and age, which was also statistically significant at $p = 0.03$). Theppeang et al. (2008b) also noted that patella Pb concentrations were also positively associated with age, although the authors did not present the data or significance levels. A statistically significant relationship was not observed between the log-transform of blood Pb and age ($\beta = 0.007$, $p = 0.11$), although the age range of subjects may not have been sufficient to discern a difference in blood Pb level.

Miranda et al. (2010) observed that older pregnant women (ages 30-34 years and 35-39 years) had statistically significant higher odds of having greater blood Pb levels than younger pregnant women (25- to 29-year-olds) in the reference age category. These results could be related to a historical component to Pb exposure among mothers. These findings were also consistent with observations that Pb storage in bones increased with age before subsequent release with bone loss occurring during pregnancy, as described in Section 4.2 and summarized in Section 6.1.

6.2.2 Sex

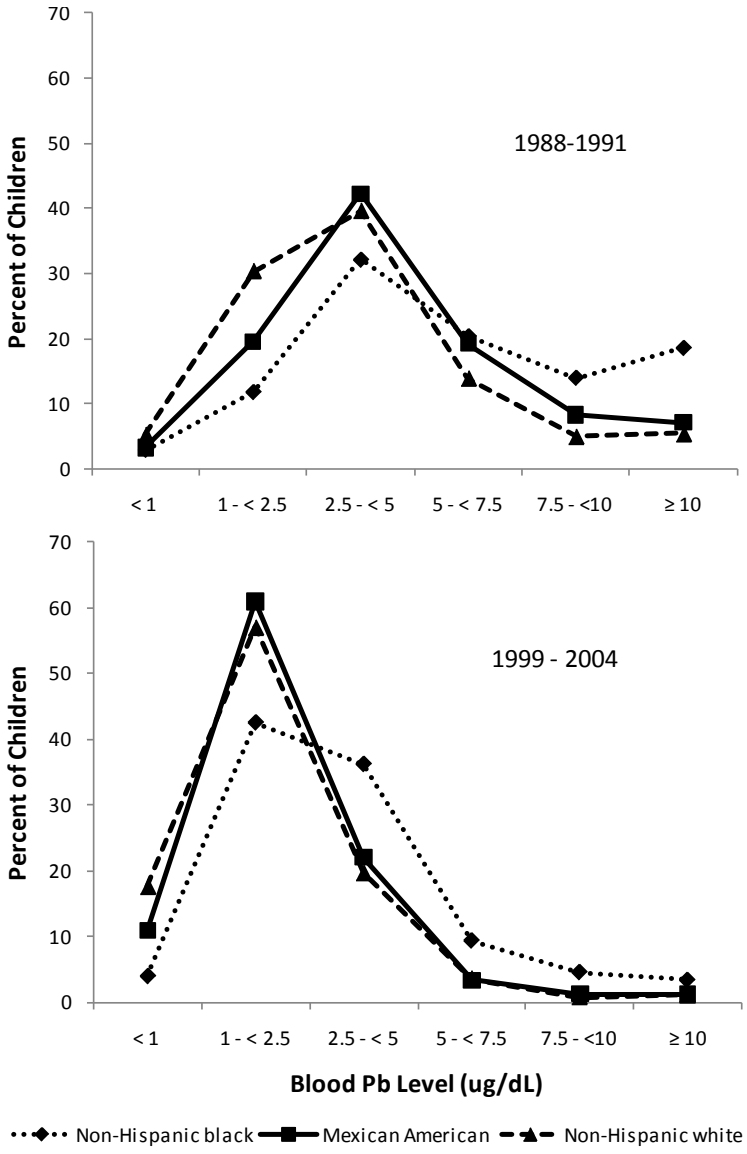
The AQCD (U.S. EPA, 2006b) described several studies showing higher Pb biomarker levels in male adults compared with female adults. The 2009-2010 NHANES showed that overall, males have significantly higher blood Pb levels (average: 1.75 µg/dL) than females (average: 1.25 µg/dL) ($p < 0.0005$). Among adults aged 20-59 years, average blood Pb levels were 64% higher for males compared with females ($p < 0.0005$). Among adults 60 years or older, average blood Pb levels were 30% higher for males compared with females ($p < 0.0005$) (NCHS, 2010). In their study of Pb burden among Baltimore adults aged 50-70 years, Theppeang et al. (2008b) observed that average blood Pb levels were statistically significantly higher ($p < 0.01$) among men (4.4 µg/dL) than women (3.1 µg/dL). For average tibia Pb levels, Theppeang et al. (2008b) noted no difference ($p = 0.12$) between men (18.0 µg/g) and women (19.4 µg/g).

Among U.S. children, the 2009-2010 NHANES data showed that blood Pb levels were higher among girls than boys for the 1- to 5-years age group (Table 6-2). Blood Pb levels became slightly higher among boys for the 6- to 11-years age group, and levels were substantially higher among adolescent males than females 12- to 19-years old. The 2009-2010 NHANES data suggest that sex-based differences in blood Pb levels are not substantial until adolescence.

6.2.3 Race and Ethnicity

Higher blood Pb and bone Pb levels among African Americans have been well documented (U.S. EPA, 2006b). Model results presented in the 2006 Pb AQCD have demonstrated not just elevations in blood Pb among African Americans but also significant associations between blood Pb and race (U.S. EPA, 2006b). Recent studies are consistent with those previous findings. For instance, Levin et al. (2008) and Jones et al. (2009a) both analyzed NHANES survey data to examine trends in childhood blood Pb levels. Data from the Jones et al. (2009a) study, using NHANES data (NCHS, 2009, 2008) from 1988-1991 and 1999-2004 are shown in Figure 6-1. The authors found that differences among children from different racial/ethnic groups with regard to the percentage with blood Pb levels ≥ 2.5 µg/dL over the period 1999-2004 have decreased since the period of 1988-1991. The non-Hispanic black group still had higher percentages with blood Pb levels ≥ 2.5 µg/dL compared with non-Hispanic whites and Mexican Americans, with large observable differences for blood Pb levels between 2.5 and <10 µg/dL. It is notable that the distributions of blood Pb levels among Mexican American and non-Hispanic white children were nearly identical in the 1999-2004 dataset. Theppeang et al. (2008b) also explored the effect of race and ethnicity on several

Pb biomarkers in a study of older adults living in Baltimore, MD. They observed a statistically significant difference between African American (AA) and Caucasian (C) subjects with respect to tibia Pb (AA: 21.8 µg/g, C: 16.7 µg/g, $p < 0.01$) but not patella Pb (AA: 7.1 µg/g, C: 7.1 µg/g, $p = 0.46$) or blood Pb levels (AA: 3.6 µg/dL, C: 3.6 µg/dL, $p = 0.69$). Greater tibia (but lower patella) Pb levels may indicate greater historical exposure among African Americans compared to Caucasians in the Baltimore population studied by Theppeang et al. (2008b).



Note: from the NHANES survey, 1988-1991 (top) and 1999-2004 (bottom).

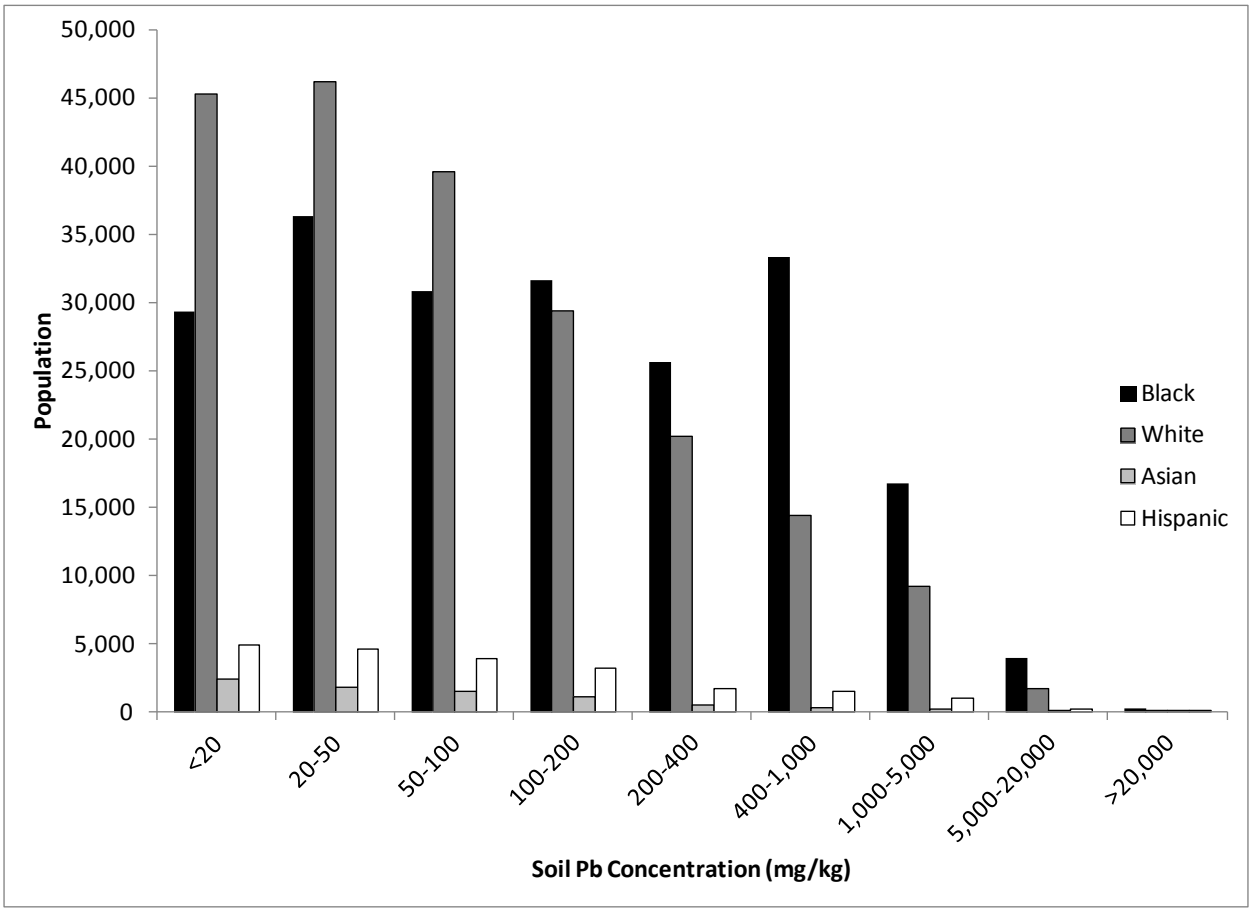
Figure 6-1 Percent distribution of blood Pb levels by race/ethnicity among U.S. children (1-5 years).

Differences in potential exposure among ethnic and racial groups have also been noted in a study in the greater metropolitan New Orleans area. Campanella and Mielke (2008) found that, in Census blocks where surface soil Pb levels were less than 20 mg/kg, the population was 36% black, 55% white, 3.0% Asian, and 6.0% Hispanic, based on the 2000 Census, with the percentage based on the total number living in Census blocks with the same soil Pb levels. In contrast, they found that for Census blocks in which soil Pb levels were between 1,000 and 5,000 mg/kg, the population was 62% black, 34% white, 1% Asian, and 4% Hispanic (Figure 6-2) , although the total population size generally declined with soil Pb concentration, with the Census blocks with soil Pb of 1,000-5,000 mg/kg having less than half the population of that in the <20 mg/kg blocks. As described in Section 6.2.4, the differences observed by Campanella and Mielke (2008) may also be attributable to SES factors, or SES may be a confounding factor in the relationship between Pb soil levels and race/ethnicity of nearby residents.



Note: By Census 2000 race/ethnicity demographic groups.

Figure 6-2 Soil Pb concentration exposure among the population of three parishes within greater metropolitan New Orleans.

6.2.4 Socioeconomic Status (SES)

Socioeconomic factors have sometimes been associated with Pb exposure biomarkers. Previous results reported in the 2006 Pb AQCD found negative associations between income or other SES metrics and blood Pb, although these relationships were not always statistically significant (U.S. EPA, 2006b). Nriagu et al. (2006) performed a multiple regression analysis of blood Pb and saliva Pb levels on various socioeconomic, demographic, and exposure variables among an adult population in Detroit, Michigan. Blood and saliva Pb were both used as indicators of Pb in unbound plasma that is available to organs. Nriagu et al. (2006) found that education ($p < 0.001$), income ($p < 0.001$), and employment status ($p = 0.04$) were all statistically significant predictors of blood Pb levels, with blood Pb decreasing with some scatter as education and income level increased. Statistically significant relationships were also reported by Nriagu et al. (2006) for saliva Pb level with respect to education ($p < 0.001$), income ($p < 0.001$), and employment ($p = 0.06$). However, the highest educational attainment and income categories had higher saliva Pb levels compared with other groups; Nriagu et al. (2006) attributed these inconsistencies to small sample sizes among the high educational attainment and income categories.

On a national level, the difference in blood Pb levels that have historically been seen to exist between different income levels has been decreasing. For example, Levin et al. (2008) cited 1991-1994 NHANES data [analyzed in Pirkle et al. (1994)] that the percentage of children aged 1-5 years with blood Pb levels ≥ 10 µg/dL was 4.5% for the lowest income group compared with 0.7% for the highest income group. Levin et al. (2008) also analyzed data from the 1999-2002 NHANES and found no statistically significant difference between the percent of children with blood Pb levels above 10 µg/dL for Medicaid-enrolled children (1.7%) compared with non-enrolled children (1.3%). However, Medicaid-enrolled children did have higher median blood Pb levels (2.6 µg/dL) compared to children not enrolled in Medicaid (1.7 µg/dL). Adding data for 2003-2004 to the analysis (i.e., for 1999-2004), widened the difference between Medicaid enrolled and non-enrolled children with regard to percentage having blood Pb levels ≥ 10 µg/dL (1.9% versus 1.1%), but the difference was still not statistically significant ($p > 0.05$) and median blood Pb levels for the two groups did not change (Levin et al., 2008). Likewise, Jones et al. (2009a) analyzed blood Pb levels with respect to poverty-income ratio (PIR), which is the ratio of family income to the poverty threshold appropriate for a given family size. They found statistically significant differences in median blood Pb for PIR ≤ 1.3 compared with PIR >1.3. The percentage of 1- to 5-year-old children having blood Pb ≥ 10 µg/dL was higher for PIR ≤ 1.3 (1.8 versus 0.8); however, this difference was not statistically significant. Additionally, in residential areas of metropolitan New Orleans with soil concentrations below 20,000 mg/kg, Campanella and Mielke (2008)

observed a linear increase in surface soil Pb concentration with decreasing median household income, suggesting a relationship of potential exposure with household income. The census block-averaged median household income in areas with soil Pb between 2.5 and 20 mg/kg was $40,000 per year, while the corresponding median income in areas with soil Pb between 5,000 and 20,000 mg/kg was $24,000 per year. The highest soil concentrations (20,000 mg/kg and above) was associated with a median income of $27,000.

6.2.5 Proximity to Pb Sources

Air and soil Pb concentrations are higher in some industrialized and urbanized areas, as described in Sections 3.2, 3.3, 3.5 and 4.1, as a result of historical and contemporary Pb sources. The highest air Pb concentrations measured using the Pb-TSP monitoring network have been measured at monitors located near sources emitting Pb. Elevated soil Pb concentrations have also been measured in urbanized areas compared with less urbanized or rural locations (Filippelli et al., 2005). Air Pb concentrations exhibit high spatial variability even at low concentrations (~0.01 μg/m^3) (Martuzevicius et al., 2004). Proximity to an industrial source likely contributes to higher Pb exposures, as described in the 2006 Pb AQCD (U.S. EPA, 2006b) for several studies of Superfund and other industrial sites. This is consistent with the observation of higher air concentrations at source oriented Pb monitoring sites compared with non-source oriented sites in the 2008-2010 data presented in Section 3.5.

Jones et al. (2010) found that neonates born near a Pb-contaminated hazardous waste site had significantly higher umbilical cord blood Pb levels (median: 2.2 μg/dL [95% CI: 1.5, 3.3 μg/dL]) compared with a reference group of neonates not living near a potentially contaminated site (median: 1.1 μg/dL [95% CI: 0.8, 1.3 μg/dL]), suggesting that Pb-contaminated hazardous waste sites contribute to neonatal Pb levels. The population studied in Jones et al. (2010) was 88% African American; 75% had a high school degree or equivalent, while 20% had a college degree and 5% attended but did not graduate from high school. However, Jones et al. (2010) did not analyze covariation between exposure and maternal characteristics, so it cannot be determined if differences in characteristics among the maternal groups (which did and did not report nearby hazardous waste sites) confounded these results.

Studies have suggested that concentration of Pb in soil, a potential exposure media, is related to land use type and historical sources, as described in Section 3.6.1. For instance, Wu et al., (2010) observed that bioavailable Pb concentrations in Los Angeles surface soil samples were significantly associated with traffic-related variables and parcel age

(i.e., length of time since the parcel was first developed), with parcel age being a highly significant predictor of bioavailable soil Pb in most models ($p < 0.0001$). Zahran et al. (2010) observed that surface soil Pb levels in 46 Census tracts of metropolitan New Orleans dropped following Hurricanes Katrina and Rita, from 330 mg/kg to 200 mg/kg (averages of median measurements across all Census tracts for 2000 and 2006) and attributed this observation to coverage by relatively cleaner river sediments. Blood Pb levels obtained from children (ages 0-6 years) also declined subsequent to the hurricanes; statistical modeling of the changes in soil and blood Pb estimated the decline to be 1.55 µg/dL for each 1% reduction in soil Pb ($p \leq 0.05$).

6.2.6 Residential Factors

Findings from a recent study of the association between blood Pb and housing factors by Dixon et al. (2009), which analyzed data from the NHANES national survey for 1999-2004, are consistent with those from previous studies presented in the 2006 Pb AQCD that observed positive associations between increased blood Pb and increased house dust Pb levels (U.S. EPA, 2006b; Lanphear et al., 1998; Laxen et al., 1987). Dixon et al. (2009) used NHANES data from 1999-2004 to perform a linear regression of blood Pb among children 12-60 months old on several factors including year of home construction, floor surface condition, floor dust Pb level, windowsill dust Pb level, and renovation in homes built before 1978. They found that blood Pb (log transformed) was significantly associated with homes being built after 1950 ($p = 0.014$), windowsill Pb level ($p = 0.002$), dust Pb level ($p < 0.001$), and occurrence of renovation in pre-1978 homes ($p = 0.045$). Detailed results of this regression are shown in Table 6-4. As part of the same study, Gaitens et al. (2009) performed a regression analysis of floor dust Pb (PbD) and windowsill dust Pb on several factors. Floor dust Pb (log transformed) was significantly associated with the following housing-related factors: floor surface condition ($p < 0.001$), windowsill dust Pb (log transformed) ($p < 0.001$), year of construction ($p < 0.001$), and renovation in a pre-1950 home ($p < 0.001$). Windowsill dust Pb (log transformed) was significantly associated with the following housing-related factors: year of construction ($p < 0.001$), window surface condition (0.001), and deteriorated indoor paint ($p = 0.028$).

Renovation activities on older homes have been shown to produce excess Pb dust concentrations. Gaitens et al. (2009) performed a regression analysis on dust Pb concentrations from 1994-2004 NHANES on demographic and housing variables and found that renovation of windows, cabinets, or walls in a pre-1950 home was significantly associated with floor dust Pb concentration ($p < 0.001$). Paint scraping within the last twelve months was nearly significantly associated with windowsill dust Pb concentration ($p = 0.053$). Dixon et al. (2009) performed a regression analysis on log-transformed blood Pb levels from NHANES (1999-2004) on several demographic and housing variables and found that renovation of windows, cabinets, or walls in pre-1978 homes was significantly associated with blood Pb concentration ($p = 0.045$). A case study by Mielke et al. (2001) reports on elevated indoor and outdoor dust Pb levels at two houses where exterior paint has been either power sanded (without confinement of released material) or hand scraped (with collection of released material) to prepare for repainting. The latter approach appeared to yield lower dust Pb levels, although given the extremely limited dataset, conclusions are uncertain. In an occupational study of men performing home renovations in the U.K., window renovation and wood-stripping workers specializing in renovation of old houses had significantly higher median blood Pb levels compared with all workers in similar occupations (wood strippers: 37 µg/dL; window renovators: 32 µg/dL; all workers: 13.7 µg/dL; $p < 0.001$) (Mason et al., 2005).

6.3 Factors Potentially Related to Increased Risk of Pb-Induced Health Effects

This section evaluates factors examined in recent studies as effect measure modifiers that potentially increase the risk of various Pb-related health effects. There was limited evidence from the 2006 Pb AQCD (U.S. EPA, 2006b) for many of potential at-risk factors described below. Where available, information on conclusions regarding at-risk populations from the 2006 Pb AQCD is included in the subsections.

6.3.1 Age

Below is information from epidemiologic and toxicological studies regarding studies of increased risk for Pb-related health effects among children and older adults. Other age groups, such as adolescents, have not been evaluated here, if they were not part of stratified studies of lifestage.

6.3.1.1 Childhood

According to the 2000 Census, 28.6% of individuals living in the U.S. were under the age of 20, with 6.8% aged 0-4 years, 7.3% aged 5-9 years, 7.3% aged 10-14 years, and 7.2% aged 15-19 years (SSDAN CensusScope, 2010a). It is recognized that Pb can cross the placenta and affect the developing nervous system of the fetus (Sections 4.2.2.4 and 5.3.2.1) and there is strong evidence of increased risk to the neurocognitive effects of Pb exposure during several lifestages throughout gestation, childhood, and into adolescence (for more detail, Section 5.3.2.1). However, most recent studies among children do not have adequate comparison groups between children of various age groups or between children and adults, and were therefore only presented in Chapter 5.

A study including multiple U.S. locations examined associations of blood Pb levels with various immune parameters among individuals living near Pb industrial sites and matched controls (Sarasua et al., 2000). For several of these endpoints, the association in the youngest group (ages 6-35 months) and the oldest group (ages 16-75 years) were in opposite directions. For example, among children ages 6-35 months, the associations between blood Pb levels and Immunoglobulin A (IgA), Immunoglobulin M (IgM), and B-cell abundance were positive, whereas the associations among 16-75 year olds were negative. The opposite associations were also present for T cell abundance. Ig antibodies, which are produced by activated B cells, are important mediators of the humoral immune response to antigens. T cells are important mediators of cell-mediated immune responses that involve activation of other immune cells and cytokines. These findings by Sarasua et al. (2000) indicate that very young children may be at increased risk for Pb-associated activation of humoral immune responses and perturbations in cell-to-cell interactions that underlie allergic, asthma, and inflammatory responses (for more information, see Sections 5.6.2.1 and 5.6.3).

A study among Lebanese children examined the association between blood Pb levels and transferrin saturation (TS) less than 12% and iron-deficiency anemia (IDA) (Muwakkit et al., 2008). A positive association was detected for blood Pb levels ≥ 10 µg/dL and both TS less than 12% and IDA among children aged 11-23 months old; however, null associations were observed among children 24-35 months old. Calculations were not performed for children aged 36-75 months because there were no children in the highest Pb group (≥ 10 µg/dL) with either TS <12% or IDA. The authors noted that it is difficult to know whether the Pb levels were “a cause or a result of” IDA levels since previous studies linked iron deficiency with Pb toxicity.

Overall evidence indicates early childhood as a lifestage of increased risk for Pb-related health effects. Both epidemiologic studies summarized above reported associations among the youngest age groups, although different age cut-points were used with one

study including only infants 35 months of age and younger. Toxicological studies provide support for increased health effects of Pb among younger age groups. Toxicological studies have reported that younger animals, whose nervous systems are developing (i.e., laying down and pruning neuronal circuits) and whose junctional barrier systems in the brain (i.e., the blood brain barrier) and GI system (i.e., gut closure) are immature, are more at risk from the effects Pb exposure (Fullmer et al., 1985). In sum, there are consistent findings, coherent across disciplines that adequate evidence exists to conclude that children are an at-risk population.

6.3.1.2 Older Adulthood

The number of Americans over the age of 65 will be increasing in upcoming years (estimated to increase from 12.4% of the U.S. population to 19.7% between 2000 to 2030, which is approximately 35 million and 71.5 million individuals, respectively) (SSDAN CensusScope, 2010a; U.S. Census Bureau, 2010). As of the 2000 Census, 7.2% of the U.S. population were ages 60-69, 5.8% were 70-79, and 3.3% were age 80 and older (SSDAN CensusScope, 2010a).

A study using the NHANES III cohort examined blood Pb levels and mortality among individuals less than 60 years old and individuals 60 years and older (Menke et al., 2006). Positive hazard ratios were observed in both age groups but the hazard ratios were greater in those less than 60 years old. The interactions terms were not statistically significant. A similar study using the NHANES III cohort examined the relationship between blood Pb levels and mortality from all-cause, cardiovascular disease, and cancer broken down into more specific age groups (Schober et al., 2006). Point estimates were elevated for the association comparing blood Pb levels ≥ 10 µg/dL to blood Pb levels <5 µg/dL and all-cause mortality for all age groups (40-74, 75-84, and 85+ year olds), although the association for 75-84 year olds did not reach statistical significance. The association was also present when comparing blood Pb levels of 5-9 µg/dL to blood Pb levels <5 µg/dL among 40-74 year olds and 75-84 year olds, but not among those 85 years and older. None of the associations between blood Pb and cardiovascular disease-related mortality reached statistical significance but the point estimates for cardiovascular disease-related mortality comparing blood Pb levels ≥ 10 µg/dL to blood Pb levels <5 µg/dL were elevated among all age groups. Finally, the association between blood Pb levels ≥ 10 µg/dL and cancer mortality was positive among those 40-74 years old and 85 years and older but the association was null for those 75-84 years old. Among 75-84 year olds the association was positive comparing blood Pb levels of 5-9 µg/dL to <5 µg/dL. The other age groups had similar point estimates but the associations were not statistically significant.

A study using the Normative Aging Study cohort reported an interaction between Pb and age (Wright et al., 2003). The inverse association between age and cognitive function was greater among those with high blood or patella Pb levels. Effect estimates were in the same direction for tibia Pb but the interaction was not statistically significant.

Finally, a study of current and former Pb workers reported that an interaction term of Pb and age (dichotomous cutpoint at 67th percentile but exact age not given) examined in models of Pb (measured from blood and patella) and blood pressure was not statistically significant (Weaver et al., 2008). Thus, no modification by age was observed in this study of Pb and blood pressure.

Toxicological studies have demonstrated Pb-related health effects among older populations. The kidneys of older animals appear to be more at-risk for Pb-related health effects from the same dose of Pb (i.e., continuous 50 mg/L Pb acetate drinking water) than younger animals (Berrahal et al., 2011). Increased risk related to older age is also observed for effects on the brain. Recent studies have demonstrated the importance of Pb exposure during early development in promoting the emergence of Alzheimer's like pathologies in aged animals. Development of pathologies of old age in brains of aged animals that were exposed to Pb earlier in life has been documented in psychopathological effects in adults (mice and monkeys), (for more details see Section 5.3.10.1). These pathologies include the development of neurofibrillary tangles and increased amyloid precursor protein and its product beta-amyloid (Basha et al., 2005; Zawia and Basha, 2005). Some of these findings were seen in animals that no longer had elevated blood Pb levels.

In summary, results for age-related modification of the association between Pb and mortality had mixed results. Limited evidence was available for the associations between Pb and cognitive function or other health effects among older adults. Toxicological studies have shown increases in Pb-related health effects by age that may be relevant in humans. Future studies will be instrumental in understanding older age as a factor that potentially affects the risk of Pb-related outcomes.

6.3.2 Sex

The distribution of males and females in the U.S. is similar. In 2000, 49.1% of the U.S. population was male and 50.9% was female. The distribution of sex varied by age with a greater prevalence of females ≥ 65 years old compared to males (SSDAN CensusScope, 2010a). The 2006 Pb AQCD reported that boys are often found to have higher blood Pb levels than girls, but findings were "less clear" regarding differences in Pb-related health effects between males and females (U.S. EPA, 2006b).

Multiple epidemiologic studies have examined Pb-related effects on cognition stratified by sex. In previous studies using the Cincinnati Lead Study cohort, Dietrich et al. (1987b) and Ris et al. (2004) observed interactions between blood Pb (prenatal and postnatal) and sex; associations of prenatal and postnatal blood Pb and subsequent decrements in memory, attention, and visuoconstruction were observed only among male adolescents. More recently, Wright et al. (2008) examined early life blood Pb levels and criminal arrests in adulthood. The risks attributable to Pb exposure were greater among males than females. Additionally, the association between childhood blood Pb levels and adult gray matter volume loss was greater among males than females (Cecil et al., 2008). In an expanded analysis of the developmental trajectory of childhood blood Pb levels on adult gray matter, researchers found that associations between yearly mean blood Pb levels and volume of gray matter loss were more pronounced in the frontal lobes of males than females (Brubaker et al., 2010). Multiple studies were also conducted in Port Pirie, Australia that examined blood Pb levels at various ages throughout childhood and adolescence (Tong et al., 2000; Baghurst et al., 1992; McMichael et al., 1992). These studies observed Pb effects on cognition deficits were stronger in girls throughout childhood and into early adolescence. A study in Poland also investigated the association between umbilical cord blood Pb levels and cognitive deficits and reported a positive association for boys at 36 months but not for girls (Jedrychowski et al., 2009a). No association was detected for boys or girls at 24 months.

An epidemiologic study examined the association between concurrent blood Pb levels and kidney function among 12-20 year olds using the NHANES III study cohort (Fadrowski et al., 2010). The results were stratified by sex and no effect measure modification was apparent.

Similarly, a study of current and former Pb workers examined an interaction term between sex and Pb for the study of blood Pb and blood pressure (Weaver et al., 2008). No modification by sex was present.

Epidemiologic studies have also been performed to assess differences between males and females for Pb-related effects on various biomarkers. A study comprised mostly of females reported positive associations between blood Pb and total immunoglobulin E (IgE) for women not taking hormone replacement therapy or oral contraceptives (Pizent et al., 2008). No association was reported in males, but other associations, such as bronchial reactivity and reactive skin prick tests were observed in the opposite of the expected direction, which questions the validity of the results among the male study participants. Analysis of an NHANES dataset detected no association between blood Pb levels and inflammatory markers (Songdej et al., 2010). Although there was no clear pattern, a few of the associations were positive between blood Pb and C-reactive protein

for males but not females. A study of children living at varying distances from a Pb smelter in Mexico reported that blood Pb was associated with increased release of superoxide anion from macrophages, which was greater among males than females (Pineda-Zavaleta et al., 2004).

Epidemiologic investigations of cancer have also examined the associations by sex. A study of the association between occupational exposure to Pb and brain tumors reported no sex-specific associations for gliomas, but a positive association for cumulative Pb exposure and meningiomas for males but not females (Rajaraman et al., 2006). An ecologic analysis of Pb pollution levels and cancer incidence among children reported weak correlations overall and the weak correlations were more apparent among males, whereas no correlation was observed among females (Absalon and Slesak, 2010).

A study of all-cause and cardiovascular mortality using the NHANES III cohort reported no modification of the association between blood Pb and all-cause or cardiovascular mortality by sex (Menke et al., 2006). This did not differ among women when classified as pre- or post-menopausal.

Toxicological studies have also reported sex differences in Pb-related effects to various organ systems. Donald et al. (1986) reported a different time course of enhanced social investigatory behavior between male and female mice exposed to Pb. In a subsequent publication, Donald et al. (1987) showed that non-social behavior in mice decreased in females and increased in males exposed to Pb. Males also had a shorter latency to aggression with Pb treatment versus controls. Pb affected mood disorders differently for males and females. Behavioral testing in rats showed males experienced emotional changes and females depression-like changes with Pb exposure (de Souza Lisboa et al., 2005). In another study, gestational exposure to Pb impaired memory retrieval in male rats at all 3 doses of Pb exposure; memory retrieval was only impaired in low-dose female rats (Yang et al., 2003). Sex-specific differences in mice were also observed for gross motor skills; at the lowest Pb dose, balance and coordination were most affected among males (Leasure et al., 2008).

Pb and stress are co-occurring factors that act in a sex-divergent manner to affect behavior, neurochemistry, and corticosterone levels. Pb and stress act synergistically to affect fixed interval operant behavior and corticosterone in female rat offspring. Virgolini et al. (2008a) found that effects on the offspring's central nervous system by developmental Pb exposure (maternal exposure and transferred to the offspring through lactation) were enhanced by combined maternal and offspring stress and females were most at risk. Behavioral related outcomes after gestational and lactational Pb exposure (with and without stress) exhibited sex-differences in exposed offspring (Virgolini et al., 2008b). Pb-induced changes in brain neurochemistry, with or without concomitant stress

exposure, are complex with differences varying by brain region, neurotransmitter type, and sex of the animal.

The brain is known to have a sexually dimorphic area in the hypothalamus, termed the sexually dimorphic nucleus (SDN). Lesions in this area affect sex-specific phenotypes including behavior. Across species the SDN has a greater cell number and larger size in males versus females. This sexually dichotomous area is especially vulnerable to perturbation during fetal life and the early postnatal period. This may be one area of the brain that could explain some of the sexually dichotomous effects that are seen with Pb exposure. One study supporting this line of thought showed that high-dose in utero Pb exposure (pup blood Pb level 64 µg/dL at birth) induced reductions in SDN volume in 35% of Pb-exposed male rats (McGivern et al., 1991). Interestingly, another chemical that is known to cause a hypothalamic lesion in this area, monosodium glutamate, is associated with adult onset obesity (Olney, 1969); adult onset obesity is seen in the Pb literature.

Obesity in adult offspring exposed to low-dose Pb in utero was reported for male but not female mice (Leasure et al., 2008). Obesity was also found in male rat offspring exposed in utero to high doses of Pb that persisted to 5 weeks of age/end of the study, but among female rats, body weight remained elevated over controls only to 3 weeks of age (Yang et al., 2003). Additionally, low-dose Pb exposure induced retinal decrements in exposed male mice offspring (Leasure et al., 2008).

A toxicological study of Pb and antioxidant enzymes in heart and kidney tissue reported that male and female rats had differing enzymatic responses, although the amount of Pb in the heart tissue or the disposition of Pb also varied between males and females (Sobekova et al., 2009; Alghazal et al., 2008a). The authors reported these results could be due to greater deposition of Pb in female rats or greater clearance of Pb by males (Sobekova et al., 2009).

Multiple associations between Pb and various health endpoints have been examined for effect measure modification by sex and results have been inconsistent. Although not observed in all endpoints, some studies reported differences between the associations for males and females, especially in neurological studies. However, studies on cognition from the Cincinnati Lead Study cohort and a study in Poland reported males to be an at-risk population, whereas studies from Australia pointed to females as an at-risk population. A difference in sex is supported by toxicological studies. Further research is needed to confirm the presence or absence of sex-specific associations between Pb and various health outcomes and to determine in which sex the associations are greater.

6.3.3 Genetics

The 2006 Pb AQCD stated that, "genetic polymorphisms in certain genes have been implicated as influencing the absorption, retention, and toxicokinetics of Pb in humans" (U.S. EPA, 2006b). The majority of discussion there focused on the aminolevulinate dehydratase (ALAD) and vitamin D receptor (VDR) polymorphisms. These two genes, as well as additional genes examined in recent studies, are discussed below.

6.3.3.1 Aminolevulinate Dehydratase

The aminolevulinate dehydratase (ALAD) gene encodes for an enzyme that catalyzes the second step in the production of heme and is also the principal Pb-binding protein (U.S. EPA, 2006b). Studies have examined whether ALAD variants altered associations between Pb and various health effects.

Associations between Pb and brain tumors observed in an epidemiologic study varied by ALAD genotype status (Rajaraman et al., 2006). Positive associations between Pb exposure (determined via interview about occupational exposures) and meningioma were reported among ALAD2 individuals, but this association was not found among individuals who had the ALAD1 allele. No associations were observed between Pb and glioma regardless of ALAD genotype.

Studies investigating the association between Pb levels and cognitive function have also examined modification by ALAD polymorphisms. The evidence is provided by an NHANES analysis (Krieg et al., 2009) as well as multiple analyses from the NAS cohort examining different tests of cognitive function (Rajan et al., 2008; Weuve et al., 2006). In the study using a cohort from NHANES III, for several indices of cognitive function, associations with concurrent blood Pb levels were more pronounced in groups with CC and CG ALAD genotypes (i.e., ALAD2 carriers) (Krieg et al., 2009). In the NAS cohort of men, Weuve et al. (2006) found that concurrent blood Pb level but not bone Pb level was associated with a larger decrease in a test of general cognitive function among ALAD2 carriers. Another NAS study examined functioning of specific cognitive domains (e.g., vocabulary, memory, visuospatial skills) and found variable evidence for effect modification by ALAD genotype across tests (Rajan et al., 2008). For example, among ALAD2 carriers, concurrent blood Pb level was associated with a more pronounced decrease in vocabulary score but less pronounced decrease in a memory index and no difference in the associations with other cognitive tests. For tibia and patella Pb levels, ALAD genotype was found to modify associations with different tests, for example, executive function and perceptual speed. It is not clear why the direction of

effect modification would vary among different cognitive domains. The limited number of populations examined, and the different cognitive tests performed in each study, make it difficult to conclusively summarize findings for effect modification by ALAD variants. However, in the limited available body of evidence, blood and bone Pb levels were generally associated with lower cognitive function in ALAD2 carriers.

A study of current and former workers exposed to Pb examined the association between blood Pb and blood pressure and reported no modification by ALAD genotype (Weaver et al., 2008). However, another study of blood Pb and blood pressure reported interactions between blood Pb and ALAD, but this varied by race/ethnicity (non-Hispanic white, non-Hispanic black, and Mexican American) (Scinicariello et al., 2010).

Individuals with ALAD2 variants had greater associations between Pb and kidney effects; among those with the variant, higher Pb was associated with higher glomerular filtration measures (Weaver et al., 2006; Weaver et al., 2005b; Weaver et al., 2003b). A study of workers at a battery plant storage facility in China reported workers with the ALAD2 allele demonstrated greater associations between blood Pb levels and renal injury (Gao et al., 2010a). Another study of renal function among Pb workers in Asia also reported greater associations between blood Pb concentrations and renal function by ALAD, especially at high blood Pb levels (Chia et al., 2006).

6.3.3.2 Vitamin D Receptor

The vitamin D receptor (VDR) is a regulator of calcium absorption and metabolism. A recent study of the NHANES III population examined the association between blood Pb levels and various neurocognitive tests with assessment of effect measure modification by SNPs and haplotypes of VDR (Krieg et al., 2010). The results were varied, even among specific SNPs and haplotypes, with some variants being associated with greater modification of the relationship between Pb and one type of neurocognitive test compared to the modification of the relationship between Pb and other neurocognitive tests. In an epidemiologic study of blood Pb levels and blood pressure among a group of current and former Pb-exposed workers, no modification was reported by VDR (Weaver et al., 2008).

6.3.3.3 Methylenetetrahydrofolate reductase

Methylenetetrahydrofolate reductase (MTHFR) catalyzes the conversion of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate, which in turn, is involved in homocysteine remethylation to the amino acid methionine. A study in Mexico of the association between Pb and Bayley's Mental Development Index (MDI) score at 24 months reported no effect measure modification by MTHFR 677T allele (Pilsner et al., 2010). Another study in Mexico examined the association between maternal Pb and birth weight (Kordas et al., 2009). No modification of the Pb-birth weight association by MTHFR was observed.

6.3.3.4 Hemochromatosis

The hemochromatosis (HFE) gene encodes a protein believed to be involved in iron absorption. A difference was observed between the association of tibia Pb levels and cognitive function for men with and without HFE allele variants (Wang et al., 2007a). No association between tibia Pb and cognitive function was present for men with HFE wildtype, but a decline in function was associated with tibia Pb levels among men with any HFE allele variant. A study of bone Pb levels and HFE reported no difference in effect estimates for bone Pb and pulse pressure between different HFE variants and HFE wild-type (Zhang et al., 2010a). An interaction was observed between an HFE variant in mothers and maternal tibia Pb in a study of maternal Pb and birth weight (Cantonwine et al., 2010b). The inverse association between maternal tibia Pb levels and birth weight was stronger for those infants whose mothers had the HFE variant. The interaction was not present between the HFE variants and maternal blood Pb or cord blood Pb concentrations.

6.3.3.5 Other Genetic Polymorphisms

Some other genetic polymorphisms were also examined as to whether they modify Pb-related health effects, but only limited data were available for these polymorphisms. These include dopamine receptor D4 (DRD4), dopamine receptor D2 (DRD2), dopamine transporter (DAT1), glutathione S-transferase Mu 1 (GSTM1), tumor necrosis factor-*alpha* (TNF-α), endothelial nitric oxide synthase (eNOS), and various SNPS.

A prospective birth cohort reported that increasing blood Pb levels were associated with poorer rule learning and reversal, spatial span, and planning in their study population (Froehlich et al., 2007). These inverse associations were exacerbated among those

lacking DRD4-7. A study of prenatal and postnatal Pb levels in Mexico City reported no modification of the associations between Pb levels and neurocognitive development by DRD2 or DAT1 (Kordas et al., 2011).

A study of university students in South Korea reported blood Pb levels to be associated with biomarkers of inflammation among individuals with GSTM1 null genotype and not among individuals with GSTM1 present (Kim et al., 2007). This study of blood Pb levels and inflammation also examined individuals with TNF-α GG, GA, or AA alleles. An association was present for those with TNF-α GG but not for those with TNF-α GA or AA.

A study of blood Pb and plasma NO_X reported no overall association but did report an inverse correlation among subjects with the eNOS TC+CC genotype (Barbosa et al., 2006c). No correlation was observed for subjects with the eNOS TT genotype; however the number of subjects in this group was small, especially for those with high blood Pb levels.

One study examined how the association between occupational Pb exposure and brain tumors varied among multiple single nucleotide polymorphisms (SNPs) (Bhatti et al., 2009). No effect measure modification of the association between Pb and glioma was observed for any of the SNPs. GPX1 (the gene encoding for glutathione peroxidase 1) modified the association for glioblastoma multiforme and meningioma. The association between Pb and glioblastoma multiforme was also modified by a RAC2 (the gene encoding for Rac2) variant, and the association between Pb and meningioma was also modified by XDH (the gene encoding for xanthine dehydrogenase) variant.

Overall, studies of ALAD observed increased Pb-related health effects associated with certain gene variants. Other genes, such as VDR, HFE, DRD4, GSTM1, TNF-α, and eNOS, may also affect the risk of Pb-related health effects but conclusions are limited due to the small number of studies.

6.3.4 Pre-existing Diseases/Conditions

Studies have also been performed to examine whether certain morbidities increase an individual's risk of Pb-related effects on health. Recent studies have explored relationships for autism, diabetes, and hypertension.

6.3.4.1 Autism

Rates of individuals with autism have increased in recent years. A study reported a prevalence rate in 2006 of 9.0 per 1,000 individuals (95% CI: 8.6, 9.3) determined from a monitoring network (Autism and Developmental Disabilities Monitoring Network) with 11 sites across the U.S. (CDC, 2009).

A cross-sectional study of children with and without autism examined the association between blood Pb levels and various immune function and inflammation genes (Tian et al., 2011). Blood Pb levels of children with and without autism were associated with expression of the genes under study; however, the associations observed were in opposite directions (for children with autism, increased blood Pb levels were associated with increased expression, whereas for children without autism, increased blood Pb levels were associated with decreased expression).

6.3.4.2 Diabetes

Approximately 8% of U.S. adults have diabetes (Pleis et al., 2009). A few studies have been conducted to investigate the possibility of diabetes as a modifying factor for Pb and various health outcomes.

Differences in the association between bone and blood Pb levels and renal function for individuals with and without diabetes at baseline were examined using the Normative Aging Study cohort (Tsaih et al., 2004). Tibia and blood Pb levels were positively associated with measures of poor renal function among individuals with diabetes but not among individuals without diabetes. However, this association was no longer statistically significant after the exclusion of individuals who were hypertensive or who used diuretic medications. Another study with this cohort reported no associations between bone Pb and heart rate variability, which did not differ among those with and without diabetes (Park et al., 2006).

The NHANES III data were used to evaluate whether the association between blood Pb and both all-cause and cardiovascular mortality varied among individuals with and without diabetes (Menke et al., 2006). The 95% CIs among those with diabetes were large and no difference was apparent among those with and without diabetes.

Overall, recent epidemiologic studies found that associations between Pb concentrations and health outcomes did not differ for individuals with and without diabetes. However, results from the 2006 Pb AQCD found that individuals with diabetes are at "increased risk of Pb-associated declines in renal function" (U.S. EPA, 2006b). Future research

examining associations between Pb and renal function, as well as other health outcomes, among individuals with and without diabetes will inform further on the potential for increased risk among individuals with diabetes.

6.3.4.3 Hypertension

Hypertension affects approximately 24% of adults in the U.S. and the prevalence of hypertension increases with age (61% of individuals ≥ 75 years old have hypertension) (Pleis et al., 2009).

The Normative Aging Study mentioned above evaluating modification of the association between Pb levels and renal function by diabetes also examined modification by hypertensive status (Tsaih et al., 2004). The association between tibia Pb and renal function, measured by change in serum creatinine, was present among individuals with hypertension but not among individuals that were normotensive. Models of the follow-up serum creatinine levels demonstrated an association with blood Pb for individuals with hypertension but not individuals without hypertension (this association was not present when using tibia or patella Pb). Another study using this population examined modification of the association between bone Pb and heart rate variability, measured by low frequency power, high frequency power, and their ratio (Park et al., 2006). Although a statistically significant association between bone Pb and heart rate variability was not observed among individuals with or without hypertension, the estimates were different, with greater odds for individuals with hypertension (bone Pb levels were positively related to low frequency power and the ratio of low frequency to high frequency power and were inversely related to high frequency power).

A study using the NHANES III cohort reported a positive association between blood Pb levels and both all-cause and cardiovascular mortality for individuals with and without hypertension but the associations did not differ based on hypertensive status (Menke et al., 2006).

The 2006 Pb AQCD reported that individuals with hypertension had increased risk of Pb-related effects on renal function (U.S. EPA, 2006b). This is supported by recent epidemiologic studies. As described above, studies of Pb-related effects on renal function and heart rate variability have observed some differences among individuals with hypertension, but the difference between adults with and without hypertension was not observed for Pb-related mortality.

Overall, studies of Pb-related health effects related to pre-existing conditions have some evidence of a potential increased risk of Pb-related health effects. The evidence is consistent for Pb-related renal effects and hypertension but is limited for other pre-existing conditions.

6.3.5 Smoking Status

The rate of smoking among adults 18 years and older in the U.S. is approximately 20% and about 21% of individuals identify as former smokers (Pleis et al., 2009). Studies of Pb and various health effects have examined smoking as an effect measure modifier.

A study of blood Pb levels and all-cause and cardiovascular mortality reported no modification of this association by smoking status, measured as current, former, or never smokers (Menke et al., 2006). The Normative Aging Study also examined the association between blood and bone Pb levels and renal function and also reported no interaction with smoking status (Tsaih et al., 2004).

A study of Pb-exposed workers and controls reported similar levels of absolute neutrophil counts (ANC) across Pb exposure categories among non-smokers (Di Lorenzo et al., 2006). However, among current smokers, higher Pb exposure was associated with higher ANC. Additionally, a positive relationship was observed between higher blood Pb levels and TNF-α and granulocyte colony-stimulating factor (G-CSF) among both smokers and nonsmokers, but this association was greater among smokers (Di Lorenzo et al., 2007). A recent study of fertile and infertile men examined blood and seminal plasma Pb levels for smokers and non-smokers (Kiziler et al., 2007). The blood and seminal plasma Pb levels were higher for smokers of both fertile and infertile groups. Additionally, the Pb levels were lowest among non-smoking fertile men and highest among smoking infertile men.

Prenatal smoking exposure was examined in a study of children's concurrent blood Pb levels and prevalence of attention-deficit/hyperactivity disorder (ADHD) among children aged 8-15 years. An interaction was observed between children's current blood Pb levels and prenatal tobacco smoke exposure; those children with high Pb levels and prenatal tobacco smoke exposure had the highest odds of ADHD (Froehlich et al., 2009).

Overall, the studies have inconsistent findings on whether smoking modifies the relationship between Pb levels and health effects. Future studies of Pb-related health effects and current, former, and prenatal smoking exposures among various health endpoints will aid in determining changes in risk by this factor.

6.3.6 Socioeconomic Status

Based on the 2000 Census data, 12.4% of Americans live in poverty (poverty threshold for family of 4 was $17,463) (SSDAN CensusScope, 2010c). Few studies have compared blood Pb level effect estimates among groups in different sociodemographic strata. Larger blood Pb-associated decreases in cognitive function were found with lower SES in some studies (Ris et al., 2004; Tong et al., 2000; Bellinger et al., 1990). In contrast, a meta-analysis of eight studies found a smaller decrement in Full Scale Intelligence Quotient (FSIQ) for studies in disadvantaged populations than for studies in advantaged populations (Schwartz, 1994). While results indicate that blood Pb level is associated with FSIQ deficits in both higher and lower sociodemographic groups, they do not clearly indicate whether groups with different socioeconomic status differ in Pb-related changes for cognitive function.

6.3.7 Race/Ethnicity

Based on the 2000 Census, 69.1% of the U.S. population is comprised of non-Hispanic whites. Approximately 12.1% of people reported their race/ethnicity as non-Hispanic black and 12.6% reported being Hispanic (SSDAN CensusScope, 2010b). Studies of multiple Pb-related health outcomes examined effect measure modification by race/ethnicity.

A study of adults from the NHANES III cohort examined the association between blood Pb levels and all-cause and cardiovascular mortality (Menke et al., 2006). Stratified analyses were conducted for non-Hispanic whites, non-Hispanic blacks, and Mexican Americans and no interaction for race/ethnicity was reported. Other studies have also used NHANES cohorts to study blood Pb levels and hypertension (Scinicariello et al., 2010; Muntner et al., 2005). While no association was observed between blood Pb and hypertension for non-Hispanic whites or Hispanics, a positive association was reported for non-Hispanic blacks in a study using the NHANES III cohort (Scinicariello et al., 2010). In another study, although none of the associations between blood Pb levels and hypertension were statistically significant, increased odds were observed among non-Hispanic blacks and Mexican Americans but not for non-Hispanic whites (Muntner et al., 2005).

A study of girls aged 8-18 years from the NHANES III cohort reported an inverse association between blood Pb levels and pubertal development among blacks and Mexican Americans (Selevan et al., 2003). For non-Hispanic whites, the associations were in the same direction but did not reach statistical significance. Of note, less than 3% of non-Hispanic whites had blood Pb levels over 5 µg/dL, whereas 11.6% and 12.8% of blacks and Mexican Americans, respectively, had blood Pb levels greater than 5 µg/dL.

A study linking educational testing data for 4th grade students in North Carolina reported declines in reading and mathematics scores with increasing levels of blood Pb (Miranda et al., 2007a). Although not quantitatively reported, a figure in the study depicted the association stratified by race, and the slopes appeared to be similar for white and black children.

Blood Pb and asthma incidence was examined for white and black children living in Michigan (Joseph et al., 2005). When utilizing separate referent groups for the two races, the only association is an increase among whites (although not statistically significant), but when restricting to the highest blood Pb levels, the association was no longer apparent. Whites with low blood Pb levels were used as the referent group for both races in additional analysis. Although the estimates were elevated for black children compared to white children (including at the lowest blood Pb levels), the confidence intervals for the associations overlapped indicating a lack of a difference by race.

The results of these recent epidemiologic studies provide some evidence that there may be race/ethnicity-related increased risk with higher Pb levels for certain outcomes, although the overall understanding of potential effect measure modification by race/ethnicity is limited by the small number of studies. Additionally, these results may be confounded by other factors, such as socioeconomic status or nutritional factors.

6.3.8 Body Mass Index

In the U.S. self-reported rates of obesity were 26.7% in 2009, up from 19.8% in 2000 (Sherry et al., 2010). The NHANES III cohort was utilized in a study of blood Pb levels and all-cause and cardiovascular mortality, which included assessment of the associations by obesity (Menke et al., 2006). Positive associations were observed among individuals within both categories of body mass index (BMI; normal [<25 kg/m^2] and overweight/obese [≥ 25 kg/m^2], determined using measured values of height and weight) but there was no difference in the association between the two categories. Using the Normative Aging Study data, an investigation of bone Pb levels and heart rate variability was performed and reported slight changes in the association based on the presence of metabolic syndrome; however, none of the changes resulted in associations that were

statistically significant (Park et al., 2006). Overall, no modification by BMI or obesity was observed among recent epidemiologic studies, but the available epidemiologic and supporting toxicological studies are limited.

6.3.9 Alcohol Consumption

There are a limited number of studies examining alcohol as a factor affecting Pb-related risk. A study using the Normative Aging Study cohort investigated whether the association between blood and bone Pb levels and renal function would be modified by an individual's alcohol consumption (Tsaih et al., 2004). No interaction with alcohol consumption was observed. However, a toxicological study reported that ethanol potentiated the effect of Pb exposure by decreasing renal total protein sulfhydryls (endogenous antioxidants) in rats. Pb and ethanol also decreased other endogenous renal antioxidants (glutathione and non-protein sulfhydryls) (Jurczuk et al., 2006). Overall, evidence to determine if alcohol consumption is a potential at-risk factor is of limited quantity and consistency.

6.3.10 Nutritional Factors

Different components of diet may affect the association between Pb concentrations and health outcomes. Recent epidemiologic and toxicological studies of specific mineral intakes/dietary components are detailed below.

6.3.10.1 Calcium

Using the Normative Aging Study (NAS) cohort, researchers examined the association between Pb levels and hypertension, modified by calcium intake (Elmarsafawy et al., 2006). The associations between Pb levels (measured and modeled separately for blood, patella, and tibia) and hypertension did not differ based on dichotomized calcium intake (800 mg/day).

6.3.10.2 Iron

The 2006 Pb AQCD included studies that indicated individuals with iron-deficiency and malnourishment had greater inverse associations between Pb and cognition (U.S. EPA, 2006b). A recent epidemiologic study of pubertal development among girls observed inverse associations between blood Pb and inhibin B. This association was modified by iron deficiency; girls with iron deficiency had a stronger inverse association between Pb and inhibin B than those who were iron sufficient (Gollenberg et al., 2010). Toxicological studies also reported that iron-deficient diets exacerbate or potentiate the effect of Pb. A study of pregnant rats given an iron-deficient diet and exposed to Pb through drinking water over GD6-GD14, had decreased litter size, more pups with reduced fetal weight and reduced crown-rump length, increased litter resorption, and a higher dam blood Pb level in the highest exposure groups (Singh et al., 1993b; Saxena et al., 1991). Thus, in this model, iron deficiency makes rat dams more at risk for Pb-dependent embryo and fetotoxicity (Singh et al., 1993b).

6.3.10.3 Folate

A study by Kordas et al. (2009) examined Pb levels and birth size among term births in Mexico City. The authors reported no interaction between maternal tibia Pb and folate levels.

6.3.10.4 Protein

No recent epidemiologic studies have evaluated protein intake as a factor affecting Pb-related health effects. However, a toxicological study demonstrated that differences in maternal protein intake levels could affect the extent of Pb-induced immunotoxicity among offspring (Chen et al., 2004).

In sum, the evidence is limited for most dietary factors but evidence for iron deficiency as a factor that potentially increases risk of Pb-induced effects is present and coherent in epidemiologic and toxicological studies.

6.3.11 Stress

A study of bone (tibia and patella) Pb levels and hypertension reported modification of the association by perceived stress levels (Peters et al., 2007). Among individuals with greater perceived stress levels, stronger associations between blood Pb levels and hypertension were present. Among the same study population, higher perceived stress was also reported to affect the association between blood Pb levels and cognitive function; the higher stress group showed a greater inverse association between Pb and cognitive function than those in the low stress group (Peters et al., 2008). In another study, the inverse association between tibia Pb levels and some measures of cognitive function were similarly strengthened by neighborhood psychosocial hazards (Glass et al., 2009).

Toxicological studies have demonstrated that early life exposure to Pb and maternal stress can result in toxicity related to multiple systems (Rossi-George et al., 2009; Cory-Slechta et al., 2008; Virgolini et al., 2008a; Virgolini et al., 2008b), including dysfunctional corticosterone responses (Rossi-George et al., 2009; Virgolini et al., 2008b). Additionally, toxicological studies have demonstrated that stressors to the immune system can also affect associations with Pb exposure. Chickens with low Pb exposure in ovo, with additional viral stressors, had increased immune cell mobilization and trafficking dysfunction (Lee et al., 2002). Similarly, mice with neonatal Pb exposure, and an additional immune challenge, had a sickness behavior phenotype, likely driven by IL-6 production (Dyatlov and Lawrence, 2002).

Although examined in a limited number of studies, recent epidemiologic studies observed modification of the association between Pb and various nervous system health effects by stress-level. Increased risk of Pb-related health effects by stress is further supported by toxicological studies.

6.3.12 Maternal Self-Esteem

Maternal self-esteem has been shown to modify associations between blood Pb levels and health effects in children. Surkan et al. (2008) studied the association between children's blood Pb levels and Bayley's MDI and Psychomotor Development Index (PDI) among mother-child pairs. High maternal self-esteem was independently associated with higher MDI score and also appeared to attenuate the negative effects of the child's increased blood Pb levels on MDI and PDI scores. Greater decreases in MDI and PDI were associated with increased blood Pb levels among children whose mothers were in the lower quartiles of self-esteem.

6.3.13 Cognitive Reserve

Cognitive reserve has been defined as "the maintenance of cognitive performance in spite of ongoing underlying brain pathology" (Bleecker et al., 2007a). A study of Pb smelter workers reported that an inverse association between lifetime weighted blood Pb levels and cognitive function was present among workers with low cognitive reserve (measured using a reading achievement test) but no association was present in workers with high cognitive reserve (Bleecker et al., 2007a). Inverse associations between lifetime-weighted blood Pb levels and motor functions existed among all workers regardless of cognitive reserve. No other recent epidemiologic studies were performed examining cognitive reserve as a factor affecting risk of Pb-related health outcomes, thus providing limited evidence to conclude that cognitive reserve is a potential at-risk factor.

6.3.14 Other Metal Exposure

The 2006 Pb AQCD reported that the majority of studies that examined other toxicants did so as confounders and not as effect measure modifiers (U.S. EPA, 2006b). Recent epidemiologic studies have begun to explore the possible interaction between Pb exposure and co-exposures with other metals. These studies, as well as toxicological studies of these metals, are described below.

6.3.14.1 Cadmium

In a study of girls in the NHANES III cohort, inverse associations were observed between blood Pb and inhibin B concentrations (Gollenberg et al., 2010). These inverse associations were stronger among girls with high cadmium (Cd) and high Pb compared to those with high Pb and low Cd. Additionally, higher blood Pb and Cd levels together were positively associated with albuminuria and reduced estimated glomerular filtration rate, compared to those with the lowest levels of Pb and Cd (Navas-Acien et al., 2009).

Toxicological studies reported that in rats, the addition of Cd to Pb exposure reduced the histological signs of renal toxicity from each element alone; however, urinary excretion of porphyrins were increased, indicating that although measured tissue burdens of Pb were reduced, the biologically available fraction of Pb was actually increased (Wang and Fowler, 2008). In other studies, Cd synergistically exacerbated Pb-dependent renal mitochondrial dysfunction (Wang et al., 2009c).

Overall, epidemiologic and toxicological studies have reported increased risk of Pb-related health effects among those with high Cd levels as well; however, the number of studies examining both metals is small.

6.3.14.2 Manganese

Among children in South Korea taking part in a study of IQ, an interaction was reported between Pb and manganese (Mn) blood levels (Kim et al., 2009b). Children with high blood Mn levels were observed to have reductions in full scale IQ and verbal IQ associated with increased blood Pb levels, whereas no association between blood Pb levels and full scale IQ and verbal IQ were noted among those children with low blood Mn levels. No effect measure modification by Mn was observed for the association between blood Pb levels and performance IQ. A study performed among children in Mexico City observed greater decreases in neurodevelopment with increases in blood levels of Pb and Mn at 12 months, compared to decreases in neurodevelopment observed for increased Pb levels with low levels of Mn (Claus Henn et al., 2012). No interaction was observed between the two metals and neurodevelopment at 24 months.

Overall, studies have reported increased risk of various health effects with exposure to other metals in addition to Pb; however, this is limited by the small number of studies. Toxicological studies, when available, have provided support for these findings.

6.4 Summary

Table 6-5 provides an overview of the factors examined as potentially increasing the risk of Pb-related health effects based on the recent evidence integrated across disciplines. They are classified according to the criteria discussed in the introduction to this chapter.

Table 6-5 Summary of evidence for factors that potentially increase the risk of Pb-related health effects.

Factor Evaluated	Classification
Childhood (Sections 6.2.1, 6.3.1)	Adequate
Older Adulthood (Sections 6.2.1, 6.3.1)	Suggestive
Sex (Sections 6.2.2, 6.3.2)	Suggestive
Genetics (Section 6.3.3)	Suggestive
Pre-existing Disease[a] (Section 6.3.4)	Suggestive
Smoking Status (Section 6.3.5)	Inadequate
Socioeconomic Status (SES) (Sections 6.2.4, 6.3.6)	Suggestive
Race/Ethnicity (Sections 6.2.3, 6.3.7)	Adequate
Proximity to Pb Sources (Section 6.2.5)	Adequate
Residential Factors (Section 6.2.6)	Adequate
Body Mass Index (BMI) (Section 6.3.8)	Inadequate
Alcohol Consumption (Section 6.3.9)	Inadequate
Nutrition (Section 6.3.10)	Adequate
Stress (Section 6.3.11)	Suggestive
Maternal Self-Esteem (Section 6.3.12)	Inadequate
Cognitive Reserve[a] (Section 6.3.13)	Inadequate
Other Metals (Section 6.3.14)	Suggestive

[a]Possible mediator

There are consistent findings, coherent across disciplines that adequate evidence exists to conclude that childhood is an at-risk lifestage. Among children, the youngest age groups were observed to be most at risk of elevated blood Pb levels, with levels decreasing with increasing age of the children. Children may have increased exposure to Pb compared with adults because children's behaviors and activities (including increased hand-to-mouth contact, crawling, and poor hand-washing), differences in diets, and biokinetic factors. Recent epidemiologic studies of infants/children detected increased risk of Pb-related health effects, and this was supported by toxicological studies, providing adequate evidence to conclude that children are an at-risk population. However, this is based on a limited number of epidemiologic studies, and more studies are needed for comparing various age groups and examining adolescents.

For adults, elevated Pb biomarkers were associated with increasing age. It is generally thought that these elevated levels are related to remobilization of stored Pb during bone loss and/or higher historical Pb exposures. Studies of older adults had inconsistent

findings for effect measure modification of Pb-related mortality but no difference was observed for other health effects. However, toxicological studies support the possibility of age-related differences in Pb-related health effects. The overall evidence is suggestive that older adults are a potential at-risk population based on limited epidemiologic evidence but support from toxicological studies and differential exposure studies.

Some studies suggest that males at some ages have higher blood Pb levels than comparably aged females; this was supported by stratifying the total sample of NHANES subjects. Sex-based differences appeared to be prominent among the adolescent and adult age groups but were not observed among the youngest age groups (1-5 years and 6-11 years). Studies of effect measure modification of Pb and various health endpoints by sex were inconsistent; although it appears that there are some differences in associations for males and females. This is also observed in toxicological studies. Overall, there is suggestive evidence to conclude that sex is a potential at-risk factor, limited due to inconsistencies between whether males or females are at greater risk of certain outcomes.

Regarding race and ethnicity, recent data suggest that the difference in blood Pb levels between black and white subjects is decreasing over time, but black subjects still tend to have higher Pb body burden and Pb exposures than white subjects. Compared to whites, non-white populations were observed to be more at risk of Pb-related health effects; however, this could be related to confounding by factors such as SES or differential exposure levels, which was noted in some of the epidemiologic studies. Studies of race/ethnicity provide adequate evidence that race/ethnicity is an at-risk factor based on the higher exposure observed among non-white populations and some modification observed in studies of associations between Pb levels and health effects.

Similar to race and ethnicity, the gap between SES groups with respect to Pb body burden appears to be diminishing. Studies of SES and its relationship with Pb-related health effects are limited and different studies demonstrate increased risk among higher or lower SES groups, providing limited evidence to determine if SES is an at-risk factor for Pb-related health effects. However, biomarkers of Pb exposure have been shown to be higher among lower SES groups even in recent studies in which differences among SES groups have lessened. Therefore, the evidence is suggestive to conclude that low SES is a potential at-risk factor for Pb-related health effects.

There is evidence associating proximity to areas with Pb sources, including areas with large industrial sources, with increased Pb body burden and risk of Pb exposure. High concentrations of ambient air Pb have been measured near sources, compared with large urban areas without sources. Additionally, high Pb exposures have been documented near Superfund sites.

Studies utilizing the NHANES dataset have reported increased Pb biomarker measures related to increase house dust Pb levels, homes built after 1950, and renovation of pre-1978 homes. These findings were consistent with those of several high quality studies. Thus, there is adequate evidence that residing in a residence with Pb exposures will increase the risk of Pb-related health effects.

There is suggestive evidence to conclude that various genes are potentially modifying the associations between Pb and health effects. Epidemiologic and toxicological studies reported that ALAD variants may increase the risk of Pb-related health effects. Other genes examined that may also affect risk of Pb-related health effects were VDR, DRD4, GSTM1, TNF-α, eNOS, and HFE, although the number of studies examining effect measure modification by these genes was small.

Among nutritional factors, diets sufficient in minerals such as Ca^{2+}, Fe, and Zn offer some protection from Pb exposure by preventing or competing with Pb for absorption in the GI tract. Additionally, those with iron deficiencies were observed to be an at-risk population for Pb-related health effects in both epidemiologic and toxicological studies. Thus, there is adequate evidence across disciplines that some nutritional factors contribute to a population being at increased risk. Other nutritional factors, such as Ca^{2+}, Zn, and protein intake, demonstrated the potential to modify associations between Pb and health effects in toxicological studies. Recent epidemiologic studies of these factors were either not performed or observed no effect modification. Folate was also examined in an epidemiologic study of birth size but no interaction was reported between Pb and folate.

There was suggestive evidence for several other factors as potentially increasing the risk of Pb-related health effects: pre-existing diseases/conditions, stress, and co-exposure with other metals. Pre-existing diseases/conditions have the potential to affect the risk of Pb-related health effects. Recent epidemiologic studies did not support modification of associations between Pb and health endpoints by the prevalence of diabetes; however, past studies have found individuals with diabetes to be an at-risk population with regard to renal function. Hypertension was observed to be a factor affecting risk in both past and recent epidemiologic studies. Studies of Pb levels and both renal effects and heart rate variability demonstrated greater odds of the associations among hypertensive individuals compared to those that are normotensive. Epidemiologic studies also examined autism as potential factors affecting Pb-related health effects; differences were observed but few studies were available to examine this factor. Stress was evaluated as a factor that potentially increases the risk of Pb-related health outcomes and although limited by the small number of epidemiologic studies, increased stress was observed to negatively impact the association between Pb and health endpoints. Toxicological studies supported this finding. Finally, interactions between Pb and co-exposure with other metals were

evaluated in recent epidemiologic and toxicological studies of health effects. High levels of other metals, such as Cd and Mn, were observed to result in greater effects for the associations between Pb and various health endpoints but evidence was limited due to the small number of studies.

Finally, there was inadequate evidence to conclude that smoking, BMI, alcohol consumption, maternal self-esteem, and cognitive reserve are potential at-risk factors due to limited quantities of studies regarding their effect on Pb-related health outcomes. Epidemiologic studies examining smoking as a factor potentially affecting risk reported mixed findings. It is possible that smoking modifies the effects of only some Pb-related health outcomes. In the limited number of studies, modification of associations between Pb and various health effects (mortality and heart rate variability) was not observed for BMI/obesity. Also, no modification was observed in an epidemiologic study of renal function examining alcohol consumption as a modifier, but a toxicological study supported the potential of alcohol to affect risk. Maternal self-esteem was examined in an epidemiologic study and individuals with mothers who had lower self-esteem had greater Pb-related decreases in MDI and PDI. An epidemiologic study evaluated cognitive reserve as a modifier of the associations between Pb and cognitive and motor functions. Cognitive reserve was an effect measure modifier for the association between Pb and cognitive function but not motor function.

7 ECOLOGICAL EFFECTS OF LEAD

This chapter synthesizes and evaluates the most policy-relevant science to help form the foundation for the review of the secondary (welfare-based) NAAQS for Pb. The Clean Air Act definition of welfare effects includes, but is not limited to, effects on soils, water, wildlife, vegetation, visibility, weather, and climate, as well as effects on materials, economic values, and personal comfort and well-being. This chapter discusses the effects of Pb on ecosystem components and processes and is organized into five sections. The introduction (Section 7.1) presents the organizing principles of this chapter and several important general ecology concepts. An overview of fate and transport of Pb in ecosystems including measured concentrations of this metal in various environmental media (i.e., soil, water, sediment) is presented in Section 7.2. Section 7.3 reviews the effects of Pb on terrestrial ecosystems; how soil biogeochemistry affects Pb bioavailability, biological effects of Pb exposure and subsequent vulnerability of particular ecosystems. A similar discussion of the effects of Pb on freshwater and saltwater ecosystems is presented in Section 7.4, including water-only exposures and sediment-related effects. The terrestrial, freshwater and saltwater sections each conclude with an integrative synthesis of new evidence for Pb effects and causal determinations, based on the synthesis of new evidence and findings from previous Pb AQCDs. Section 7.5 summarizes the causal determinations. Areas not addressed here include literature related to ingestion of Pb shot or pellets and studies that examine human health-related endpoints which are described in other chapters of this document.

7.1 Introduction to Ecological Concepts

Metals, including Pb, occur naturally in the environment at measurable concentrations in soils, sediments, and water. Organisms have developed adaptive mechanisms for living with metals, some of which are required micronutrients (but not Pb). However, anthropogenic enrichment can result in concentrations that exceed the capacity of organisms to regulate internal concentrations, causing a toxic response and potentially death. Differences in environmental chemistry may enhance or inhibit uptake of metal from the environment, thus creating a spatial patchwork of environments that are at greater risk than other environments. Similarly, organisms vary in their degree of adaptation to, or tolerance of, the presence of metals. These fundamental principles of how metals interact with organisms and ecosystems are described in detail in EPA's *Framework for Metals Risk Assessment* (U.S. EPA, 2007c). This section introduces critical concepts for understanding how Pb from atmospheric deposition may affect

organisms, communities, and ecosystems. The sections that follow provide more detail for how aquatic and terrestrial ecosystems respond to Pb and how environmental chemistry interacts with organisms to affect exposure and uptake.

7.1.1 Ecosystem Scale, Function, and Structure

For this assessment, an ecosystem is defined as the interactive system formed from all living organisms (biota) and their abiotic (chemical and physical) environment within a given area (IPCC, 2007).The boundaries of what could be called an ecosystem are somewhat arbitrary, depending on the focus of interest or study. Thus, the extent of an ecosystem may range from very small spatial scales to, ultimately, the entire Earth (IPCC, 2007). Ecosystems cover a hierarchy of spatial scales and can comprise the entire globe, biomes at the continental scale, or small, well-circumscribed systems such as a small pond (U.S. EPA, 2008e). A pond may be a small but complex system with multiple trophic levels ranging from phytoplankton to several feeding guilds of fish plus fish-eating birds or mammals. A large lake, on the other hand, may be a very simple ecosystem, such as the Great Salt Lake in Utah that covers approximately 1,700 square miles but contains only bacteria, algae, diatoms, and two invertebrate species. All ecosystems, regardless of size or complexity, share the commonality of multiple interactions between biota and abiotic factors, and a reduction in entropy through energy flow from photosynthetic organisms to top predators. This includes both structural (e.g., soil type and food web trophic levels) and functional (e.g., energy flow, decomposition, nitrification) attributes. Changes are often considered undesirable if important structural or functional components of ecosystems are altered following pollutant exposure (U.S. EPA, 1998).

Ecosystems are most often defined by their structure, and are based on the number and type of species present. Structure may refer to a variety of measurements including the species richness, abundance, community composition and biodiversity as well as landscape attributes. Individual organisms of the same species are similar in appearance and genetics, and can interbreed and produce fertile offspring. Interbreeding groups of individual organisms within the same species that occupy some defined geographic space form populations, and populations of different species form communities (Barnthouse et al., 2008). The community composition may also define an ecosystem type, such as a pine forest or a tall grass prairie. Pollutants can affect the ecosystem structure at any of these levels of biological organization (Suter et al., 2005). Individual plants or animals may exhibit changes in metabolism, enzyme activities, hormone function, or overall growth rates or may suffer gross lesions, tumors, deformities, or other pathologies. Effects on the nervous system of animals may cause behavioral changes that alter

breeding behaviors or predator avoidance. However, only some organism-level endpoints such as growth, survival and reproductive output have been definitively linked to effects at the population level and above. Examples of organism-level endpoints with direct links to population level effects include mass mortality, gross anomalies, survival, fecundity and growth (Suter et al., 2004). Population level effects of pollutants include changes over time in abundance or density (number of individuals in a defined area), age or sex structure, and production or sustainable rates of harvest (Barnthouse et al., 2008). Community level attributes affected by pollutants include species richness and abundance (also known as biodiversity), dominance of one species over another, or size (area) of the community. Pollutants may affect communities in ways that are not observable in organisms or populations (Bartell, 2007), including: (1) effects resulting from interactions between species, such as altering predation rates or competitive advantage; (2) indirect effects, such as reducing or removing one species from the assemblage and allowing another to emerge (Petraitis and Latham, 1999); and (3) alterations in trophic structure.

Alternatively, ecosystems may be defined on a functional basis. "Function" refers to the suite of processes and interactions among the ecosystem components and their environment that involve nutrient and energy flow as well as other attributes including water dynamics and the flux of trace gases such as rates of photosynthesis, decomposition, nitrification, or carbon cycling. Pollutants may affect abiotic conditions (e.g., soil chemistry), which indirectly influences biotic structure and function (Bartell, 2007). Feedback loops or networks influence the stability of the system, and can be mathematically described through simplistic or complex process, or energy flow, models (Bartell, 2007). For example, the Comprehensive Aquatic Systems Model (CASM) is a bioenergetics-based multicompartment model that describes the daily production of biomass (carbon) by populations of aquatic plants and animals over an annual cycle (DeAngelis et al., 1989). CASM, originally designed to examine theoretical relationships between food web structure, nutrient cycling, and ecosystem stability, has since been adapted for risk assessments and has been applied to numerous lakes with a variety of pollutants (Bartell, 2007). Likewise, other theoretical ecosystem models are being modified for use in assessing ecological risks from pollutant exposures (Bartell, 2007).

Some ecosystems, and some aspects of particular ecosystems, are less vulnerable to long-term consequences of pollutant exposure. Other ecosystems may be profoundly altered if a single attribute is affected. Thus, spatial and temporal definitions of ecosystem structure and function become an essential factor in defining impacted ecosystem services and critical loads of particular pollutants, either as single pollutants or in combination with other stressors. Both ecosystem services (Section 7.1.2) and critical loads (Section 7.1.3) serve as benchmarks or measures of the impacts of pollutants on ecosystems.

7.1.2 Ecosystem Services

Ecosystem structure and function may be translated into ecosystem services (Daily, 1997). Ecosystem services are the benefits people obtain from ecosystems (UNEP, 2003). Ecosystem services are defined as the varied and numerous ways that ecosystems are important to human welfare and how they provide many goods and services that are of vital importance for the functioning of the biosphere. This concept has gained recent interest and support because it recognizes that ecosystems are valuable to humans, and are important in ways that are not generally appreciated (Daily, 1997). Ecosystem services also provide a context for assessing the collective effects of human actions on a broad range of the goods and services upon which humans rely.

In general, both ecosystem structure and function play essential roles in providing goods and services. Ecosystem processes provide diverse benefits including absorption and breakdown of pollutants, cycling of nutrients, binding of soil, degradation of organic waste, maintenance of a balance of gases in the air, regulation of radiation balance and climate, and fixation of solar energy (WRI, 2000; Daily, 1997; Westman, 1977). These ecological benefits, in turn, provide economic benefits and values to society (Costanza et al., 1997; Pimentel et al., 1997). Goods such as food crops, timber, livestock, fish and clean drinking water have market value. The values of ecosystem services such as flood control, wildlife habitat, cycling of nutrients and removal of air pollutants are more difficult to measure (Goulder and Kennedy, 1997).

Particular concern has developed within the past decade regarding the consequences of decreasing biological diversity (Tilman, 2000; Ayensu et al., 1999; Wall, 1999; Chapin et al., 1998; Hooper and Vitousek, 1997). Human activities that decrease biodiversity also alter the complexity and stability of ecosystems and change ecological processes. In response, ecosystem structure and function can be affected (Daily and Ehrlich, 1999; Wall, 1999; Chapin et al., 1998; Levin, 1998; Peterson et al., 1998; Tilman, 1996; Tilman and Downing, 1994; Pimm, 1984). Biodiversity is an important consideration at all levels of biological organization, including species, communities, populations, and ecosystems. Human-induced changes in biotic diversity and alterations in the structure and functioning of ecosystems are two of the most dramatic ecological trends of the past century (U.S. EPA, 2004; Vitousek et al., 1997).

Hassan et al. (2005) identified four broad categories of ecosystem services:

- Supporting services are necessary for the production of all other ecosystem services. Some examples include biomass production, production of atmospheric O_2, soil formation and retention, nutrient cycling, water cycling and provisioning of habitat. Biodiversity is a supporting service in that it is increasingly recognized to sustain many of the goods and services that humans enjoy from ecosystems. These supporting services provide a basis for an additional three higher-level categories of services.
- Provisioning services such as products (Gitay et al., 2001) i.e., food (including game meat, roots, seeds, nuts, and other fruit, spices, fodder), water, fiber (including wood, textiles) and medicinal and cosmetic products.
- Regulating services that are of paramount importance for human society such as (1) carbon sequestration, (2) climate and water regulation, (3) protection from natural hazards such as floods, avalanches, or rock-fall, (4) water and air purification, and (5) disease and pest regulation.
- Cultural services that satisfy human spiritual and aesthetic appreciation of ecosystems and their components.

7.1.3 Critical Loads as an Organizing Principle for Ecological Effects of Atmospheric Deposition

A critical load is defined as, "a quantitative estimate of an exposure to one or more pollutants below which significant harmful effects on specified sensitive elements of the environment do not occur according to present knowledge" (Nilsson and Grennfelt, 1988). Critical loads are a powerful organizing principle for information that links atmospheric deposition with ecological impairment. They allow for heterogeneity in ecosystem sensitivity and exposure which often results in critical load values that vary by ecosystem (e.g., aquatic-water; aquatic-sediment; terrestrial), and differ by endpoint of concern. It is important to consider that critical loads are often calculated assuming steady state conditions (i.e., how much input is required to balance the rate of output), and there may be time required to reach the critical load (i.e., the lag time between onset of exposure and induction of measurable effects). The following types of information are required to calculate a critical load, each of which is discussed in more detail in the subsequent sections of this chapter:

- Ecosystem at risk;
- Receptors of concern (plants, animals, etc.);
- Endpoints of concern (organism, population or community responses, changes in ecosystem services or functions);
- Dose (concentration) - response relationships and threshold levels of effects;
- Bioavailability and bioaccumulation rates;
- Naturally occurring (background) Pb (or other metal) concentrations; and
- Biogeochemical modifiers of exposure.

There is no single "definitive" critical load for a pollutant, partly because critical load estimates reflect the current state-of-knowledge and policy priorities, and also because of local or regional differences among ecosystems (U.S. EPA, 2008e). Changes in scientific understanding may include, for example, expanded information about dose-response relationships, better understanding of bioavailability factors, and improved quantitative models for effects predictions. Changes in policy may include new mandates for resource protection, inclusion of perceived new threats that may exacerbate the effects of the pollutant of concern (e.g., climate change), and a better understanding of the value of ecosystem services.

7.2 Fate and Transport of Pb in Ecosystems

Fate and transport of Pb in ecosystems are difficult to assess because Pb detected in the environment could have multiple sources and passes through various environmental media within a watershed. These issues are described in detail in Section 3.3. Pb can be emitted to air, soil, or water and then cycle through any or all of these media. In addition to primary emission of particle-bound or gaseous Pb to the atmosphere, Pb can be resuspended to the air from soil or dust (Section 7.2.2). Additionally, Pb-bearing PM can be deposited from the air to soil or water through wet and dry deposition. The complicated nature of Pb fate and transport in ecosystems is illustrated in Figure 7-1 in which the Venn diagram depicts how Pb can cycle through multiple environmental media that encompass both terrestrial and aquatic systems (see also Figure 3-9). The "air/soil/water" arrows illustrate Pb exposures to plants and animals. Many of the studies presented in the subsequent material focus on observations of Pb exposure via one medium: air, soil, sediment, or water.

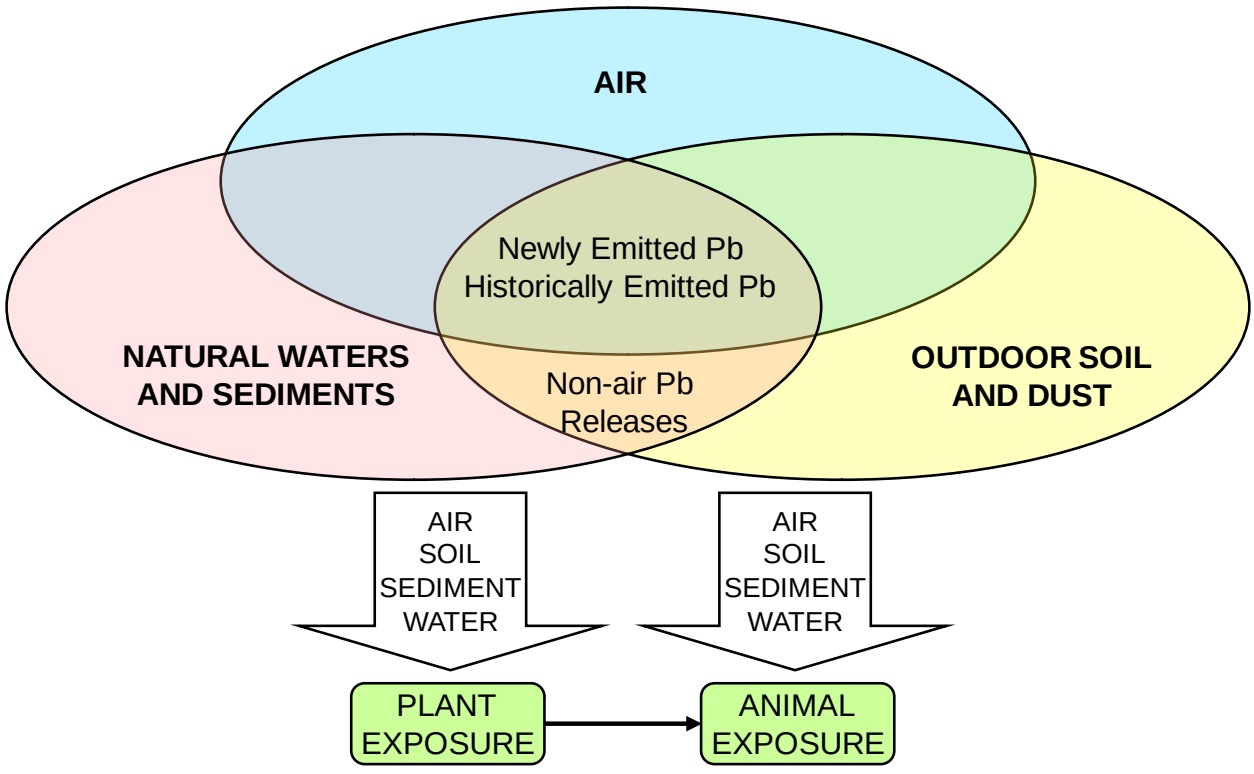

Figure 7-1 Fate of atmospheric Pb in ecosystems.

7.2.1 Fate and Transport

This section provides a brief overview of the fate and transport of Pb in ecosystems. Fate of Pb is determined by the chemical and physical properties of the medium in wet deposition, bodies of water, or soil (e.g., pH, salinity, oxidation status, flow rate and the suspended sediment load and its constituents). Desorption, dissolution, precipitation, sorption and complexation processes can all occur concurrently and continuously, leading to transformations and redistribution of Pb within a watershed. The pH of water is of primary importance in determining the likely chemical fate of Pb in terms of solubility, precipitation, or organic complexation. For more detailed information about the fate and transport of Pb, please see Section 3.3.

Soluble Pb in air is mostly removed by wet deposition, and most of the insoluble Pb is removed by dry deposition. As a result, dry deposition is the major removal mechanism for Pb in coarse PM (which is mainly insoluble) and wet deposition is the most important removal mechanism for fine PM and Pb halides (which were more soluble) (Section 3.3.1). Recent research provides considerable evidence that appreciable amounts of Pb can accumulate on coarse PM during transport, and that the physical and chemical characteristics of Pb can be altered by this process due to accompanying transformations (Section 3.3.1.1). Atmospheric removal of metals by wet or dry deposition is largely controlled by solubility of Pb in rain water. The relative importance of wet and dry deposition is highly variable with respect to location and season, probably reflecting both variations in Pb speciation and variations in external factors such as pH and rain water composition (Section 3.3.1.2).

Pb deposited to terrestrial ecosystems may remain in soils or eventually be transported in runoff to streams, lakes or rivers in the watershed. Pb has a relatively long retention time in the organic soil horizon, although its movement through the soil column also suggests potential for contamination of groundwater (Section 3.3.3). Pb deposition to soils has decreased since the phase-out of leaded on-road gasoline (Section 3.3.3.1). Recent studies of metal concentrations in leaf litter and organic roadside debris suggest that the litter can act as a temporary sink for metals from the soil around and below leaves on the ground (Section 3.3.3.2). Leaching has been consistently observed to be a slower process for Pb than for other contaminants because Pb is only weakly soluble in pore water, but anthropogenic Pb is more available for leaching than naturally occurring Pb in soil (Section 3.3.3.3). Overall, recent research confirms the generally low mobility of Pb in soil. This limited mobility is strongly dependent on colloid amount and composition, as well as pH, and may be greater in some contaminated soils. Low mobility allows soils to act as a sink for atmospheric Pb potentially for decades or longer. Hence, atmospheric Pb concentrations that peaked several decades ago may still be present in soil in the absence of remediation.

Sources of Pb to surface waters include direct atmospheric deposition and indirect deposition via runoff and industrial discharge (Section 3.3.2). Because dispersal in waterways is a relatively rapid process, concentrations in surface waters are highest near sources of pollution before substantial Pb removal by flushing, evaporation, and sedimentation occurs. Transport in surface water is largely controlled by exchange with sediments, and the cycling of Pb between water and sediments is governed by chemical, biological, and mechanical processes that are affected by many factors, including salinity, organic complexation, oxidation-reduction potential, and pH. Metals in waterways are transported primarily as soluble chelates and ions, or adsorbed on colloidal surfaces, including secondary clay minerals, Fe and Mn oxides or hydroxides, and organic matter, and adsorption on organic or inorganic colloids is particularly important for Pb. The extent of sorption strongly depends on particle size as smaller particles have larger collective surface areas. Pb is relatively stable in sediments, with long residence times and limited mobility (Section 3.3.2.1). As described in previous sections, Pb enters and is distributed in bodies of water largely in PM form. In rivers, particle-bound metals can often account for ≥ 75% of the total load (Section 3.3.2.2). The flux of Pb in aquatic ecosystems is therefore influenced by the dynamic physical and chemical interactions within a watershed.

Particles associated with runoff are mostly PM, with a relatively small dissolved fraction, and dissolution of carbonate and related compounds are important contributors to Pb pollution in runoff waters. Pb release into runoff is dependent on storm intensity and length of dry periods between rain events. A “first flush effect” occurs with highest runoff concentrations observed at the beginning of a rain event. Most recent studies have concluded that, during storm events, Pb is transported together with large PM. Some studies, however, found that Pb was concentrated in the fine PM fraction and, occasionally, Pb was found predominantly in the dissolved fraction. Since the 2006 Pb AQCD, snowmelt and rain-on-snow events are better understood, and it has been observed that greater runoff occurs from snowmelt and in rain on snow events than when snow is not present, and that metals, including Pb, are often associated with coarse PM under these circumstances. Runoff in rural areas is strongly controlled by soil type and the presence of vegetation, with less runoff and greater retention in mineral soils or when grass is present, and more runoff for soils high in organic matter (OM).

Sediments can be either a source or a sink for metals in the aquatic environment (Section 3.3.2). Release can be via re-suspension of the sediment bed via wind, wave, and tidal action or by dissolution from sediment to the water column. Sediment resuspension from marine environments is important, with disturbance of bed sediments by tidal action in estuarine areas resulting in a general greater capacity for re-suspension of PM. Recent research on Pb flux from sediments in natural waters has demonstrated that resuspended

Pb is largely associated with OM or Fe and Mn particles, but that anoxic or depleted oxygen environments in sediments play an important role in Pb cycling. This newer research indicated that resuspension and release from sediments largely occurs during discrete events related to storms. It has also confirmed that resuspension is an important process that strongly influences the lifetime of Pb in bodies of water. Finally, there have been important advances in understanding and modeling of Pb partitioning in complex aquatic environments.

7.2.2 Ecosystem Exposure, Lag Time and Re-entrainment of Historically Deposited Pb

Ecosystem exposure from atmospheric emissions of Pb depends upon the amount of Pb deposited per unit time. Ecosystem response will also depend upon the form in which the Pb is deposited, the areal extent of such deposition, and modifying factors that affect Pb bioavailability in soil, sediments, and water (e.g., pH, organic matter) (Sections 7.3.2, 7.4.2 and 7.4.3). However, there is frequently a lag in time between when metals are emitted and when an effect is seen, particularly in terrestrial ecosystems and, to a lesser extent, in aquatic sediments. This is because the buffering capacity of soils and sediments permits Pb to become sequestered into organic matter, reducing its availability for uptake by organisms. The lag time from start of emissions to achieving a critical load can be calculated as the time to reach steady state after Pb was initially added to the system. Excluding erosion processes, the time required to achieve 95% of steady state is about 4 half-lives ($t_{1/2}$)[1] (Smolders et al., 2007). Conversely, once emissions cease, the same amount of time is required to reduce metal concentrations to background levels.

[1] Time required to reduce the initial concentration by 50% if metal input is zero.

Time to steady state for metals in soils depends upon rates of erosion, uptake by plants, and leaching or drainage from soils. Ignoring erosion, half-life of metals can be predicted (Smolders et al., 2007) for a soil as:

$$t_{1/2} = \frac{0.69 \times d \times 10{,}000}{y \times TF + \frac{R}{\rho K_d}}$$

Equation 7-1

where:

d is the soil depth in meters (m)

y is the annual crop yield (tons/ha·yr)

TF is the ratio of the metal concentration in plant to that in soil

R is the net drainage loss from the soil depth of concern (m^3/ha·yr)

P is the bulk density of soil [kg(dry weight)/L]

K_d is the ratio of the metal concentration in soil to that in soil pore solution (L/kg)

Metals removed by crops (or plants in general) comprise a very small fraction of the total soil metal and can be ignored for the purpose of estimating time to steady state. Thus, equation 7-1 is simplified to:

$$t_{1/2} = \frac{0.69 \times d \times 10{,}000}{\frac{R}{\rho K_d}}$$

Equation 7-2

and becomes a function of soil depth, the amount of rainfall, soil density, and soil properties that affect K_d. Pb has a relatively long time to steady state compared to other metals, as shown in Table 7-1.

Table 7-1 Comparison among several metals: Time to achieve 95% of steady state metal concentration in soil; example in a temperate system.

Metal	Loading rate (g/ha·yr)	K_d (L/kg)	Time (years)
Se	100	0.3	1.3
Cu	100	480[a]	1,860[a]
Cd	100	690[a]	2,670[a]
Pb	100	19,000[a]	73,300[a]
Cr	100	16,700[a]	64,400[a]

[a]Mean K_d (ratio of total metal concentrations in soils to that in soil pore water); and Time to achieve 95% of steady-state concentration in soil. (49 Dutch soils) (de Groot et al., 1998).

Note: Based on a soil depth of 25 cm, a rain infiltration rate of 3,000 m^3/ha·yr, and the assumption that background was zero at the start of loading.

In aquatic systems, $t_{1/2}$ for Pb in the water column depends on the ratio of the magnitudes of the fluxes coming from and going into the sediment, the ratio of the depths of the water column and sediment, and the sediment $t_{1/2}$. Sediment $t_{1/2}$ is dependent upon the particulate and dissolved fractions and is calculated as for soils (Equation 7-2).

Re-entrainment of Pb particles via windblown dust from surface soils or dry sediments may occur. Amount and distance of re-entrained particles and deposition rates are dependent upon wind velocity and frequency; size, density, shape, and roughness of the particle; soil or sediment moisture; and terrain features including openness (including amount of vegetation), aspect relative to wind direction, and surface roughness. Resuspension is defined in terms of a resuspension factor, K, with units of m^{-1}, or a resuspension rate (Λ), with units of sec^{-1} (Equation 7-3). The resuspension rate, Λ, is the fraction of a surface contaminant that is released per time and is defined by:

$$\Lambda = \frac{R}{C}$$

Equation 7-3

where:

R is the upward resuspension flux ($\mu g/m^2/sec$)

C is the soil (or dry sediment) Pb concentration ($\mu g/m^2$)

Such emissions may have local impacts, but are not likely to have long-range effects, as particles generally remain low to the ground and are not lifted into the atmosphere. Although re-entrainment may alter the particle size distribution in a local area, it generally does not alter the bioavailable fraction, and deposited particles will be subject

to the same biogeochemical forces affecting bioavailability. Therefore, exposure via re-entrainment should be considered additive to exposure from atmospheric particulate deposition in terrestrial and aquatic ecosystems.

7.2.3 Concentrations in Non-Air Media

Pb from multiple sources moves through environmental media as described in Section 7.2.1 and Figure 7-1 and has led to measurable Pb concentrations in soil, water, sediment and biota in terrestrial and aquatic ecosystems (Table 7-2). The highest concentrations of Pb in the environment are currently found near Pb sources, such as metal smelters and industrial processing. After phase-out of Pb from on-road gasoline, Pb concentrations have decreased considerably in rain, snowpack and surface waters. Declining Pb concentrations in tree foliage, trunk sections, and grasses, as well as surface sediments and soils in some locations, have also been observed (U.S. EPA, 2006b). In contrast, Pb is retained in soils and sediments, where it may provide a historical record of deposition and associated concentrations. In remote lakes, sediment profiles indicate higher Pb concentrations in near surface sediment as compared to pre-industrial era sediment from greater depth, with peak concentrations between 1960 and 1980 (when leaded on-road gasoline was at peak use).

Atmospheric deposition has led to measurable Pb concentrations observed in rain, snowpack, soil, surface waters, sediments, agricultural plants, livestock and wildlife. Concentrations of Pb in moss, lichens, peat, and aquatic bivalves have been used to understand spatial and temporal distribution patterns of air Pb concentrations. The amount of Pb in ecosystems is influenced by numerous factors, however, and it is not currently possible to determine the contribution of atmospherically-derived Pb from total Pb. Food, drinking water, and inhalation are major routes of exposure for livestock and terrestrial wildlife. Ingestion and water intake are the major routes of Pb exposure for aquatic organisms. In these exposure pathways, the bioavailable Pb may be from multiple sources. Information on ambient Pb concentrations in non-air media and biota is reported in Section 3.6, and concentrations considered in the interpretation of the ecological evidence are tabulated in Table 7-2.

Table 7-2 Ambient Pb Concentrations in Non-Air Media and Biota Considered for Ecological Assessment.

Media	Pb Concentration	Years Data Obtained	References
Soil	National Average: 18.9 mg Pb/kg (dry weight) Range of state averages: 5-38.6 mg Pb/Kg (dry weight)	1961-1997	U.S. EPA (2007d, 2006b, 2003b)
Freshwater Sediment	Median: 73 mg Pb/kg (dry weight)	1996-2001	Mahler et al. (2006)
	Median: 28 mg Pb/kg[b] (dry weight)	1991-2003	U.S. EPA (2006b)
Saltwater Sediment	Range: 0.6 to 1,050 mg Pb/kg[a]	Dates not available	Sadiq (1992)
Fresh Surface Water (Dissolved Pb)[b]	Median: 0.50 µg Pb/L[b]; Max: 30 µg Pb/L, 95th percentile 1.1 µg Pb/L	1991-2003	U.S. EPA (2006b)
	Range: 0.0003-0.075 µg Pb/L (Set of National Parks in western U.S.)	2002-2007	Field and Sherrell (2003), U.S. National Park Service (2011)
Saltwater[c]	Range: 0.01 – 27 µg Pb/L	Dates not available	Sadiq (1992)
Vegetation	Lichens: 0.3-5 mg Pb/kg (dry weight) (Set of National Parks in western U.S.)	2002-2007	U.S. National Park Service (2011)
	Grasses: 31% (percent of soil Pb in grass)	1980s-2000s	Vandenhove et al. (2009)
Vertebrate	Fish: Geometric Mean: 0.59 mg Pb/kg (dry weight) (whole fish) 0.15 mg Pb/kg (dry weight) (liver) Range: 0.08-22.6 mg Pb/kg (dry weight) (whole fish) 0.01-12.7 mg Pb/kg (dry weight) (liver)	1991-2001	U.S. EPA (2006b)
	Fish (from a set of national parks in western U.S.): 0.0033 (fillet) to 0.97 (liver) mg Pb/kg (dry weight) Moose[d]: 0.008-0.029 mg Pb/kg (dry weight) (meat) 0.012-0.023 mg Pb/kg (dry weight) (liver)	2002-2007	U.S. National Park Service (2011)

[a]No information available regarding wet or dry weight

[b]Based on synthesis of NAWQA data reported in 2006 Pb AQCD (U.S. EPA, 2006b)

[c]Data from a combination of brackish and marine saltwater samples. In general, Pb in seawater is higher in coastal areas and estuaries since these locations are closer to sources of Pb contamination and loading from terrestrial systems.

[d]Three moose in one Alaskan park

The most extensive survey of background soil Pb concentration in the contiguous U.S. was conducted between 1961 and 1976, and comprised 1,319 non-urban, undisturbed sampling locations, where 250 cm^3 of soil was collected at a depth of 20 cm (Shacklette and Boerngen, 1984). The lower detection limit was 10 mg Pb/kg, and 14% of the 1,319

samples were below it. The mean Pb concentration was 19.3 mg Pb/kg, the median 15 mg Pb/kg, and the 95th percentile 50 mg/kg. Sixteen locations had Pb concentrations between 100 and 700 mg Pb/kg. These results were in agreement with 3 previous surveys. When creating the Ecological Soil Screening Level (Eco-SSL) guidance document, the U.S. EPA (2007d, 2003b) augmented these data with observations from an additional 13 studies conducted between 1982 and 1997, most of them limited to one state. The resulting data were summarized using state means for each of the fifty states. Those state means ranged between 5 and 38.6 mg Pb/kg, with an overall national mean of 18.9 mg Pb/kg. No new data on background concentrations of Pb in U.S. soils have been published since 2005.

The 2006 Pb AQCD reported representative median and range of Pb concentrations in surface waters (median 0.50 µg Pb/L, range 0.04 to 30 µg Pb/L) and sediments (median 28 mg Pb/kg dry weight, range 0.5 to 12,000 mg Pb/kg dry weight) in the U.S. based on a synthesis of National Water Quality Assessment (NAWQA) data (U.S. EPA, 2006c). In an additional study using data collected from 1996-2001 the median Pb concentration in sediment was reported to be 73 mg Pb/kg dry weight (Mahler et al., 2006). A range of 0.01 to 27 µg Pb/L for saltwater was reported by Sadiq although the values are not specific to the U.S. and include open sea areas as well as estuarine and coastal waters (Sadiq, 1992). In general, Pb in seawater is higher in coastal areas and estuaries since these locations are closer to sources of Pb contamination and loading from terrestrial systems (Sadiq, 1992).

Measured concentrations of Pb in soils, sediment and water are not necessarily representative of the amount of Pb that is bioavailable to plants, invertebrates and vertebrates. Both bioaccessibility and bioavailability (Sections 7.3.3, 7.4.3, and 7.4.11) of Pb are dependent upon the physical, chemical, and biological conditions under which an organism is exposed at a particular geographic location. Experimental exposures may be difficult to compare with exposures under natural field conditions in terrestrial and aquatic systems where a variety of abiotic and biotic modifying factors affect Pb toxicity.

7.3 Terrestrial Ecosystem Effects

7.3.1 Introduction to Effects of Pb on Terrestrial Ecosystems

Numerous studies of the effects of Pb on components of terrestrial systems were reviewed in the 1977 Pb AQCD, the 1986 Pb AQCD and the 2006 Pb AQCD. The focus of the present document is on studies published since the last AQCD. Many of those studies were conducted near stationary sources of atmospheric Pb such as metal

industries and mines, or using soil collected near those sources. Increasing proximity to the source was often used to generate a gradient of increasing exposure. As may be expected, concentrations found in close proximity to those sources are many times greater than those found at most locations around the country (data on concentrations of Pb in U.S. soils are reviewed in Section 7.2.3 and summarized in Table 7-2), and as indicated in the present document's Preamble, concentrations within one to two orders of magnitude of current conditions were considered. In addition, it is important to note that in all studies where a gradient of multiple concentrations was used, effects increased with increasing concentration. This is an important aspect in determining causality (see Preamble), and therefore justifies inclusion of some studies with very high exposures. Inclusion of those studies also provides potential data for establishing dose-response relationships, and predicting effects at all concentrations, including those found away from stationary sources. Finally, some studies at very high concentrations were used to provide mechanistic information on Pb toxicity, allow for comparison of Pb uptake across taxa, or demonstrate the wide range of sensitivity among closely-related species.

Concentrations used in studies where Pb was added to soil experimentally are difficult to relate to concentrations found in natural environments that have been exposed to Pb pollution. As reviewed in the following sections, there is ample evidence that multiple factors, many of them known but not quantified, interact with Pb concentration to produce responses of widely varying magnitude for similar concentrations, or similar responses for varying concentrations of Pb. Thus, experimental concentrations that appear relatively low may be most comparable to relatively high concentrations in natural soils, and vice-versa. The various factors that interact with Pb concentration, and the evidence for those interactions, are discussed in the following sections. However, the same justifications for inclusion apply to added-Pb experiments as they do to studies where proximity to sources is used to vary exposure: gradients of Pb concentrations create gradients of response, and they often provide information on underlying mechanisms of toxicity even if the concentrations cannot be easily compared to natural ones.

The literature on terrestrial ecosystem effects of Pb published since the 2006 Pb AQCD, is considered with brief summaries from the 1977 Pb AQCD, the 1986 Pb AQCD and the 2006 Pb AQCD, where relevant. Section 7.3 is organized to consider uptake of Pb and effects at the species level, followed by community and ecosystem level effects. Recent evidence for Pb effects on reproduction, growth and survival in terrestrial plants, invertebrates and vertebrates is summarized in Table 7-4. Alterations to reproduction, growth and survival of terrestrial organisms can lead to changes at the community and ecosystem levels of biological organization such as decreased abundance, reduced taxa richness, and shifts in species composition (Section 7.1). Soil biogeochemistry of Pb is

reviewed in Section 7.3.2. Section 7.3.3 considers the bioavailability and uptake of Pb by plants, invertebrates, and vertebrates in terrestrial systems. Biological effects of Pb on terrestrial ecosystem components including plants and lichen, invertebrates, and vertebrates (Section 7.3.4) are followed by data on exposure and response of terrestrial species (Section 7.3.5). Effects of Pb at the ecosystem level of biological organization are discussed in Section 7.3.6. Section 7.3 concludes with a discussion of critical loads in terrestrial systems (Section 7.3.7), soil screening levels (Section 7.3.8), characterization of sensitivity and vulnerability of ecosystem components (Section 7.3.9), and effects on ecosystem services (Section 7.3.10). Concentration of Pb in soil is expressed in mg Pb/kg soil, and concentration in solutions applied to soil or extracted from soil is expressed in mg Pb/L solution.

7.3.2 Soil Biogeochemistry and its Influence on Bioavailability

According to data presented in the 2006 Pb AQCD (U.S. EPA, 2006b), the fraction of soil metal that is directly available to plants is the fraction found in soil pore water, even though the concentration of metals in pore water is generally small relative to bulk soil concentration. At any given bulk soil concentration, the amount of Pb dissolved in soil solution is controlled by at least six variables: (1) solubility equilibria; (2) adsorption-desorption relationship of total Pb with inorganic compounds (e.g., oxides of Al, Fe, Si, Mn; clay minerals); (3) adsorption-desorption reactions of dissolved Pb phases on soil organic matter; (4) pH; (5) cation exchange capacity (CEC); and (6) aging. Adsorption-desorption of Pb to soil solid phases is largely controlled by total metal loading. Therefore, areas with high Pb deposition will exhibit a lower fraction of total Pb partitioned to inorganic and organic matter. Decreasing soil pH, CEC, and organic matter have been strongly correlated to increases in the concentration of dissolved Pb species. Aging of metals in soils results in decreased amounts of labile metal as the Pb becomes incorporated into the soil solid phase (McLaughlin et al., 2010). Data from recent studies have further defined the impact of pH, CEC, organic matter (OM), and aging on Pb mobilization and subsequent bioavailability in soils.

7.3.2.1 pH, CEC and Salinity

Models of metal bioavailability calibrated from 500+ soil toxicity tests on plants, invertebrates, and microbial communities indicated that soil pH and CEC are the most important factors governing both metal solubility and toxicity (Smolders et al., 2009). The variability of derived EC_{50} values was most closely associated with CEC. Smolders et al. (2007) determined that 12 to 18 months of artificial aging of soils amended with

metal decreased the soluble metal fraction by approximately one order of magnitude. Relatedly, lower soil pH in forest environments relative to adjacent agricultural land resulted in higher solubility, and the mobility of smelter-produced metals was found to be greater in forest than in agricultural lands (Douay et al., 2009). Further, decreasing the soil pH via simulated acid rain events increased naturally occurring Pb bioavailability in field tests (Hu et al., 2009b). Miretzky et al. (2007) also showed that the concentration of mobile Pb was increased in acidic soils, and discovered that Pb adsorption to sandy loam clay was a function of weak electrostatic bonds with charged soil surfaces and was influenced by Fe and Mn oxide. Dayton et al. (2006) and Bradham et al. (2006) used path analysis to help identify the main determinants of both organism Pb content and responses from among multiple soil characteristics. In parallel studies with lettuce and earthworms, they amended an array of 21 soils with varying characteristics with the same amount of Pb (2,000 mg /kg as Pb nitrate), and found that in lettuce, the main determinant of both accumulation and biological responses was OC, with contribution from pH and Fe/Al oxides. These later characteristics only influenced accumulation and responses through their own impact on CEC. In earthworms, the main determinant of accumulation was pH, with contribution from CEC, but only through its association with other variables including OC, Fe/Al oxides, and pH. The main determinant of reproductive effects in earthworms was Fe/Al oxides, while pH drove differential mortality between the various soils.

Salinity can also alter Pb mobility and bioavailability in soils. Application of $CaCl_2$, MgCl, or NaCl salts to field-collected soils containing 31 to 2,764 mg Pb/kg increased the proportion of mobile metal. As the strength of the salt application was increased from 0.006 to 0.3 M, the proportion of released Pb increased from less than 0.5% to over 2% for $CaCl_2$ and from less than 0.5% to over 1% for MgCl (Acosta et al., 2011). However, the majority of salinity-induced effects occurred in soils containing less than 500 mg Pb/kg, and the proportion of released Pb decreased with increasing total soil Pb concentrations. In addition, the authors noted that Pb release from soils under increasing salinity was reduced at higher carbonate concentrations, indicating that the effect of soil salinity on Pb release is dependent on still other soil factors. A sequential extraction procedure was employed by Ettler et al. (2005) to determine the relative bioavailability of different Pb fractions present in soils collected from a mining and smelting area in the Czech Republic. Five Pb fraction categories were identified: (Fraction A) exchangeable, (Fraction B) acid extractable (bound to carbonates), (Fraction C) reducible (bound to Fe and Mn oxides), (Fraction D) oxidizable (complexed with organic carbon), and (Fraction E) residual (silicates). Tilled agricultural soils were found to have decreased Pb, likely as a result of repeated cultivation, with the majority of Pb represented as the reducible Fraction C. Pb concentration in undisturbed forest soils, however, was largely present as the exchangeable fraction (A), weakly bound to soil OM. However, the validity of

associating sequentially extracted fractions with discrete geochemical components has not been definitively established, and as a consequence, the association between fractionation and bioavailability remains uncertain.

7.3.2.2 Organic Matter

Organic matter decreases bioavailability of Pb, but as it is turned over and broken down, pedogenic minerals become more important in Pb sequestration (Schroth et al., 2008). Shaheen and Tsadilas (2009) noted that soils with higher clay content, organic matter, total calcium carbonate equivalent, and total free sesquioxides also exhibited higher total Pb concentration, indicating that less Pb had been taken up by resident plant species. Huang et al. (2008) examined the re-mobilization potential of Pb in forest soils, and determined that mobilization of total Pb was strongly associated with dissolved organic matter (DOM). Groenenberg et al. (2010) used a non-ideal competitive adsorption Donnan model to explain the variability of organic matter binding affinity and uncertainties associated with metal speciation. They found that natural variations in fulvic acid binding properties were the most important variable in predicting Pb speciation. Guo et al. (2006b) determined that the -COOH and -OH groups associated with soil OM were important factors in Pb sequestration in soil, and Pb sorption was increased as pH was raised from 2 to 8. Because organic content increased the Pb sequestration efficiency of soils, OM content had an inhibitory effect on Pb uptake by woodlouse species *Oniscus asellus* and *Porcellio scaber* (Gál et al., 2008). Vermeulen et al. (2009) demonstrated that invertebrate bioaccumulation of Pb from contaminated soils was dependent on pH and OM, but that other unidentified habitat-dependent factors also contributed. The relationship of bioaccumulation and soil concentration was modified by pH and OM, and also by habitat type. Kobler et al. (2010) showed that the migration of atmospherically deposited Pb in soil matrices was strongly influenced by soil type, indicating that certain soil types may retain Pb for longer periods of time than others. In soils characterized by well-drained substrate and limestone bedrock, Pb concentration decreased over time, likely as a result of water drainage and percolation. The authors contrasted this observation with reports of prolonged residence time in humic soils, particularly at the lower depths of the humus layer. They theorized that the most significant Pb migration route was transportation of particulate-bound Pb along with precipitation-related flow through large soil pores.

A number of recent laboratory studies have further defined the relationship of soil biogeochemical characteristics and Pb uptake by plants. As noted above, Dayton et al. (2006) found through path analysis that the main determinant of both accumulation and biological responses in lettuce grown on amended soil was OC. As part of a metal

partitioning study, Kalis et al. (2007) determined that not only did metal concentration in the soil solution decrease as pH increased, but pH-mediated metal adsorption at the root surface of *Lolium perenne* determined root Pb concentration, with concentration in the shoot correlated with root concentration. Interestingly, Kalis et al. (2007) and Lock et al. (2006) also observed that the influx of Pb in the water-soluble fraction had an impact on soil pH. In addition, 1 µM humic acid decreased root Pb concentration in *L. perenne* plants grown in 0.1 and 1 µM Pb solution, likely as a result of Pb complexation and sequestration with the added OM (Kalis et al., 2006). Ma et al. (2010) also reported that long-term agricultural cultivation can decrease the rate of Pb desorption in soil through a gradual OM-enrichment. Phosphorous soil amendments equivalent to 35 mg P/kg soil were observed to reduce the quantity of DPTA-extractable Pb from an average of 19 and 24 mg Pb/kg in unamended soils to 12 to 15 mg Pb/kg in P-amended soils. As a result, maize and soybean seedlings accumulated significantly less Pb: average concentrations in soybean shoot and root ranged from 4.4 to 5.2 mg Pb/kg with P addition (versus 9.21 mg Pb/kg without), while maize shoot concentrations average between 4.8 to 5.3 mg Pb/kg in P-amended soils (as compared with 10.16 mg Pb/kg in controls) (Xie et al., 2011).

7.3.2.3 Aging

Smolders et al. (2007) defined aging as the process responsible for decreasing the bioavailability of metals in soils independently of their persistence. Smolders et al. (2009) reviewed the effects of aging of Pb in soils on the toxicity of Pb to plants and soil invertebrates, with aging achieved in most studies primarily by leaching amended soil, but also through natural binding and complexation. In nearly half of the Pb soil studies reviewed, responses that were observed with freshly amended soil could no longer be detected following soil leaching, indicating that aged soils likely contain less bioavailable Pb. The authors concluded that competitive binding between soil ligands and biotic ligands on plant roots or invertebrate guts can be used to model the relationship of observed availability and toxicity of metals in soils. Because this concept is the basis of the Biotic Ligand Model (BLM) (Section 7.3.3), the authors proposed a terrestrial BLM approach to estimate the risk of metals to terrestrial organisms. However, Antunes et al. (2006) noted that there were several key challenges involved in development of a terrestrial BLM applicable to plants, particularly the reliable measurement of free ion activities and ligand concentration in the rhizosphere, the identification of the organisms' ligands associated with toxicity, and the possible need to incorporate kinetic dissolution of metal-ligand complexes as sources of free ion. Further, Pb in aged field soils has been observed to be less available for uptake into terrestrial organisms, likely as a result of increased sequestration within the soil particles (Antunes et al., 2006). Magrisso et al.

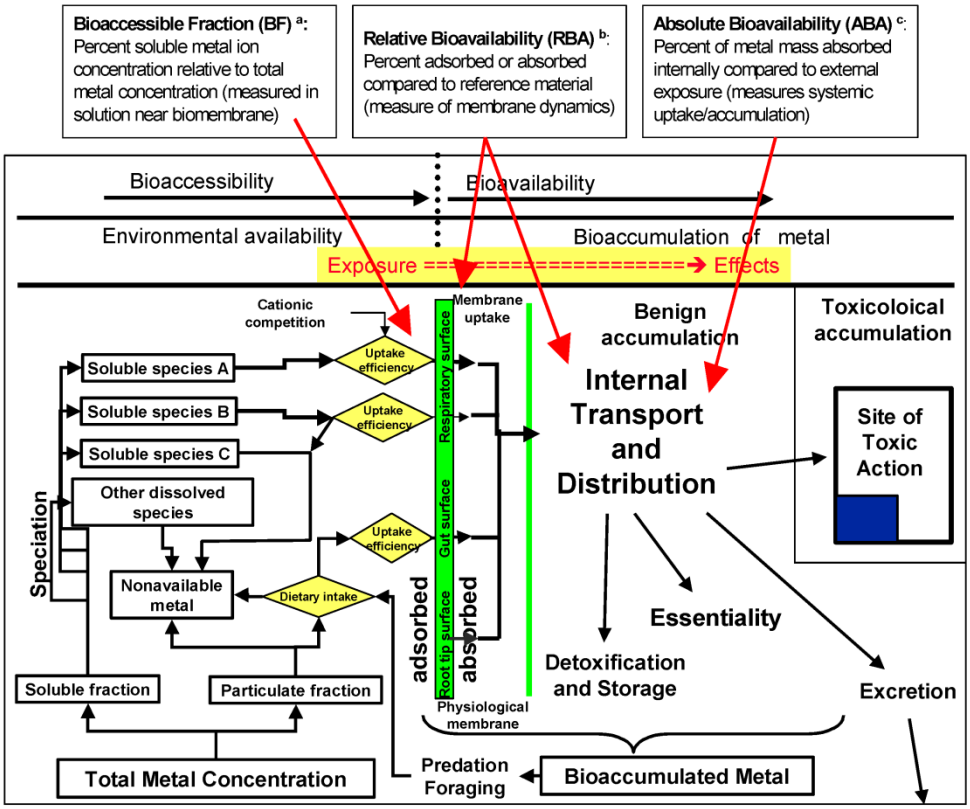
(2009) used a bioluminescent strain of the bacterium *Cupriavidus metallidurans* to detect and quantify Pb bioavailability in soils collected adjacent to industrial and highway areas in Jerusalem, Israel, and in individual simulated soil components freshly spiked with Pb. The bacterium was genetically engineered to give off the bioluminescent reaction as a dose-dependent response, and was inoculated in soil slurries for three hours prior to response evaluation. Spiked soil components induced the bioluminescent response, and field-collected components did not. However, the comparability of the simulated soils and their Pb concentration with the field-collected samples was not entirely clear. Lock et al. (2006) compared the Pb toxicity to springtails (*Folsomia candida*) from both laboratory-spiked soils and field-collected Pb-contaminated soils of similar Pb concentrations. Total Pb concentrations of 3,877 mg Pb/kg dry weight and higher always caused significant effects on *F. candida* reproduction in the spiked soils. In field soils, only the soil with the highest Pb concentration of 14,436 mg Pb/kg dry weight significantly affected reproduction. When expressed as soil pore-water concentrations, reproduction was never significantly affected at Pb concentrations of 0.5 mg Pb/L, whereas reproduction was always significantly affected at Pb concentrations of 0.7 mg Pb/L and higher, independent of the soil treatment. Leaching soils prior to use in bioassays had only a slight effect on Pb toxicity to resident springtails, suggesting that among the processes that constitute aging of Pb in field soils, leaching is not particularly important with respect to bioavailability.

Red-backed salamanders (P*lethodon cinereus*) exposed to Pb-amended soils (553 mg Pb/kg, 1,700 mg Pb/kg, 4,700 mg Pb/kg, and 9,167 mg Pb/kg) exhibited lowered appetite and decreased white blood cell counts at the two highest concentrations, as compared to controls (Bazar et al., 2010). However, salamanders tolerated field-collected, aged soils containing Pb concentration of up to 16,967 mg Pb/kg with no significant deleterious effects.

In summary, studies published during the past 5 years continue to substantiate the important role that soil geochemistry plays in sequestration or release of Pb. Soil pH and CEC have long been known to be the primary controlling factors of the amount of bioavailable Pb in soils, and a recent review of more than 500 studies corroborates these findings (Smolders et al., 2009). Fe and Mn oxides are now known to also play an important role in Pb sequestration in soils. Pb binds to OM, although relatively weakly, and as the OM is broken down the Pb may be released into soil solution. Leaching of metal through soil pores may be the primary route for loss of bioavailable soil Pb; OM may reduce leaching and thus appear to be associated with Pb sequestration. Aging of Pb in soils (through incorporation of the metal into the particulate solid-phase of the soil) results in long term binding of the metal, and reduced bioavailability of Pb to plants and soil organisms.

7.3.3 Bioavailability in Terrestrial Systems

Bioavailability was defined in the 2006 Pb AQCD as "the proportion of a toxin that passes a physiological membrane (the plasma membrane in plants or the gut wall in animals) and reaches a target receptor (cytosol or blood)" (U.S. EPA, 2006c). In 2007, EPA took cases of bioactive adsorption into consideration and revised the definition of bioavailability as "the extent to which bioaccessible metals absorb onto, or into, and across biological membranes of organisms, expressed as a fraction of the total amount of metal the organism is proximately exposed to (at the sorption surface) during a given time and under defined conditions" (U.S. EPA, 2007c). The bioavailability of metals varies widely depending on the physical, chemical, and biological conditions under which an organism is exposed (U.S. EPA, 2007c). Characteristics of the toxicant itself that affect bioavailability are: (1) chemical form or species, (2) particle size, (3) lability, and (4) source. The bioavailability of a metal is also dependent upon the fraction of metal that is bioaccessible. As stated in the Framework for Metals Risk Assessment (U.S. EPA, 2007c), the bioaccessible fraction of a metal is the portion (fraction or percentage) of environmentally available metal that actually interacts at the organism's contact surface and is potentially available for absorption or adsorption by the organism. The Framework states that "the bioaccessibility, bioavailability, and bioaccumulation properties of inorganic metals in soil, sediments, and aquatic systems are interrelated and abiotic (e.g., organic carbon) and biotic (e.g., uptake and metabolism). Modifying factors determine the amount of an inorganic metal that interacts at biological surfaces (e.g., at the gill, gut, or root tip epithelium) and that binds to and is absorbed across these membranes. A major challenge is to consistently and accurately measure quantitative differences in bioavailability between multiple forms of organic metals in the environment." A conceptual diagram presented in the Framework for Metals Risk Assessment (U.S. EPA, 2007c) summarizes metals bioavailability and bioaccumulation in aquatic, sediment and soil media (Figure 7-2).



[a]BF is most often measured using in vitro methods (e.g., artificial stomach), but it should be validated by in vivo methods.
[b]RBA is most often estimated as the relative absorption factor, compared to a reference metal salt (usually calculated on the basis of dose and often used for human risk, but it can be based on concentrations).
[c]ABA is more difficult to measure and used less in human risk; it is often used in ecological risk when estimating bioaccumulation or trophic transfer.

Figure 7-2 Conceptual diagram for evaluating bioavailability processes and bioaccessibility for metals in soil, sediment, or aquatic systems.

The BLM attempts to integrate the principal physical and chemical variables that influence Pb bioavailability. The model considers the reactions of Pb with biological surfaces and membranes (the site of action) to predict the bioavailability and uptake of the metal (Figure 7-3), and integrates the binding affinities of various natural ligands and the biological uptake rates of organisms to predict both the bioaccessible and bioavailable fraction of Pb in the environment, and to determine the site-specific toxicity of the bioavailable fraction. In principle, the BLM can be used for determining toxicity in water, sediment, and soil media, however, the parameter values that influence BLM are, in general, characterized to a greater extent in aquatic systems than in terrestrial systems (Section 7.4.4).

Figure 7-3 Schematic diagram of the biotic ligand model.

New information on sources of Pb in terrestrial ecosystems, and their influence on subsequent bioavailability, was reviewed in Chapter 3, while new information on the influence of soil biogeochemistry on speciation and chemical lability was presented in Section 7.3.2. This section summarizes recent literature on uptake and subsequent presence of Pb in tissues. The 2006 Pb AQCD (U.S. EPA, 2006b) extensively reviewed the methods available for quantitative determination of the mobility, distribution, uptake, and fluxes of atmospherically delivered Pb in ecosystems, and they are not reviewed in this section. The 2006 Pb AQCD also reported bioaccumulation factors (BAF) and bioconcentration factors (BCF). BAF is defined as the field measurement of metal concentration in tissues, including dietary exposures, divided by metal concentration in environmental media (Smolders et al., 2007). BCF is defined as the same measurement carried out in artificial media in the laboratory that does not include dietary exposure (Smolders et al., 2007). The EPA Framework for Metals Risk Assessment states that the latest scientific data on bioaccumulation do not currently support the use of BCFs and BAFs when applied as generic threshold criteria for the hazard potential of metals (U.S. EPA, 2007c).

7.3.3.1 Terrestrial Plants

At the time of the 1977 Pb AQCD, it was understood that Pb uptake in plants was influenced by plant species and by the available Pb pool in the soils (U.S. EPA, 1977). The role of humic substances in binding Pb was better characterized by the 1986 Pb AQCD where it was stated that most plants cannot survive in soil containing 10,000 µg Pb/g (mg Pb/kg) dry weight if the pH is below 4.5 and the organic content is below 5% (U.S. EPA, 1986b). At the time of the 1986 AQCD , it was thought that Pb can be absorbed across the leaf surface into internal plant tissues, but that the vast majority of uptake is via roots (U.S. EPA, 1986b). The 2006 Pb AQCD (U.S. EPA, 2006b) noted that terrestrial plants accumulate atmospheric Pb primarily via two routes: direct stomatal uptake into foliage, and incorporation of atmospherically deposited Pb from soil into root tissue, followed by variable translocation to other tissues. Foliar Pb may include both incorporated Pb (i.e., from atmospheric gases or particles) and surficial particulate Pb deposition. Although the plant may eventually absorb the surficial component, its main importance is its likely contribution to the exposure of plant consumers. This section will first review recent studies on uptake of Pb by plants through foliar and soil routes, and their relative contribution, followed by the consideration of translocation of Pb from roots to shoots, including a discussion of variability in translocation among species. Data on ambient Pb levels associated with vegetation are summarized in Section 3.6.6.

Leaf and Root Uptake

Although Pb is not an essential metal, it is taken up from soils through the symplastic route, the same active ion transport mechanism used by plants to take up water and nutrients and move them across root cell membranes (U.S. EPA, 2006c). As with all nutrients, only the proportion of a metal present in soil pore water is directly available for uptake by plants. In addition, soil-to-plant transfer factors in soils enriched with Pb have been found to better correlate with bioavailable Pb soil concentration, defined as DTPA-extractable Pb, than with total Pb concentration (U.S. EPA, 2006c). Since the publication of the 2006 Pb AQCD, suggestive evidence has become available that a substantial proportion of Pb accumulated in shoots of some species of trees originates in direct leaf uptake of atmospheric Pb. Evidence for such direct uptake is weaker in herbaceous plants, and all data came from near stationary sources.

Field studies carried out in the vicinity of Pb smelters have determined the relative importance of direct foliar uptake and root uptake of atmospheric Pb deposited in soils. Hu and Ding (2009) analyzed ratios of Pb isotopes in the shoots of commonly grown vegetables and in soil at three distances from a smelter (0.1, 0.2, 5.0 km). Pb isotope ratios in plants and soil were different at two of those locations, leading the authors to the

conclusion that airborne Pb was being assimilated via direct leaf uptake. Soil Pb concentration in the rhizosphere at the three sites ranged between 287 and 379 mg Pb/kg (Site I), 155 and 159 mg Pb/kg (Site II), and 58 and 79 mg Pb/kg (Site III, selected as the control site). The median shoot and root Pb concentrations at each site were 36 and 47 mg Pb/kg, 176 and 97 mg Pb/kg, and 1.3 and 7 mg Pb/kg, respectively, resulting in shoot:root Pb ratios exceeding 1.0 in Site I (for Malabar spinach [*Basella alba*], ratio = 1.6, and amaranth [*Amaranthus spinosus*], ratio = 1.1), and in Site II (for the weeds *Taraxacum mongolicum*, ratio = 1.9, and *Rostellaria procumbens*, ratio = 1.7). However, the two species studied at Site II were not studied at Site I or Site III. In the control site (Site III), no plant was found with a Pb shoot:root ratio greater than 1.0. Hu and Ding (2009) concluded that metal accumulation was greater in shoot than in root tissue, which suggested both high atmospheric Pb concentration and direct stomatal uptake into the shoot tissue.

Cui et al. (2007) studied seven weed species growing in the vicinity of an old smelter (average soil Pb concentration of 4,020 mg Pb/kg) in Liaoning, China, to measure Pb accumulation rates in roots and shoots. Cutleaf groundcherry (*Physalis angulata*) accumulated the most Pb, with root and shoot concentration of 527 and 331 mg Pb/kg, respectively, and velvetleaf (*Abutilon theophrasti*) was the poorest absorber of Pb (root and shoot concentration of 39 and 61 mg Pb/kg, respectively). In all cases, weed species near the smelter accumulated more Pb than plants from non-polluted environments (5 mg Pb/kg), indicating that aerially deposited Pb produced by smelting is bioavailable to plants. However, the ratio of root:shoot Pb concentration varied by species, and the authors presented no data to differentiate Pb taken up from soil from Pb incorporated via foliar uptake. Angelova et al. (2010) examined Pb uptake by rapeseed plants (*Brassica napus*) grown in heavy metal contaminated soils 0.5 km and 15 km from the Non-Ferrous Metal Works, in Bulgaria. Average surface soil Pb concentration decreased with distance from the plant (200.3 and 24.6 mg Pb/kg, respectively), as did average DTPA-extractable Pb (69.7 and 4.9 mg Pb/kg, respectively). Pb content in stems and leaves in rapeseed grown at 0.5 km from the plant averaged 1.73 and 8.69 mg Pb/kg ; average stem and leaf Pb concentrations in rapeseed grown at the more distant location were reported as 0.72 and 1.42 mg Pb/kg, respectively (Angelova et al., 2010).

Pb plant BAFs for plants grown in 70 actively cropped fields in California averaged 0.052 for vegetable crops and 0.084 for grains; the highest reported Pb BAF (0.577) was found in onions. Authors compared the BAFs based on total Pb and Pb in solution and determined that both were accurate predictors of plant uptake (Chen et al., 2009b). Likewise, Zhang et al. (2011b) compiled Pb uptake data for several crop species in China, and reported an average BAF for grains (rice) of 0.009 (0.0009-0.03) and 0.41(0.0007-0.17) for leafy vegetables, such as spinach, Chinese cabbage and celery

(Zhang et al., 2011b). Chrastny et al. (2010) characterized the Pb contamination of an agricultural soil in the vicinity of a shooting range. Pb was predominantly in the form of PbO and $PbCO_3$, and Pb was taken up by plants through both atmospheric deposition onto the plant and by root uptake.

The Pb content of ripe date palm (*Phoenix dactylifera*) fruit collected in Riyadh, Saudi Arabia was determined to be indicative of areas of heavy industrialization and urbanization; Pb concentrations in fruit flesh ranged from 0.34 to 8.87 mg Pb/kg dry weight, with the highest Pb date concentrations detected near freeways and industrial areas (Aldjain et al., 2011). Likewise, Pb concentrations in rosemary (*Rosmarinus officinalis*) flowers, stems, and leaves were significantly higher in the urban areas of Al-Mafraq and Irbid, Jordan than in the smaller town of Ma'an, Jordan (53.6 to 86.5 mg Pb/kg versus 16.2 to 16.7 mg Pb/kg). Authors noted a significant difference between Pb concentrations in washed and unwashed rosemary samples, indicating that aerial deposition and surface dust is likely a significant source of plant-associated Pb (El-Rjoob et al., 2008).

Bilberry (*Vaccinium myrtillus*), accumulated the highest amount of Pb out of four total herbaceous species growing in Slovakian spruce ecosystems with variable soil Pb concentrations, giving BAFs of 0.09 to 0.44, depending on location (Kuklova et al., 2010). Because of their long life spans, trees can provide essential information regarding the sources of bioavailable Pb. A Scots pine forest in northern Sweden was found to incorporate atmospherically derived Pb pollution directly from ambient air, accumulating this Pb in bark, needles, and shoots (Klaminder et al., 2005). Nearly 50% of total tree uptake was estimated to be from direct adsorption from the atmosphere, as determined using isotopic ratios and a binary mixing model. Further, Aznar et al. (2009a) found that the Pb content of black spruce (*Picea mariana*) needles collected along a metal contamination gradient emanating from a Canadian smelter in Murdochville, Quebec, showed a significant decrease in Pb concentration with increasing distance from the smelter. Interestingly, older needles were determined to accumulate larger quantities of Pb than younger ones. Foliar damage and growth reduction were also observed in the trees (Aznar et al., 2009a). They were significantly correlated with Pb concentration in the litter layer. In addition, there was no correlation between diminished tree growth and Pb concentration in the deeper mineral soil layers, strongly suggesting that only current atmospheric Pb was affecting trees (Aznar et al., 2009b). Similarly, Kuang et al. (2007) noted that the Pb concentration in the inner bark of *Pinus massoniana* trees growing adjacent to a Pb-Zn smelter in the Guangdong province of China was much higher (1.87 mg Pb/kg dry weight) than in reference-area trees. Because concentration in the inner bark was strongly correlated with concentration in the outer bark, they concluded that the origin of the Pb was atmospheric.

Dendrochronology (tree ring analysis) has become an increasingly important tool for measuring the response of trees to Pb exposure (Watmough, 1999). Tree ring studies reviewed in the 1977 Pb AQCD showed that trees could be used as indicators of increasing environmental Pb concentrations with time. Additional studies in the 1986 Pb AQCD indicated that Pb could be translocated from roots to the upper portions of the plant and that the amounts translocated are in proportion to concentrations of Pb in soil (U.S. EPA, 1986b). The advent of laser ablation inductively coupled plasma mass spectrometry has made measurement of Pb concentration in individual tree rings possible (Witte et al., 2004; Watmough, 1999). This allows for close analysis of the timing of Pb uptake relative to smelter activity and/or changes in soil chemistry. For example, Aznar et al. (2008a) measured Pb concentration in black spruce tree rings to determine the extent and timing of atmospheric deposition near the Murdochville smelter. Variability in tree-ring Pb content seemed to indicate that trees accumulated and sequestered atmospheric Pb in close correlation with the rates of smelter emission, but that sequestration lagged about 15 years behind exposure. However, the ability to determine time of uptake from the location in growth rings is weakened in species that transfer Pb readily from outer bark to inner bark. Cutter and Guyette (1993) identified species with minimal radial translocation from among a large number of tree species, and recommended the following temperate zone North American species as suitable for metal dendrochronology studies: white oak (*Quercus alba*), post oak (*Q. stellata*), eastern red cedar (*Juniperus virginiana*), old-growth Douglas fir (*Pseudotsuga menziesii*), and big sagebrush (*Artemisia tridentata*). In addition, species such as bristlecone pine (Pinus aristata), old-growth redwood (*Sequoia sempervirens*), and giant sequoia (*S. gigantea*) were deemed suitable for local purposes. Patrick and Farmer (2006) determined that European sycamore (*Acer pseudoplatanus*) are not suitable for this type of dendrochronological analysis because of the formation of multiple annual rings.

Pb in sapwood and heartwood is more likely a result of soil uptake than of direct atmospheric exposure (Guyette et al., 1991). Differentiation of geogenic soil Pb in tree tissue from Pb that originated in the atmosphere requires measurement of stable Pb isotope ratios (Patrick, 2006). Tree bark samples collected from several areas of the Czech Republic were subjected to stable Pb isotope analysis to determine the source and uptake of atmospheric Pb (Conkova and Kubiznakova, 2008). Results indicated that beech bark is a more efficient accumulator of atmospheric Pb than spruce bark. A decrease in the $^{206}Pb/^{207}Pb$ ratio was measured in bark and attributed to increased usage of leaded gasoline between 1955 and 1990; an increased $^{206}Pb/^{207}Pb$ ratio was ascribed to coal combustion (Conkova and Kubiznakova, 2008). Similarly, Savard et al. (2006) compared isotope ratios of $^{206}Pb/^{207}Pb$ and $^{208}Pb/^{206}Pb$ in tree rings from spruce trees sampled at a control site near Hudson Bay, with those sampled near the Horne smelter active since 1928, in Rouyn-Noranda, Canada. The concentration of total Pb showed a

major increase in 1944 and a corresponding decrease of the $^{206}Pb/^{207}Pb$ ratios, suggesting that the smelter was responsible for the increased Pb uptake (Savard et al., 2006). The authors suggested that the apparent delay of 14 years may have been attributable to the residence time of metals in airborne particles the buffering effect of the soils and, to a lesser extent, mobility of heavy metals in tree stems. Furthermore, through the use of the two different isotope ratios, Savard et al. (2006) were able to differentiate three types of Pb in tree rings: natural (derived from the mineral soil horizons), industrial (from coal burning urban pollution), and mining (typical of the volcanogenic massive sulfide ore deposits treated at the Horne smelter).

Devall et al. (2006) measured Pb uptake by bald-cypress trees (*Taxodium distichum*) growing in a swamp near a petroleum refinery and along a bank containing Pb-contaminated dredge spoils. They measured Pb in tree cores and showed greater uptake of Pb by trees in the swamp than by trees growing on the dredge spoil bank, attributing the difference to exposure source (refinery versus dredge spoils) and differences in soil chemistry between the swamp and the dredge spoil bank (Devall et al., 2006). Similarly, Gebologlu et al. (2005) found no correlation between proximity to roadway and accumulated Pb in tomato and bean plants at sites adjacent to two state roads in Turkey (average Pb concentration 5.4 and 6.0 mg Pb/kg), indicating that uptake may be influenced by multiple factors, including wind direction, geography, and soil chemistry. Average Pb levels in leaves were 0.6 and 0.5 mg Pb/kg for tomato and bean plants, respectively, while fruit concentration averaged 0.4 mg Pb/kg for both species. Conversely, if foliar contamination is due primarily to dust deposition, distance from a source such as a road may be easily correlated with Pb concentration on the plants. For example, Ai-Khlaifat and Al-Khashman (2007) collected unwashed date palm (*Phoenix dactylifera*) leaves at 3-meter trunk height from trees in Jordan to assess the extent of Pb contamination from the city of Aqaba. Whereas relatively low levels of Pb were detected in leaves collected at background sites (41 mg Pb/kg), leaves collected adjacent to highway sites exhibited the highest levels of Pb (177 mg Pb/kg). The authors determined that Pb levels in date palm leaves correlated with industrial and human activities (e.g., traffic density) (Ai-Khlaifat and Al-Khashman, 2007). Likewise, Pb concentrations were significantly enriched in tree bark samples and road dust collected in highly urbanized areas of Buenos Aires, Argentina (approximate average enrichment factors of 30 and 15 versus reference samples) (Fujiwara et al., 2011). However, decreases in tissue Pb concentration with increasing distance from stationary sources can also follow from decreasing Pb in soil. Bindler et al. (2008) used Pb isotopes to assess the relative importance of pollutant Pb versus natural Pb for plant uptake and cycling in Swedish forested soils. The Pb isotopic composition of needles/leaves and stemwood of different tree species and ground-cover plants indicated that the majority of Pb present in these plant components was derived from the atmosphere, either through aerial interception or

actual uptake through the roots. For the ground-cover plants and the needles/leaves, the $^{206}Pb/^{207}Pb$ isotopic ratios (1.12 to 1.20) showed that the majority of Pb was of anthropogenic origin. Stemwood and roots have higher $^{206}Pb/^{207}Pb$ ratio values (1.12 to 1.30) which showed the incorporation of some natural Pb as well as anthropogenic Pb. For pine trees, the isotopic ratio decreased between the roots and the apical stemwood suggesting that much of the uptake of Pb by trees is via aerial exposure. Overall, it was estimated that 60-80% of the Pb in boreal forest vegetation originated from pollution; the Pb concentrations were, however, quite low – not higher than 1 mg Pb/kg plant material, and usually in the range of 0.01-0.1 mg Pb/kg plant material (while soils had a range of 5 to 10 mg Pb/kg in the mineral horizons and 50 to 150 mg Pb/kg in the O horizons). Overall, the forest vegetation recycles very little of the Pb present in soils (and thus does not play a direct role in the Pb biogeochemical cycle in boreal forest soils).

Fungal species, as represented by mushrooms, accumulate Pb from soils to varying degrees. Based on the uptake of naturally occurring ^{210}Pb, Guillen et al. (2009) established that soil-associated Pb was bioavailable for uptake by mushrooms, and that the highest ^{210}Pb accumulation was observed in *Fomes fomentarius* mushrooms, followed by *Lycoperdon perlatum*, *Boletus aereus*, and *Macrolepiota procera*, indicating some species differences. Benbrahim et al. (2006) also showed species differences in uptake of Pb by wild edible mushrooms, although they found no significant correlations between Pb content of mushrooms and soil Pb concentration. Pb concentrations in mushroom carpophores ranged from 0.4 to 2.7 mg Pb/kg from sites with soil concentrations ranging from 3.6 and 7.6 mg Pb/kg dry soil. Likewise, Semreen and Aboul-Enein (2011), reported the heavy metal uptake of wild edible mushrooms collected in various mountainous regions of Jordan. Pb BCFs ranged between 0.05 *(Russula delica*) and 0.33 (*Bovista plumbea)* for six mushroom species. Pb BAFs for edible mushrooms collected from quartzite acidic soils in central Spain (containing 19.2 mg Pb/kg) ranged from 0.07 (*Macrolepiota procera*) to 0.45 (*Lepista nuda*) (Campos and Tejera, 2011).

Translocation and Sequestration of Pb in Plants

In the 1977 Pb AQCD it was recognized that most Pb taken up from soil remains in the roots and that distribution to other portions of the plant is variable among species (U.S. EPA, 1977). The 2006 Pb AQCD (U.S. EPA, 2006b) stated that most of the Pb absorbed from soil remains bound in plant root tissues either because (1) Pb may be deposited within root cell wall material, or (2) Pb may be sequestered within root cell organelles. More recent research largely confirms that Pb taken up from soil largely remains in roots, but suggests that some species translocate meaningful amounts into shoot tissue. Sequestration of Pb may be a protective mechanism for the plant. Recent findings have been consistent with this hypothesis: Han et al. (2008) observed Pb deposits in the cell

walls and cytoplasm of malformed cells of *Iris lactea* exposed to 0 to 10 mM Pb (0 to 2,072 mg Pb/L) solution in sand culture for 28 days. They hypothesized that preferential sequestration of Pb in a few cells, which results in damage to those cells, helps in maintaining normal overall plant activities through the sacrifice of a small number of active cells. Similarly, macroscopic analysis of the roots of broad bean (*Vicia faba*) cultivated in mine tailings (average Pb concentration of 7,772 mg Pb/kg) by Probst et al. (2009) revealed dark ultrastructural abnormalities that were demonstrated to be metal-rich particles located in or on root cell walls. It is unclear whether the presence of these structures had any effect on overall plant health.

Clark et al. (2006) investigated Pb bioavailability in garden soils in Roxbury and Dorchester, MA. The sources of Pb were considered to be Pb from paints and from leaded gasoline additives, with 40 to 80% coming from paint. The average Pb concentration in foliar tissue of bean plants was 14 ± 5 mg Pb/kg while the concentration in the bean pod was only 20.6 mg Pb/kg. For mustard plants, there was a linear relationship (R^2=0.85) between Pb concentration in plant tissues and Pb concentration in the soil (both for plants grown in situ and those grown under greenhouse conditions).

Murray et al. (2009) investigated the uptake and accumulation of Pb in several vegetable species (carrot [*Daucus carota*], radish [*Raphanus sativus*], lettuce [*Lactuca sativa*], soybean [*Glycine max*], and wheat [*Triticum aestivum*]) from metal-contaminated soils, containing 10 to 40 mg Pb/kg and demonstrated that most Pb remained in the roots. No Pb was measured in the above-ground edible soybean and wheat tissues, while carrots, the most efficient accumulator of Pb, contained a maximum Pb tissue concentration of 12 mg Pb/kg dry mass. Similarly, (Cho et al., 2009) showed that green onion (*Allium fistulosum*) plants also take up little Pb when planted in soil spiked with Pb nitrate. No plant tissues contained a Pb concentration greater than 24 mg Pb/kg when grown for 14 weeks in soils of up to 3,560 mg Pb/kg, and the majority of bioavailable Pb was determined to be contained within the roots. Chinese spinach (*Amaranthus dubius*) also translocates very little Pb to stem and leaf tissue, and uptake from Pb-containing soils (28 to 52 mg Pb/kg) is minimal (Mellem et al., 2009). Wang et al. (2011c) determined tissue-specific BCFs for wheat grown in soils containing 93 to 1,548 mg Pb/kg. Although the average calculated root BCF was 0.3, very little Pb was translocated to shoots (average BCF=0.02), shells (0.006), and kernels (0.0007) (Wang et al., 2011c). Sonmez et al. (2008) reported that Pb accumulated by three weed species (*Avena sterilis*, *Isatis tinctoria*, *Xanthium strumarium*) grown in Pb-spiked soils was largely concentrated in the root tissues, and little was translocated to the shoots (Sonmez et al., 2008).

The Pb BCFs for alfalfa (*Medicago sativa*) and crimson clover (*Trifolium incarnatum*) grown in mixtures of heavy metals (Pb concentrations of 10 to 500 µg Pb/kg) were reportedly low. For alfalfa, BCFs ranged from 0.02 to 0.12, while for crimson clover, these values were between 0.04 and 0.06 (Comino et al., 2011). The low shoot-root translocation factors reported for alfalfa (0.17 to 0.43) indicated that plant Pb content was largely contained in root tissue. Businelli et al. (2011) calculated whole-plant Pb BAFs for lettuce, radish, tomato and Italian ryegrass using Pb-spiked soils (average values of 0.025, 0.021, 0.032, and 0.65, respectively). Again, the majority of accumulated Pb was stored in root tissue, with comparatively little translocated to above-ground tissues (Businelli et al., 2011).

Recent research has shown that Pb translocation to stem and leaf tissues does occur at significant rates in some species, including the legume *Sesbania drummondii* (Peralta-Videa et al., 2009) and buckwheat (*Fagopyrum esculentum*) (Tamura et al., 2005). Wang et al. (2006b) noted that Pb soil-to-plant transfer factors were higher for leafy vegetables (Chinese cabbage, pak-choi, and water spinach) than for the non-leafy vegetables tested (towel gourd, eggplant, and cowpea). Tamura et al. (2005) demonstrated that buckwheat is an efficient translocator of Pb. Buckwheat grown in Pb-containing soils collected from a shooting range site (average 1M HCl extractable Pb= 6,643 mg Pb/kg) preferentially accumulated Pb in leaves (8,000 mg Pb/kg) and shoots (4,200 mg Pb/kg), over root tissues (3,300 mg Pb/kg). Although plant growth was unaffected, this level of leaf and shoot accumulation is likely to have significant implications for exposure of herbivores. Similarly, Shaheen and Tsadilas (2009) reported that vegetables (pepper, okra, and eggplant) grown in soils containing 24 to 30 mg Pb/kg total Pb were more likely to accumulate Pb in leaves (range: undetected to 25 mg Pb/kg) rather than in fruits (range: undetected to 19 mg Pb/kg); however, no significant correlation between soil Pb concentration and plant tissue Pb concentration could be established (Shaheen and Tsadilas, 2009). Tobacco plants were also observed to take up significant amounts of Pb into leaf tissue. Field-grown plants in soils containing an average of 19.8 mg Pb/kg contained average lower, middle and upper leaf Pb concentrations of 11.9, 13.3, and 11.6 mg Pb/kg respectively (Zaprjanova et al., 2010). Uptake by tobacco plants was correlated with both total soil Pb concentrations and the mobile Pb fraction (average 3.8 mg Pb/kg soil).

There is broad variability in uptake and translocation among plant species, and interspecies variability has been shown to interact with other factors such as soil type. By studying multiple species in four Pb-Zn mining sites in Yunnan, China, Li et al. (2009d) demonstrated not only significant differences in uptake and translocation among the species studied, but also modification of the effect on species by type of soil. Plants sampled represented nine species from four families—Caryophyllaceae, Compositae,

Cruciferae, and Pteridaceae. Overall, soil Pb concentration averaged 3,772 mg Pb/kg dry weight, with the highest site average measured at the Minbingying site (5,330 mg Pb/kg), followed by Paomaping (2,409 mg Pb/kg), Jinding (1,786 mg Pb/kg), and Qilinkeng (978 mg Pb/kg). The highest average shoot Pb concentration (3,142 mg Pb/kg) was detected in *Stellaria vestita* (Caryophyllaceae) collected at Paomaping, while *Sinopteris grevilloides* (Pteridaceae) collected from Minbingying exhibited the lowest shoot Pb concentration (69 mg Pb/kg). A similar trend was detected in root tissues. *S. vestita* root collected from the Paomaping area contained the maximum Pb concentration measured (7,457 mg Pb/kg), while the minimum root Pb levels were measured in *Picris hieracioides* (Pteridaceae) tissues collected from Jinding. These results indicate significant interspecies differences in Pb uptake, as well as potential soil-specific differences in Pb bioavailability. *S. vestita*, in particular, was determined to be an efficient accumulator of Pb, with a maximum enrichment coefficient of 1.3. Significant correlations between soil Pb concentration and average shoot and root Pb levels were also established (Li et al., 2009d). Within plant species, the variability in uptake and translocation of Pb may extend to the varietal level. Antonious and Kochhar (2009) determined uptake of soil-associated Pb for 23 unique genotypes from four species of pepper plants (*Capsicum chinense, C. frutescens, C. baccatum,* and *C. annum*). Soil Pb concentration averaged approximately 0.6 mg Pb/kg dry soil. No Pb was detected in the fruits of any of the 23 genotypes, except two out of seven genotypes of *C. baccatum*, which had 0.9 and 0.8 mg Pb/kg dry weight Pb in fruit.

Recent studies substantiated findings from the 2006 Pb AQCD that plants store a large portion of Pb in root tissue. Pb soil-to-plant transfer factors are higher for leafy vegetables than for the non-leafy vegetables (Wang et al., 2006b) and buckwheat has recently been shown to be an efficient translocator of Pb from soil to above-ground shoots (Tamura et al., 2005).

Field studies carried out in the vicinity of Pb smelters (Hu et al., 2009b) show that Pb may accumulate in shoot tissue through direct stomatal uptake rather than by soil-root-shoot translocation. For instance, Hovmand and Johnsen (2009) determined that about 98% of Pb sequestered in Norway spruce needles and twigs was derived from atmospheric sources, and that less than 2% of Pb was translocated from the roots (Hovmand et al., 2009). Dendrochronology has become more advanced in recent years and is a useful tool for monitoring historical uptake of Pb into trees exposed to atmospheric or soil Pb. Trees accumulate and sequester atmospheric Pb in close correlation with the rate of smelter emissions, although one study indicated that sequestration can lag behind exposure from emissions by 15 years. Pb in the outer woody portion of the tree is more likely the result of direct atmospheric exposure, while Pb in

sapwood is more likely a result of soil uptake. This difference provides an important tool for analyzing source apportionment of Pb accumulation in plants (Guyette et al., 1991).

7.3.3.2 Terrestrial Invertebrates

At the time of publication of the 2006 Pb AQCD (U.S. EPA, 2006b), little information was available regarding the uptake of atmospheric Pb pollution (direct or deposited) by terrestrial invertebrate species. Consequently, few conclusions could be drawn concerning the Pb uptake rate of particular species although there was some evidence that dietary or habitat preferences may influence exposure and uptake. Recent literature indicates that invertebrates can accumulate Pb from consuming a Pb-contaminated diet and from exposure via soil, and that uptake and bioaccumulation of Pb by invertebrates is lower than that observed for other metals.

Snails

Pauget et al. (2011) reported that uptake of Pb from soil by the land snail (*Cantareus asperses*) was most significantly influenced by soil pH and organic matter, as increases in these variables were correlated to decreased Pb bioavailability. *Cantareus asperses* snails exposed to dietary Pb at 3.3, 86, and 154 mg/kg of diet (spiked with Pb sulfate) for up to 64 days were found to assimilate a significant proportion of Pb, and feeding rates were unaffected by the presence of the metal (Beeby and Richmond, 2010). While BCFs for Cd were observed to increase over the 64-day study period, the rate of Pb assimilation remained consistent over time and the authors inferred the absence of a regulatory mechanism for uptake of Pb. The authors speculated that uptake is a function of growth or cell turnover instead. *Helix aspersa* snails rapidly accumulated Pb from contaminated soil (1,212 mg Pb/kg) and from eating contaminated lettuce (approximately 90 mg Pb/kg after 16 weeks' growth on Pb-contaminated soil) during the first 2 weeks of exposure, at which point snail body burdens reached a plateau (Scheifler et al., 2006b). There were no observed effects of Pb exposure or accumulation on survival or growth in *C. asperses* or *H. aspersa*. In another study (Ebenso and Ologhobo, 2009b), juvenile *Achatina achatina* snails confined in cages on former Pb-battery waste dump sites were found to accumulate Pb from both plant and soil sources. Soil Pb concentration averaged 20, 200, and 1,200 mg Pb/kg at the three main waste sites, while leaf tissues of radish (*Raphanus sativus*) grown at these sites averaged 7, 30, and 68 mg Pb/kg dry weight, respectively. Concentration of Pb in snail tissues rose with concentration in both soil and plants, and the authors found that for both sources, a log-log relationship could be estimated with a very close fit (r^2 =0.94 and 0.95, respectively). Pb concentration in snail tissues averaged

12, 91, and 468 mg Pb/kg, respectively, at the three sites, which the authors stipulated were above the maximum permissible concentration of Pb for human consumption of mollusks, mussels, and clams (1.5 mg Pb/kg tissue) as determined by the U.K. Food Standards Agency. Pb concentration in snail tissues generally is much lower than that of the soil substrates upon which they were reared, but higher than in other soil-dwelling organisms. De Vaufleury et al. (2006) exposed *Helix aspersa* snails to standardized (International Organization for Standardization methodology [ISO 11267:1999]) artificial-substrate soils amended with sewer sludge containing 13, 26, 39, or 52 mg Pb/kg for 28 days without supplemental food. After the exposure period, snail foot tissue contained increased levels of Pb—1.9, 1.7, and 1.5 mg Pb/kg dry weight versus concentration averaging 0.4 mg Pb/kg in control organisms. Viscera also exhibited increased Pb levels at the two highest exposures, with measured tissue concentration of 1.2 and 1.1 mg Pb/kg, respectively, as compared with control tissue Pb levels of 0.4 mg Pb/kg. However, there was no significant increase in snail-tissue Pb concentration when natural soil was used in place of ISO medium, and there was no relationship between soil Pb concentration and snail tissue concentration, strongly suggesting the presence of soil variables that modify bioavailability. Notten et al. (2008) investigated the origin of Pb pollution in soil, plants, and snails by means of Pb isotope ratios. They found that a substantial proportion of Pb in both plants and snails was from current atmospheric exposure.

Finally, a study by Coeurdassier et al. (2007) found that the presence of snails was associated with higher Pb content in earthworms, suggesting that snails themselves may have an effect on bioavailability.

Earthworms

Accumulation studies conducted with *Eisenia* sp. earthworms documented the difficulty of extrapolating accumulation kinetic constants from one soil type to another, and showed that many soil physiochemical properties, including pH, organic matter, and CEC, among others, affect metal bioavailability (Nahmani et al., 2009). Source of Pb, and proportion of soil:leaf litter also affect Pb bioavailability. Bradham et al. (2006) examined the effect of soil chemical and physical properties on Pb bioavailability. *Eisenia andrei* earthworms were exposed to 21 soils with varying chemical and physical properties that were freshly spiked with Pb to give a standard concentration of 2,000 mg Pb/kg dry weight. At equivalent Pb exposure, the main determinants of both internal earthworm Pb concentration and mortality were pH first (with lower pH resulting in higher concentration and mortality), then CEC. However, the apparent importance of CEC was due to its correlation with several other less important soil characteristics. These data corroborate that Pb bioavailability and toxicity are increased in acidic soils

and in soils with a low CEC (Section 7.3.2). This finding was confirmed by Gandois et al. (2010), who determined that the free-metal-ion fraction of total Pb concentration in field-collected soils was largely predicted by pH and soil Fe content.

The role of soil profile and preferred depth was studied using eight species of earthworms from 27 locations in Switzerland, representing three ecophysiological groups (Ernst et al., 2008): epigeic (surface-dwelling worms), endogeic (laterally burrowing worms that inhabit the upper soil layers), and anecic (vertically burrowing worms that reach depths of 6 inches). For epigeic and anecic earthworms, the total concentration of Pb in leaf litter and in soil, respectively, were the most important drivers of Pb body burdens. By contrast, the level of Pb in endogeic earthworms was largely determined by soil pH and CEC. As a result of these differences, the authors suggested that atmosphere-sourced Pb may be more bioavailable to epigeic than endogeic species, because it is less dependent on modifying factors. Suthar et al. (2008), on the other hand, found higher Pb bioaccumulation in the endogeic earthworm *Metaphire posthuma* than in the anecic earthworm species *Lampito mauritii*, and speculated that differences in Pb tissue level arose from differing life-history strategies, such as feeding behaviors, niche preferences, and burrowing patterns, all of which exposed the endogeic species to greater Pb concentration. Garg et al. (2009) reported that the smaller native earthworm *Allolobophora parva* accumulated significantly greater Pb concentrations than *E. fetida*. Subsequently, it was concluded that native earthworm species may exhibit a higher Pb accumulation potential as a result of increased tolerance to the heavy metal (Garg et al., 2009).

Earthworm activity can alter Pb bioavailability and subsequent uptake by earthworms themselves and other organisms. Sizmur and Hodson (2009) speculated that earthworms affect Pb mobility by modifying the availability of cations or anions. The concentration of water-soluble Pb was observed to increase following earthworm (*Lumbricus terrestris*) feeding activity in field-collected soils containing 132.7, 814.9, and 821.4 mg total Pb/kg (calculated BAFs of 0.27, 0.33, and 0.13, respectively) (Alonso-Azcarate et al., 2011). However, Coeurdassier et al. (2007) found that snails did not have a higher Pb content when earthworms were present, and that unexpectedly, Pb was higher in earthworm tissue when snails were present.

Despite significant Pb uptake by earthworms, Pb in earthworm tissue may not be bioavailable to predators. Pb in the earthworm (*Aporrectodea caliginosa*) was determined to be contained largely in the granular fraction (approximately 60% of total Pb), while the remaining Pb body burden was in the tissue, cell membrane, and intact cell fractions (Vijver et al., 2006). However, this may vary by species, as (Li et al., 2008b) found that more than half of the Pb accumulated by *E. fetida* was contained within earthworm tissue

and cell membranes. Regardless, Vijver et al. (2006) concluded that only a minority of earthworm-absorbed Pb would be toxicologically available to cause effects in the earthworms or in their predators.

Arthropods

Pb and other metals were analyzed in honeybees (*Apis mellifera*) foraging in sampling sites that included both urban areas and wildlife reserves in central Italy. (Perugini et al., 2011). Pb in whole bees ranged from 0.28 to 0.52 mg Pb/kg with the highest concentration in honeybees caught in hives near an airport. Cicadas pupating in historically Pb-arsenate-treated soils accumulated Pb at concentrations similar to those reported previously for earthworms (Robinson et al., 2007). Likewise, tissue Pb levels measured in Coleoptera specimens collected from areas containing average soil concentration of 45 and 71 mg Pb/kg exhibited a positive relationship with soil Pb content, although abundance was unaffected (Schipper et al., 2008). By contrast, two grasshopper species inhabiting Pb and Cd-contaminated areas near Zn smelting facilities exhibited different Pb accumulation rates. Locust (*Locusta migratoria*) collected from areas with an average Pb soil concentration of 540mg Pb/kg contained 47 mg Pb/kg, while grasshoppers (*Acrida chinensis*) inhabiting the same area accumulated 93.9 mg Pb/kg (Zhang et al., 2012). This gives respective BAFs of 0.09 and 0.17. Similarly, the Pb sequestration rates that were observed in two woodlouse species, *O. asellus* and *P. scaber*, were species-dependent (Gál et al., 2008). Both species were field collected at Pb-contaminated sites (average concentration, 245 mg Pb/kg dry weight; range, 21-638 mg Pb/kg dry weight), with *O. asellus* Pb levels averaging 43 mg Pb/kg over all sites, while *P. scaber* contained no detectable Pb residues. Pb concentration measured in granivorous rough harvester ants (*Pogonomyrmex rugosus*), in the seeds of some plant species they consume, and in surface soil, were all shown to decline with increasing distance from a former Pb smelter near El Paso, Texas, where soil leachable Pb at the three sites of ant collection ranged from 0.003 to 0.117 mg Pb/kg (Del Toro et al., 2010). Ants accumulated approximately twice as much Pb as was measured in seeds, but the study did not separate the effects of dietary exposure from those of direct contact with soil or respiratory intake.

7.3.3.3 Terrestrial Vertebrates

At the time of the 1977 Pb AQCD few studies of Pb exposure and effects in wild animals other than birds had been conducted. A limited number of rodent trapping studies near roadsides indicated general trends of species differences in Pb uptake and higher

concentrations of Pb in habitats adjacent to high-traffic areas (U.S. EPA, 1977). In the 1986 Pb AQCD concentration of Pb in bone tissue was reported for selected herbivore, omnivore and carnivore species [Table 8-2 in (U.S. EPA, 1986b)].

Tissue Pb residues in birds and mammals associated with adverse toxicological effects were presented in the 2006 Pb AQCD. In general, avian blood, liver, and kidney Pb concentrations of 0.2-3 µg Pb/dL, 2-6 mg Pb/kg wet weight, and 2-20 mg Pb/kg wet weight, respectively, were linked to adverse effects. A few additional studies of Pb uptake and tissue residues in birds and mammals conducted since 2006 are reviewed here.

In a study of blood Pb levels in wild Steller's eiders (*Polysticta stelleri*) and black scoters (*Melanitta nigra*) in Alaska, the authors compiled avian blood Pb data from available literature to develop reference values for sea ducks (Brown et al., 2006). The background exposure reference value of blood Pb was <20 µg Pb/dL, with levels between 20 and 59 µg Pb/dL as indicative of Pb exposure. Clinical toxicity was in the range of 60-99 µg Pb/dL in birds while >100 µg Pb/dL results in acute, severe toxicity. In measurement of blood Pb with a portable blood Pb analyzer, only 3% of birds had values indicating exposure and none of the birds had higher blood Pb levels or clinical signs of toxicity. Tissue distribution of Pb in liver, kidney, ovary and testes of rain quail (*Coturnix coramandelica*) following oral dosing of 0.5 mg Pb/kg, 1.25 mg Pb/kg or 2.5 mg Pb/kg Pb acetate for 21 days indicated that Pb uptake was highest in liver and kidney and low in ovary and testes (Mehrotra et al., 2008). Resident feral pigeons (*Columba livia*) captured in the urban and industrial areas of Korea exhibited increased lung Pb concentration, ranging from 1.6 to 1.9 mg Pb/kg wet weight (Nam and Lee, 2006). However, tissue concentration did not correlate with atmospheric Pb concentration, so the authors concluded that ingestion of particulate Pb (paint chips, cement, etc.) in the urban and industrial areas was responsible for the pigeons' body burden. Similarly, 70% of American woodcock (*Scolopax minor*) chicks and 43% of American woodcock young-of-year collected in Wisconsin, U.S., exhibited high bone Pb levels of 9.6-93 mg Pb/kg dry weight and 1.5-220 mg Pb/kg, respectively, even though radiographs of birds' gastrointestinal tracts revealed no evidence of shot ingestion (Strom et al., 2005). Authors hypothesized that unidentified anthropogenic sources may have caused the observed elevated Pb levels.

In addition to birds, soil-dwelling mammals can also bioaccumulate atmospherically-sourced Pb. Northern pocket gophers (*Thomomys talpoides*) trapped within the Anaconda Smelter Superfund Site were shown to accumulate atmospherically deposited Pb. Gopher liver and carcass Pb concentration averaged 0.3 and 0.4 mg Pb/kg wet weight on low Pb soils (47 mg Pb/kg), 0.4 and 0.9 mg Pb/kg wet weight in medium Pb soils (95 mg Pb/kg)

and 1.6 and 3.8 mg Pb/kg wet weight in high Pb soils (776.5 mg Pb/kg) (Reynolds et al., 2006). Likewise, rats trapped in the vicinity of a Kabwe, Zambia Pb-Zn mine had significantly elevated liver and kidney Pb concentrations. Soil Pb concentrations were measured between 9 and 51,188 mg Pb/kg (approximate average of 200 mg Pb/kg dry weight), while rat liver and kidney Pb concentrations ranged between 0.009 and 7.3 mg Pb/kg dry weight and 0.3 and 22.1 mg Pb/kg dry weight, respectively. Consequently, residence in the mining region was correlated to significantly increased Pb body burdens for rats (Nakayama et al., 2011). Angelova et al. (2010) reared rabbits on a fodder mixture containing Pb-contaminated rapeseed grown adjacent to a metal works plant. Following a four-week exposure, Pb was most heavily concentrated in rabbit kidney tissue (3.9 mg Pb/kg and 1.9 mg Pb/kg, for high and low diet respectively), bone (1.0 and 0.3 mg Pb/kg, respectively), and liver (0.6 and 0.4 mg Pb/kg, respectively). Yucatan micropigs (*Sus scrofa*) and Sprague-Dawley rats (*Rattus norvegicus*) reared on Pb-contaminated soil (5% of 1,000 mg Pb/kg soil as dietary component) consumed significantly different amounts of Pb. Over a 30-day period, rats consumed an average of 19.4 mg Pb, while micropig intake averaged 948 mg Pb (Smith et al., 2009a). This resulted in significantly higher Pb accumulation in micropigs, based on liver, blood, kidney and bone Pb concentrations (average concentrations of 1.2, 25, 0.9, and 9 mg Pb/kg for micropigs, and 0.2, 7, 0.5, and 1.5 mg Pb/kg for rats, respectively).

Casteel et al. (2006) found that bioavailability of Pb from environmental soil samples in swine (*Sus domestica*) depended on Pb form or type, with high absorption of cerussite and Mn-Pb oxides and poor absorption of galena and anglesite. Juvenile swine (approximately 5-6 weeks old and weighing 8-11 kg) were fed Pb-contaminated soils collected from multiple sources for 15 days (concentration range of 1,270 to 14,200 mg Pb/kg) to determine the relative bioavailability. While Pb concentrations were roughly equivalent in blood, liver, kidney, and bone tissues, individual swine exhibited different uptake abilities (Casteel et al., 2006).

Consistent with observations in humans, dietary Ca^{2+} deficiency (0.45 mg Ca^{2+} daily versus 4 mg under normal conditions) was linked to increased accumulation of Pb in zebra finches (*Taeniopygia guttata*) that were provided with drinking water containing 20 mg Pb/L (Dauwe et al., 2006). Liver and bone Pb concentration were increased by an approximate factor of three, while Pb concentration in kidney, muscle, and brain tissues were roughly doubled by a Ca^{2+}-deficient diet. However, it is not known whether this level of dietary Ca^{2+} deficiency is common in wild populations of birds.

7.3.3.4 Food Web

In addition to the organism-level factors reviewed above, understanding the bioavailability of Pb along a simple food chain is essential for determining risk to terrestrial animals. While the bioavailability of ingested soil or particles is relatively simple to measure and model, the bioavailability to secondary consumers of Pb ingested and sequestered by primary producers and primary consumers is more complex. Kaufman et al. (2007) caution that the use of total Pb concentration in risk assessments can result in overestimation of risk to ecological receptors, and they suggest that the bioaccessible fraction may provide a more realistic approximation of receptor exposure and effects. This section reviews recent literature that estimates the bioaccessible fraction of Pb in dietary items of higher order consumers, and various studies suggesting that Pb may be transferred through the food chain but that trophic transfer of Pb results in gradual attenuation, i.e., lower concentration at each successive trophic level.

Earthworm and plant vegetative tissue collected from a rifle and pistol range that contained average soil Pb concentration of 5,044 mg Pb/kg were analyzed for Pb content and used to model secondary bioavailability to mammals (Kaufman et al., 2007). Earthworms were determined to contain an average of 727 mg Pb/kg, and the Pb content of unwashed leaf tissues averaged 2,945 mg Pb/kg. Canonical correspondence analysis detected no relationship between earthworm and soil Pb concentration, but did show correlation between unwashed vegetation and soil concentration. The authors noted that the relatively high Pb concentration of unwashed as opposed to washed vegetation indicated the potential importance of aerial deposition (or dust resuspension) in determining total vegetative Pb concentration. Based on the mammalian gastric model, they noted that 50% of vegetation tissue Pb and 77% of earthworm tissue Pb was expected to be bioavailable to consumers. The avian gizzard model indicated that 53% of soil Pb and 73% of earthworm Pb was bioaccessible to birds; and, for both mammals and birds, the bioaccessible fraction of Pb was a function of total Pb concentration.

The transfer of Pb from soils contaminated by a Pb-Zn mine was limited along a soil-plant-insect-chicken food chain (Zhuang et al., 2009). In soils averaging 991 mg Pb/kg, plants of the fodder plant *Rumex patientia X tianschanicus* sequestered an average of 1.6 mg Pb/kg wet weight in the shoot tissue, while larvae of the leafworm *Spodoptera litura* accumulated an average Pb concentration of 3.3 mg Pb/kg wet weight *S. litura*-fed chickens (*Gallus gallus domesticus*) accumulated 0.58 mg Pb/kg and 3.6 mg Pb/kg in muscle and liver tissue, respectively, but only liver Pb burden was increased significantly relative to controls. A large proportion of ingested Pb was excreted with the feces. Likewise, an insectivorous bird species, the black-tailed godwit (*Limosa limosa*) was shown to accumulate Pb from earthworms residing in Pb-contaminated soils (Roodbergen

et al., 2008). Pb concentration in eggs and feathers was increased in areas with high soil and earthworm Pb concentration (336 and 34 mg Pb/kg, respectively): egg Pb concentration averaged 0.17 mg Pb/kg and feather concentration averaged 2.8 mg Pb/kg. This suggests that despite a residence breeding time of only a few months, this bird species could accumulate Pb when breeding areas are contaminated.

Rogival et al. (2007) showed significant positive correlations between soil Pb concentration along a gradient (approximately 50 to 275 mg Pb/kg) at a metallurgical plant, and Pb concentration in both acorns (from *Quercus robur*) and earthworms (primarily *Dendrodrilus rubidus* and *Lumbricus rubellus*) collected on site. Acorn and earthworm Pb contents were, in turn, positively correlated with the Pb concentration in the liver, kidney, and bone tissues of locally trapped wood mice (*Apodemus sylvaticus*).

The uptake and transfer of Pb from soil to native plants and to red deer (*Cervus elaphus*) was investigated in mining areas of the Sierra Madrona Mountains in Spain (Reglero et al., 2008). The authors reported a clear pattern between plant Pb concentration and the Pb content of red deer tissues with attenuation (i.e., decreasing concentration) of Pb up the food chain. Interestingly, soil geochemistry likely was affected by mining activity as Holm oak (*Quercus ilex*), gum rockrose (*Cistus ladanifer*), elm leaf blackberry (*Rubus ulmifolius*), and grass (Graminae) tissues collected from mining areas exhibited increased Pb levels (up to 98 mg Pb/kg in grasses and 21 mg Pb/kg in oak) despite the fact that total soil Pb concentrations were not significantly greater than those of the non-mining areas.

Positive relationships were observed between *Cepaea nemoralis* snail tissue Pb levels and Pb concentration measured in *Urtica dioica* leaves in field-collected samples from areas characterized by metal soil contamination (approximately 200 to 400 mg Pb/kg) (Notten et al., 2005). Inouye et al. (2007) found that several invertebrate prey of fence lizards, including *Acheta domestica* crickets, *Tenebrio molitor* beetles, and *P. scaber* isopods, accumulate Pb from dietary exposures (10, 50, 100, 250, 500, 750, and 1,000 mg Pb/kg) lasting between 44 and 72 days. By day 44, Pb body burdens of crickets were 31, 50 and 68 mg Pb/kg (wet weight) at the three highest dietary exposures, respectively. Isopods and beetle larvae accumulated significantly less Pb, with average body burdens of 10, 15, and 14 mg Pb/kg following 56 days of exposure; and 12, 14, and 31 mg Pb/kg following 77 days of exposure, respectively. For all invertebrates tested, Pb was sequestered partly in the exoskeleton, and partly in granules. Exoskeleton Pb may be available to predators, but returns to background level with each shedding, while granular Pb is likely unavailable, at least to other invertebrates (Vijver et al., 2004).

In a comparison of rural and urban blackbirds (*Turdus merula*), Sheifler et al.(2006a) found that while Pb concentration in unwashed tail feathers was equivalent in both populations, urban birds had higher tissue concentrations. Pb content of urban

earthworms was also higher than that of rural earthworms. Hypothesizing that tail feather Pb reflected deposition from air and resuspended dust, the authors suggested that elevated Pb in the urban birds was mostly dietary in origin.

Overall, studies of Pb transfer in food webs have established the existence of pervasive trophic transfer of the metal, but no consistent evidence of trophic magnification. It appears that on the contrary, attenuation is common as Pb is transferred to higher trophic levels. However, many individual transfer steps, as from particular plants to particular invertebrates, result in concentration, which may then be undone when stepping to the next trophic level. It is possible that whether trophic transfer is magnifying or attenuating depends on Pb concentration itself. Kaufman et al. (2007) determined that, at low concentrations of soil Pb, risk to secondary consumers (birds and mammals) was driven by the bioavailability of Pb in worm tissues, while at high soil concentrations, bioavailability of soil-associated Pb was more critical. The authors concluded that incorporation of bioavailability/bioaccessibility measurements in terrestrial risk assessments could lead to more accurate estimates of critical Pb levels in soil and biota. Finally, while trophic magnification does greatly increase exposure of organisms at the higher levels of the food web, these studies establish that atmospherically deposited Pb reaches species that have little direct exposure to it. For those species, detrimental effects are not a function of whether they accumulate more Pb than the species they consume, but of the absolute amount they are exposed to, and their sensitivity to it.

7.3.4 Biological Effects of Pb in Terrestrial Systems

Various effects can be observed in exposed terrestrial species following uptake and accumulation of Pb. While many of the responses are specific to organism type, induction of antioxidant activities in response to Pb exposure has been reported in plants, invertebrates, and vertebrates. In this section, the observed biological effects caused by exposure to atmosphere-derived Pb will be discussed, while the results of dose-response experimentation will be addressed in Section 7.3.5. Because environmental releases of Pb often include simultaneous release of other metals, it can be difficult to identify Pb-specific effects in field studies, with the exception of effects from leaded gasoline and some Pb smelter deposition. Many laboratory studies that expose organisms to natural soils (or to biosolids-amended soils) also include exposure to multiple metals. There is some information about mechanisms of metal interactions, such as through competition for binding locations on specific enzymes or on cellular receptors, but generally such interactions (particularly of multiple metals) are not well understood (ATSDR, 2004). Despite a few well-known examples of metal antagonism (e.g., Cu and Mo or Cd and Zn), it is common practice to assume additivity of effects (Fairbrother et al., 2007).

Because this review is focused on effects of Pb, studies reviewed for this section and the following include only those for which Pb was the only, or primary, metal to which the organism was exposed. All reported values are from exposures in which concentrations of Pb were analytically verified unless nominal concentrations are stated.

7.3.4.1 Terrestrial Plants and Lichen

Pb exposure has been linked to decreased photosynthesis in affected plants, significant induction of antioxidant activities, genetic abnormalities, and decreased growth. Induction of antioxidant responses in plants has been shown to increase tolerance to metal soil contamination, but at sufficiently high levels, antioxidant capacity is exceeded, and metal exposure causes peroxidation of lipids and DNA damage, eventually leading to accelerated senescence and potentially death (Stobrawa and Lorenc-Plucinska, 2008).

Effects on Photosystem and Chlorophyll

Photosynthesis and mitosis were recognized as targets of Pb toxicity in plants in the 1977 Pb AQCD and additional effects of Pb on these processes were reported in subsequent Pb AQCDs (U.S. EPA, 2006c, 1986b, 1977). The effect of Pb exposure on the structure and function of plant photosystem II was recently studied in giant duckweed, *Spirodela polyrrhiza* (Ling and Hong, 2009). Although this is an aquatic plant, photosystem II is present in all plants. This finding thus provides support for effects on photosystem II being the cellular-level mechanism that leads to decreases photosynthesis observed in other plants. The Pb concentration of extracted photosystem II particles was found to increase with increasing environmental Pb concentration, and increased Pb concentration was shown to decrease emission peak intensity at 340 nm, amino acid excitation peaks at 230 nm, tyrosine residues, and absorption intensities. This results in decreased efficiency of visible light absorption by affected plants. The authors theorized that Pb^{2+} may replace either Mg^{2+} or Ca^{2+} in chlorophyll or the oxygen-evolving center, inhibiting photosystem II function through an alteration of chlorophyll structure. Consistently with these results, Wu et al. (2008c) demonstrated that Pb exposure interfered with and decreased light absorption by spinach (*Spinacia oleracea*) plants. Spinach seeds were soaked in 5, 12, or 25 mM Pb chloride (1036, 2486, or 5180 mg Pb/L) for 48 hours prior to germination, and following 42 days of growth, plants were sprayed with Pb chloride solutions. Chloroplast absorption peak intensity, fluorescence quantum yield at 680 nm, and whole-chain electron transport rate all decreased with Pb exposure, as did photosystem II photoreduction and oxygen evolution. Similarly, the photosynthetic rate of maize (*Zea mays*) seedlings decreased over 21 days exposure to Pb, and measured leaf Pb

concentrations in photosynthetically-depressed seedlings ranged from approximately 100 to 300 mg Pb/kg dry weight (Ahmad et al., 2011). Liu et al. (2010a) observed that chlorophyll *a* and *b* content in wheat grown in soils spiked with Pb nitrate rose with length of exposure until 14 days, at which point chlorophyll decreased. At nominal exposures of 0.1 and 0.5 mM Pb (20.72 and 103.6 mg Pb/L) in hydroponic solution for 50 days, concentration of chlorophyll *a* and b was decreased in radish (*R. sativus)* (Kumar and Tripathi, 2008). Changes in chlorophyll content in response to Pb were also observed in lichen and moss species following exposures intended to simulate atmospheric deposition (Carreras and Pignata, 2007). *Usnae amblyoclad*a lichen was exposed to aqueous Pb solutions of 0.5, 1, 5, and 10 mM Pb nitrate (103.6, 207.2, 1,036, and 10,360 mg Pb/L); chlorophyll *a* concentration was shown to decrease with increasing Pb exposure. However, the ratio of lichen dry weight to fresh weight increased following Pb exposures. It should be noted that highly productive *Sphagnum* mosses accumulated atmospheric Pb at the same rate as slower growing mosses, indicating that moss growth allowed for further Pb uptake, rather than a "dilution" effect (Kempter et al., 2010). As compared to other metals, however, Pb caused less physiological damage, which the authors attributed to the metal's high affinity for binding to and sequestration within cell walls (Carreras and Pignata, 2007).

The effect of Pb exposure on chlorophyll content of the moss and liverwort species *Thuidium delicatulum*, *T. sparsifolium*, and *Ptychanthus striatus* was investigated following immersion in six solutions of Pb nitrate containing from 10^{-10} to 10^{-2} M Pb (0.00002 to 2,072 mg Pb/L) (Shakya et al., 2008). Both chlorophyll *a* and total chlorophyll content of the mosses (*T. delicatulum* and *T. sparsifolium*) decreased with increasing Pb exposure. For the liverwort, increasing Pb exposure resulted in decreases in content of chlorophyll *a*, chlorophyll *b*, and total chlorophyll. Further, the total chlorophyll content of *Hypnum plumaeforme* mosses was decreased by 5.8% following exposure to the highest concentration, while lower exposures slightly elevated chlorophyll content.

These studies suggest that exposure to Pb has an impact on photosynthetic pigments, but the exposure methods (seed soaking, spraying of Pb chloride solutions, hydroponic growth systems) make it difficult to compare these effects to what might occur under the uncontrolled conditions encountered in natural environments. These experiments bring to light the presence of effects, and the underlying mechanisms, but strong uncertainties remain regarding the natural concentrations at which theses effects would be observed.

Response of Antioxidants

Increased antioxidant activity is a common response to Pb exposure, although this endpoint may not necessarily be an indication of deleterious effects on plant vitality. Increases in reactive oxygen species with increasing exposure to Pb from 20 mg Pb/kg soil to 2,000 mg Pb/kg have been demonstrated in broad bean (*Vicia faba*) (Wang et al., 2010c; Wang et al., 2010a; Wang et al., 2008b) and tomato (*Lycopersicon esculentum*) (Wang et al., 2008a), where they were accompanied up to approximately 500mg Pb/kg by proportional increases in superoxide dismutase (SOD), glutathione, guaiacol peroxidase, and lipid peroxidation, as well as decreases in catalase. Spinach seedlings grown in soil containing six increasing concentrations of Pb from 20 to 520 mg Pb/kg exhibited higher production of reactive oxygen species, increased rates of lipid peroxidation and increased SOD concentrations. Many of these responses persisted for 50 days after germination and growth in the Pb-contaminated soil (Wang et al., 2011a). Similarly, the bryophyte mosses *Hypnum plumaeforme*, *Thuidium cymbifolium*, and *Brachythecium piligerum* exposed to Pb solutions of greater than 0.1 mM Pb for 48 hours exhibited increased production of $\bullet O_2^-$ and H_2O_2, although no single moss species could be identified as most sensitive to Pb exposure (Sun et al., 2011). Increased rates of lipid peroxidation were also observed in Pb-exposed mosses; however, SOD and catalase activity was suppressed or unaffected by Pb.

Reddy et al. (2005) found that horsegram (*Macrotyloma uniflorum*) and bengalgram (*Cicer arietinum*) plants watered with Pb solutions containing 200, 500, and 800 mg Pb/L exhibited increased antioxidant activity: at exposures of 800 mg Pb/L, root and shoot SOD activity increased to 2–3 times that of controls, and induction was slightly higher in *M. uniflorum*. Similarly, catalase, peroxidase, and glutathione-S-transferase activities were elevated in Pb-stressed plants, but were again higher for *M. uniflorum*. Antioxidant activities were also markedly greater in the root tissues than the shoot tissues of the two plants, and were very likely related to the higher Pb accumulation rate of the roots. The effectiveness of the up-regulation of antioxidant systems in preventing damage from Pb uptake was evidenced by lower malondialdehyde (MDA) (a chemical marker of lipid peroxidation) concentration in *M. uniflorum* versus *C. arietinum*, indicating a lower rate of lipid peroxidation in response to *M. uniflorum's* higher antioxidant activity.

Gupta et al. (2010) contrasted responses of two ecotypes of *Sedum alfredii* (an Asian perennial herb), one an accumulator of Pb collected from a Pb and Zn mining area, and the other not. Glutathione level was increased in both, and root and shoot lengths were decreased following long-term exposures to Pb up to 200 µM (41.4 mg Pb/L) in hydroponic solution. However, the accumulator plants exhibited greater SOD and ascorbate peroxidase activity, likely as a result of greater Pb uptake and a concurrent increased detoxification capacity. Similar results were reported by Islam et al. (2008):

following Pb exposures of 200 µM (41.4 mg Pb/L), catalase, ascorbic acid, and glutathione levels of another Chinese herb, *Elsholtzia argyi*, were increased, while SOD and guaiacol peroxidase activities decreased. Microscopic analysis also showed that affected plants exhibited abnormal chloroplast structures. The response of glutathione was further confirmed in wheat (Liu et al., 2010a) grown in soils spiked with Pb nitrate. Evidence of increasing lipid peroxidation (MDA accumulation) with increasing Pb exposure was also found in mosses (Sun et al., 2009) and lichens. Lichens field-collected from the trunks of poplar (*Populus tremula*) trees in eastern Slovakia were chemically analyzed for metal concentration arising from exposure to smelter pollution (Dzubaj et al., 2008). These concentrations (ranging from 13 to 1,523 mg Pb/kg dry weight) were assessed in relation to physiological variables, including chlorophyll *a* and *b*, carotenoids, photosystem II activity, CO_2 gas exchange (respiration), and MDA content. Lichen Pb levels were significantly correlated only with MDA content. Determination of plant chitinase content following exposure to As, Cd and Pb indicated that while levels of these defense proteins were elevated by As and Cd, chitinase levels were not increased following exposure to Pb (Békésiová et al., 2008). As in studies of effects on photosynthesis, the methods used for exposure make it difficult to compare these effects to what might occur under the uncontrolled conditions encountered in natural environments.

Growth

Evidence of effects of Pb on higher growth processes in terrestrial plants was reported in early NAAQS reviews. Impacts to growth can lead to effects at the population-level of biological organization and higher (Section 7.1.1). Growth effects of Pb on plants in the 1977 Pb AQCD primarily included visible growth responses observed in laboratory studies with plants grown in artificial nutrient culture (U.S. EPA, 1977). No Pb toxicity was observed in plants growing under field conditions at the time of the 1977 Pb AQCD. Indirect effects of Pb on plant growth (i.e., inhibition of uptake of other nutrients when Pb is present in the plant) were also reported in the 1977 Pb AQCD. In the 1986 Pb AQCD mechanisms of Pb effects on growth included reduction of photosynthetic rate, inhibition of respiration, cell elongation, root development or premature senescence (U.S. EPA, 1986b). All of these effects were observed to occur in isolated cells or in plants grown hydroponically in solutions comparable to 1 to 2 mg Pb/kg soil or in soils with 10,000 mg Pb/kg or greater (U.S. EPA, 1986b). Pb effects on other plant processes, especially maintenance, flowering and hormone development had not been studied at the time of the 1986 Pb AQCD and remain poorly characterized.

Recent evidence for growth effects in terrestrial plants available since the 2006 Pb AQCD is reviewed below and summarized in Table 7-4. Both growth and carotenoid and chlorophyll content of *Brassica juncea* (mustard) plants were negatively affected by Pb exposure (John et al., 2009). Nominal Pb treatments of 1,500 µM (311 mg Pb/L) as Pb acetate solution decreased root lengths and stem heights by 50% after 60 days. Exposure to 600 µM Pb (124 mg Pb/L) and greater decreased carotenoid content, while chlorophyll *a* was decreased at Pb exposures of 450 µM (93 mg Pb/L) and higher. However, when smelter ash–spiked soils containing 1,466 mg Pb/kg (and 18.6 mg Cd/kg) or 7,331 mg Pb/kg (98.0 mg/kg Cd) were used to grow maize (*Zea mays*), as well as other metals in high concentrations, effects were seen in growth or chlorophyll production only at the higher concentration (Komarek et al., 2009). Given the low solubility of smelter ash, these observations are consistent with solubility being a key determinant of bioavailability. Similarly, wheat seedling growth was unaffected when exposed to soil leachate containing up to 0.7 mg Pb/L for six weeks. Lettuce seedling root growth was negatively correlated to leachate Pb concentration, but this correlation was only significant for week 3 and week 6 measurements. Authors concluded that although the total concentrations of multiple metals in tested soils and leachates exceeded Canadian Environmental Quality Guidelines, no toxic or only slightly toxic effects occurred following exposure to the metal mixture (Chapman et al., 2010).

Chinese cabbage (*Brassica pekinensis*) exposed to Pb-containing soils exhibited depressed nitrogen assimilation as measured by shoot nitrite content, nitrate reductase activity, and free amino acid concentration (Xiong et al., 2006). The authors planted germinated cabbage seeds in soils spiked with Pb acetate to give final soil concentrations of 0.2, 4, and 8 mM Pb/kg dry weight total Pb (41.4, 828.8 and 1,657.6 mg Pb/kg) and collected leaf samples for 11 days. At exposures of 4 and 8 mM Pb/kg (828.8 and 1,657.6 mg Pb/kg), leaf nitrite content was decreased by 29% and 20%, while nitrate content was affected only at the highest Pb exposure (70% of control levels). Free amino acid content in exposed plants was 81% and 82% of control levels, respectively. *B. pekinensis* shoot biomass was observed to decrease with increasing Pb exposures, with biomass at the two highest Pb exposures representing 91% and 84% of control growth, respectively.

Nitrogen, potassium, and phosphorus concentrations in the shoot and root tissues of four canola cultivars (*Brassica napus*) also decreased as spiked soil Pb concentrations increased from 0 to 90 mg/kg. At the highest soil Pb concentration, nitrogen concentrations were reduced 56% in roots and 58% in shoots versus control levels, while phosphorous concentrations were reduced 37% and 45%, respectively, and potassium content decreased by 42% in both tissues (Ashraf et al., 2011). Cultivation in Pb-spiked soils was also linked to decreased shoot and root biomass (32% and 62%, respectively at 90 mg Pb/kg).

Genetic and Reproductive Effects

Exposure to Pb also resulted in genetic abnormalities, including bridges, condensed bivalents, and laggards, in the meiotic cells of pea plants (*Lathyrus sativus*) (Kumar and Tripathi, 2008). Seeds were germinated in soils amended with Pb nitrate at concentrations of 25, 50, 100, 200, and 300 mg Pb/kg, and concentrations of 100 mg Pb/kg and greater were found to be genotoxic or detrimental to pea viability. Cenkci et al. (2010) exposed fodder turnip (*B. rapa*) to 0.5 to 5 mM of Pb nitrate (103.6 to 1036 mg Pb/L) for 6 days and showed decreased genetic template stability (as quantified by random amplified polymorphic DNA profiles) and decreased photosynthetic pigments.

Two genotypes of maize seedlings exhibited a significant and concentration-dependent reduction in seed germination following 7 days of Pb treatment in nutrient solution of 0.01, 0.1 and 1 mg Pb/L as Pb sulfate (Ahmad et al., 2011). Pb exposure also decreased germination rate and growth, and increased pollen sterility in radish grown for 50 days in hydroponic solutions containing 0.5 mM Pb (104 mg Pb/L) (Kumar and Tripathi, 2008). Plants exposed to Pb exhibited decreased growth, curling and chlorosis of young leaves, and decreased root growth. In addition, Gopal and Rizvi (2008) showed that Pb exposure increased uptake of phosphorus and iron and decreased sulfur concentration in radish tops.

Interestingly, as in zebra finch (Section 7.3.3.3) Ca^{2+} was found to moderate the effects of Pb in both monocotyledon and dicotyledon plant seedlings, with tomato (*Lycopersicon esculentum*), rye (Lolium sp.), mustard, and maize plants exhibiting increased tolerance to Pb exposures of 5, 10, and 20 mg Pb/L in the presence of Ca^{2+} concentration of 1.2 mM (249 mg Pb/L) and higher (Antosiewicz, 2005).

7.3.4.2 Terrestrial Invertebrates

Exposure to Pb also causes antioxidant effects, reductions in survival and growth, as well as decreased fecundity in terrestrial invertebrates as summarized in the 2006 Pb AQCD (U.S. EPA, 2006b). Alterations in reproduction, growth and survival at the species level can lead to effects at the population-level of biological organization and higher (Section 7.1.1). In addition to these endpoints, recent literature also indicates that Pb exposure can cause significant neurobehavioral aberrations, and in some cases, endocrine-level impacts. Second-generation effects have been observed in some invertebrate species.

The morphology of γ-aminobutyric acid (GABA) motor neurons in *Caenorhabditis elegans* nematodes was affected following exposure to Pb nitrate for 24 hours (Du and

Wang, 2009). The authors determined that exposures as low as 2.5 µM Pb nitrate (0.5 mg Pb/L) could cause moderate axonal discontinuities, and observed a significant increase in the number of formed gaps and ventral cord gaps at Pb nitrate exposures of 75 and 200 µM (6 and 41 mg Pb/L). Younger *C. elegans* larvae were more likely to exhibit neurobehavioral toxicity symptoms in response to Pb exposure at 2.5 µM (0.5 mg Pb/L) (Xing et al., 2009b). Neural degeneration, as demonstrated by dorsal and ventral cord gaps and neuronal loss was also more pronounced in young larval *C. elegans* than in older larvae and adults (Xing et al., 2009c). *C. elegans* nematodes exposed to Pb concentration as low as 2.5 µM (0.5 mg Pb/L) for 24 hours also exhibited significantly altered behavior characterized by decreased head thrashes and body bends. Exposures of 50 µM Pb (10 mg Pb/L) and greater decreased the number of nematode forward turns (Wang and Xing, 2008). Chemotaxis toward NaCl, cAMP, and biotin was also decreased in *C. elegans* nematodes exposed to Pb concentration greater than 2.5 µM (0.5 mg Pb/L) (Xing et al., 2009a). This evidence suggests that Pb may exert neurotoxic action in invertebrates as it does in vertebrates. However, it is unclear how these behavioral aberrations would affect fitness or survival (Wang and Xing, 2008).

In a study of *C. elegans* exposed to 4 sub-lethal concentrations of Pb nitrate between 25 and 100 µM (5 and 21 mg Pb/L), Vigneshkumar et al. (In Press) observed upregulation of both catalase and antimicrobial response-related genes. When challenged with addition of a pathogenic strain of *Pseudomonas aeruginosa*, exposed *C. elegans* showed greater resistance to microbial colonization than controls.

Younger individuals also appear to be more sensitive to the reproductive effects of Pb exposure. Guo et al. (2009) showed that concentrations of 2.5, 50, and 100 µM Pb (0.5, 10, and 21 mg Pb/L) had greater significant adverse effects on reproductive output when early-stage larval *C. elegans* were exposed. Adult *C. elegans* exhibited decreased brood size only when exposed to the highest Pb concentration.

The progeny of *C. elegans* nematodes exposed nominally to 2.5, 75, and 200 µM Pb nitrate (0.5, 16, and 41 mg Pb/L) exhibited significant indications of multi-generational toxicity (Wang and Peng, 2007). Life spans of offspring were decreased by increasing parental Pb exposure, and were comparable to the reductions in parental life-spans. Similarly, diminished fecundity was observed in the progeny of *C. elegans* exposed to Pb (9%, 19%, and 31% reductions of control fecundity, respectively), although the decrease was smaller than in the exposed parental generation (reductions of 52%, 58%, and 65%, respectively). Significant behavioral defects affecting locomotion were also observed in the offspring, but these impacts were not determined to be concentration-dependent. Reproductive effects of Pb exposure were also observed in springtails *F. candida* following 10-day exposure to Pb-spiked soils. Egg hatch

significantly decreased at nominal concentrations of 1,600 mg Pb/kg dry soil and higher and the EC_{50} for hatching was 2,361 mg Pb/kg dry soils (Xu et al., 2009b).

E. andrei earthworms exposed to 21 different soils, each containing 2,000 mg Pb/kg freshly added Pb, for 28 days exhibited highly variable mortality, ranging from 0% to 100%, (Bradham et al., 2006). Pb body burden of exposed worms ranged from 29 to 782 mg Pb/kg. Internal Pb concentration was also negatively correlated to reproductive output. CEC and pH were found to be the principal soil characteristics determining the differences in those effects, although the apparent role of CEC may only have been due to its correlation with other soil characteristics. Low soil Pb concentration (5 mg Pb/kg) also decreased the protein content of *E. fetida* earthworms during a 7-day exposure (Li et al., 2009b). Higher Pb concentration had no effect on protein production. However, cellulase activity was increased by the 7-day exposures to Pb at all exposure concentrations (31%, 13%, and 23% of control activity at exposures of 5, 50, and 500 mg Pb/kg, respectively), which the authors reported as an indication of detrimental effects on worm metabolism. By contrast, Svendsen et al. (2007) found that *L. rubellus* earthworms exposed for 42 days to field-collected smelter-polluted soils containing average Pb concentration of 106, 309, and 514 mg Pb/kg dry weight exhibited normal survival and cocoon production rates, even though they accumulated more Pb with increased environmental concentration. The much smaller effect may be explained by the increased aging time undergone by field soil, causing a larger fraction of the total Pb to be complexed and sequestered by organic and inorganic compounds. Similarly, earthworms (*E. fetida*) exposed to field-collected soils with concentrations of Pb and As up to 390 mg/kg and 128 mg/kg, respectively, due to historical treatments of Pb-arsenate pesticides, exhibited no change in survival, behavior or morphology (Delistraty and Yokel, In Press). Soil aging (e.g., from of the time of Pb-arsenate applications in 1942 to soil collection in approximately 2009) likely reduced Pb bioavailability to earthworms.

As in plants, induction of metal chelating proteins and antioxidant activity in invertebrates is affected by exposure to Pb. Metallothionein production in earthworms (*Lampito mauritii*) was significantly induced following exposure to Pb-contaminated soil. Tissue metallothionein levels increased after a two-week exposure to 75 to 300 mg Pb/kg soil, although by 28 days levels had begun to decrease, perhaps as a result of Pb toxicity (Maity et al., 2011). Further, the induction of antioxidant activity was correlated to standard toxicity measurements in *Theba pisana* snails (Radwan et al., 2010). Topical application of Pb solutions (estimated to be 500 to 2,000 µg Pb per animal) to snails resulted in decreased survival, increased catalase and glutathione peroxidase activities, and decreased glutathione concentration. The 48-hour LD_{50} concentration was determined to be 653 µg per snail, as measured in digestive gland tissue. Snail glutathione content was decreased at exposures of 72.2% of the 48-hour LD_{50} value,

while Pb exposure at 40% of the 48-hour LD_{50} value induced catalase and glutathione peroxidase activities.

Dietary exposure to Pb also affected *T. pisana* snail growth. After three weeks on Pb-contaminated diet, snail feeding rates were depressed by all Pb exposures (nominal concentration of 50 to 15,000 mg Pb/kg diet dry weight) (El-Gendy et al., 2011). A five week dietary exposure to 1,000 mg Pb/kg and greater resulted in reduced snail growth. Food consumption, growth, and shell thickness were also observed to decrease with increasing diet Pb in juvenile *A. achatina* snails (7 levels between 0 and 1,344 mg Pb/kg feed, for 12 weeks) (Ebenso and Ologhobo, 2009a). A similar depression of growth was observed in sentinel juvenile *A. achatina* snails deployed at Pb-polluted sites in the Niger Delta region of Nigeria. Although snail mortality was not increased significantly by exposure to soil Pb up to 1,200 mg Pb/kg, a concentration-dependent relationship was established for growth, with significant reduction observed at 12-week exposures to 20 mg Pb/kg (Ebenso and Ologhobo, 2009b). However, consumption of field-collected Pb-polluted *U. dioica* leaves containing 3 mg Pb/kg stopped all reproductive output in *C. nemoralis*. Snails also exhibited diminished food consumption rates when offered leaves with both low (1.5 mg Pb/kg) and high Pb content, but the mechanism of the dietary aversion was not defined (Notten et al., 2006).

Chronic dietary exposure to Pb was also examined in post-embryonic oribatid mites (*Archegozetes longisetosus*) (Kohler et al., 2005). Both algae and bark samples were soaked in 100 mg/L Pb as Pb nitrate and provided as diet and substrate, respectively, to larval mites. In addition to elevated heat shock proteins (hsp70), 90.8% of the protonymphs exhibited significant leg deformities, including abnormal claws, shortened and thickened legs, and translocated setae. Although not specifically discussed, it is very likely that these deformities would decrease mite mobility, prey capture, and reproductive viability. While there is some evidence that oribatid mites exhibit Pb avoidance behavior, this response may not significantly reduce Pb exposure and effects. Although soil-inhabiting mites (*Oppia nitens*) were observed to avoid high Pb concentrations, the EC_{50} for this behavior was approximately five times higher than the chronic EC_{50} for reproduction (8,317 and 1,678 mg Pb/kg, respectively) (Owojori et al., 2011). Consequently, it is unlikely that oribatid mites will avoid soils containing toxic Pb concentrations.

Lock et al. (2006) compared the toxicity of both laboratory-spiked soils and field-collected Pb-contaminated soils to springtails (*F. candida*). The 28-day EC_{50} values derived for *F. candida* ranged from 2,060 to 3,210 mg Pb/kg in leached and unleached Pb-spiked soils, respectively, whereas field-collected soils had no significant effect on springtail reproduction up to (but not including) 14,436 mg Pb/kg (Lock et al., 2006).

Consequently, leaching soils prior to use in bioassays had only a slight effect on Pb toxicity to resident springtails, and did not provide an appropriate model for field-weathered, Pb-contaminated soils. This indicates that physiochemical factors other than leaching may be more important determinants of Pb bioavailability. A 4-week exposure to Pb-amended soils containing up to 3,200 mg Pb/kg (nominal concentration) had no significant effect on *Sinella curviseta* springtail survival or reproduction (Xu et al., 2009a).

Carabid beetles (*Pterostichus oblongopunctatus*) inhabiting soils contaminated by pollution from a Pb-Zn smelter (containing 136 to 2,635 mg Pb/kg) were field-collected and then laboratory-reared for two generations (Lagisz and Laskowski, 2008). While fecundity was positively correlated to soil metal concentration (e.g., more eggs were produced by females collected from contaminated areas), the hatching rate of eggs diminished with increasing soil metal contamination. For the F1 generation, females produced by parents inhabiting highly polluted areas exhibited decreased body mass. The authors stated that these results indicate that invertebrates inhabiting metal- (or Pb-) contaminated soils could face "significantly altered life-history parameters." Similarly, aphids (*Brevicoryne brassicae*) reared on cabbage and radish plants exposed to 0.068 mg Pb daily exhibited altered development and reproduction when compared to those reared on non-exposed plants. Development time was increased by approximately two days, which led to a reduction in relative fecundity (Görür, 2007). Although the authors noted that study exposures were greater than what would be expected in naturally polluted areas, Pb exposure under field conditions could alter invertebrate life history patterns.

Several studies suggest that Pb may disrupt hormonal homeostasis in invertebrates. Shu et al. (2009) reported that vitellogenin production in both male and female *S. litura* moths was disrupted following chronic dietary exposure to Pb. Adult females reared on diets containing 25, 50, 100, or 200 mg Pb/kg exhibited decreased vitellogenin mRNA induction, and vitellogenin levels decreased with increasing Pb exposure. In addition, vitellogenin mRNA induction was detected in males exposed to 12 and 25 mg Pb/kg, and low levels of vitellogenin were found at those lower Pb exposures, when males normally do not produce any. In the Asian earthworm (*Pheretima guillelmi*) , sperm morphology was found to be altered significantly following 2-week exposure to soils containing nominal concentration of 1,000, 1,400, 1,800, and 2,500 mg Pb/kg (Zheng and Li, 2009). Common deformities were swollen head and head helices, while head bending was also recorded in some cases. These deformities were observed following exposures to concentration below the 14-day LC_{50} (3,207 mg Pb/kg) and below the concentration at which weight was diminished (2,800 mg Pb/kg). Experimentation with the model organism Drosophila indicates that Pb exposure may increase time to pupation and

decrease pre-adult development, both of which are endocrine-regulated (Hirsch et al., 2010).

7.3.4.3 Terrestrial Vertebrates

Pb poisoning is one of the earliest recognized toxicoses of terrestrial vertebrates, occurring primarily through the ingestion of spent shot by birds. While the focus of the ISA is on more environmentally relevant exposures, studies of Pb poisoning provide historical context for the review. The widespread nature of this toxicosis was first noticed in American waterfowl around the turn of the last century (see (Jones, 1939) for an historical summary). Wetmore (1919) demonstrated that Pb shot caused the observed effects and described in detail the species affected, associated symptoms, and additional factors involved. By 1959, the estimated annual loss of waterfowl to Pb poisoning was 2−3 percent of the fall population (Bellrose, 1959). Smaller numbers of shorebirds and upland game birds were also found poisoned by Pb (Locke and Thomas, 1996).

The first reported Pb poisoning of a bald eagle (*Haliaeetus leucocephalus*) was described by Mulhern et al. (1970), and subsequently several hundred bald eagle Pb poisonings were diagnosed throughout the U.S. prior to the ban on use of Pb shot for waterfowl hunting (Kramer and Redig, 1997). Eagles and other raptors are poisoned by consuming Pb pellets imbedded in the flesh of ducks or upland prey species and may also be exposed to other sources of Pb, such as fishing sinkers and weights (Kramer and Redig, 1997). The use of Pb shot for waterfowl hunting was banned in 1991 due to the poisoning of bald eagles, which had been previously added to the endangered species list and were specially protected under the Bald Eagle Protection Act of 1940.

Anderson et al. (2000) reported that by 1997, mallard (*Anas platyrhynchus*) deaths from Pb poisoning in the Mississippi flyway were reduced by 64 percent, and ingestion of toxic pellets had declined by 78 percent. They estimated the ban prevented approximately 1.4 million duck deaths in the first 6-year period. However, Pb exposure remains widespread in bald eagles, although blood Pb concentrations have significantly decreased (Kramer and Redig, 1997). The endangered California condor (*Gymnogyps californianus*) also continues to have significantly elevated blood Pb levels as well as Pb-associated mortality resulting from exposure to ammunition fragments contained in food items (Cade, 2007; Church et al., 2006). Although there is a significant amount of information on Pb tissue residues of mammals, there are very few reports of Pb poisoning; exceptions are reports of Pb poisoned bats in a cave in the southern U.S. and small mammals in the vicinity of several smelters (Shore and Rattner, 2001).

At the time of the 1977 Pb AQCD few studies of the effects of exposure to Pb had been conducted in wild animals other than birds, and the majority of those studies were of direct poisoning (U.S. EPA, 1977). Several studies of domestic animals grazing near Pb smelters indicated that horses are more susceptible than cattle to chronic Pb exposure although the findings were not conclusive due to the presence of other metals. Delta-aminolevulinic acid dehydratase (ALAD) was recognized as a sensitive indicator of Pb exposure in rats and waterfowl. In the 1986 Pb AQCD, additional effects of Pb on small mammals and birds were reported. According to the 2006 Pb AQCD (U.S. EPA, 2006b), commonly observed effects of Pb on avian and mammalian wildlife include decreased survival, reproduction, and growth, as well as effects on development and behavior. More recent experimental data presented here expand and support these conclusions, and also indicate that Pb can exert other effects on exposed terrestrial vertebrates, including alteration of hormones and other biochemical variables.

Since the 2006 Pb AQCD, there is additional evidence for hematological effects of Pb exposure in terrestrial vertebrates. Red-backed salamanders (*Plethodon cinereus*) exposed to Pb-amended soils (553, 1,700, 4,700, and 9,167 mg Pb/kg) by Bazar et al. (2010) exhibited lowered appetite and decreased white blood cell counts at the two highest concentrations, but tolerated field-collected, aged soils containing Pb concentrations of up to 16,967 mg Pb/kg with no significant deleterious effects. The white blood cell count of adult South American toads, (*Bufo arenarum)* was also decreased by weekly sublethal i.p. injections of Pb acetate at 50 mg Pb/kg body weight, (Chiesa et al., 2006). The toads also showed altered serum profiles and increased number of circulating blast cells. Final toad blood Pb levels were determined to be 8.6 mg Pb/dL, although it is unclear whether this is representative of Pb concentrations observed in field *B. arenarum* populations exposed to Pb. The authors suggested that, based on these findings, long-term environmental exposure to Pb could affect toad immune response. In western fence lizards (*S. occidentalis*), sub-chronic (60-day) dietary exposure to 10 to 20 mg Pb/kg per day resulted in significant sublethal effects, including decreased cricket consumption, decreased testis weight, decreased body fat, and abnormal posturing and coloration (Salice et al., 2009). Long-term dietary Pb exposures are thus likely to decrease lizard fitness.

Even in cases of high environmental Pb exposures, however, linking Pb body burdens to biological effects can be difficult. Pb concentration in the breast feathers, washed tail feathers, and blood of field-collected blackbirds (*Turdus merula*) were determined to be 3.2 mg Pb/kg, 4.9 mg Pb/kg, and 0.2 mg Pb/kg wet mass in urban birds, as opposed to 1.4 mg Pb/kg, 1 mg Pb/kg, and 0.05 mg Pb/kg in rural birds (Scheifler et al., 2006a). However, the elevated Pb tissue concentrations in urban birds were not significantly correlated to any index of body condition.

The long-term effect of atmospheric Pb deposition on pied flycatcher (*Ficedula hypoleuca*) nestlings was determined in native communities residing in the Laisvall mining region of Sweden (Berglund et al., 2010). Moss samples indicated that Pb deposition in study areas ranged between 100 and 2,000 mg Pb/kg dry weight during operations and 200 and 750 mg Pb/kg when operations ceased. A simultaneous slight reduction was observed in pied flycatcher blood Pb levels, from 0.4 to 0.3 mg Pb/kg. However, clutch size was decreased in pied flycatchers inhabiting the mining area both during and after mining operations, and mean nestling mortality was 2.5 times higher in the mining region than in reference areas during mining operations, and 1.7 higher five years after cessation of mining operations. The authors noted that Pb deposition in the mining region remained elevated even after mining operations ceased, and that stable Pb isotope analysis suggested that smelter Pb remained available to pied flycatcher through the transfer of historically deposited Pb in soil to prey items.

Berglund et al. (2010) also analyzed ALAD activity in pied flycatchers at the later period, and found that it was 46% lower at the mine site. Beyer et al. (2004) observed that elevated blood Pb levels in several types of birds inhabiting the Tri-State Mining District (Oklahoma, Kansas, Missouri) were correlated with decreases in ALAD activity. Based on reduction in ALAD activity, robins (*Turdus migratorius*) were most sensitive to Pb exposure (35% reduction), followed by cardinals (*Cardinalis cardinalis*), waterfowl, and bobwhite quail (*Colinus virginianus*) (40%, 41%, and 56% reductions, respectively). Eagle owl (*Bubo bubo*) nestlings living in a historical mining area in Spain also exhibited elevated blood Pb levels (average 8.61 µg/dL as compared to an average reference area value of 3.18 µg/dL), and this was correlated to an approximate 60% reduction in ALAD activity (Gómez-Ramírez et al., 2011). Hansen et al. (2011a) determined that ground-feeding songbirds were frequently exposed to Pb within the Coeur d'Alene, ID mining region. Robins, in particular, were significantly likely to exhibit blood Pb levels in the clinical and severe clinical poisoning ranges (50 to 100 µg/dL and >100 µg/dL, respectively). Ingested soil Pb accounted for almost all of the songbirds' exposure to Pb, with Pb exposure correlated with estimated soil ingestion rates (20% for robins, 17% for song sparrows, and 0.7% for Swainson's thrushes, *Catharus ustulatus*). More than half of the robins and song sparrows from all contaminated sites and more than half of the Swainson's thrushes from highly contaminated sites showed at least 50% inhibition of ALAD. The highest hepatic Pb concentration of 61 mg/kg (dry weight) was detected in a song sparrow (Hansen et al., 2011a).

Blood Pb was significantly elevated in waterfowl in the Lake Coeur d'Alene areas of Blackwell Island and Harrison Slough (mean sediment concentrations of 679 and 3,507 mg Pb/kg dry weight, respectively). Twenty-seven percent of the waterfowl sampled in the Blackwell Island region had blood Pb concentrations suggestive of severe

clinical poisoning (average concentration=0.17 mg Pb/kg); in the Harrison Slough, 60% of sampled waterfowl had highly elevated blood Pb levels that exceeded the severe clinical poisoning threshold (average concentration=2,2 mg Pb/kg) (Spears et al., 2007). The level of corticosteroid hormones in field populations of white stork nestlings (*Ciconia ciconia*) in a mining area affected by Pb and other metals was positively correlated with blood Pb levels (Baos et al., 2006). The effect was more pronounced for single nestlings than for multiple-chick broods. Surprisingly, average blood Pb levels in chicks inhabiting reference areas was 910 µg Pb/dL (± 51), which was higher than blood Pb levels from the mining area (440 ± 340 µg Pb/dL). However, the correlation between blood Pb levels and the corticosteroid stress response in white stork nestlings was observed in both groups of birds. Burger and Gochfeld (2005) exposed herring gull (*Larus argentatus*) chicks to Pb acetate via an i.p. injection of 100 mg Pb/kg body weight, to produce feather Pb concentration approximately equivalent to those observed in wild gulls. Pb-exposed gulls exhibited abnormal behaviors, including decreased walking and food begging, erratic behavioral thermoregulation, and diminished recognition of caretakers. Interestingly, subchronic exposure of Japanese quail (*Coturnix coturnix japonica*) to 5 and 50 mg Pb/L in drinking water caused an increase in their immune response. Exposed quail exhibited significantly lower rates of death or health effects (including septicemia, perihepatitis, and pericarditis among others) than control animals following infection with *Escherichia coli*, and the incidence of infection-related effects was dependent on Pb exposure (Nain and Smits, 2011). These observations contrast with immunotoxicology results in mice reported in Section 5.6.5.1.

Again, dietary or other health deficiencies unrelated to Pb exposure are likely to exacerbate the effects of Pb. Ca^{2+}-deficient female zebra finches (*T. guttata*) had a suppressed secondary humoral immune response following 28-day exposures to 20 mg Pb/L in drinking water (Snoeijs et al., 2005). This response, however, was not observed in birds fed sufficient Ca^{2+}. Although a significant finding, these data are difficult to interpret under field conditions where the overall health of avian wildlife may not be easily determined.

Chronic Pb exposures were also demonstrated to affect several mammalian species. Young adult rats reared on a diet containing 1,500 mg Pb/kg Pb acetate for 50 days demonstrated less plasticity in learning than non-exposed rats (McGlothan et al., 2008), indicating that Pb exposure caused significant alteration in neurological function. Yu et al. (2005) showed that dietary Pb exposure affected both the growth and endocrine function of gilts (*S. domestica*). Consumption of 10 mg Pb/kg diet resulted in lower body weight and food intake after 120 days of dietary exposure; Pb exposure decreased final weight by 8.2%, and average daily food intake of Pb-exposed pigs was decreased by 6.8% compared to control intake. Additionally, concentration of estradiol, luteinizing

hormone, and pituitary growth hormone were decreased (by 12%, 14%, and 27% versus controls, respectively), while blood Pb level was increased by 44% to an average 2.1 µg/dL. In cattle grazing near Pb-Zn smelters in India, blood Pb levels were positively correlated with plasma levels of the thyroid hormones thyroxine (T4) and tri-iodothyronine (T3) and the hepatic biomarkers alanine transaminase and aspartate transaminase (Swarup et al., 2007). Total lipids, total protein and albumin levels were decreased in the same animals. Rodriguez-Estival et al. (2011) determined that red deer (*Cervus elaphus*) and wild boar (*Sus scrofa*) inhabiting a Pb-contaminated mining area in Spain exhibited increased liver and bone Pb concentrations (geometric means of 0.35 and 0.46 mg Pb/kg for red deer, and 0.81 and 7.36 mg Pb/kg for wild boar, respectively). These tissue concentrations were correlated to a significant decrease in red deer glutathione production, but corresponded to an increase in wild boar glutathione (Rodríguez-Estival et al., 2011). Authors proposed that the different antioxidant responses may be indicative of different Pb susceptibilities in the two species.

Following previous reports of in vivo follicle and oocyte damage in animals with low-level Pb accumulation, Nandi et al. (2010) treated oocytes of buffalo (*Bubalus bubalis*) in vitro with Pb at concentrations ranging from 0.005 to 10 mg/L in one-day cultures indicated a significant decline in viability of oocytes at 1 mg/L. Dose-dependent effects on oocyte viability, morphological abnormalities, cleavage, blastocyst yield and blastocyst hatching were observed in Pb-treated oocytes with maturation significantly reduced at 2.5 mg/L and 100% oocyte death at 32 mg/L. These results appear to confirm previous reports, but the in vitro concentrations of Pb are difficult to relate to in vivo exposures. On the other hand, the reproductive viability of wild red deer from the Pb-contaminated mining area of Spain studied by Rodriguez-Estival et al. (2011) was shown to be altered, with 11% and 15% reductions in spermatozoa and acrosome integrity observed in male deer from the mining area compared with those residing in reference areas (Reglero et al., 2009a).

7.3.5 Exposure and Response of Terrestrial Species

Evidence regarding exposure-response relationships and potential thresholds for Pb effects on terrestrial populations can inform determination of standard levels that are protective of terrestrial ecosystems. Given that exposure to Pb may affect plants, invertebrates and vertebrates at the organism, population, or community level, determining the rate and concentration at which these effects occur is essential in predicting the overall risk to terrestrial organisms. This section updates available information derived since the 2006 Pb AQCD, summarizing several dose-response studies with soil invertebrates. As shown in the studies summarized in Table 7-4, several

experiments have been published that used multiple levels of Pb under controlled conditions. However, none of them treated Pb concentration as a continuous variable, i.e., none attempted to analyze results as a concentration–response relationship. In addition, given the well-established presence of strong interactions with variables such as pH, CEC, OC, or aging, applying exposure–response relationships from those experiments to natural conditions with different values of those interacting variables could be difficult.

Dose-dependent responses in antioxidant enzymes were observed in adult *L. mauritii* earthworms exposed to soil-associated Pb contamination (75, 150, 300 mg Pb/kg) (Maity et al., 2008). By day seven of exposure, glutathione-S-transferase activity and glutathione disulfide concentration were positively correlated with increasing Pb exposures, while glutathione concentration exhibited a negative dose-response relationship with soil Pb concentration. However, these trends had become insignificant by the end of the total exposure period (28 days), as a result of normalization of antioxidant systems following chronic exposure. This strongly suggests that changes to earthworm antioxidant activity are an adaptive response to Pb exposures.

Both survival and reproductive success of *E. fetida* earthworms showed concentration-dependent relationships with soil Pb concentration during the course of standard 14- and 56-day toxicity tests (Jones et al., 2009b). Five levels of Pb soil concentration were prepared for the acute 14-day study via spiking with Pb nitrate—0, 300, 711, 1,687, and 2,249 mg Pb/kg, while soil concentration of 0, 355, 593, 989, and 1,650 mg Pb/kg were used in chronic (56-day) earthworm bioassays. A 14-day acute LC_{50} of 2,490 mg Pb/kg was determined from the dose-response relationship, while the approximate 56-day NOEC (no observed effect concentration) and EC_{50} values were about 400 mg Pb/kg and 1,000 mg Pb/kg, respectively. Jones et al. (2009b)made use of continuous (regressional) models to characterize the relationship between Pb soil concentration and Pb accumulation in earthworms, but did not use continuous models for the relationship of exposure and other responses. Currie et al. (2005) observed mortality of *E. fetida* after 7 and 14 days in spiked field soil at seven levels of Pb (0 to 10,000 mg Pb/kg). They reported LC_{50} values of 2,662 mg Pb/kg at 7 days and 2,589 mg Pb/kg at 14 days or 2,827 mg Pb/kg at both 7 and 14 days, depending on the number of worms in the experimental enclosure.

Other studies have shown no correlation between Pb concentration in either earthworm tissue or soil, and earthworm survival rate. Although the Pb content of *E. fetida* held in metal-contaminated soils containing between 9.7 and 8,600 mg Pb/kg was positively correlated with Pb concentration of fully aged soil collected from disused mines, there was no statistical relationship with earthworm survival during a 42-day exposure period

(Nahmani et al., 2007). However, Pb concentration in soil leachate solution was significantly correlated with decreased earthworm survival and growth (linear regression: R^2= 0.64, p<0.0001). The 42-day Pb EC_{50} for *E. fetida* growth was 6,670 mg Pb/kg.

Langdon et al. (2005) exposed three earthworm species (*E. andrei*, *L. rubellus*, and *A. caliginosa*) to Pb nitrate-amended soils at concentrations of 1,000 to 10,000 mg Pb/kg to determine species variability in uptake and sensitivity. Twenty-eight-day LC_{50} values for the three species were 5,824 mg Pb/kg, 2,867 mg Pb/kg, and 2,747 mg Pb/kg, respectively, indicating that *L. rubellus* and *A. caliginosa* are significantly more vulnerable to Pb contamination than *E. andrei*, a common laboratory species. This is comparable to previous findings by Spurgeon et al. (1994) who reported 14-day LC_{50} of 4,480 mg Pb/kg and 50-day LC_{50} of 3,760 mg Pb/kg for *E. fetida*, another standard laboratory test species. In the more recent study of *E. fetida* sensitivity summarized above, Jones (2009b) reported LC_{50} values for *E. fetida* that are similar to those for *L. rubellus* and *A. caliginosa*. It is likely that these apparent species differences are a result of differential bioavailability of the Pb in test soils. However, the Pb body burden of all three species in the study by Langdon et al. (2005) increased with increasing environmental concentration, and there were no species differences in Pb tissue content. When given a choice between treated and untreated soils, all worm species exhibited significant avoidance of Pb-contaminated soils, and altering pH (and, consequently, Pb bioavailability) had no impact on avoidance (Langdon et al., 2005). Field earthworms may thus be able to reduce their exposure to Pb through behavior.

Reproductive success of other soil invertebrates is impacted by Pb. The organismal and population-level responses of the springtail *Paronychiurus kimi* to Pb were determined by Son et al. (2007) using artificial soils, following the 1999 ISO methodology. The 7-day Pb LC_{50} was determined to be 1,322 mg Pb/kg dry weight, while the 28-day reproduction EC_{50} was established as 428 mg Pb/kg. The intrinsic rate of population increase was lower at a Pb soil concentration of 1,312 mg Pb/kg, and the authors estimated that, at this level, *P. kimi* populations would be extirpated. The authors noted that, in this case, the reproductive endpoint overestimated the population-level risk for *P. kimi* springtails exposed to Pb, and proposed that more specific measures of population-level endpoints (such as the reduction in intrinsic rate of increase) be used to determine risk to populations. Menta et al. (2006) showed that a nominal soil concentration of 1,000 mg Pb/kg decreased the reproductive output of two collembolans, *Sinella coeca* and *F. candida*. Pb concentration of 50, 100, and 500 mg Pb/kg slightly but significantly depressed *S. coeca* adult survival, while *F. candida* survival was statistically unaffected by Pb exposure. The hatching success of *F. candida* eggs was diminished by 10-day exposure to Pb-spiked soils; the 10-day EC_{50} for hatching success was reported as

2,361 mg/kg Pb (Xu et al., 2009b). However, authors noted that egg development was more sensitive to Cu and Zn exposure, and by comparison, was less susceptible to Pb.

In addition to species variability, physical and chemical factors affecting Pb bioavailability were also demonstrated to significantly influence the toxicity of Pb to terrestrial species. As noted previously in Section 7.3.2, laboratory-amended artificial soils provide a poor model for predicting the toxicity of Pb-contaminated field soils, because aging and leaching processes, along with variations in physiochemical properties (pH, CEC, OM), influence metal bioavailability. Consequently, toxicity values derived from exposure-response experimentation with laboratory-spiked soils probably overestimate true environmental risk, with the possible exception of highly acidic sandy soils. Because toxicity is influenced by bioavailability of soil biogeological and chemical characteristics, extrapolation of toxic concentrations between different field-collected soils will be difficult. Models that account for those modifiers of bioavailability, such as the terrestrial BLM proposed by Smolders et al. (2009), have proven difficult to develop due to active physiological properties of soil organisms affecting either uptake (such as root phytochelatins) or sequestration of Pb (such as granule formation in root tissues and earthworms, or substitution of Pb for calcium in bones).

7.3.6 Terrestrial Community and Ecosystem Effects

A study reviewed in the 1977 Pb AQCD provided evidence for Pb effects on forest-nutrient cycling and shifts in community composition. Reduced arthropod density, biomass and richness were observed in the vicinity of a smelting complex in southeastern Missouri where Pb, Cd, Zn and Cu were measured in the litter layer and soil (U.S. EPA, 1977; Watson et al., 1976). In the 1986 Pb AQCD it was reported that Pb at environmental concentrations occasionally found near roadsides and smelters (10,000 to 40,000 mg Pb/kg dry weight) can eliminate populations of bacteria and fungi on leaf surfaces and in soil. At soil concentrations of 500 to 1,000 mg Pb/kg or higher, populations of plants, microorganisms, and invertebrates may shift toward Pb-tolerant populations of the same or different species (U.S. EPA, 1986b).

According to the 2006 Pb AQCD (U.S. EPA, 2006b), natural terrestrial ecosystems near significant Pb stationary sources (such as smelters and mines) exhibited a number of ecosystem-level effects, including decreased species diversity, changes in floral and faunal community composition, and decreasing vigor of terrestrial vegetation. These findings are summarized in Table AX7-2.5.2 of the Annex to the 2006 Pb AQCD (U.S. EPA, 2006c). More recent literature explored the interconnected effects of Pb

contamination on soil bacterial and fungal community structure, earthworms, and plant growth, in addition to impacts on soil microbial community function.

Inoculation of maize plants with *Glomus intraradices* arbuscular mycorrhizal fungi isolates decreased Pb uptake from soil, resulting in lower shoot Pb concentration and increased plant growth and biomass (Sudova and Vosatka, 2007). Similarly, Wong et al. (2007) showed that the presence of arbuscular mycorrhizal fungi improved vetiver grass (*Vetiveria zizanioides*) growth, and while Pb uptake was stimulated at low soil concentration (10 mg Pb/kg), it was depressed at higher concentration (100 and 1,000 mg Pb/kg). Bojarczuk and Kieliszewska-Rokicka (2010) found that the abundance of ectomycorrhizal fungi was negatively correlated with the concentration of metals, including Pb, in the leaves of silver birch seedlings. Arbuscular mycorrhizal fungi may thus protect plants growing in Pb-contaminated soils. Microbes too may dampen Pb uptake and ameliorate its deleterious effects: biomass of plants grown in metal-contaminated soils (average Pb concentration 24,175 mg Pb/kg dry weight) increased with increasing soil microbial biomass and enzymatic activity (Epelde et al., 2010). However, above certain Pb concentration, toxic effects on both plants and microbial communities may prevent these ameliorating effects. R.Y. Yang et al. (2008b) found that both the mycorrhizal colonization and the growth of *Solidago canadensis* were negatively affected by soil Pb contamination. They suggested that, more generally, Pb-mediated alterations in plant-fungal dynamics may be the cause of ecological instability in terrestrial vegetative communities exposed to metals.

The presence of both earthworms and arbuscular mycorrhizal fungi decreased the mobility of Pb in mining soils undergoing phytoremediation (Ma et al., 2006). Inoculation with both earthworms and fungi increased plant growth at sites contaminated with mine tailings compared to that observed at sites with 75% less Pb contamination. Most likely, this was a result of the decrease in bioavailable (DTPA-extractable and ammonium acetate-extractable) Pb to 17% to 25% of levels in areas without the earthworm and arbuscular mycorrhizal fungi amendments. The presence of earthworms in metal-contaminated soils decreased the amount of water-soluble Pb (Sizmur and Hodson, 2008), but despite this decrease, ryegrass accumulated more Pb from earthworm-worked soils than soils without worms present. Sizmur and Hodson speculated that increased root dry biomass may explain the increased uptake of Pb in the presence of earthworms. However, Sizmur et al. (2011) found that the presence of anecic (deep-burrowing) earthworms (*L. terrestris*) increased soil leachate Pb concentrations by 190%. The authors observed that worms promoted a faster breakdown of organic matter, which caused a decrease in soil pH and a concurrent increase in Pb solubility. As a result, ryegrass (*L. perenne*) accumulated a greater amount of Pb in systems with earthworms (Sizmur et al., 2011). Further, the presence of earthworms (*Lumbricus terrestris*) was

found to increase Pb concentrations in both maize and barley, although growth of these species was unaffected (Ruiz et al., 2011). Authors noted that worm activity increased Pb extraction yields by factors of 4.4 and 7.6, for barley and maize. By contrast, Coeurdassier et al. (2007) found that Pb was higher in earthworm tissue when snails were present, but that snails did not have a higher Pb content when earthworms were present.

Microbial communities of industrial soils containing Pb concentrations of 61, 456, 849, 1,086, and 1,267 mg Pb/kg dry weight were also improved via revegetation with native plants, as indicated by increased abundances of fungi, actinomycetes, gram-negative bacteria, and protozoa, as well as by enhanced fatty acid concentration (Zhang et al., 2006). Increased plant diversity ameliorated the effects of soil Pb contamination (300 and 600 mg Pb/kg) on the soil microbial community (Yang et al., 2007).

The effect of Pb on microbial community function has been quantified previously using functional endpoints such as respiration rates, fatty acid production, and soil acid phosphatase and urease activities, which may provide an estimate of ecological impacts separate from microbial diversity and abundance measurements. Most studies of metal-induced changes in microbial communities have been conducted using mixtures of metals. However, Akerblom et al. (2007) tested the effects of six metals (Cr, Zn, Mo, Ni, Cd, and Pb) individually. All tested metals had a similar effect on the species composition of the microbial community. Exposure to a high Pb concentration (52 mg Pb/kg) also negatively affected respiration rates. Total phospholipid fatty acid content was determined to negatively correlate with increasing Pb exposure, indicating alteration of the microbial community. When Yang et al. (2006) compared the microbial properties of metal-contaminated urban soils to those of rural soils, significant differences were detected in basal community respiration rates and microbial abundance. The urban soils studied contained multiple metal contaminants, but microbial biomass was the only measured endpoint to be significantly and negatively correlated to Pb concentration. Similarly, the fungal community in a naturally Pb-enriched forest in Norway exhibited differences in community composition and abundance when compared with other, low Pb sites. The number of colony–forming fungal units was diminished by soil Pb, and was approximately 10 times lower in the highest Pb soil concentration (~4300 mg Pb/kg). Further, only one fungus species was isolated from both high Pb and control soils, indicating highly divergent communities; species diversity was also reduced by high soil Pb concentrations (Baath et al., 2005). These studies suggest that anthropogenic Pb contamination may affect soil microbial communities, and alter their ecological function. However, (Khan et al., 2010c) reported that it is possible for indicators of microbial activity to recover after an initial period depression. (Khan et al., 2010c) found that following a 2-week exposure to three levels of Pb (150, 300, and 500 mg Pb/kg), the number of culturable bacteria at the highest exposure concentration tested was decreased.

Acid phosphatase and urease levels (measures of soil microbial activity) decreased significantly, but they had recovered by the ninth week. Another study (Bamborough and Cummings, 2009) reported that no changes in bacterial and actinobacterial diversity in metallophytic soils containing 909 to 5,280 mg Pb/kg (43 to 147 mg Pb/kg bioavailable Pb (as defined by the study authors)). Soil bacteria community structure and basal respiration rates were examined in natural soils with pH values ranging from 3.7 to 6.8 (Lazzaro et al., 2006). Six soil types of differing pH were treated with Pb nitrate concentrations of 0.5, 2, 8, and 32 mM (104, 414, 1,658, and 6,630 mg Pb/L). Basal respiration was decreased in two soil types tested at the highest Pb treatment (32 mM, =6,630 mg Pb/L), and in a third at the two highest Pb treatments (8 and 32 mM, =1658 and 6,630 mg Pb/L). Terminal Restriction Fragment Length Polymorphism analysis indicated that bacterial community structure was only slightly altered by Pb treatments. While pH was correlated with the amount of water-soluble Pb, these increases were apparently not significant enough to affect bacterial communities, because there were no consistent relationships between soil pH and respiration rate or microbial community structure at equivalent soil Pb concentration. Pb contamination was also demonstrated to reduce phenol oxidase activity in several type of soils; concentrations between 5 and 50 nM Pb (0.001 and 0.01 mg Pb/L) significantly decreased phenol oxidase activity in all soils tested, while 400 nM (0.08 mg Pb/L) and greater completely arrested phenol oxidase activity in one soil tested (a high pH sandy loam) (Carine et al., 2009). Carine et al. (2009) suggested that the decreased soil enzymatic activity resulted from changes in the microbial community following Pb exposure. Pb concentrations between 50 and 500 mg Pb/kg significantly reduced microbial abundance and diversity, and also resulted in lower soil phosphatase, urease, and dehydrogenase activities (Gao et al., 2010b). Further, the weekly soil carbon dioxide evolution rate was significantly reduced by concentrations of 5, 10, and 50 mg Pb/g, which also indicated decreased microbial respiration and adverse effects on the microbial community (Nwachukwu and Pulford, 2011). Gai et al. (2011) examined the microbial activity of three soils via microcalorimetric methods following Pb exposure. They noted an increase in activity immediately following Pb application (giving 10, 20, 40, 80, and 160 mg Pb/kg), and theorized that this was a result of rapid mortality of sensitive microbial species, followed by a concurrent proliferation of Pb-tolerant microorganisms. As Pb concentrations increased, however, the calculated microbial growth rate constant decreased, indicating a suppression of microbial activity (Gai et al., 2011). Authors also noted a strong correlation between microcalorimetry estimates and the number of colony forming units isolated from soil samples.

Pb exposure negatively affected the prey capture ability of certain fungal species. Nematophagous fungi are important predators of soil-dwelling nematodes, collecting their prey with sticky nets, branches, and rings. The densities of traps they constructed

decreased in soils treated with 0.15 mM Pb chloride (31 mg Pb/L) (Mo et al., 2008). This suppression caused a subsequent reduction in fungal nematode capturing capacity, and could result in increased nematode abundance.

In a study of microbial communities and enzyme activity, Vaisvalavicius et al. (2006) observed that high concentration of soil metals were linked to a significant reduction in soil microorganism abundance and diversity. Soil columns spiked with Cu, Zn, and Pb acetate (total Pb concentration of 278 to 838 mg Pb/kg, depending on depth) exhibited a 10- to 100-fold decrease in microbial abundance, with specific microbe classes (e.g., actinomycetes) seemingly more affected than others (Vaisvalavicius et al., 2006). Concurrently, decreases in soil enzymatic activity were also observed, with saccharase activity decreased by 57–77%, dehydrogenase activity by 95–98%, and urease activity 65–97%. Although this suggests that Pb contamination may alter the nutrient cycling capacity of affected soil communities, it is difficult to separate the impact of Pb in this study from the contributions of Cu and Zn that were also added. In contrast, Zeng et al. (2007) reported that soil concentrations of 300 mg Pb/kg and less stimulated soil enzymatic activity. Both urease and dehydrogenase levels were increased and rice dry weight was unaffected by concentrations of 100 and 300 mg Pb/kg. However, at 500 mg Pb/kg, both rice and soil enzyme activities and microbial biomass were decreased suggesting impacts at the community level for the soil-rice system. The authors proposed that these concentrations could be considered the critical Pb concentration in rice paddy systems (Zeng et al., 2007).

The microbial communities of soils collected from a Pb-Zn mine and a Pb-Zn smelter were significantly affected by Pb and other metals (e.g., Cd) (Hu et al., 2007b). At a mine site, Pb concentration of 57 to 204 mg Pb/kg and Cd concentration of 2.4 to 227 mg Cd/kg decreased the number of bacteria-forming colonies extracted from soils. Principal component analysis of microbial community structure demonstrated that different communities were associated with different metal soil concentration. Similarly, soil microbial communities exposed to metal contamination from a smelter site (soil Pb concentration ranging from 30 to 25,583 mg Pb/kg dry weight) showed decreased bacterial functional diversity (although fungal functional diversity increased) and no effects on soil respiration rates were observed (Stefanowicz et al., 2008). This led the authors to conclude that bacterial diversity is a more sensitive endpoint and a better indicator of metal exposure than fungal diversity or microorganism activity. In a similar study, Kools et al. (2009) showed that soil ecosystem variables measured after a 6-month exposure to metal-contaminated soil indicated that Pb concentration (536 or 745 mg Pb/kg) was an important driver of soil microbial species biomass and diversity.

Pb-resistant bacterial and fungal communities were extracted regularly from soil samples at a shooting range site in southern Finland (Hui et al., 2009). While bioavailable Pb concentration averaged 100 to 200 mg Pb/kg as determined by water extraction, the total Pb concentrations measured on site were 30,000 to 40,000 mg Pb/kg. To determine Pb tolerance, bacterial colonies extracted and cultured from shooting range and control soils were grown on media containing either 0.4 or 1.8 mM Pb (83 or 373 mg Pb/L). While bacteria isolated from control soil did not proliferate on high-Pb media, shooting-range soil microbe isolates grew on high-Pb media and were deemed Pb tolerant. The authors noted that bacterial species common in control samples were not detected among the Pb-tolerant species isolated from shooting-range soils. They speculated that if long-term exposure to minimally bioavailable Pb can alter the structure of soil decomposer communities, decomposition rates could be altered. However, this would require that the microbial ecosystem decomposing function be altered along with structure, and the authors provided no evidence for alteration of function.

Microbial communities associated with habitats other than soils are also affected by exposure to atmospherically deposited Pb. Alder (*Alnus nepalensis*) leaf microorganism populations were greater in number at non-affected sites than at sites adjacent to a major Indian highway with increased Pb pollution (Joshi, 2008). The density, species richness, and biomass of testate amoebae communities grown on *Sphagnum fallax* mosses were significantly decreased following moss incubation in Pb solutions of either 0.6 or 2.5 mg Pb/L (Nguyen-Viet et al., 2008). More importantly, species richness and density were negatively correlated with Pb concentration accumulated within the moss tissue. The structure of microbial communities associated with lichen surfaces was affected by lichen trace-element accumulation, including Pb content. Lichens collected from industrial areas had elevated Pb concentration (10 to 20 mg Pb/kg versus 5 to 7 mg Pb/kg in urban and rural areas, respectively) and housed bacterial communities characterized by increased cyanobacteria biomass (Meyer et al., 2010).

Following a 28-day exposure to field-collected soils contaminated with metals (including Pb at 426 mg Pb/kg), both population growth and individual growth of the earthworm *L. rubellus* were diminished (Klok et al., 2006). The authors proposed that, although these reductions were unlikely to result in extirpation, avian predators such as the godwit (*Limosa limosa*) that feed heavily on earthworms may be affected by a reduction of available earthworm biomass.

During the past 5 years, there has been increasing interest in the effects of Pb and other metals on the functional aspects of soil microbial communities. Most studies show that Pb decreases diversity and function of soil microorganisms. However, in an example of ecological mutualism, plant-associated arbuscular mycorrhizal fungi were found to

protect the host plant from Pb uptake, while fungal viability is protected by the host plants. Similarly, soil microbial communities (bacterial species as well as fungi) in Pb-contaminated soils are improved by revegetation. A few studies have reported on effects of Pb to populations of soil invertebrates. They demonstrated that Pb can decrease earthworm population density, although not to levels that would result in local extinction. There have been no recently reported studies on the potential effects of Pb on terrestrial vertebrate populations or communities, or possible indirect effects through reduction of prey items such as earthworms.

7.3.7 Critical Loads in Terrestrial Systems

The general concept and definition of critical loads is introduced in Section 7.1.3 of this chapter [also see Section 7.4 of the 2006 Pb AQCD (U.S. EPA, 2006c)]. An international workshop was conducted in 2005 on the development of critical loads for metals and other trace elements (Lofts et al., 2007). Among the findings of the workshop it was reported that soil transport and transformation processes are key in controlling the fate of metals and trace elements, thus their importance in the input-output mass balance needs to be considered. The degree to which these processes are understood and can be quantified varies. Complexation, sorption, ion exchange and precipitation are well understood under laboratory conditions, but to a lesser extent in the field (Lofts et al., 2007). Slower processes of weathering and fixation are less well understood or studied than leaching (Lofts et al., 2007).

As noted in previous sections, soil pH and organic matter influence Pb availability. De Vries et al. (2007) demonstrate that critical limits, measured as critical reactive metal content, can significantly vary between soil types that differ in pH and organic matter. Critical limits of Pb increased from 30 to 64 (mg Pb/kg) over a pH range of 4-7 when soil organic matter content was 5%, while these limits increased from 187 to 400 (mg Pb/kg) over the same pH range when organic content was 80%. These implications suggest that critical limits increase with increasing soil organic matter. This has important consequences for forest soils because many are covered by an organic layer where roots, fungi and other microorganisms are located. Baath (1989) evaluated the effects of organic matter on critical limits for microorganisms, measured via enzyme synthesis, litter decomposition and soil respiration. Results indicate critical limits are up to four times higher in the organic (135 to 976 mg Pb/kg) than the mineral soil layer (32 to 690 mg Pb/kg) at hazardous concentration ranging from 5-50% of species. In general, De Vries et al. (2007) found support that ecotoxicological critical limits in European soils for Pb decrease with increasing pH.

Several methods are routinely used for Pb risk assessment of terrestrial animals. Buekers et al. (2009) proposed the use of a Tissue Residue Approach as a risk estimation method for terrestrial vertebrates that eliminates the need for quantitative estimation of food intake or Pb species bioavailability. Blood Pb no observed effect concentration (NOEC) and lowest observed effects concentration (LOEC) data derived from 25 studies examining the effects of Pb exposure on growth, reproduction, and hematological endpoints were used to construct a series of species sensitivity distributions for mammals and birds. They also used the HC5 criterion (5th percentile of species NOEC values for collection of species) proposed by Aldenberg and Slob (1993). For mammals, the HC5 values obtained ranged from 11 to 18 µg Pb/dL blood; HC5 values for birds ranged from 65 to 71 µg Pb/dL. The authors proposed the use of 18 and 71 µg Pb/dL as critical threshold values for mammals and birds respectively, which are below the lowest NOEC for both data sets used, and are above typical background Pb values. It is difficult to determine environmental Pb toxicity given the variation of physiochemical and soil properties that alter bioavailability and toxicity. This variability makes it difficult to extrapolate between areas. Furman et al. (2006) proposed the use of a physiologically based extraction test to predict risks posed to waterfowl from environmental Pb contamination. The extraction process was modeled after gastric and intestinal conditions of waterfowl, and was used to gauge the bioavailability of Pb from freshly amended and aged contaminated soils. The concentration of Pb extracted through the use of the physiologically based extraction test was demonstrated to be significantly correlated to Pb tissue concentration in waterfowl exposed via in vivo studies of the same soils.

There are few critical loads for Pb reported for terrestrial ecosystems in the U.S.; however, work has been conducted in Europe. Given that local conditions (including historic loading, soil transport and transformation processes) are key elements to critical load calculation the utility of critical loads that are developed from other countries for application to U.S. ecosystems is unclear. The most recent European publications on Pb critical loads include assessments of the U.K., Netherlands and Italy. Hall et al. (2006) used the critical load approach to conduct a national risk assessment of atmospheric Pb deposition for the U.K. While specific regions were determined to have low critical load values for Pb (central England, the Pennines, and southern Wales), the authors noted that this approach can be significantly biased, as available ecotoxicological data used in the modeling were from studies that were not conducted in soils representative of all U.K. soils. De Vries et al. (2009) similarly observed that the uncertainty inherent in a critical load approach to Pb risk assessment is influenced by the critical concentration of dissolved metal and the absorption coefficients of exposed soils. However, this approach did indicate that for forest soils in the Netherlands, 29% of the areas would be expected to exceed the critical load, based on currently available toxicity data and Pb pollution data (de Vries and Groenenberg, 2009). Similarly, although Pb soil concentrations in the

Bologna Province of Italy were far below concentrations harmful to soil organisms, current atmospheric Pb deposition rates suggest that critical load exceedances are likely in the future, unless annual Pb emissions are decreased (Morselli et al., 2006).

Given the heterogeneity of ecosystems affected by Pb, and the differences in expectations for ecosystem services attached to different land uses, it is expected that there will be a range of critical load values for Pb for soils within the U.S. In the short term, metal emissions generally have greater effects on biota in freshwater systems than in terrestrial systems because metals are more readily immobilized in soils than in sediment. However, over the longer term, terrestrial systems may be more affected particularly by those metals with a long soil residence time, such as Pb.

7.3.8 Soil Screening Levels

Developed by EPA, ecological soil screening levels (Eco-SSLs) are maximum contaminant concentrations in soils that are predicted to result in little or no quantifiable effect on terrestrial receptors. These conservative values were developed so that contaminants that could potentially present an unacceptable hazard to terrestrial ecological receptors are reviewed during the risk evaluation process while removing from consideration those that are highly unlikely to cause significant effects. The studies considered for the Eco-SSLs for Pb and detailed consideration of the criteria for developing the Eco-SSLs are provided in the 2006 Pb AQCD (U.S. EPA, 2006c). Preference is given to studies using the most bioavailable form of Pb, to derive conservative values. Soil concentration protective of avian and mammalian diets are calculated by first converting dietary concentration to dose (mg/kg body weight per day) for the critical study, then using food (and soil) ingestion rates and conservatively derived uptake factors to calculate soil concentration that would result in unacceptable dietary doses. This frequently results in Eco-SSL values below the average background soil concentration [19 mg Pb/kg dry weight (U.S. EPA, 2005b, 2003b)], as is the case with Pb for birds. The Pb Eco-SSL was completed in March 2005 and has not been updated since. Values for terrestrial birds, mammals, plants, and soil invertebrates are 11, 56, 120, and 1,700 mg Pb/kg soil (dry weight), respectively.

7.3.9 Characterization of Sensitivity and Vulnerability

Research has long demonstrated that Pb affects survival, reproduction, growth, metabolism, and development in a wide range of species. The varying severity of these effects depends in part upon species differences in metabolism, sequestration, and elimination rates. Dietary factors also influence species sensitivity to Pb. Because of effects of soil aging and other bioavailability factors discussed above (Section 7.3.2), in combination with differing species assemblages and biological accessibility within prey items, ecosystems may also differ in their sensitivity and vulnerability to Pb. The 2006 Pb AQCD reviewed many of these factors which are updated herein by reference to recent literature.

7.3.9.1 Species Sensitivity

There is wide variation in sensitivity of terrestrial species to Pb exposure, even among closely related organisms. Langdon et al. (2005) showed a two-fold difference in LC_{50} values among three common earthworm species, with the standard laboratory species, *E. andrei*, being the least sensitive. Mammalian NOEC values expressed as blood Pb levels were shown to vary by a factor of 8, while avian blood NOECs varied by a factor of 50 (Buekers et al., 2009). Age at exposure, in particular, may affect sensitivity to Pb. For instance, earlier instar *C. elegans* were more likely than older individuals to exhibit neurobehavioral toxicity following Pb exposure (Xing et al., 2009b), and also demonstrated more pronounced neural degeneration than older larvae and adults (Xing et al., 2009c).

7.3.9.2 Nutritional Factors

Dietary factors can exert significant influence on the uptake and toxicity of Pb in many species of birds and mammals. The 2006 Pb AQCD (U.S. EPA, 2006b) describes how Ca^{2+}, Zn, Fe, vitamin E, Cu, thiamin, P, Mg, fat, protein, minerals, and ascorbic acid dietary deficiencies increase Pb absorption and its toxicity. For example, vitamin E content was demonstrated to protect against Pb-induced lipid peroxidation in mallard ducks. Generally, Pb exposure is more likely to produce behavioral effects in conjunction with a nutrient-deficient diet. As previously reported in the 2006 Pb AQCD, Ca^{2+} deficiencies may increase the susceptibility of different terrestrial species to Pb, including plant (Antosiewicz, 2005), avian (Dauwe et al., 2006; Snoeijs et al., 2005) and invertebrate species. Antosiewicz (2005) determined that, for plants, Ca^{2+} deficiency decreased the sequestration capacity of several species (tomato, mustard, rye, and maize),

and that this likely resulted in an increased proportion of Pb at sites of toxic action. Because Pb ions can interact with plant Ca^{2+} channel pores, in the presence of low Ca^{2+} and high Pb concentration, a higher proportion of Pb can interact with these channels and be taken up by plants. A similar phenomenon has been observed in invertebrates, where the metabolic pathway of metals mimics the metabolic pathway of Ca^{2+} [Simkiss et al. (1982), as cited in Jordaens et al. (2006)]. Hence, in environments with disproportionately high Pb versus Ca^{2+} concentration, accumulation of Pb may be accelerated, as in plants. Ca^{2+} deficiency in birds was demonstrated to stimulate the production of Ca^{2+}-binding proteins in the intestinal tract, which extract more Ca^{2+} from available diet; however, this response also enhances the uptake and accumulation of Pb from diet and drinking water [Fullmer (1997), as cited in Dauwe et al. (2006)].

7.3.9.3 Soil Aging and Site-Specific Bioavailability

Total soil Pb concentration is a poor predictor of hazards to avian or mammalian wildlife, because site-specific biogeochemical and physical properties (e.g., pH, OM, metal oxide concentration) can affect the sequestration capacity of soils. Additionally, soil aging processes have been demonstrated to decrease the bioavailable Pb fraction; as such, laboratory toxicity data derived from spiked soils often overestimate the environmental risk of Pb. Smolders et al. (2009) compared the toxicity of freshly Pb-spiked soils to experimentally aged spiked soils and field-collected Pb-contaminated soils. Experimental leaching and aging was demonstrated to increase invertebrate Pb EC_{50} values by factors of 0.4 to greater than 8; in approximately half the cases, the proportionality of toxicity to Pb content disappeared following experimental aging of freshly spiked soils through leaching. The leaching-aging factor for Pb was determined to be 4.2, and represented the ratio of ED_{10} values derived in aged soils to freshly spiked soils (factors greater than one indicate decreased toxicity in aged field soils relative to laboratory spiked soils). Consequently, the sensitivity of terrestrial vertebrates to environmental Pb exposures will be heavily dependent on the relative rate of aging and site-specific bioavailability.

7.3.9.4 Ecosystem Vulnerability

Relative vulnerability of different terrestrial ecosystems to effects of Pb can be inferred from the information discussed above on species sensitivity and how soil geochemistry influences the bioavailability and toxicity of Pb. Soil ecosystems with low pH, particularly those with sandy soils, are likely to be the most sensitive to the effects of Pb. Examples of such systems are forest soils, including oak, beech, and conifer forests. The Pine Barrens in southern New Jersey (also known as the Pinelands) is an example of

a highly vulnerable ecosystem: it is a dense coniferous (pine) forest with acidic, sandy, nutrient poor soil. As agricultural areas are taken out of production and revert to old fields and eventually forests, their vulnerability to Pb is likely to increase as a result of decreasing OM and acidification of soils (from discontinuation of fertilizing and liming). On the other hand, increasing density of native or invasive plants with associated arbuscular mycorrhizal fungi will likely act to ameliorate some of the effects of Pb (see previous discussion of studies by Sudova and Vostka (2007) and Wong et al. (2007). It is, however, difficult to categorically state that certain plant or soil invertebrate communities are more vulnerable to Pb than others, as the available toxicity data have not yet been standardized for differences in bioavailability (because of use of different Pb salts, different soil properties, and different lengths of aging of soil prior to testing), nutritional state, or organism age, or other interacting factors. Data from field studies are complicated by the co-occurrence of other metals and alterations of pH, such as acidification from SO_2 in smelter emissions, which are almost universal at sites of high Pb exposure, especially at mine or smelter sites. However, because plants primarily sequester Pb in the roots, uptake by soil invertebrates is the most likely pathway for Pb exposure of higher trophic level organisms. Invertivores are likely at higher risk than herbivores. In fact, estimations of Pb risk at a former Pb smelter in northern France indicated that area Pb concentration presented the greatest threat to insectivorous bird and mammal species, but only minimal risk to soil invertebrate and herbivorous mammals (Fritsch et al., 2010). By extension, birds and mammals in ecosystems with a richer biodiversity of soil invertebrates may be more vulnerable to Pb than those in ecosystems with fewer invertebrates (e.g., arid locations). Regardless, the primary determinant of terrestrial ecosystem vulnerability is soil geochemistry, notably pH, CEC, and amount of OM.

7.3.10 Ecosystem Services Associated with Terrestrial Systems

Pb deposited on the surface of, or taken up by organisms has the potential to alter the services provided by terrestrial biota to humans. There are no publications at this time that specifically focus on the ecosystem services affected by Pb in terrestrial systems and the directionality of impacts is not always clear. For example, terrestrial soils provide a service to aquatic ecosystems by sequestering Pb through sorption and precipitation. At the same time, the sequestration of Pb by soils may result in a degredation in the quality of soil and may result in decreased crop productivity. The evidence reviewed in the present document illustrates that Pb can cause ecological effects in each of the four main categories of ecosystem services (Section 7.1.2) as defined by Hassan et al. (2005). These effects are sorted into ecosystem services categories and summarized here:

- Supporting: altered nutrient cycling, decreased biodiversity, decline of productivity, food production for higher trophic levels
- Provisioning: plant yields
- Regulating: decline in soil quality, detritus production
- Cultural: ecotourism and cultural heritage values related to ecosystem integrity and biodiversity, impacts to terrestrial vertebrates.

A few studies since the 2006 Pb AQCD, consider the impact of metals in general on ecosystem services. Honeybees are important for provisioning services such as pollination and production of honey. They can be exposed to atmospheric Pb by direct deposition or through Pb associated with plants, water or soil. In a study of heavy metals in honeybees in central Italy, there was a statistically significant difference in Pb between bees collected in wildlife reserves compared to bees collected in urban areas with the highest concentration of Pb detected from bees caught in hives near an airport (Perugini et al., 2011). In a review of the effects of metals on insect behavior, ecosystem services provided by insects such as detritus reduction and food production for higher trophic levels were evaluated by considering changes in ingestion behavior and taxis (Mogren and Trumble, 2010). Pb was shown in a limited number of studies to affect ingestion by insects. Crickets (Chorthippus spp) in heavily contaminated sites reduced their consumption of leaves in the presence of increasing Cd and Pb concentrations (Migula and Binkowska, 1993). Decreased feeding activity in larval and adult Colorado potato beetle (*Leptinotarsa decemlineata*) were observed as a result of dietary exposures of Pb and Cu (Kwartirnikov et al., 1999), while no effects were found in ingestion studies of Pb with willow leaf beetle, *Lochmaea caprae* (Rokytova et al., 2004) mottled water hyacinth

weevil, *Neochetina eichhorniae* (Kay and Haller, 1986) and hairy springtail, *Orchesella cincta (*van Capelleveen et al., 1986*)*.

Soil health for agricultural production and other soil-associated ecosystem services is dependent upon the maintenance of four major functions: carbon transformations, nutrient cycles, soil structure maintenance, and the regulation of diseases and pests and these parameters may be altered by metal deposition (Kibblewhite et al., 2008). Pb impacts to terrestrial systems reviewed in the previous sections provide evidence for impacts to supporting, provisioning, and regulating ecosystem services provided by soils. For example, earthworms were shown to impact soil metal mobility and availability, which in turn resulted in changes to microbial populations (biodiversity), pH, dissolved organic carbon, and metal speciation (Sizmur and Hodson, 2009), all of which may directly affect soil fertility.

Pb is bioaccumulated in plants, invertebrates and vertebrates inhabiting terrestrial and aquatic systems that receive Pb from atmospheric deposition. This represents a potential route for Pb mobilization into the food web or into food products. For example, Pb bioaccumulation in leaves and roots of an edible plant may represent an adverse impact to the provisioning of food, an essential ecosystem service. Although there is no consistent evidence of trophic magnification there is substantial evidence of trophic transfer. It is through consumption of Pb-exposed prey or Pb-contaminated food that atmospherically deposited Pb reaches species that may have very little direct exposure to it.

There is limited evidence of Pb impacts to plant productivity. Productivity of gray birch (*Betula populifolia*) was impaired in soils with elevated As, Cr, Pb, Zn and V (Gallagher et al., 2008). Tree growth measured in both individuals and at the assemblage level using satellite imagery and field spectrometry was significantly decreased with increasing metal load in soil.

7.3.11 Synthesis of New Evidence for Pb Effects in Terrestrial Systems

This synthesis of the effects of Pb on terrestrial ecosystems covers information from the publication of the 2006 Pb AQCD to present. It is followed in Section 7.5 by determinations of causality that take into account evidence dating back to the 1977 Pb AQCD.

High concentrations of Pb

The state-level mean concentration of Pb in U.S. soils ranges from 5 to 39 mg Pb/kg. Studies of the effects of Pb use much higher concentrations, whether they use soils that

have been exposed to Pb pollution, or experimental amendment with salts of Pb (Table 7-4). Studies that were conducted in situ or used soil collected from natural environments all took place near stationary sources, i.e., in highly contaminated areas. All of them took advantage of gradients of exposure produced by distance from the source to create several levels of Pb, sometimes with only two sampling locations–control and elevated–rather a larger set of levels representative of the whole gradient. In most cases, the highest concentration of Pb in the study is very high relative to those found anywhere except heavily exposed sites. In amendment experiments, variation in Pb was generated by addition of Pb salts to either natural or artificial soils. These experiments often included concentrations that were even higher than those found in heavily exposed natural environments. In either type of study, however, effects gradually increased with increasing exposure, and studies that include very high exposures were thus informative for lower exposures as well. This would not be true if there was clear evidence of the presence of discontinuity (breakpoint) in the relationship of exposure and effects, but without evidence of discontinuity, the presence of effects at elevated exposures implies effects at lower exposures. Using concentration-response models where concentration is taken as a continuous variable to analyze data with multiple values of Pb concentration would allow better estimation of the size of effects at any value of exposure, including low ones, and also better estimation of uncertainties around the size of effects. However, none of studies with multiple Pb concentrations used a continuous model to characterize the relationship between concentration and effects.

Comparability of effect concentrations

Strong interactions of Pb concentration and several other soil variables, including pH, CEC, OC, and Fe/Al oxides have been amply demonstrated with respect to various biological responses. For example, Dayton et al.(2006) and Bradham et al.(2006) tested an array of different soils to which the same amount of Pb was added, using lettuce and earthworms, respectively. They found differences in biological effects that were as large as 27, 35, or even 72-fold between soils.

In studies where Pb was introduced through amendment, those interacting variables can be changed experimentally in a controlled way, or held constant. In studies where natural soils were used in which Pb originated from pollution, they are left to vary freely. In either case, the presence and magnitude of those interactions make calculations of expected responses under other sets of conditions particularly difficult, as well as comparisons between studies conducted under different conditions.

In addition, the amount of Pb dissolved in soil pore water determines the impact of soil Pb on terrestrial ecosystems to a much greater extent than the total amount present. It has

long been established that the amount of Pb dissolved in soil solution is controlled by at least six variables: (1) solubility equilibria; (2) adsorption-desorption relationship of total Pb with inorganic compounds; (3) adsorption-desorption reactions of dissolved Pb phases on soil OM; (4) pH; (5) CEC; and (6) aging. Since 2006, further details have been contributed to the understanding of the role of pH, CEC, OM, and aging. Smolders et al. (2009) demonstrated that the two most important determinants of solubility (and also toxicity) in soils are pH and CEC. However, they had previously shown that aging, primarily in the form of initial leaching following deposition, decreases soluble metal fraction by approximately one order of magnitude (Smolders et al., 2007). Since 2006, OM has been confirmed as an important influence on Pb sequestration, leading to longer-term retention in soils with higher OM content, and also creating the potential for later release of deposited Pb. Aging, both under natural conditions and simulated through leaching , was shown to substantially decrease bioavailability to plants, microbes, and vertebrates. However, most studies report some measure of total extracted Pb, or total added Pb, rather than pore water or soluble fraction.

Plants

Recent studies with herbaceous species growing at various distances from smelters added to the existing strong evidence that atmospherically transported Pb is taken up by plants. These studies did not establish the relative proportion that originated from atmospheric Pb deposited in the soil, as opposed to that taken up directly from the atmosphere through the leaves. Studies found that in trees, Pb that is taken up through the roots is then generally translocated from the roots to other parts. However, multiple recent studies showed that in trees, the proportion of Pb that is taken up through the leaves is likely to be very substantial. One study attempted to quantify it, and suggested that 50% of the Pb contained in Scots Pine in Sweden is taken up directly from the atmosphere (Section 7.3.3.1). Studies with herbaceous plants found that in most species tested, soil Pb taken up by the roots is not translocated into the stem and leaves, but when growth and survival were reported, growth of the whole plant decreased with increasing Pb, and mortality increased (Table 7-4). Experimental studies have added to the existing evidence of photosynthesis impairment in plants exposed to Pb, and have found damage to photosystem II due to alteration of chlorophyll structure, as well as decreases in chlorophyll content in diverse taxa, including lichens and mosses. A substantial amount of evidence of oxidative stress in response to Pb exposure has also been produced. Reactive oxygen species were found to increase in broad bean and tomato plants exposed to increasing concentrations of soil Pb, and a concomitant increase in superoxide dismutase, glutathione, peroxidases, and lipid peroxidation, as well as decreases in catalase were observed in the same plants. Monocot, dicot, and bryophytic taxa grown in

Pb-contaminated soil or in experimentally spiked soil all responded to increasing exposure with increased antioxidant activity. In addition, genotoxicity, decreased germination, and pollen sterility were observed in some experiments. All effects were small outside of contaminated areas (Section 7.3.4.1).

Invertebrates

Since the 2006 Pb AQCD, various species of terrestrial snails have been found to accumulate Pb from both diet and soil, although effects on growth, survival and reproduction are inconsistent. Recent studies with earthworms have found that both internal concentration of Pb and mortality increase with decreasing soil pH and CEC. In addition, tissue concentration differences have been found in species of earthworms that burrow in different soil layers. The rate of accumulation in each of these species could result from layer differences in interacting factors such as pH and CEC (Section 7.3.3.2). Because earthworms often sequester Pb in granules, some authors have suggested that earthworm Pb is not bioavailable to their predators. There is some evidence that earthworm activity increases Pb availability in soil, but it is inconsistent. In arthropods collected at contaminated sites, recent studies found gradients in accumulated Pb that corresponded to gradients in soil with increasing distance from stationary sources. Recently published studies have shown neuronal damage in nematodes exposed to low concentrations of Pb (2.5 μM = 0.5 mg Pb/L), accompanied by behavioral abnormalities. Reproductive effects were found at lower exposure in younger nematodes, and effects on longevity and fecundity were shown to persist for several generations. Increased mortality was found in earthworms, and was strongly dependent on soil characteristics including pH, CEC, and aging. Snails exposed to Pb through either topical application or through consumption of Pb-exposed plants had increased antioxidant activity and decreased food consumption, but effects on growth and survival were inconsistent. Effects on arthropods exposed through soil or diet varied with species and exposure conditions, and included diminished growth and fecundity in springtails, endocrine and reproductive anomalies, and body deformities. Increasing concentration of Pb in the exposure medium generally resulted in increased effects within each study, but the relationship between concentration and effects varied between studies, even when the same medium, e.g., soil, was used (Section 7.3.4.2). Evidence suggested that aging and pH are important modifiers.

Vertebrates

There were few recent studies of Pb bioavailability and uptake in vertebrates since the 2006 Pb AQCD. A study of two species of sea ducks in Alaska found that 3% of the birds had tissue levels of Pb that indicated exposure above background. Urban pigeons in Korea were found to accumulate 1.6 to 1.9 mg Pb/kg wet weight Pb in the lungs, while in

Wisconsin 70% of American woodcock chicks and 43% of young-of-year had elevated bone Pb (9.6 to 93 mg Pb/kg dry weight in chicks, 1.5 to 220 mg Pb/kg dry weight in young-of-year). None of the locations for these studies was in proximity to stationary sources of heavy contamination, and none was able to identify the origin of the Pb (Section 7.3.3.3). Effects on amphibians and reptiles included decreased white blood cell counts, decreased testis weight, and behavioral anomalies. However, large differences in effects were observed at the same concentration of Pb in soil, depending on whether the soil was freshly amended, or field-collected from contaminated areas. As in most studies where the comparison was made, effects were smaller when field-collected soils were used. A study at the Anaconda Smelter Superfund site found increasing Pb accumulation in gophers with increasing soil Pb around the location of capture. Effects of dietary exposure were studied in several mammalian species, and cognitive, endocrine, immunological, and growth effects were observed. Pigs fed various Pb-contaminated soils showed that the form of Pb determined accumulation, and another study showed lower feed efficiency and weight in pigs with 2,08 versus 1.44 μg Pb/dl in blood, originating in Pb-sulfate feed supplement. In some birds, maternal elevated blood Pb level was associated in recent studies with decreased hatching success, smaller clutch size, high corticosteroid level, and abnormal behavior. Some species show little or no effect of elevated blood Pb level. A study of Japanese quail found that Pb added to the diet could improve survival and incidence of several pathologies, and a long term study of pied flycatchers at a mine site produced mixed evidence for the effects of Pb (Section 7.3.4.3).

Food web

Recent studies were able to measure Pb in the components of various food chains that included soil, plants, invertebrates, arthropods and vertebrates. They confirmed that trophic transfer of Pb is pervasive, but no consistent evidence of trophic magnification was found (Section 7.3.3.4).

Community and Ecosystem Effects

New evidence of effects of Pb at the community and ecosystem levels of biological organization include several studies of the ameliorative effects of mycorrhizal fungi on plant growth, attributed to decreased uptake of Pb by plants, although both mycorrhizal fungus and plant were negatively affected. The presence of both earthworms and mycorrhizal fungi decreased solubility and mobility of Pb in soil in one study, but the presence of earthworms was associated with higher uptake of Pb by plants in another. The presence of snails increased uptake of Pb by earthworms, but not vice-versa. Most recently published research on community and ecosystem effects of Pb has focused on soil microbial communities, which have been shown to be impacted in both composition

and activity. Many recent studies have been conducted using mixtures of metals, but have tried to separate the effects of individual metals when possible. One study compared the effects of 6 metals individually (Åkerblom et al., 2007), and found that their effects on community composition were similar. In studies that included only Pb, or where effects of Pb could be separated, soil microbial activity was generally diminished, but in some cases recovered over time. Species and genotype composition were consistently altered, and those changes were long-lasting or permanent (Section 7.3.6) .

Exposure-Response

Several studies with various organisms have included gradients of Pb exposure. None has characterized the exposure-relationship using a continuous model of exposure-response. However, evidence indicates clearly that increased exposure to Pb is associated with increases in observed effects in terrestrial ecosystems. Evidence also demonstrates that many factors, including species and various soil physiochemical properties, interact strongly with Pb concentration to modify those effects. In terrestrial ecosystems, where soil is generally the main component of the exposure route, Pb aging is a particularly important factor, and one that may be difficult to reproduce experimentally. Without adequate quantification of those interactions, characterizations of exposure-response relationships may be difficult to transfer outside of experimental settings.

7.3.12 Causal Determinations for Pb in Terrestrial Systems

In the following sections, organism-level effects on reproduction and development, growth and survival are considered first since these endpoints can lead to effects at the population level or above and are important in ecological risk assessment. Neurobehavioral effects are considered next followed by sub-organismal responses (hematological effects, physiological stress) for which Pb has been shown to have an impact in multiple species and across taxa, including humans. Causal determinations for terrestrial, freshwater and saltwater ecological effects are summarized in Table 7-3.

7.3.12.1 Reproductive and Developmental Effects-Terrestrial Biota

In terrestrial invertebrates and vertebrates, evidence assessed for the present document and in Pb AQCDs indicates an association between reproductive effects and Pb exposure. Impaired fecundity at the organism level of biological organization can result in a decline in abundance and/or extirpation of populations, decreased taxa richness, and decreased relative or absolute abundance at the community level (Suter et al., 2005; U.S. EPA, 2003a). Evaluation of the literature on Pb effects in terrestrial species indicates that

exposure to Pb is associated with reproductive effects. Various endpoints have been measured in various taxa of terrestrial organisms to assess the effect of Pb on fecundity, development, and hormone homeostasis. Although reproductive effects were demonstrated, no single endpoint in a single taxon has been extensively studied. Recent evidence available since the 2006 Pb AQCD for effects of Pb on reproductive endpoints in terrestrial species is summarized in Table 7-4.

In terrestrial plants, few studies were available to the 2006 Pb AQCD (U.S. EPA, 2006b), and few are available more recently that specifically address reproductive effects of Pb exposure. Two genotypes of maize seedlings exhibited a significant and concentration-dependent reduction in seed germination following 7 days of Pb treatment in nutrient solution of nominal concentration of 0, 0.007, 0.7 and 7 mg Pb/L as Pb sulfate (Ahmad et al., 2011). Germination inhibition and chromosomal abnormalities also increased in a concentration-dependent manner in Grass pea grown in soil irrigated with solutions containing nominal concentration of 0 to 188 mg Pb/L (Kumar and Tripathi, 2008). However, germination increased in a broad sample of soils when amended with 2,000 mg Pb/kg (Dayton et al., 2006).

In terrestrial invertebrates, Pb can alter developmental timing, hatching success, sperm morphology and hormone homeostasis. The number of species studied has been small, but reproductive effects consistently increase with increasing exposure. The 2006 Pb AQCD reported effects on reproduction in collembolans and earthworms, with LOECs and NOECs typically well above Pb soil concentrations observed away from stationary sources of contamination. more recently, an increase in development time (approximately two days) and a reduction in relative fecundity were observed in aphids feeding on plants exposed to high concentrations of Pb (Görür, 2007). Hatching success of the collembolan *F. candida* was decreased following 10 day nominal exposure to Pb-spiked soils (EC_{50} 2,361 mg Pb/kg dry soils) (Xu et al., 2009b). Sperm morphology in Asian earthworms was significantly altered following 2-week exposures to soils containing nominal concentration of 1,000, 1,400, 1,800 and 2,500 mg Pb/kg soil (Zheng and Li, 2009). Pb may also disrupt hormonal homeostasis in invertebrates as studies with moths have suggested (Shu et al., 2009). Adult female moths reared on diets containing 25, 50, 100, or 200 mg Pb/kg exhibited decreased vitellogenin mRNA induction, and vitellogenin levels were demonstrated to decrease with increasing Pb exposure. Evidence of multi-generational toxicity effects of Pb is also present in terrestrial invertebrates, specifically springtails, mosquitoes, carabid beetles and nematodes where decreased fecundity in progeny of Pb-exposed individuals was observed. The magnitude of effects is variable, but they are present in multiple phyla, and increase with increasing exposure within studies. Reproductive effects in terrestrial invertebrates are also coherent with similar effects observed in aquatic invertebrates.

In terrestrial vertebrates, there is evidence for reproductive effects associated with Pb exposure in recent evidence and Pb AQCDs. The 2006 Pb AQCD (U.S. EPA, 2006c) concluded that exposure to affects reproduction and development in terrestrial vertebrates. Effects reported in that document included declines in clutch size, number of young hatched, number of young fledged, decreased fertility, and decreased eggshell thickness observed in birds near areas of Pb contamination and in birds with elevated Pb tissue concentration regardless of location. More recently, decreased testis weight was observed in lizards administered a sublethal dose of 10 or 20 mg Pb/kg day by oral gavage for 60 days (Salice et al., 2009). Few studies in the field have addressed reproductive effects of Pb specifically in mammals, due to most available data in wild or grazing animals being from near smelters, where animals are co-exposed to other metals. For example, the reproductive viability of red deer (*C. elaphus*) inhabiting a Pb-contaminated mining area of Spain was shown to be altered, with 11% and 15% reductions in spermatozoa and acrosome integrity observed in male deer from the mining area compared with those residing in reference areas (Reglero et al., 2009a), but multiple other metals were present at high concentrations. Evidence from AQCDs and the present document for terrestrial vertebrates is coherent with evidence from freshwater amphibians, and fish (Section 7.4.12.1). However, experimental evidence obtained using mammals in the context of human health research demonstrates a consistency of adverse effects of Pb on sperm (Section 5.8.4.1) and the onset of puberty in males and females (Sections 5.8.1.1 and 5.8.1.2) with strong evidence from both toxicology and epidemiology studies. Other reproductive endpoints including spontaneous abortions, pre-term birth, embryo development, placental development, low birth weight, subfecundity, hormonal changes, and teratology were also affected, but less consistently (Section 5.8).

For reproductive and developmental effects in terrestrial ecosystems, the current body of evidence is inadequate to conclude that exposure to Pb is causal in plants, and is sufficient to conclude that there is a causal relationship in invertebrates and vertebrates.

7.3.12.2 Growth Effects-Terrestrial Biota

Alterations in growth at the organism level of biological organization can have impacts at the population, community and ecosystem levels. In terrestrial ecosystems, evidence for effects of Pb on growth is strongest in terrestrial plants, although these effects are typically observed in laboratory studies with high exposure concentrations or in field studies near stationary sources. In terrestrial plants, there is evidence over several decades of research that Pb inhibits photosynthesis and respiration, all of which can reduce the growth of the plant (U.S. EPA, 2006c, 1986a, 1977).Decreases in chlorophyll *a* and *b*

content have been observed in various algal and plant species. Many laboratory toxicity studies report effects on the growth of plants in synthetic growing media, but observed effects typically occur at concentrations higher than the average background concentrations in U.S. soils (19 mg Pb/kg dry weight) (U.S. EPA, 2005b) and there are few field studies. Effects on plant growth can result in reduced productivity and decreased biomass. The 2006 Pb AQCD relied principally on evidence assembled in the *Ecological Soil Screening Levels for Lead* document (U.S. EPA, 2005b), which concluded that growth (biomass) was the most sensitive and ecologically relevant endpoint for plants.

Evidence for growth effects in terrestrial fauna is sparse. In the 1986 Pb AQCD, a study was reviewed in which the F1 and F2 generations of the springtail *Onychiurus armatus* fed a diet of Pb-exposed fungi (0.008 to 3.1 mg Pb/g) experienced a delay in achieving maximum length (Bengtsson et al., 1983). The authors suggested that the reduced growth may be accompanied by delayed sexual maturity. The 2006 Pb AQCD (U.S. EPA, 2006b) reported that growth effects observed in both terrestrial invertebrates and vertebrates were more pronounced in juvenile organisms, underscoring the importance of lifestage to overall Pb susceptibility. Recent evidence available since the 2006 Pb AQCD for effects of Pb on growth endpoints in terrestrial species is summarized in Table 7-4: reduced growth of garden snail *T. pisana*, increasing with increasing exposure, was observed following a five week dietary exposure to eight nominal concentrations of Pb (El-Gendy et al., 2011). Studies also show concentration-dependent inhibition of growth in earthworms raised in Pb-amended soil (Zheng and Li, 2009; Currie et al., 2005; Langdon et al., 2005). In AQCDs, growth effects of Pb have been reported in birds (changes in juvenile weight gain), at concentrations typically higher than currently found in the environment away from heavily exposed sites. The current body of evidence is sufficient to conclude that there is a causal relationship between Pb exposures and growth effects in terrestrial plants, and that a causal relationship is likely to exist between Pb exposure and growth effects in terrestrial invertebrates. Evidence is inadequate to establish causal relationship between Pb exposures and growth effects in terrestrial vertebrates.

7.3.12.3 Survival-Terrestrial Biota

The relationship between Pb exposure and survival has been well demonstrated in terrestrial species as presented in the Pb AQCDs and in Section 7.3.5 of the present document. Exposure can be either lethal, or produce sublethal effects that diminish survival probabilities. In the 1977 Pb AQCD, deaths from Pb poisoning in domestic animals caused by emissions from stationary sources were reported (U.S. EPA, 1977).

Additional studies in the 1986 and 2006 Pb AQCDs and current ISA provide evidence for a concentration-dependent response of mortality in terrestrial biota. Recent evidence available since the 2006 Pb AQCD for effects of Pb on survival in terrestrial species is summarized in Table 7-4.

Survival is a biologically important response that can have direct impact on population size. Survival is often quantified using LC_{50} (the concentration of toxicant where 50% mortality is observed or modeled), which may be a better metric for acute toxicity than for typical environmental exposure, which is more often comparatively low, and cumulative or chronic. From the LC_{50} data on Pb in this review and previous Pb AQCDs, a wide range of sensitivity to Pb is evident across taxa and within genera. As expected, reported LC_{50} are usually much higher than current environmental levels of Pb in the U.S away from heavily exposed sites, even though physiological dysfunction that adversely impacts the fitness of an organism often occurs well below concentrations that result in mortality. When available, LC_{10}, NOEC or LOEC have been reported in the present document.

Pb is generally not phytotoxic to plants at concentrations found in the environment away from heavily exposed sites, probably due to the fact that plants often sequester large amounts of Pb in roots, and that translocation to other parts of the plant is limited. No data have become available to change this assessment since the 2006 Pb AQCD.

Survival of soil-associated organisms is adversely affected by Pb exposure. In the 1986 Pb AQCD it was reported that Pb at the high extreme of concentrations found near roadsides and smelters at the time (10,000 to 40,000 mg Pb/kg dry weight) can eliminate populations of bacteria and fungi on leaf surfaces and in soil. Severe impairment of decomposition has long been accepted to be one of the most apparent results of soil contamination with Pb and other metals. In nematodes, the 2006 Pb AQCD reported LC_{50} values varying from 10 to 1,550 mg Pb/kg dry weight dependent upon soil OM content and soil pH (U.S. EPA, 2006c). In earthworms, 14 and 28 day LC_{50} values typically fell in the range of 2,400-5,800 mg Pb/kg depending upon the species tested. More recent evidence has been consistent with these values, and also showed concentration-dependent decreases in survival in collembolans and earthworms under various experimental conditions. The evidence in terrestrial invertebrates is coherent with evidence in freshwater invertebrates.

In terrestrial avian and mammalian species, toxicity is observed in laboratory studies over a wide range of doses (<1 to >1,000 mg Pb/kg body weight-day) as reviewed for the development of Eco-SSLs (U.S. EPA, 2005b), and subsequently reported in the 2006 Pb AQCD. The NOAELs for survival ranged from 3.5 to 3,200 mg Pb/kg-day. Surprisingly, the only study to have reported survival data following exposure to Pb in an

avian species since the 2006 Pb AQCD, found that survival was greater than in controls in quail exposed to 50 mg Pb/L in drinking water for 7 weeks (Nain and Smits, 2011). Evidence for association of Pb exposure with mortality in terrestrial vertebrates is coherent with observations in freshwater vertebrates (Section 7.4.12.3). The evidence is, therefore, sufficient to conclude that a causal relationship is likely to exist between Pb exposures and survival in terrestrial vertebrates and that there is a causal relationship between Pb exposures and survival in terrestrial invertebrates. The evidence is inadequate to conclude that there is a causal relationship between Pb exposures and survival in terrestrial plants.

7.3.12.4 Neurobehavioral Effects-Terrestrial Biota

The central nervous system of animals was recognized as a target of Pb toxicity in the 1977 Pb AQCD (U.S. EPA, 1977), and subsequent Pb reviews have provided additional supporting evidence of Pb as a neurotoxicant in terrestrial invertebrates and vertebrates. Effects of Pb on neurological endpoints in terrestrial animal taxa include changes in behaviors that may decrease the overall fitness of the organism such as food consumption, prey capture ability and avoidance behaviors.

Some organisms exhibit behavioral avoidance while others do not seem to detect the presence of Pb (U.S. EPA, 2006c). Decreased food consumption of Pb-contaminated diet has been demonstrated in some invertebrates (snails) and vertebrates (lizards, pigs). Decreased food consumption were observed in juvenile *A. achatina* snails exposed to Pb-contaminated (concentration greater than 134 mg Pb/kg) diet for 12 weeks (Ebenso and Ologhobo, 2009a). Similarly, feeding rate in *T. pisana* snails was depressed in 3 week dietary nominal exposures of 50 to 15,000 mg Pb/kg (El-Gendy et al., 2011), while other snails exposed to Pb at similar concentrations have shown no effects on feeding rate (Beeby and Richmond, 2010). Consumption of 10 mg/Pb kg diet resulted in lower food intake after 120 days of dietary exposure in pigs (*S. domestica*) (Yu et al., 2005).

In limited studies available on nematodes there is evidence that Pb may affect the ability to escape or avoid predation (Wang and Xing, 2008). Additional new evidence of changes in the morphology of GABA motor neurons was also found in nematodes (*C. elegans*) (Du and Wang, 2009).

Gull chicks experimentally exposed to Pb exhibited abnormal behaviors such as decreased walking, erratic behavioral thermoregulation and food begging that could make them more vulnerable in the wild (Burger and Gochfeld, 2005). Pb was administered via injection to reach a Pb concentration in feathers equivalent to Pb levels in feathers of wild

gull populations. Lizards exposed to Pb through diet of 10 to 20 mg Pb/kg per day for 60 days in the laboratory exhibited abnormal coloration and posturing behaviors.

These findings in terrestrial invertebrates and vertebrates are coherent with findings from studies in aquatic biota that showed neurobehavioral alterations in various species of fish, and also in some aquatic invertebrates (Section 7.4.12.4). They are also coherent with findings in laboratory animals that show that Pb induces changes in learning and memory (Section 5.3.2.3), as well as attention and motor skills (Section 5.3.3.1). New behaviors induced by exposure to Pb reviewed in Chapter 5 that are relevant to effects of Pb observed in terrestrial systems include hyperactivity and mood disorders, effects on visual and auditory sensory systems, changes in structure and function of neurons and supporting cells in the brain, and effects on the blood brain barrier. Mechanisms that include the displacement of physiological cations, oxidative stress and changes in neurotransmitters and receptors are also reviewed. Data from ecological studies are highly coherent with these data from animal experiments, especially neurobehavioral findings and evidence of structural changes. Overall, the evidence from aquatic and terrestrial systems is sufficient to conclude that a causal relationship is likely to exist between Pb exposures and neurobehavioral effects in invertebrates and vertebrates in terrestrial ecosystems.

7.3.12.5 Hematological Effects-Terrestrial Biota

Hematological responses are commonly reported effects of Pb exposure in vertebrates in terrestrial systems. In the 1977 Pb AQCD, ALAD was recognized as the most sensitive indicator of Pb exposure in rats (U.S. EPA, 1977). Furthermore, inhibition of ALAD was associated with death of waterfowl following ingestion of Pb shot. In the 1986 Pb AQCD, decreases in red blood cell ALAD activity were documented in birds and mammals near a smelter (Beyer et al., 1985). Additional evidence for effects on blood parameters and their applicability as biomarkers of Pb exposure in terrestrial birds and mammals were presented in the 2005 *Ecological Soil Screening Levels for Lead*, the 2006 Pb AQCD and the current ISA (U.S. EPA, 2006c, 2005b). Field studies available since the 2006 Pb AQCD, include evidence for elevated blood Pb levels correlated with decreased ALAD activity in songbirds and owls living in historical mining areas (Gómez-Ramírez et al., 2011; Hansen et al., 2011a).

This evidence is strongly coherent with evidence from freshwater invertebrates and vertebrates (Section 7.4.12.5) and observations from human epidemiologic and animal toxicology studies showing that exposure to Pb induces effects on hematological endpoints, including altered heme synthesis mediated through decreased ALAD and

ferrochelatase activities, decreased red blood cell survival and function, and increased red blood cell oxidative stress. Taken together, the overall weight of human epidemiologic and animal toxicological evidence is sufficient to conclude that a causal relationship exists between Pb exposure and decreased RBC survival and function, and altered heme synthesis in humans and in laboratory animals (Section 5.7). Based on observations in terrestrial birds and mammals and additionally supported by observations in aquatic organisms, and toxicological and epidemiological findings in laboratory animals and humans evidence is sufficient to conclude that there is a causal relationship between Pb exposures and hematological effects in terrestrial vertebrates. The evidence is inadequate to conclude that there is a causal relationship between Pb exposures and hematological effects in terrestrial invertebrates.

7.3.12.6 Physiological Stress-Terrestrial Biota

Induction of enzymes associated with oxidative stress response in terrestrial plants, invertebrates and vertebrates is a recognized effect of Pb exposure (U.S. EPA, 2006c). Several studies from the 2006 Pb AQCD in birds and plants provide evidence that Pb induces lipid peroxidation, however, exposures in these studies were higher than would be found generally in the environment (U.S. EPA, 2006c). Building on the body of evidence presented in the 2006 Pb AQCD, recent studies provide evidence of upregulation of antioxidant enzymes and increased lipid peroxidation associated with Pb exposure in many species of plants, invertebrates and vertebrates. In plants, increases of antioxidant enzymes with Pb exposure occur in some terrestrial species at concentrations approaching the average Pb concentrations in U.S. soils (18.9 mg Pb/kg). For example, in a series of studies Wang et al. observed increases in reactive oxygen species with increasing exposure to Pb from 20 mg Pb/kg soil to 2,000 mg Pb/kg in broad bean (*V. faba*) (Wang et al., 2010c; Wang et al., 2010a; Wang et al., 2008b) and tomato (*L. esculentum*) (Wang et al., 2008a), where they were accompanied up to approximately 500mg Pb/kg by proportional increases in SOD, glutathione, guaiacol peroxidase, and lipid peroxidation, as well as decreases in catalase. Spinach seedlings grown in soil containing six increasing concentrations of Pb from 20 to 520 mg Pb/kg exhibited higher production of reactive oxygen species, increased rates of lipid peroxidation and increased SOD concentrations. (Wang et al., 2011a). Markers of oxidative damage are also observed in terrestrial invertebrates, including snails and earthworms, and in terrestrial mammals. Across these biota, there are differences in the induction of antioxidant enzymes that appear to be species-dependent.

The oxidative stress responses associated with Pb exposure in terrestrial plants, invertebrates and vertebrates are consistent with responses in freshwater (Section 7.4.12.6) and saltwater organisms (Section 7.4.21.6), and in humans (Section 5.2.4). This oxidative stress is characterized by increased presence of reactive oxygen species and membrane and lipid peroxidation that can promote tissue damage, cytotoxicity, and dysfunction. Increases in reactive oxygen species are often followed by a compensatory and protective upregulation in antioxidant enzymes, such that this upregulation is itself indicative of oxidative stress conditions. Continuous production of reactive oxygen species may overwhelm this defensive process, leading to further oxidative stress and injury.

Upregulation of antioxidant enzymes and increased lipid peroxidation are considered reliable biomarkers of stress, and provide evidence that Pb exposure induces a stress response in those organisms which may itself increase susceptibility to other stressors and reduce individual fitness. Evidence is sufficient to conclude that there is a causal relationship between Pb exposures and physiological stress in terrestrial plants, and that a causal relationship is likely to exist between Pb exposure and physiological stress in terrestrial invertebrates and vertebrates.

7.3.12.7 Community and Ecosystem Level Effects-Terrestrial Biota

Most direct evidence of community and ecosystem level effects is from near stationary sources where Pb concentrations are higher than typically observed environmental concentrations for this metal. Impacts of Pb on terrestrial ecosystems near smelters, mines, and other industrial sources have been studied for several decades. Emissions of Pb from smelting and other industrial activities are accompanied by other trace metals (e.g., Zn, Cu, Cd) and SO_2 that may cause toxic effects independently or in concert with Pb. Those impacts include decreases in species diversity and changes in floral and faunal community composition. Ecosystem-level field studies are complicated by the confounding of Pb exposure with other factors such as the presence of trace metals and acidic deposition and the inherent variability in natural systems. In natural systems, Pb is often found co-existing with other stressors, and observed effects may be due to cumulative toxicity.

In laboratory and microcosm studies where it is possible to isolate the effect of Pb, this metal has been shown to alter competitive behavior of species, predator-prey interactions and contaminant avoidance. These dynamics may change species abundance and community structure at higher levels of ecological organization. Uptake of Pb into aquatic and terrestrial organisms and subsequent effects on mortality, growth,

physiological stress, blood, neurobehavioral and developmental and reproductive endpoints at the organism level are expected to have ecosystem-level consequences, and thus provide consistency and plausibility for causality in ecosystem-level effects.

In the 1977 Pb AQCD the potential for Pb to interfere with ecosystem level processes was explored in a detailed review of a study on the effects of Pb on relationships between arthropods and leaf litter decomposition (U.S. EPA, 1977). Reduced arthropod density, biomass and richness were observed in the vicinity of a Pb smelting complex in Missouri. There were also several studies correlating feeding habits, habitat, and Pb concentrations in body tissues reported in the 1977 Pb AQCD, specifically in insects and small mammals indicating that species differences in Pb concentrations are determined in part by trophic position and habitat preference.

In the 1986 Pb AQCD it was reported that Pb at environmental concentrations occasionally found near roadsides and smelters (10,000 to 40,000 mg Pb/kg dry weight [mg Pb/kg]) can eliminate populations of bacteria and fungi on leaf surfaces and in soil (U.S. EPA, 1986b). Some key populations of soil microorganisms and invertebrates die off at 1,000 mg Pb/kg soil interrupting the flow of energy through decomposition processes and altering community structure. At soil concentrations of 500 to 1,000 mg Pb/kg or higher, populations of plants, microorganisms, and invertebrates may shift toward Pb-tolerant populations of the same or different species (U.S. EPA, 1986b).

The 2006 Pb AQCD reported that decreased species diversity, changes in floral and faunal community composition and decreased vigor of terrestrial vegetation were observed in ecosystems surrounding former smelters including the Anaconda smelter in southwestern Montana (U.S. EPA, 2006c). Several studies in the 2006 Pb AQCD documented reduced organic matter decomposition rates and decreased microbial biomass in areas heavily polluted by metals. Lower abundance and reduced biodiversity of soil invertebrate communities were observed in field surveys in proximity to Pb stationary sources.

Recent evidence published since the 2006 Pb AQCD (summarized in Table 7-4) supports previous findings of a link between high concentration of soil metals and substantial changes in soil microorganism community composition, as well as decreased abundance and diversity. In a naturally Pb-enriched forest in Norway, The number of fungal colony forming units was approximately 10 times lower in the highest Pb soil concentration (~4.5 mg Pb/g dry weight) than in control soils (Baath et al., 2005). The composition of the fungal community was drastically altered, with only one species common to both soils, and the number of species present was substantially lower.

The effect of Pb on microbial community function has been quantified previously using functional endpoints such as respiration rates, fatty acid production, and soil acid phosphatase and urease activities. These may provide estimate of ecological impacts that emphasize functionality irrespective of microbial diversity or abundance measurements. Studies available since the 2006 Pb AQCD provide further evidence of Pb effects on microbial processes. Pb contamination reduced phenol oxidase activity in several types of soils; concentrations between 5 and 50 nM Pb 0.001 and 0.01 mg Pb/L significantly decreased phenol oxidase activity in all soils tested, while 400 nM (0.08 mg Pb/L) and greater completely arrested phenol oxidase activity in one soil tested (a high pH sandy loam) (Carine et al., 2009). Pb concentrations between 50 and 500 mg Pb/kg significantly reduced microbial abundance and diversity, and also resulted in lower soil phosphatase, urease, and dehydrogenase activities (Gao et al., 2010b). When the microbial properties of metal-contaminated urban soils were compared to those of rural soils, significant differences (Sudova and Vosatka, 2007) were detected in basal community respiration rates and microbial abundance (Yang et al., 2006). Gai et al. (2011) examined the microbial activity of three soils via microcalorimetric methods following Pb exposure. They noted an increase in activity immediately following Pb application (giving 10, 20, 40, 80, and 160 mg Pb/kg), and theorized that this was a result of rapid mortality of sensitive microbial species, followed by a concurrent proliferation of Pb-tolerant microorganisms. As Pb concentrations increased, however, the calculated microbial growth rate constant decreased, indicating a suppression of microbial activity (Gai et al., 2011). Akerblom et al. (2007) tested the effects of six metals (Cr, Zn, Mo, Ni, Cd, and Pb) individually. All tested metals had a similar effect on the species composition of the microbial community. Exposure to a high Pb concentration (52 mg Pb/kg) negatively affected respiration rates.

In addition to microbial communities, there is new evidence for effects of Pb on other terrestrial ecosystem components. Increased plant diversity was shown to ameliorate effects of Pb contamination on a microbial community (Yang et al., 2007). The presence of arbuscular mycorrhizal fungi may protect plants growing in Pb-contaminated soils (Bojarczuk and Kieliszewska-Rokicka, 2010; Sudova and Vosatka, 2007). Invertebrates affected by Pb in terrestrial systems may be altering community structure. Recent evidence since the 2006 Pb AQCD, indicates that some species of worms avoid Pb-contaminated soils (Langdon et al., 2005). Reductions in microbial and detritivorous populations can affect the success of their predators (U.S. EPA, 2006c). Following a 28-day exposure to field-collected soils contaminated with metals (including Pb at 426 mg Pb/kg), both population growth and individual growth of the earthworm *L. rubellus* were diminished (Klok et al., 2006). The authors proposed that, although these reductions were unlikely to result in extirpation, avian predators such as the godwit (*Limosa limosa*) that feed heavily on earthworms may be affected by a reduction of

available earthworm biomass. Furthermore, the presence of earthworms increased Pb uptake by plants (Ruiz et al., 2011; Sizmur et al., 2011).

In terrestrial ecosystems, most studies show decreases in microorganism abundance, diversity, and function with increasing soil Pb concentrations in areas near point-sources. Specifically, shifts in nematode communities, bacterial species, and fungal diversity have been observed. Most evidence for Pb toxicity to terrestrial plants, invertebrates and vertebrates is from single-species assays in laboratory studies. Although the evidence is strong for effects of Pb on growth (Section 7.3.12.2) , reproduction (Section 7.3.12.1) and survival (Section 7.3.12.3) in certain species, considerable uncertainties exist in generalizing effects observed under small-scale, particular conditions up to predicted effects at the ecosystem level of biological organization. In many cases it is difficult to characterize the nature and magnitude of effects and to quantify relationships between ambient concentrations of Pb and ecosystem response due to existence of multiple stressors, variability in field conditions, and to differences in Pb bioavailability at that level of organization. However, the cumulative evidence for Pb effects at higher levels of ecological organization is sufficient to conclude that a causal relationship is likely to exist between Pb exposures and the alteration of species richness, species composition and biodiversity in terrestrial ecosystems.

7.4 Aquatic Ecosystem Effects

7.4.1 Introduction to Effects of Pb on Aquatic Ecosystems

This section of the Pb ISA reviews the recent literature published since the 2006 Pb AQCD (U.S. EPA, 2006c), on the effects of Pb on freshwater and saltwater ecosystems. Freshwater and marine/estuarine systems are considered separately due to differences in Pb speciation, bioavailability of Pb, salinity, and physiological adaptations of organisms in freshwater versus saltwater environments, as modifying factors for Pb toxicity. The focus is on the effects of Pb to aquatic organisms including algae, aquatic plants, invertebrates, vertebrates, and other biota with an aquatic lifestage (e.g., amphibians). In the freshwater and saltwater sections, aqueous concentrations of Pb are reported as µg Pb/L and sediment concentrations are in mg Pb/kg.

In the present document, studies in some freshwater and saltwater organisms are included where responses are observed at very high Pb concentrations that might not be expected in most environmental scenarios or where the relevance of the exposure method to atmospherically-deposited Pb is unknown. These studies can provide mechanistic information on Pb toxicity, allow for comparison of Pb uptake across taxa, or

demonstrate the wide range of sensitivity among closely-related species. Furthermore, although exposure to Pb in natural systems is likely characterized as a chronic, low dose exposure, it is not always feasible to conduct long-term experiments under natural conditions. Observations from short-term experiments in which high concentrations are used can help to elucidate the shape of concentration-response relationships and provide evidence for a gradient of response to Pb exposure but the extent to which effects would be observed at concentrations of Pb typically found in the environment is uncertain.

There are a few studies in the following sections for which effects are reported at very low concentrations of Pb that appear to be below analytical detection limits. These studies are included to the extent that they provide information on responses to Pb. However, the difficulty in maintaining low concentrations of Pb and the potential for contamination limits the interpretation of the reported observations and consideration of the observed effects in the absence of analytical verification. In these cases, less weight is placed on study findings in drawing conclusions regarding the effects of Pb exposure.

In the following sections, the literature on aquatic ecosystem effects of Pb, published since the 2006 Pb AQCD, is considered with brief summaries from the 1977 Pb AQCD, the 1986 Pb AQCD and the 2006 Pb AQCD where relevant. Biogeochemistry of Pb in aquatic systems is reviewed in Section 7.4.2. Sections 7.4.3 and 7.4.4 consider the bioavailability and uptake of Pb by freshwater plants, invertebrates, and vertebrates. Biological effects of Pb on freshwater ecosystem components (plants, invertebrates, and vertebrates) are discussed in Section 7.4.5. In this section, effects are generally presented from sub-organismal responses (i.e., enzymatic activities, changes in blood parameters) to endpoints relevant to the population-level and higher (growth, reproduction and survival; summarized in Table 7-5). Biological effects are followed by data on exposure and response of freshwater species (Section 7.4.6). Effects of Pb at the freshwater ecosystem level of biological organization are discussed in Section 7.4.7. Section 7.4 includes a discussion of critical loads in freshwater systems (Section 7.4.8), characterization of sensitivity and vulnerability of freshwater ecosystem components (Section 7.4.9) and a discussion of Pb effects on ecosystem services (Section 7.4.10). A synthesis of the new evidence for Pb effects on freshwater organisms (Section 7.4.11) is followed by causal determinations based on evidence dating back to the 1977 Pb AQCD (Section 7.4.12). Corresponding sections on saltwater systems introduced in Section 7.4.13 include bioavailability of Pb in saltwater (Section 7.4.14), biological effects of Pb in saltwater (Section 7.4.15), exposure and response of saltwater species (Section 7.4.16), community and ecosystem level effects (Section 7.4.17) and characterization of sensitivity and vulnerability in saltwater species (Section 7.4.18) and ecosystem services (Section 7.4.19). The saltwater ecosystem section concludes with a synthesis of new evidence for Pb effects in marine/estuarine systems (Section 7.4.20) and

causal determinations based on evidence dating back to earlier AQCDs when available (Section 7.4.21).

7.4.2 Biogeochemistry and Chemical Effects of Pb in Freshwater and Saltwater Systems

Quantifying Pb speciation in aquatic environments is critical for determining the toxicity of the metal to aquatic organisms. As reviewed in the 2006 Pb AQCD (U.S. EPA, 2006b) and discussed in detail in Sections 3.3 and 7.2 of this assessment (Fate and Transport), the speciation process is controlled by many environmental factors. Although aerially deposited Pb largely consists of the labile Pb fraction, once the atmospherically-derived Pb enters surface waters its fate and bioavailability are influenced by Ca^{2+} concentration, pH, alkalinity, total suspended solids, and dissolved organic carbon (DOC), including humic acids. In sediments, Pb is further influenced by the presence of sulfides and Fe and Mn oxides. For instance, in neutral to acidic aquatic environments, Pb is typically present as $PbSO_4$, $PbCl_4$, Pb^{2+}, cationic forms of Pb hydroxide, and ordinary hydroxide [$Pb(OH)_2$], while in alkaline waters, common forms of Pb include Pb carbonates [$Pb(CO_3)$] and hydroxides [$Pb(OH)_2$]. In addition to these inorganic forms, Pb humate is present in the solid phase and Pb fulvate is present in solution. In freshwater systems, Pb complexes with inorganic OH^- and CO_3^{2-} and forms weak complexes with Cl^-; conversely, Pb speciation in seawater is a function of chloride concentration and the primary species are $PbCl_3$, $PbCO_3$, $PbCl_2$, and $PbCl^+$. In many, but not all aquatic organisms, Pb dissolved in water can be the primary exposure route to gills or other biotic ligands. The toxicity associated with Pb in the water column or sediment pore waters is directly affected by the competitive binding of Pb to the anions listed above.

Currently, national and state ambient water quality criteria for Pb attempt to adjust measured concentrations to better represent the bioavailable free ions, and express the criteria value as a function of the hardness (i.e., amount of Ca^{2+} and Mg ions) of the water in a specific aquatic system. Models such as the BLM (Figure 7-3) (Paquin et al., 2002; Di Toro et al., 2001) include an aquatic speciation model (WHAM V; see below) combined with a model of competitive binding to gill surfaces, and provides a more comprehensive method for expressing Pb concentrations at specific locations in terms of the bioavailable metal. Sediment quality criteria have not been established, although the EPA has developed methods based on equilibrium partitioning theory to estimate sediment benchmarks for Pb and a few other metals (U.S. EPA, 2005d). The approach is based on the ratio of the sum of simultaneously extracted metals and amount of AVS, adjusted for the fraction of organic carbon present in the sediments, and is reviewed in detail in the 2006 Pb AQCD (U.S. EPA, 2006c). It is important to note that this method

cannot accurately predict which sediments are toxic or which metal is the primary risk driver.

A more detailed understanding of the biogeochemistry of Pb in aquatic systems (both the water column and sediments) is critical to accurately predicting toxic effects of Pb to aquatic organisms. It should be recognized, however, that in addition to exposure via sediment and water, chronic exposures to Pb also include dietary uptake, even though the toxicokinetics of this exposure pathway are not yet well understood in aquatic organisms and the influence of the bioavailability factors described above is unknown. Furthermore, changes in environmental factors that reduce the bioaccessible Pb fraction can result in either sequestration in sediments or subsequent release as mobile, bioaccessible forms. This section provides updated information about the influence of chemical parameters that affect Pb bioaccessibility in the aquatic environment (in sediments and the water column).

Several models are available for estimating the speciation of dissolved Pb. These models were tested by Balistrieri and Blank (2008) by comparing the speciation of dissolved Pb in aquatic systems affected by historical mining activities with that predicted by several models, including Windermere humic aqueous model (WHAM VI), non-ideal competitive absorption Donnan-type model (NICA-Donnan), and Stockholm humic model (SHM). Accurate prediction of labile Pb concentrations was achieved only with SHM, although other metal concentrations were better described by the WHAM model. Whereas both WHAM VI and NICA-Donnan predicted that the bulk of Pb contamination would be complexed with Fe, SHM predicted Pb speciation predominantly characterized by Fe and inorganic Pb complexes. Predicted dynamic Pb concentrations developed with the WHAM VI and NICA-Donnan methods overestimated Pb concentrations measured using diffusive gradients in thin-films in Lake Greifen (Switzerland), but underestimated concentrations in Furbach stream (located in both the Coeur d'Alene and Spokane River Basins in Idaho), indicating that such models may not be able to accurately describe metal speciation under all environmental conditions (Balistrieri and Blank, 2008).

Quantification of different sediment metal-binding phases, including sulfide, organic carbon (OC), Fe, and Mn phases, is important to fully understand the bioaccessible fraction of Pb and the toxicity to benthic organisms (Simpson and Batley, 2007). However, physical disturbance, pH change, and even the biota themselves also alter sediment binding or release of Pb. Atkinson et al. (2007) studied the effects of pH on sequestration or release of Pb from sediments. Although high and circumneutral water pH (8.1 and 7.2) did not affect the release of sequestered Pb from sediments, lowering the pH to 6 increased the concentration of Pb in overlying waters from less than 100 µg Pb/L to 200-300 µg Pb/L. Physical sediment disturbance also increased the amount of sediment-

bound Pb released into the aqueous phase. When Pb-contaminated sediment was physically disturbed, the dissolved oxygen content of the overlying water was observed to significantly impact Pb mobilization, with greater Pb mobilization at lower dissolved oxygen levels (3 to 9 mg/L O_2) (Atkinson et al., 2007). In addition, although Pb concentrations in the sediments of a mine-impacted wetland in Hezhang, China, were determined to be strongly associated with organic/sulfide and residual fractions (e.g., 34 to 82% of total Pb), the presence of aquatic macrophytes altered the Pb speciation, increasing the fraction of Pb bound to Fe-Mn oxides (42% to 47% of total Pb) (Bi et al., 2007). This phenomenon was investigated in greater depth by Sundby et al. (2005), who determined that release of oxygen from macrophyte roots resulted in the oxidation of sediment-bound Pb, leading to the release of bioaccessible Pb fractions (Sundby et al., 2005).

7.4.2.1 Other Metals

Multiple metals are present simultaneously in many aquatic environments and may interact with one another influencing Pb uptake and toxicity. Interactions of Pb with other metals were reviewed in the 2006 Pb AQCD, and more recent evidence supports previous findings of altered bioavailability associated with metal mixtures. Komjarova and Blust (2008) looked at the effect of the presence of Cd^{2+} on the uptake of Pb by the freshwater cladoceran *Daphnia magna*. While Pb uptake rates were not affected by Cu, Ni or Zn, enhanced Pb accumulation was observed in the presence of 0.2 µM Cd. The highest Pb concentration, 0.25 µM (51.8 µg Pb/L) in turn facilitated Cu uptake. Area-specific and whole organism Pb transport rates were greatest in the mid-intestine. It was concluded that Pb-induced disruptions of ion homeostasis and metal absorption processes might be a possible explanation of stimulated Pb uptake in the presence of Cd, as well as the increase in Cu uptake rates provoked by presence of Pb at its highest studied concentration. Komjarova and Blust (2009b) then considered the effect of Na, Ca^{2+} and pH on simultaneous uptake of Cd, Cu, Ni, Pb and Zn. Cd and Pb showed increased uptake rates at high Na concentration. It was thought that increased Na uptake rates promoted Pb entrance to the cell. With respect to the effect of pH, reduced proton competition begins to influence Pb uptake in waters with high pH. A clear suppression of Cd, Ni, Pb and Zn uptake was observed in the presence of Ca^{2+} (2.5 mM). Ca^{2+} has been reported to have a protective effect in other studies (involving other organisms). The presence of other metals may also affect the uptake of Pb by fish. At low concentrations, Cd in a Pb-Cd mixture out-competed Pb at gill tissue binding sites in rainbow trout (*Oncorhynchus mykiss*), resulting in a less-than additive toxicity when fish were exposed to both metals in tandem (Birceanu et al., 2008). Evidence for the presence of Pb

influencing the uptake of other metals was observed in the marine bivalves *Macomona liliana* and *Austrovenus stutchburyi*. Significantly, more Zn bioaccumulated in the presence of Pb in these mussels than with Zn alone following a 10-day exposure to spiked sediments (Fukunaga and Anderson, 2011).

7.4.2.2 Biofilm

Farag et al. (2007) measured Pb concentrations in various media (water, colloids, sediment, biofilm) as well as invertebrates and fish collected within the Boulder River watershed, MT, U.S. They concluded that the fraction of Pb associated with Fe-oxides was most frequently transferred to biofilms and the other biological components of the sampled systems (Farag et al., 2007). Consequently, an increase in the Pb Fe-oxide fraction could signify a potential increase in the bioaccessible pool of Pb. The authors also noted that this fraction may promote downstream transport of Pb contamination. Ancion et al. (2010) investigated whether urban runoff metal contaminants could modify biofilm bacterial community structure and diversity and therefore potentially alter the function of biofilms in stream ecosystems. They found that accumulation rates for metals in biofilm were maximal during the first day of exposure and then decreased with time. Equilibrium between metal concentrations in the water and in the biofilm was reached for all metals after 7-14 days of exposure. The affinity of the biofilm for Pb was, however, much greater than for Cu and Zn. With respect to recovery, the release of metals was slow and after 14 days in clean water 35% of Pb remained in the biofilm. By retaining and releasing such metal pollutants, biofilms may play a key role in determining both the concentration of the dissolved metals in the water column and the transfer of the metals to invertebrates and fish grazing on them. An enrichment factor of 6,000:1 for Pb between the biofilm and the water was measured after 21 days exposure to synthetic urban runoff. The relatively slow release of such metal may greatly influence the transfer of Pb to organisms feeding on the biofilms. This may be of particular importance during storm events when large amounts of Pb are present in the urban runoff. It was suggested that biofilms constitute an integrative indicator of metal exposure over a period of days to weeks.

7.4.2.3 Carbonate

An investigation of heavy metal concentrations in an industrially impacted French canal (Deule canal) indicated that total extractable Pb in sediments ranged from 27 to 10,079 mg Pb/kg, with 52.3% present in Fe-Mn oxide fractions, 26.9% as organic sulfide fraction, 10.7% in carbonates, and 10.1% in the residual fraction (Boughriet et al., 2007). The relatively high fraction of Pb associated with carbonates was not observed at other sites, as sediments in these areas contained low proportions of carbonates. Hence, addition of carbonates (either from anthropogenic or natural sources) can significantly impact Pb speciation in sediments, and potential bioavailability to resident organisms. In addition, increased surface water carbonate concentrations also reduced the bioaccessible Pb fraction as measured by chronic Pb accumulation in the fathead minnow, (*Pimephales promelas*) (Mager et al., 2010), and by Pb toxicity to fathead minnow and the cladoceran (*Ceriodaphnia dubia*) (Mager et al., 2011b).

7.4.2.4 Dissolved Organic Matter (DOM)

Uptake of Pb by water-column organisms is affected by the concentration of DOM (Mager et al., 2011a; Mager et al., 2010). In a 7-day chronic study with *C. dubia*, DOM protected against toxicity while water hardness was not protective (Mager et al., 2011a). The specific composition of DOM has been shown to affect the bioaccessibility of environmental Pb. Humic acid-rich DOM resulted in decreased free Pb ion concentration when compared to systems containing DOM with high concentrations of polysaccharides (Lamelas and Slaveykova, 2008). When the sequestering abilities of various components of DOM were compared, humic acid again was shown to be most efficient at reducing the Pb free ion concentration, followed by fulvic acid, alginic acid, polygalacturonic acid, succinoglycan, and xanthan (Lamelas et al., 2005). Lamelas et al. (2009) considered the effect of humic acid on Pb(II) uptake by freshwater algae taking account of kinetics and cell wall speciation. The uptake flux was described by a Michaelis-Menten type equation. Comparison of Cu(II), Cd(II) and Pb(II) uptake by green freshwater algae, (*Chlorella Kessleri)*, in the presence of either citric acid or humic acid was made. The uptake fluxes, percentage adsorbed and percentage internalized for Cu and Cd were identical in the presence of either citric or humic acid. In contrast, however, there was a ten-fold increase in the respective values for Pb. The increase in adsorbed Pb was attributed to the increase in adsorption sites from the adsorbed humic acid on the surface of the algae. Two hypotheses were considered to explain the increase in internalized Pb and the internalization flux: (1) direct interaction of Pb-humic acid complexes with the internalization sites, and (2) uptake of Pb(II) after dissociation from the Pb-humic acid complex. The authors favor the former hypothesis but no evidence is presented for the

proposed ternary Pb-humic acid-internalized site complexes, nor is there an explanation as to why this behavior is not observed for Cd or Cu.

There is evidence, however, that DOC/DOM does not have the same effect on free Pb ion concentration in marine systems as in freshwater systems. No correlation was observed between DOM concentration or composition and Pb toxicity when examined using the sea urchin (*Paracentrotus lividus)* embryo-larval bioassay (Sanchez-Marin et al., 2010a). For marine invertebrates, the presence of humic acid increased both the uptake and toxicity of Pb, despite the fact that a larger fraction of Pb is complexed with humic acid (25 to 75%). Although the authors could not provide a precise explanation for this, they theorized that in marine environments, addition of humic acid could induce and enhance uptake of Pb via membrane Ca^{2+} channels (Sanchez-Marin et al., 2010b). This mechanism was observed in the marine diatom (*Thalassiosira weissflogii)*, in that humic acids absorbed to cell surfaces increased metal uptake; however, water column Pb-humic acid associations did appear to reduce free Pb ion concentrations (Sanchez-Marin et al., 2010b). Formation of a ternary complex that is better absorbed by biological membranes was another proposed mechanism that could describe the increased bioaccessibility to marine invertebrates of Pb bound to humic acid (Sánchez-Marín et al., 2007).

Sanchez-Marin et al. (2011) subsequently have shown that different components of DOM have different effects on Pb bioavailability in marine systems. Their initial research using Aldrich humic acid found that increasing humic acid concentrations increased Pb uptake by mussel gills and increased toxicity to sea urchin larvae in marine environments (Sánchez-Marín et al., 2007). In contrast, a subsequent investigation found that fulvic acid reduced Pb bioavailability in marine water (Sánchez-Marín et al., 2011). The contradictory effects of different components of DOM on marine bioavailability likely reflect their distinct physico-chemical characteristics. More hydrophobic than fulvic acid, humic acid may adsorb directly with cell membranes and enhance Pb uptake through some (still unidentified) mechanism (Sánchez-Marín et al., 2011).

As little as 1 µM of humic acid introduced into surface waters was sufficient to reduce Pb uptake by perennial ryegrass, *Lolium perenne,* grown in nutrient solution. This resulted from a decrease in the concentration of the free Pb fraction by several orders of magnitude following complexation with the OM. Pb content on the root surface was reduced to 1,658 mg Pb/kg from 4,144 mg Pb/kg following humic acid addition, and relative Pb absorption (absorption in the presence of humic acid divided by absorption in the absence of humic acid) was determined to be approximately 0.2 (Kalis et al., 2006). Conversely, humic acid may increase the bioaccessible Pb fraction for green algae through formation of a ternary complex that promotes algal uptake of the metal. Lamelas and Slaveykova (2007) found that aqueous Pb formed complexes with humic acid, which

in turn would become adsorbed to *C. kesslerii* algal surfaces, and that the presence of Pb sorbed to humic acid did not interfere with humic acid-algae complexation. The authors concluded that humic acids bound to algae acted as additional binding sites for Pb, thus increasing the concentrations associated with the algal fraction (Lamelas and Slaveykova, 2007).

Based on the above, the recent literature indicates the existence of a number of deviations from current models used to predict bioaccessibility of Pb. In marine aquatic systems, for instance, surface water DOM was found to increase (rather than decrease) uptake of Pb by fish gill structures, potentially through the alteration of membrane Ca^{2+}-channel permeability. This phenomenon would not be accurately predicted by a BLM developed using data from freshwater organisms. Further, in both freshwater and marine environments, algal biosorption of labile Pb fraction was also increased by humic acid and DOM, likely through the formation of ternary complexes that increase Pb binding sites on the algal surface. Although it is unclear whether Pb in this form is available for toxic action on algae, it is likely to comprise a significant source of dietary Pb for primary consumers. Moreover, the attempted field verification of freshwater bioaccessibility models was conducted at sites with distinct point-sources of Pb contamination, and only one model (SHM) adequately predicted Pb bioaccessibility.

7.4.2.5 Sulfides

In sediments, Pb bioavailability is further influenced by sulfides. In the presence of sulfides, most of the reactive metal in sediments will form insoluble metal sulfide that is not bioavailable for uptake by benthic organisms. Acid volatile sulfide (AVS) has been used to predict the toxicity of Pb and other metals in sediments (Ankley et al., 1996; Di Toro et al., 1992) and in the development of sediment quality criteria (Section 7.4.3). The role of sulfides in the flux of Pb from sediments is discussed further in Section 3.3.2.3.

7.4.3 Introduction to Bioavailability and Biological Effects of Pb in Freshwater Ecosystems

Freshwater ecosystems across the U.S. encompass many habitats including ponds, streams, rivers, wetlands and lakes. Concentrations of Pb available for fresh surface-water and freshwater sediments are reported in Section 7.2.3 and Table 7-2 and are summarized here. Representative median and range of Pb concentrations in surface waters (median 0.50 µg Pb/L, range 0.04 to 30 µg Pb/L), sediments (median 28 mg Pb/kg dry weight, range 0.5 to 12,000 mg Pb/kg dry weight) and fish tissues (geometric mean

0.54 mg Pb/kg dry weight, range 0.08 to 23 mg Pb/kg dry weight [whole body]) in the U.S. based on a synthesis of NAWQA data reported in the previous 2006 Pb AQCD (U.S. EPA, 2006c). Additional information on ambient Pb levels in waters, sediments and biota is presented in Section 3.6.5 and Table 7-2 including new data from the Western Airborne Contaminants Assessment Project (WACAP) on Pb in environmental media and biota from remote ecosystems in the western U.S. WACAP assessed concentrations of semi-volatile organic compounds and metals in up to seven ecosystem components (air, snow, water, sediment, lichen, conifer needles and fish) in watersheds of eight core national parks during a multi-year project conducted from 2002-2007 (Landers et al., 2008). The goals of the study were to assess where these contaminants were accumulating in remote ecosystems in the western U.S., identify ecological receptors for the pollutants, and to determine the source of the air masses most likely to have transported the contaminants to the parks.

The 2006 Pb AQCD (U.S. EPA, 2006b) provided an overview of regulatory considerations for water and sediments in addition to consideration of biological effects and major environmental factors that modify the response of aquatic organisms to Pb exposure. Regulatory guidelines for Pb in water and sediments have not changed since the 2006 Pb AQCD, and are summarized below with consideration of limited new information on these criteria since the last review. This section is followed by new information on biogeochemistry, bioavailability and biological effects of Pb since the 2006 Pb AQCD.

The most recent ambient water quality criteria for Pb in freshwater were released in 1985 (U.S. EPA, 1985) by the EPA Office of Water which employed empirical regressions between observed toxicity and water hardness to develop hardness-dependent equations for acute and chronic criterion. These criteria are published pursuant to Section 304(a) of the Clean Water Act and provide guidance to states and tribes to use in adopting water quality standards for the protection of aquatic life and human health in surface water. The ambient water quality criteria for Pb are expressed as a criteria maximum concentration (CMC) for acute toxicity and criterion continuous concentration (CCC) for chronic toxicity (U.S. EPA, 2009b). In freshwater, the CMC is 65 µg Pb/L and the CCC is 2.5 µg Pb/L at a hardness of 100 mg/L.

The 2006 Pb AQCD summarized two approaches for establishing sediment criteria for Pb based on either bulk sediment or equilibrium partitioning (Section 7.2.1 and Section AX7.2.1.4). The first approach is based on empirical correlations between metal concentrations in bulk sediment and associated biological effects to derive threshold effect concentrations (TEC) and probable effects concentrations (PEC) (MacDonald et al., 2000). The TEC/PEC approach derives numeric guidelines to compare against bulk

sediment concentrations of Pb. The other approach in the 2006 Pb AQCD was the equilibrium partitioning procedure published by the EPA for developing sediment criteria for metals (U.S. EPA, 2005d). The equilibrium partitioning approach considers bioavailability by relating sediment toxicity to pore water concentration of metals. The amount of simultaneously extracted metal (SEM) is compared with the metals extracted via AVS since metals that bind to AVS (such as Pb) should not be toxic in sediments where AVS occurs in greater quantities than SEM.

Since the 2006 Pb AQCD, both of these methods for estimating sediment criteria for metals, have continued to be used and refined. The SEM approach was further refined in the development of the sediment BLM (Di Toro et al., 2005). The BLM is discussed further in Sections 7.3.3 and 7.4.4. Comparison of empirical approaches with AVS-SEM in metal contaminated field sediments shows that samples where either method predicted there should be no toxicity due to metals, no toxicity was observed in chronic amphipod exposures (Besser et al., 2009; MacDonald et al., 2009). However, when the relationship between invertebrate habitat (epibenthic and benthic) and environmental Pb bioaccumulation was investigated, De Jonge et al. (2010) determined that different environmental fractions of Pb were responsible for invertebrate uptake and exposure. Pb uptake by benthic invertebrate taxa was not significantly correlated to AVS Pb levels, but rather to total sediment concentrations (De Jonge et al., 2009). Conversely, epibenthic invertebrate Pb body burdens were better correlated to AVS concentrations, rather than total Pb sediment concentrations (De Jonge et al., 2010).

In the following sections, recent information since the 2006 Pb AQCD on Pb in freshwater ecosystems will be presented. Throughout the sections, brief summaries of conclusions from the 1977 Pb AQCD, the 1986 Pb AQCD and 2006 Pb AQCD are included where appropriate. The sections are organized to consider uptake of Pb and effects at the species level, followed by community and ecosystem level effects. New research on the bioavailability and uptake of Pb into freshwater organisms including plants, invertebrates and vertebrates is presented in Section 7.4.4. Effects of Pb on the physiology of freshwater flora and fauna (Section 7.4.5) are followed with data on exposure and response of freshwater organisms (Section 7.4.6). Responses at the community and ecosystem levels of biological organization are reviewed in Section 7.4.7 followed by a brief consideration of critical loads in freshwater systems (Section 7.4.8), characterization of sensitivity and vulnerability of ecosystem components (Section 7.4.9) and a discussion of ecosystem services (Section 7.4.10). The freshwater ecosystem section concludes with a synthesis of new evidence (Section 7.4.11) and causal determinations based on evidence dating back to the 1977 Pb AQCD (Section 7.4.12).

7.4.4 Bioavailability in Freshwater Systems

Bioavailability was defined in the 2006 Pb AQCD as "the proportion of a toxin that passes a physiological membrane (the plasma membrane in plants or the gut wall in animals) and reaches a target receptor (cytosol or blood)." In 2007, EPA took cases of bioactive adsorption into consideration and revised the definition of bioavailability as "the extent to which bioaccessible metals absorb onto, or into, and across biological membranes of organisms, expressed as a fraction of the total amount of metal the organism is proximately exposed to (at the sorption surface) during a given time and under defined conditions" (U.S. EPA, 2007c). See Section 7.3.3 for additional discussion of bioavailability.

The bioavailability of metals varies widely depending on the physical, chemical, and biological conditions under which an organism is exposed (U.S. EPA, 2007c). The bioavailability of a metal is also dependent upon the bioaccessible fraction of metal. The bioaccessible fraction of a metal is the portion (fraction or percentage) of environmentally available metal that actually interacts at the organism's contact surface and is potentially available for absorption or adsorption by the organism (U.S. EPA, 2007c). The processes for evaluating bioavailability and bioaccessibility are presented in Figure 7-2 and in Section 7.3.3. In brief, trace metals, and their complexes, must first diffuse from the external medium to the surface of the organism (mass transport). Metal complexes may dissociate and re-associate in the time that it takes to diffuse to the biological surface. These processes are considered further in Chapter 3. To have an effect on the organism, metals must then react with a sensitive site on the biological membrane (adsorption/desorption processes), often but not necessarily followed by biological transport (internalization). Any of these processes may be the rate limiting step for the overall biouptake process. Internalization is, however, the key step in the overall biouptake process. Although the transport sites often have a high affinity for required metals they do not always have high selectivity and so a toxic metal may bind to the site of an essential metal with a similar ionic radius or co-ordination geometry, e.g., Pb^{2+}, Cd^{2+} and Zn^{2+} are similar to Ca^{2+}. At the molecular level, there are three major classes of transition metal transporter: P-type ATPases, Zn regulated transporter/iron-regulated transporter, and natural resistance associated macrophage proteins (Worms et al., 2006). Of these, natural resistance associated macrophage proteins have been shown to promote the uptake of various metals including Pb. This type of trace metal transport can be described by Michaelis-Menten uptake kinetics and equilibrium considerations.

Routes of Exposure

According to the 2006 Pb AQCD (U.S. EPA, 2006b), Pb adsorption, complexation, chelation, etc., are processes that alter its bioavailability to different aquatic species, and it was suggested that multiple exposure routes may be important in determining overall bioavailability of Pb. Given its low solubility in water, bioaccumulation of Pb by aquatic organisms may preferentially occur via exposure routes other than direct absorption from the water column, including ingestion of contaminated food and water, uptake from sediment pore waters, or incidental ingestion of sediment. If uptake and accumulation are sufficiently faster than depuration and excretion, Pb tissue levels may become sufficiently high to result in physiological effects (Luoma and Rainbow, 2005). Pb accumulation rates are controlled, in part, by metabolic rate. Other factors that influence bioavailability of Pb to organisms in aquatic systems are reviewed in Section 7.4.2. As summarized in the 2006 Pb AQCD, organisms exhibit three Pb accumulation strategies: (1) accumulation of significant Pb concentrations with low rate of loss resulting in substantial accumulation; (2) balance between excretion and bioavailable metal in the environment; and (3) very low metal uptake rate without significant excretion, resulting in weak net accumulation (Rainbow, 1996). Uptake experiments with aquatic plants, invertebrates and vertebrates reviewed in the 2006 Pb AQCD showed increases in Pb uptake with increasing Pb in solution. The 2006 Pb AQCD findings included consideration of bioaccumulation in different trophic levels. Pb concentrations were found to be typically higher in algae and benthic organisms and lower in higher trophic-level consumers.

In this section:

1) Recent information on bioavailability and uptake in algae, plants, invertebrates and vertebrates from freshwater systems are reviewed with summary material from the 2006 Pb AQCD and earlier Pb AQCDs where appropriate.

2) An overview of the BLM is presented as the most widely used method for predicting both the bioaccessible and bioavailable fractions of Pb in the aquatic environment. This is followed by a discussion of

3) Bioavailability in algae, plants, invertebrates and vertebrates. As reviewed by Wang and Rainbow (2008), aquatic organisms exhibit distinct patterns of metal bioaccumulation. The authors suggest that the observed differences in accumulation, body burden, and elimination between species are due to metal biogeochemistry and physiological and biological responses of the organism. The studies presented below generally support the observations of Wang and

Rainbow (2008) that closely related species can vary greatly in bioaccumulation of Pb and other non-essential metals.

The bioaccumulation and toxicity of Pb to aquatic organisms are closely linked to the environmental fate of the metal under variable environmental conditions (Section 3.3) as they are highly dependent upon the relative proportion of free metal ions in the water column. However, information is lacking on the uptake of Pb through ingestion of Pb-sorbed particles or dietary exposure to biologically-incorporated Pb. Such routes of exposure are not included in models such as the BLM that predict toxicity as a function of Pb concentration in the water column. This uncertainty may be greater for Pb than for other more soluble metals (such as Cu) as a greater proportion of the total mass of Pb in an aquatic ecosystem is likely to be bound to particulate matter. Therefore, estimating chronic toxicity of Pb to aquatic receptors may have greater uncertainty than predicting acute effects.

BLM Models

In addition to the biogeochemical effects that govern the environmental pool of accessible Pb, reactions of Pb with biological surfaces and membranes determines the bioavailability and uptake of the metal by aquatic organisms. The BLM (Figure 7-3) predicts both the bioaccessible and bioavailable fraction of Pb in the aquatic environment, and can be used to estimate the importance of environmental variables such as DOC in limiting uptake by aquatic organisms (Alonso-Castro et al., 2009). The BLM integrates the binding affinities of various natural ligands in surface waters and the biological uptake rates of aquatic organisms to determine the site-specific toxicity of the bioavailable fraction.

In the 2006 Pb AQCD, limitations of the use of BLM in developing air quality criteria were recognized including the focus of this model on acute endpoints and the absence of consideration of dietary uptake as a route of exposure. Atmospheric deposition of Pb to aquatic systems and subsequent effects on ecosystem receptors is likely characterized as a chronic, cumulative exposure rather than an acute exposure. Recommendations from the 2006 Pb AQCD included developing both chronic toxicity BLMs and BLMs that consider the dietary route of Pb uptake. The EPA recently incorporated the BLM into the Framework for Metal Risk Assessment (U.S. EPA, 2007c) and has published an ambient freshwater criteria document for Cu based on the BLM model (U.S. EPA, 2007a). This section reviews the literature from the past 5 years on applications of the BLM to predicting bioavailability of Pb to aquatic organisms. However, the primary focus of initial BLMs has been acute toxicity endpoints for fish and invertebrates following gill or cuticular uptake of metals.

Di Toro et al. (2005) constructed BLMs for metals exposure in sediments, surface water, and sediment pore water to determine how to most accurately predict the toxicity of metals-contaminated sediments. Results from models were compared with literature-derived acute toxicity values for benthic and epibenthic invertebrates to establish the accuracy of the developed models. Although the models tended to overestimate the toxicity of aqueous and sediment-bound Pb in freshwater environments, it was determined that the model significantly underestimated Pb toxicity to marine invertebrates (Di Toro et al., 2005). This may be because pore water metal concentrations were not modeled. Consequently, these results may suggest that either 1) mobilization of Pb concentrations from sediments into pore water is greater in marine environments, or 2) marine invertebrates are significantly more sensitive to Pb exposures than are freshwater species.

A number of deviations from results predicted by Pb exposure models (such as the BLM) were documented by Ahlf et al. (2009). They highlighted that uptake of metals by sediment-dwelling bivalves was significantly greater than predicted, because bivalves accumulate Pb from multiple sources not included in the model, such as ingestion of algae, bacteria, and colloidal matter. Species-specific dietary assimilation of ingested particulate-bound metals is also likely to play a role in the toxicity of Pb to aquatic organisms, yet insufficient data are available to permit modeling of this additional factor (Ahlf et al., 2009). The authors outlined the need for additional data in developing bioavailability models for chronic metal exposures. As recent evidence suggests that the hydrophobic DOC fraction (e.g., humic and fulvic acids) sequesters the greatest fraction of Pb in aquatic systems (Pernet-Coudrier et al., 2011), understanding the influence of this adsorption on Pb toxicity is critical for the prediction of chronic aquatic Pb toxicity. For instance, although the presence of humic acid is considered to reduce the bioavailable fraction of metals in surface water, green algae uptake and biosorption of metals, including Pb, was actually increased by humic acid. The authors determined that humic acid bound to algal surfaces served to increase the total number of metal binding sites over those afforded solely by the algal surface (Lamelas and Slaveykova, 2007). This highlights the complexity of modeling chronic metals bioavailability through multiple exposure routes, as humic acid would decrease gill or cuticular uptake of metals from the water column, but could potentially enhance dietary exposure by increasing algal metal content. Slaveykova and Wilkinson (2005) also noted that humic acid is likely to interact with other biological membranes and alter their permeability to metals, especially in acidic environments. Further, they observed that increased surface water temperatures can not only increase membrane permeability but also change metabolic rates, both of which can enhance metals uptake and assimilation; however, this factor is not included in bioavailability models such as the BLM (Slaveykova and Wilkinson, 2005). Despite this,

the authors noted that, in most cases, the BLM could predict acute metals toxicity with a reasonable degree of accuracy.

7.4.4.1 Freshwater Plants and Algae

In the 1977 Pb AQCD, the root system of plants was recognized as the major route of uptake for Pb (U.S. EPA, 1977). Uptake and translocation studies of Pb in plants and algae reviewed in the 1977 Pb AQCD and the 2006 Pb AQCD indicated that plants tend to sequester larger amounts of Pb in their roots than in their shoots. Recent studies on bioavailability of Pb to plants support the findings of the previous Pb AQCDs and provide additional evidence for species-dependent differences in responses to Pb in water and sediments.

Most biouptake studies in aquatic plants and algae available since the 2006 Pb AQCD, were typically conducted at very high concentrations of Pb that are not representative of current levels of Pb typically encountered in freshwater. However, most of these exposures included a series of increasing concentrations of Pb and generally, Pb was accumulated in a dose-dependent manner. Studies in which high concentrations of Pb are used and an exposure-response relationship is observed may imply effects at lower concentrations but uncertainty remains to the extent to which effects would be observed at concentrations of Pb typically found in the environment. The role of modifying factors, such as the presence of other metals, on uptake rates as well as species differences in Pb uptake rates can be determined from experimental Pb concentrations that are higher than measured Pb in the environment. Plants that are hyperaccumulators of Pb and other metals may be used for phytoremediation at highly contaminated sites and there is a large body of literature on uptake of very high concentrations of metals by different species. This chapter focuses on environmentally relevant concentrations of Pb and also those studies with doses or exposures in the range of one or two orders of magnitude above current or ambient conditions, as described in the Preamble. In freshwater ecosystems in the U.S., the average Pb concentration in surface water is 0.5 µg Pb/L (Table 7-2), however, total Pb in water has been measured as high as 2,000 µg Pb/L where mining and smelting operations have affected streams (Table 3-11).Studies with freshwater algae available since the 2006 Pb AQCD, are primarily limited to nominal media exposures at high concentrations of Pb with metal quantified in tissues. For example, the microalgae *Spirulina platensis* was demonstrated to accumulate Pb from Zarrouk culture medium in a concentration-dependent manner with nominal initial concentrations of 5,000, 10,000, 30,000, 50,000 and 100,000 µg Pb/L (Pb in medium was measured every two days thereafter), following a 10-day incubation period (Arunakumara et al., 2008). Pb concentrations accumulated by algae appeared to decrease when culture time increased

from 2 to 10 days. This may have occurred as a result of a gradual recovery of growth and an addition of biomass that would have reduced the concentration of Pb in algal tissue. An aquatic moss, *Fontinalis antipyretica*, accumulated up to an average of 622 mg Pb/kg dry weight over a 7-day nominal exposure to 20,700 µg Pb/L despite saturation of intracellular Pb concentrations after 5 days of exposure (Rau et al., 2007). Interestingly, experimentation with concurrent Cu and Pb exposure indicated that the presence of Cu increased the uptake of Pb by the green algae *Chlamydomonas reinhardtii* (Chen et al., 2010c). The authors noted that, in the case of Cu-Pb binary exposures, uptake rates of Pb exhibited complex non-linear dynamics in other aquatic organisms as well.

Additional uptake studies conducted since the 2006 Pb AQCD, include new information for freshwater macrophytes. When exposed to nominal water concentrations of up to 20,700 µg Pb/L, floating (non-rooted) coontail plants (*Ceratophyllum demersum*) accumulated an average Pb concentration of 1,748 mg Pb/kg after 7 days, although this was not significantly higher than levels accumulated in the first day of exposure (Mishra et al., 2006b). Induction of the antioxidant system improved the tolerance of the aquatic plant *Najas indica* for bioaccumulated Pb, allowing for increased biomass and the potential to accumulate additional Pb mass. High Pb accumulation (3,554 mg Pb/kg dry weight tissue following a 7-day exposure to 20,720 µg Pb/L) was considered to be a function of plant morphology; as a submerged, floating plant, *N. indica* provides a large surface area for the absorption of Pb (Singh et al., 2010).

Given that atmospherically-derived Pb is likely to become sequestered in sediments (Section 7.2), uptake by aquatic macrophytes is a significant route of Pb removal from sediments, and a potential route for Pb mobilization into the aquatic food web. The rooted aquatic macrophyte *Eleocharis acicularis* was determined to be a hyperaccumulator of Pb in an 11-month bioaccumulation experiment with mine tailings. When grown in sediments containing 1,930 mg Pb/kg, the maximum concentration of Pb in *E. acicularis* was determined to be 1,120 mg Pb/kg dry weight. However, calculated BCFs for Pb were all less than one, indicating that Pb uptake, although high, was less efficient than for other metals present (Ha et al., 2009).

Aquatic plants inhabiting a wetland containing an average sediment Pb concentration of 99 mg Pb/kg exhibited variable Pb tissue concentrations, but these do not appear to be related to macrophyte type (e.g., submerged, floating, emergent, etc.). Consequently, the authors concluded that uptake of Pb by aquatic plants appears to be dependent on species, at the exclusion of habitat or type. For instance, among the submerged plant species, *Ceratophyllum demersum* accumulated the greatest amount of Pb (22 mg Pb/kg dry weight), while *Potamogeton malainus* tissue contained the least amount of Pb, 2.4 mg Pb/kg dry weight (Bi et al., 2007). Tissues of the floating plants *Azolla imbricata* and

Spirogyra communis were found to contain 12 and 20 mg Pb/kg dry weight, respectively, while emergent macrophytes *Scirpus triqueter* and *Alternanthera philoxeroides* accumulated 1.4 and 10 mg Pb/kg dry weight. Fritioff and Greger (2006) determined that anywhere from 24–59% of the total Pb taken up by *Potamogeton natans* aquatic plants was sequestered in the cell wall fraction, depending on plant tissue and environmental Pb concentration. More importantly, no translocation of Pb was observed when plant tissues (leaf, stem, root) were exposed to Pb solutions separately (Fritioff and Greger, 2006).

Dwivedi et al. (2008) reared nine different species of aquatic plants in a fly-ash contaminated medium containing approximately 7 mg Pb/kg dry weight. Not only did species exhibit different Pb accumulation efficiencies but they also compartmentalized sequestered Pb differently. The submerged macrophyte *Hydrilla verticillata* accumulated the greatest amount of Pb (approximately 180 mg Pb/kg dry weight tissue), but Pb was sequestered solely in the shoot tissue. In contrast, other plant species accumulated between 15 and 100 mg Pb/kg dry weight (*Ranunculus scloralus* and *Marsilea quadrifolia*) with the majority compartmentalizing the metal in root tissue, except for *C. demersum* and *M. quadrifolia*, which also utilized shoot tissue for Pb storage (Dwivedi et al., 2008).

Pb concentrations in the root, leaf, and stem tissues of three aquatic plant species were found to correlate most closely with the concentration of the exchangeable Pb fraction (e.g., the fraction of Pb that is easily and freely leachable from the sediment). Authors noted that seasonal variations can alter the amount of Pb present in the exchangeable fraction, and that Pb was more likely than Cd or Cu to remain tightly bound to sediments, and therefore the relationship between total sediment Pb and Pb in aquatic plant tissues was weaker (Ebrahimpour and Mushrifah, 2009).

Lemna sp., a free floating macrophyte, incubated in a water extract of waste ash containing 19 µg Pb/L accumulated 3.5 mg Pb/kg dry weight over 7 days of exposure. Slight toxic effects, including suppression of growth, were observed over this exposure period, but this may have been a result of exposures to multiple metals in the water extract, including Cr, Mn, Cu, and Zn (Horvat et al., 2007). Lemna sp. was also demonstrated to be effective in the biosorption of Pb from solution, even in the presence of sediments (1 g per 700 mL water). Over 7 days of exposure to 3,600 and 7,000 µg Pb/L, plant biomass was found to contain an average of 2,900 and 6,600 mg/kg (wet weight) Pb, respectively, versus 200 and 300 mg/kg (dry weight) in sediment (Hurd and Sternberg, 2008).

Young *Typha latifolia*, another rooted macrophyte, were grown in analytically verified concentrations of 5,000 and 7,500 µg/L Pb-spiked sediment for 10 days to determine their value as metal accumulators. Within the exposure period, plants exposed to the

lower concentration were able to remove 89% of Pb, while 84% of the Pb present in the higher treatment was taken up by *T. latifolia*. Pb concentrations measured in root and leaf tissue ranged from 1,365 to 4,867 mg Pb/kg and 272 to 927 mg Pb/kg, respectively, and were higher at the greater Pb exposure (Alonso-Castro et al., 2009).

Uptake studies available for aquatic macrophytes since the 2006 Pb AQCD, include some studies where Pb was measured in field collected plants growing in metal-contaminated areas. Common reeds (*Phragmites australis*) grown in metal-impacted aquatic environments in Sicily, Italy, preferentially accumulated Pb in root and rhizome tissues (Bonanno and Lo Giudice, 2010). Pb concentrations in water and sediment averaged 0.4 µg Pb/L and 2.7 mg Pb/kg. These levels yielded root and rhizome concentrations of 17 and 15 mg Pb/kg, respectively, whereas stem and leaf Pb concentrations were lower (9.9 and 13 mg Pb/kg). These tissue concentrations were significantly correlated to both water and sediment concentrations (Bonanno and Lo Giudice, 2010). Conversely, the semi-aquatic plant *Ammania baccifera*, grown in mine tailings containing 35 to 78 mg Pb/kg, did not accumulate analytically detectable levels of Pb in either root or shoot tissues, despite the fact that other metals (Cu, Ni, Zn) were bioaccumulated (Das and Maiti, 2007). This would indicate that at low/moderate environmental Pb concentrations, some plant species may not bioaccumulate significant (or measurable) levels of Pb.

The average concentration of Pb in the tissues of rooted aquatic macrophytes (*Callitriche verna*, *P. natans*, *C. demersum*, *Polygonum amphibium*, *Veronica beccabunga*) collected from two metals-polluted streams in Poland (average sediment concentration 38 to 58 mg Pb/kg) was less than 30 mg Pb/kg. Pb bioaccumulation in plants was significantly correlated with sediment Pb concentrations (Samecka-Cymerman and Kempers, 2007). A similar significant correlation was established between reed sweet grass root Pb concentration and sediment Pb concentrations (Skorbiowicz, 2006).

Pb tissue concentrations of aquatic plants *P. australis* and *Ludwigia prostrata* collected from wetlands containing an average of 52 mg Pb/kg in surficial sediments were predominantly in root tissues, indicating poor translocation of Pb from roots. In the former, Pb decreased from an average of 37 mg Pb/kg in roots to 17, 14, and 12 mg Pb/kg in rhizome, stem and leaf tissues, respectively, while *L. prostrata* Pb tissue concentrations decreased from 77 mg Pb/kg in fibrous root to 7 and 43 mg Pb/kg in stem and leaf tissues (Yang et al., 2008a). The authors proposed that this diminished transfer ability explained the relatively low BCFs for Pb uptake in these two species, when compared with those of other metals.

Despite no significant seasonal effect on surface water Pb concentrations, shining pondweed (*Potamogeton lucens*), a rooted aquatic macrophyte grown in an urbanized metal-contaminated lake in Turkey, exhibited seasonal alterations in Pb tissue

concentrations. Average water Pb concentrations were 28 µg Pb/L in spring, 27 µg Pb/L in summer, and 30 µg Pb/L in autumn. Over this same time period, root tissue Pb concentrations significantly increased from 6 mg Pb/kg dry weight in spring, to 9 mg Pb/kg dry weight in summer, and to 10 mg Pb/kg dry weight in autumn (Duman et al., 2006). No differences were detected in stem Pb concentrations between spring and summer (approximately 4 mg Pb/kg dry weight), but stem Pb concentrations were found to be significantly higher in autumn (6 mg Pb/kg dry weight). In the same system, *P. australis* plants accumulated the most Pb during winter: 103, 23, and 21 mg Pb/kg dry weight in root, rhizome, and shoot tissue, respectively, in sediments containing 13 mg Pb/kg dry weight. By contrast, *Schoenoplectus lacustris* accumulated maximum rhizome and stem Pb concentrations of 5.1 and 7.3 mg Pb/kg dry weight in winter, but sequestered the greatest amount of Pb in root tissues during the spring (30 mg Pb/kg dry weight) at a comparable sediment concentration, 18 mg Pb/kg dry weight (Duman et al., 2007). The authors suggest that this indicated that metal uptake was regulated differently between species.

Tree species that inhabit semi-aquatic environments have also been shown to absorb Pb from Pb-contaminated sediments. Bald-cypress trees (*Taxodium distichum*) growing in sediments of a refinery-impacted bayou in Louisiana accumulated significantly greater amounts of Pb than did trees of the same species growing in bankside soil, despite the lower Pb concentrations of sediments. Bankside soils contained greater than 2,700 mg Pb/kg versus concentrations of 10 to 424 mg Pb/kg in sediments, yet Pb concentrations in trees averaged 4.5 and 7.8 mg Pb/kg tissue, respectively (Devall et al., 2006). The authors theorized that Pb was more readily released from sediments and that soil dispersion to the swamp sediments provides additional, if periodic, loads of Pb into the system. Willow seedlings planted in Pb-contaminated sediment were more effective at removing Pb from the media than a diffusive gradient in thin film technique predicted (Jakl et al., 2009). The authors proposed that the plant's active mobilization of nutrients from soil during growth also resulted in increased Pb uptake and sequestration.

Given that sediments are a significant sink for Pb entering aquatic systems, it is not surprising that rooted macrophytes bioaccumulate significant quantities of the metal. Although there are some similarities to Pb accumulation observed in terrestrial plants (e.g., preferential sequestration of the metal in root tissue), Pb appears to be more bioavailable in sediment than it is in soil. This may be a result of differences in plant physiology between aquatic and terrestrial plants (e.g., more rapid growth or more efficient assimilation of nutrients and ions from a water-saturated medium). While rooted macrophytes are likely to be chronic accumulators of Pb sequestered in sediments, aerial deposition of Pb into aquatic systems may result in pulsed inputs of labile Pb that would be available for uptake by floating macrophytes and algae.

7.4.4.2 Freshwater Invertebrates

Uptake and subsequent bioaccumulation of Pb in freshwater invertebrates varies greatly between species and across taxa as previously characterized in the 2006 Pb AQCD. This section expands on the findings from the 1986 Pb AQCD and 2006 Pb AQCD on bioaccumulation and sequestration of Pb in aquatic invertebrates. In the case of invertebrates, Pb can be bioaccumulated from multiple sources, including the water column, sediment, and dietary exposures, and factors such as proportion of bioavailable Pb, lifestage, age, and metabolism can alter the accumulation rate. In this section, new information on Pb uptake from freshwater and sediments by invertebrates will be considered, followed by a discussion on dietary and water routes of exposure and factors that influence species-specific Pb tissue concentrations such as invertebrate habitat and functional feeding group.

In a recent uptake study in freshwater mussels available since the 2006 Pb AQCD, the Eastern elliptio mussel (*Elliptio complanata*) was shown to accumulate Pb rapidly from water and then reach an equilibrium with exposure level and tissue concentration by two weeks following average daily exposures of 1, 4, 14, 57 or 245 µg Pb/L as Pb nitrate (Mosher et al., 2012). Tissue concentrations of Pb increased at an exposure-dependent rate for the first 14 days and then did not change significantly for the remainder of the 28-day exposure although mussels continued to accumulate Pb. At the end of the exposure period, average Pb in tissue ranged from 0.33 to 898 mg Pb/kg. The authors concluded that the mussels were likely eliminating Pb via pseudo feces and through storage of Pb in shell.

The 2006 Pb AQCD (U.S. EPA, 2006b) summarized studies of uptake of Pb from sediment by aquatic invertebrates and noted that sediment pore water, rather than bulk sediment, is the primary route of exposure. However, a recent study suggests that in the midge, *Chironomus riparius*, total metal concentrations in bulk sediment are better predictors of metal accumulation than dissolved metal concentrations in sediment pore water based on bioaccumulation studies using contaminated sediments from six different sites (Roulier et al., 2008a). Vink (2009) studied six river systems and found that, for a range of metals, uptake by benthic organisms (the oligochaete, Limnodrilus (Family Tubificidae) and the midge, *C. riparius*) from the sediment pore water (as compared with surface water) was observed only occasionally, and solely for Pb. The physiological mechanisms of Pb uptake are still unclear but it is suggested that uptake and elimination of Pb obey different mechanisms than for other heavy metals.

The 2006 Pb AQCD recognized the potential importance of the dietary uptake pathway as a source of Pb exposure for invertebrates. Specifically, in a study with the freshwater amphipod *Hyalella azteca,* dietary exposure was found to contribute to the chronic

toxicity of Pb, while acute toxicity was unaffected (Besser et al., 2004). Since the 2006 Pb AQCD, additional studies have considered the relative importance of water and dietary uptake of Pb in aquatic invertebrates. A stable isotope technique was used to simultaneously measure uptake of environmentally relevant concentrations of Pb (10.4 µg Pb/L) in the water column by the freshwater cladoceran *D. magna* directly from water and through food, the green algae *Pseudokirchneriella subcapitata*. (Komjarova and Blust, 2009a). *D. magna* accumulated the metal from both sources, but the relative proportion of uptake from each source changed over the exposure period. After the first day of exposure, 12% of accumulated Pb was determined to have been absorbed from dietary (algal) sources, but this percentage decreased by day four of exposure to 4%. Pb absorbed from water exposure only resulted in Daphnia body burdens of approximately 62.2 mg Pb/kg dry weight (300 µmol Pb/kg dry weight), and was similar to the amount absorbed by algae (Komjarova and Blust, 2009a). In a comparison of dietary and waterborne exposure as sources of Pb to aquatic invertebrates, no correlation between Pb uptake and dietary exposure was observed in the amphipod *H. azteca (*Borgmann et al., 2007*)*.

Stable isotope analysis was to used measure uptake and elimination simultaneously in net-spinning caddisfly larvae (Hydropsyche sp.) exposed to aqueous Pb concentrations of 0.2 (control) or 0.6 µg Pb/L for 18 days (Evans et al., 2006). The measured uptake constant for Pb in this study was 7.8 g/dry weight per day, and the elimination rate constant of 0.15/day for Pb-exposed larvae was similar in both presence and absence of the metal in the water. Tissue concentrations ranged from approximately 15 to 35 mg Pb/kg. Hydropsychid Pb BCFs ranged from 41 to 65, and averaged 54, indicating a relatively high accumulation when compared to other metals tested (average BCF of 17 for Cd, 7.7 for Cu, and 6.3 for Zn) (Evans et al., 2006).

Recent reports on Pb distribution in freshwater organisms generally support the findings of the 2006 Pb AQCD that Pb is primarily sequestered in the gills, hepatopancreas, and muscle. Uptake of Pb by the crayfish *Cherax destructor* exposed to nominal concentration of 5,000 µg Pb/L as Pb nitrate for 21 days resulted in accumulation at the highest concentration in gill, followed by exoskeleton >mid-gut gland >muscle >hemolymph (Morris et al., 2005). Body burden analysis following 96 hour nominal exposure to 50, 100 and 500 µg Pb/L as Pb nitrate in the freshwater snail *Biomphalaria glabrata* indicated that bioaccumulation increased with increasing concentrations of Pb and the highest levels were detected in the digestive gland (Ansaldo et al., 2006).

When the relationship between invertebrate habitat (epibenthic and benthic) and environmental Pb bioaccumulation was investigated, De Jonge et al. (2010) determined that different environmental fractions of Pb were responsible for invertebrate uptake and

exposure. Pb uptake by benthic invertebrate taxa was not significantly correlated to AVS Pb levels, but rather to total sediment concentrations (De Jonge et al., 2009). Conversely, epibenthic invertebrate Pb body burdens were better correlated to AVS concentrations, rather than total Pb sediment concentrations (De Jonge et al., 2010). For instance, the biologically available Pb (e.g., bound to metal-rich granules or metallothioneins) accumulated by the oligochaete *Tubifex tubifex* was determined to correlate with sediment SEM-AVS Pb concentrations (De Jonge et al., 2011). Similarly, Desrosiers et al. (2008) reported that Pb accumulation by chironomid larvae from St. Lawrence river sediments was significantly correlated to both total Pb and reactive Pb sediment concentrations.

Both inter- and intra-specific difference in Pb uptake and bioaccumulation may occur in macroinvertebrates of the same functional-feeding group. Cid et al. (2010) reported significant differences in Pb bioaccumulation between field collected *Ephoron virgo* mayflies and Hydro psyche sp, caddisflies, with only the mayfly exhibiting increased Pb tissue concentrations when collected from Pb-contaminated sites; the caddisfly Pb tissue concentrations were similar between reference and Pb-contaminated areas. The authors also examined the lifestage specific accumulation of Pb for *E. virgo* mayflies, and although there was no statistical difference in Pb tissue concentrations between different lifestages, Pb bioaccumulation did change as mayflies aged (Cid et al., 2010).

Reported BAF values for Pb in aquatic invertebrates from the 2006 Pb AQCD ranged from 499 to 3,670 [Table AX7-2.3.2 (U.S. EPA, 2006c)]. Since the 2006 Pb AQCD, additional BAF values have been established for invertebrates in field studies which tend to be higher than BCF values calculated in laboratory exposures (Casas et al., 2008; Gagnon and Fisher, 1997). A complicating factor in establishing BAF values is that laboratory studies usually assess uptake in water-only or sediment only exposures while field studies take into account dietary sources of Pb as well as waterborne Pb resulting in BAF values that are frequently 100-1,000 times larger than BCF values for the same metal and species (DeForest et al., 2007). The EPA Framework for Metals Risk Assessment states that the latest scientific data on bioaccumulation do not currently support the use of BCFs and BAFs when applied as generic threshold criteria for the hazard potential of metals (U.S. EPA, 2007c). See Section 7.3.3 for further discussion.

As reviewed by Wang and Rainbow (2008) and supported by additional studies reviewed in the present document, there are considerable differences between species in the amount of Pb taken up from the environment and in the levels of Pb retained in the organism. The bioaccumulation and subsequent toxicity of Pb to aquatic organisms (Section 7.4.5) are closely linked to the environmental fate of the metal under variable

environmental conditions (Sections 3.3 and 7.2) as they are highly dependent upon the proportion of free metal ions in the water column.

7.4.4.3 Freshwater Vertebrates

Uptake of Pb by vertebrates considered here includes data from fish species as well as a limited amount of new information on amphibians and aquatic mammals. The bioaccessibility and bioavailability of Pb is affected by abiotic and biotic modifying factors considered in Sections 7.4.2 and 7.4.4. In fish, Pb is taken up from water via the gills and from food via ingestion. Amphibians and aquatic mammals are exposed to waterborne Pb primarily through dietary sources. In the 2006 Pb AQCD, dietary Pb was recognized as a potentially significant source of exposure to all vertebrates since Pb adsorbed to food, particulate matter and sediment can be taken up by aquatic organisms.

Since the 2006 Pb AQCD, tissue accumulation of Pb via gill and dietary uptake has been further characterized in freshwater fish and new techniques such as the use of stable isotopes have been applied to further elucidate bioaccumulation of Pb. For example, patterns of uptake and subsequent excretion of Pb in fish as measured by isotopic ratios of Pb in each tissue can determine whether exposure was due to relatively long term sources (which favor accumulation in bone) or short term sources (which favors accumulation in liver) (Miller et al., 2005). Recent information since the 2006 Pb AQCD, on uptake of Pb by fish from freshwater is reviewed below, followed by studies on dietary uptake as a route of Pb exposure. Next, tissue accumulation patterns in fish species are reported with special consideration of the anterior intestine as a newly identified target of Pb from dietary exposures. Finally, studies that report Pb tissue concentrations in amphibians, reptiles and freshwater mammals are considered.

Freshwater Fish

Pb uptake in freshwater fish is accomplished largely via direct uptake of dissolved Pb from the water column through gill surfaces and by ingestion of Pb-contaminated diets. According to the data presented in the 2006 Pb AQCD (U.S. EPA, 2006b), accumulation rates of Pb are influenced by both environmental factors, such as water pH, DOC, and Ca^{2+} concentrations, and by species-dependent factors, such as metabolism, sequestration, and elimination capacities. The effects of these variables on Pb bioaccumulation in fish are largely identical to the effects observed for invertebrates (discussed above).

Pb in fish is primarily found in bone, gill, blood, kidney and scales (Spry and Wiener, 1991). Since the 2006 Pb AQCD, multiple studies on uptake of Pb from water by fathead

minnow and subsequent tissue distribution have been conducted. Spokas et al. (2006) showed that Pb accumulates to the highest concentration in gill when compared to other tissues over a 24-day exposure. This pattern was also observed in larval fathead minnows exposed to 26 µg Pb/L for 10-30 days, where gill exhibited the highest Pb concentration compared to carcass, intestine, muscle and liver (Grosell et al., 2006a). In the larval minnows, Pb concentration in the intestine exhibited the highest initial accumulation of all tissues on day 3 but then decreased for the remainder of the experiment while concentrations in the other organs continued to increase. By day 30, gill tissue exhibited the highest Pb concentration (approximately 120 mg Pb/kg), followed by whole fish and carcass (whole fish minus gill, liver, muscle and intestine) Pb concentrations (approximately 70 to 80 mg Pb/kg). However, in considering overall internal Pb body burden, nearly 80% was largely concentrated in the bone tissue, while gill contributed <5%.

In another study with fathead minnow, chronic (300 day) exposure to 120 µg Pb/L resulted in accumulation of approximately 41 mg Pb/kg tissue, although this number was decreased from initial body burdens of greater than 104 mg Pb/kg at test initiation (Mager et al., 2010). Tissue distribution at 300 days was consistent with Grosell et al. (2006a) with highest concentration in gill, followed by kidney, anterior intestine, and carcass. Addition of humic acid and carbonate both independently reduced uptake of Pb in these fish over the exposure time period. Interestingly, fathead minnow eggs collected daily during 21 day breeding assays that followed the chronic exposure described above accumulated similar levels of Pb from the test solutions regardless of Pb concentration or water chemistry (e.g., addition of humic acid and carbonate) (Mager et al., 2010). Direct acute exposure from water rather than parental transfer accounted for the majority of the Pb accumulation in eggs. Similarly, exposure of fish to 32.5 µg Pb/L in base water for 150 days resulted in fathead minnow whole body concentrations of approximately 31 mg Pb/kg, with the most rapid accumulation rate occurring within the first 10 days of exposure, followed by an extended period of equilibrium (Mager et al., 2008). In this same study, fish were tested in two additional treatments: 36.7 µg Pb/L in hard water (Ca^{2+} 500 µM) or 38.7 µg Pb/L in humic acid supplemented water (4 mg/L). While the addition of humic acid significantly reduced Pb bioaccumulation in minnows (to approximately 10.4 mg Pb/kg on a whole body basis), Ca^{2+} sulfate did not alter uptake. Despite the fact that Ca^{2+}-mediated Pb toxicity occurred in larval fathead minnow, there was no concurrent effect on whole body Pb accumulation.

Uptake studies in other freshwater teleosts have generally followed the pattern of Pb uptake described above for fathead minnow. In the cichlid, Nile tilapia (*Oreochromis niloticus*), Pb accumulated significantly in gill (45.9 ±34.4 µg/g dry weight at 2,070 µg Pb/L), 57.4 ±26.1 µg/g dry weight at 4,100 µg Pb/L) and liver (14.3 µg/g dry

weight at2,070 µg Pb/L) and 10.2 µg/g dry weight at 4,100 µg Pb/L) during a 14-day nominal exposure (as Pb nitrate) (Atli and Canli, 2008). In rainbow trout exposed to 100 µg Pb/L (as Pb acetate) for 72 hours, the accumulation in tissues was gill >kidney >liver and this same pattern was observed in all concentrations tested (100-10,000 µg Pb/L) (Suicmez et al., 2006). In contrast to uptake in teleosts, in Pb-uptake studies with the Chondrostei fish Chinese Sturgeon (*Acipenser sinensis*), muscle tissue accumulated higher levels of Pb than gills (Hou et al., 2011).

Sloman et al. (2005) investigated the uptake of Pb in dominant-subordinate pairings of rainbow trout exposed to 46 µg/L or 325 µg Pb/L (as Pb nitrate) for 48 hours. Significant Pb accumulation in gill, liver and kidney was only observed in the highest concentration. Pb accumulated preferentially in liver of subordinate trout when compared to dominant trout. Brown trout (*Salmo trutta*) exposed to aqueous Pb concentrations ranging from 15 to 46 µg Pb/L for 24 days accumulated 6 mg Pb/kg dry weight in gill tissue and Pb concentrations in liver tissue reached 14 mg Pb/kg dry weight. Interestingly, Pb in gill tissue peaked on day 11 and decreased thereafter, while liver Pb concentrations increased steadily over the exposure period, which may indicate translocation of Pb in brown trout from gill to liver (Heier et al., 2009).

Zebrafish (*Danio rerio*) Pb uptake rates from media containing 5.2 µg Pb/L was significantly increased by neutral pH (versus a pH of 6 or 8) and by Ca^{2+} concentrations of 0.5 mM; uptake rate of Pb was increased from 10 L/kg·h to 35 L/kg·h by increasing pH from 6 to 7, and from 20 L/kg·h to 35 L/kg·h by increasing Ca^{2+} concentration from 0.1 to 0.5 mM (Komjarova and Blust, 2009c). This study also demonstrated that zebrafish gill tissue is the main uptake site for the metal, as Pb concentrations in these tissues were up to eight times as high as that in other tissues.

The Eurasian silver crucian carp (*Carassius auratus*) collected from a pond containing an average of 1,600 mg Pb/kg in the sediments exhibited increased average Pb whole body burden of 36.5 mg Pb/kg dry weight (range 12 to 68 mg Pb/kg dry weight) (Khozhina and Sherriff, 2008). Pb was primarily sequestered in skin, gill, and bone tissues, but was also detected at elevated levels in muscle and liver tissues, as well as in eggs. Two fish species (*Labeo rohita* and *Ctenopharyngodon idella*) collected from the Upper Lake of Bhopal, India with average Pb concentration 30 µg Pb/L in the water column contained elevated Pb tissue concentrations (Malik et al., 2010). However, while liver and kidney Pb concentrations were similar between the two species (1.5 and 1.1 mg Pb/kg tissue and 1.3 and 1.0 mg Pb/kg tissue for *C. idella* and *L. rohita*, respectively), they accumulated significantly different amounts of Pb in gill and muscle tissues. *C. idella* accumulated more than twice the Pb in these tissues (1.6 and 1.3 mg Pb/kg) than did *L. rohita* (0.5 and 0.4 mg Pb/kg).

The studies reviewed above generally support the conclusions of the 2006 Pb AQCD (U.S. EPA, 2006b) that the gill is a major site of Pb uptake in fish and that there are species-dependent differences in the rate and pattern of Pb accumulation. As indicated in the 2006 Pb AQCD, exposure duration can be a factor in Pb uptake from water. In a 30-day exposure study, Nile tilapia fingerlings had a three-fold increase in Pb uptake at the gill on day 30 compared to Pb concentration in gill at day 10 and 20 (Kamaruzzaman et al., 2010). In addition to uptake at the gill, a time-dependent uptake of Pb into kidney in rainbow trout exposed to 570 µg Pb/L for 96 hours (Patel et al., 2006) was observed. Pb was accumulated preferentially in the posterior kidney compared to the anterior kidney. A similar pattern was observed by Alves and Wood (2006) in a dietary exposure. In catla (*Catla catla*) fingerlings, the accumulation pattern of Pb was kidney >liver >gill >brain >muscle in both 14 day and 60 day Pb exposures (Palaniappan et al., 2009). In multiple studies with fathead minnow at different exposure durations, tissue uptake patterns were similar at 30 days (Grosell et al., 2006a) and 300 days (Mager et al., 2010). In the larval minnows, Pb concentration in the intestine exhibited the highest initial accumulation of all tissues on day 3 but then decreased for the remainder of the experiment while concentrations in the other organs continued to increase (Grosell et al., 2006a). By day 30, gill tissue exhibited the highest Pb concentration followed by whole fish and carcass (whole fish minus gill, liver, muscle and intestine). The most rapid rate of Pb accumulation in this species occurs within the first 10 days of exposure (Mager et al., 2008). African catfish (*Clarias gariepinus*) exposed to nominal Pb concentrations of 50 to 1,000 µg Pb/L (as Pb nitrate) for 4 weeks accumulated significant amounts of Pb in heart (520-600 mg Pb/kg), liver (150-242 mg Pb/kg), and brain (120-230 mg Pb/kg) tissues (Kudirat, 2008). Doubling the exposure time to 8 weeks increased sequestration of Pb in these tissues as well as in skin (125-137.5 mg Pb/kg) and ovaries (30-60 mg Pb/kg).

Since the 2006 Pb AQCD, several studies have focused on dietary uptake of Pb in teleosts. Metals have been shown to assimilate differently in tissues depending on the exposure route (Rozon-Ramilo et al., 2011; Meyer et al., 2005). Alves et al. (2006) administered a diet of three concentrations of Pb (7, 77 and 520 mg Pb/kg dry weight) to rainbow trout for 21 days. Doses were calculated to be 0.02 µg Pb/day (control), 3.7 µg Pb/day (low concentration), 39.6 µg Pb/day (intermediate concentration) and 221.5 µg Pb/day (high concentration). Concentrations in the study were selected to represent environmentally relevant concentrations in prey. After 21 days exposure to the highest concentration, Pb accumulation was greatest in the intestine, followed by carcass, kidney and liver leading the authors to hypothesize that the intestine is the primary site of exposure in dietary uptake of Pb. All tissues, (gill, liver, kidney, intestine, carcass) sequestered Pb in a dose-dependent manner. The gills had the greatest concentration of Pb on day 7(8.0 mg Pb/kg tissue wet weight) and this accumulation decreased to 2.2 mg Pb/kg tissue wet weight by the end of the experiment suggesting that the Pb was

excreted or redistributed (Alves et al., 2006). Furthermore, with increasing dietary concentrations, the percentage of Pb retained in the fish decreased. Additionally, in this study red blood cells were identified as a reservoir for dietary Pb. Plasma did not accumulate significant Pb (0.012 mg Pb kg wet weight in the high dose), however, Pb was elevated in blood cells (1.5 mg Pb kg wet weight in the high dose) (Alves et al., 2006).

Additional studies have supported the anterior intestine as a target for Pb in fish. Nile tilapia exposed to dietary Pb for 60 days (105, 418, and 803 mg Pb/kg dry weight) accumulated the greatest concentration of Pb in the intestine, followed by the stomach and then the liver (Dai et al., 2009a). The amount of Pb in tissue increased with increasing dietary Pb concentration. In a 42 day chronic study of dietary uptake in rainbow trout, fish fed 45 or 480 mg Pb/kg, accumulated Pb preferentially in anterior intestine (Alves and Wood, 2006). Pb accumulation in the gut was followed by bone, kidney, liver, spleen, gill, carcass, brain and white muscle (Alves and Wood, 2006). Ojo and Wood (2007) investigated the bioavailability of ingested Pb within different compartments of the rainbow trout gut using an in vitro gut sac technique. Although a significant increase in Pb uptake was observed in the mid-intestines, this was determined to be much lower than Pb uptake rates via gill surfaces. However, given that intestinal uptake rate for Pb did not significantly differ from those derived for essential metals (e.g., Cu, Zn, and Ni), this uptake route is likely to be significant when aqueous Pb concentrations are low and absorption via gill surfaces is negligible (Ojo and Wood, 2007).

Following a chronic 63-day dietary exposure to Pb, male zebrafish had significantly increased Pb body burdens, but did not exhibit any significant impairment when compared with controls. Fish were fed diets consisting of field-collected *Nereis diversicolor* oligochaetes that contained 1.7 or 33 mg Pb/kg dry weight. This resulted in a daily Pb dose of either 0.1 or 0.4 mg Pb/kg (Boyle et al., 2010). At the end of the exposure period, tissue from male fish reared on the high-Pb diet contained approximately 0.6 mg Pb/kg wet weight, as compared with approximately 0.48 mg Pb/kg wet weight in the low-Pb dietary exposure group. Pb level was elevated in female fish fed the high-Pb diet, but not significantly so.

Ciardullo et al. (2008) examined bioaccumulation of Pb in rainbow trout tissues following a 3-year chronic dietary exposure to the metal. Diet was determined to contain 0.19 mg Pb/kg wet weight. Fish skin accumulated the greatest Pb concentrations (0.02 to 0.05 mg Pb/kg wet weight), followed by kidney, gills, liver, and muscle. Pb accumulation in muscles (.005 mg Pb/kg) remained constant over all sampled growth stages (Ciardullo et al., 2008). The authors concluded that dietary Pb was poorly absorbed by rainbow

trout. Comparison of dietary and water-borne exposures suggest that although accumulation of Pb can occur from dietary sources, toxicity does not correlate with dietary exposure, but does correlate with gill accumulation from waterborne exposure (Alves et al., 2006). Comparison of uptake rates across the gut and gill have shown that transporter pathways in the gill have a much higher affinity for Pb than do similar pathways in the gut (Ojo and Wood, 2007).

Since the 2006 Pb AQCD, several field studies have considered Pb uptake and bioaccumulation in fish as a tool for environmental assessment. Pb tissue concentrations were elevated in several species of fish exposed in the field to Pb from historical mining waste, and blood Pb concentrations were highly correlated with elevated tissue concentrations, suggesting that blood sampling may be a useful and potentially non-lethal monitoring technique (Brumbaugh et al., 2005).

This review of the recent literature indicates that the primary and most efficient mode of Pb absorption for freshwater fish is assimilation of labile Pb via gill surfaces; recent research indicates that chronic dietary Pb exposure may result in some Pb bioaccumulation although it is not the predominant route of exposure. Nevertheless, if benthic invertebrates comprise a large portion of fish diets in chronically contaminated systems, assimilated Pb loads may be significant. This was demonstrated by Boyle et al. (2010), who showed that laboratory diets consisting of less than one third field-collected Pb-contaminated invertebrates were sufficient to raise fish tissue Pb levels. However, data from field sites suggest that fish accumulation of Pb from dietary sources is highly variable and may be strongly dependent on the physiology of individual species and absorption capacities.

Amphibians

Since the 2006 Pb AQCD, there are a few recent field measurements and laboratory-based studies that consider uptake of Pb in amphibians. Whole body Pb measured in three species of field-collected tadpoles in the Mobile-Tensaw River Delta in Alabama averaged 1.19 mg Pb/kg dry weight in *Rana clamitans*, 0.65 mg Pb/kg dry weight in *Rana catesbeiana* and 1.32 mg Pb/kg dry weight in *Hyla cinerea (*Albrecht et al., 2007*)*. Blood-Pb levels in Ozark hellbender salamanders (*Cryptobranchus alleganiensis bishopi*), a candidate species for the Endangered Species Act, ranged from 0.044 to 0.055 mg/kg dry whole blood weight, in three rivers in Missouri (Huang et al., 2010). In the same study, Pb-blood levels were measured from Eastern hellbenders (*Cryptobranchus alleganiensis alleganiensis*), a species of concern, collected from four rivers and ranged from 0.075 to 0.088 mg Pb/kg dry whole blood weight.

In a chronic laboratory-based study with tadpoles of the Northern Leopard frog (*Rana pipiens*), Pb tissue concentrations were evaluated following exposures to 3, 10, and 100 µg Pb/L from embryo to metamorphosis. The tadpole tissue concentrations ranged from 0.1 to 224.5 mg Pb/kg dry mass and were positively correlated to Pb concentrations in the water (Chen et al., 2006b). Dose-dependent bioaccumulation of Pb was observed in the livers of tadpoles of the African clawed frog (*Xenopus laevis*) exposed to nominal concentrations ranging from 1.0 to 30,000 µg Pb/L (3 to 115 mg Pb/kg wet weight) for 12 days (Mouchet et al., 2007). Pb concentrations were measured in livers, bodies without liver and whole bodies in Southern leopard frog (*Rana sphenocephala*) tadpoles exposed to Pb in sediment (45 to 7,580 mg Pb/kg dry weight) with corresponding pore water concentrations of 123 to 24,427 µg Pb/L from embryonic stage to metamorphosis (Sparling et al., 2006). There was 100% mortality at 3,940 mg Pb/kg and higher. In all body residues analyzed there was a significant positive correlation between Pb in sediment and Pb in sediment pore water. Concentrations of Pb in liver were similar to results with whole body and bodies without liver indicating that Pb is not preferentially sequestered in liver.

Reptiles

Recent field surveys of Pb in water snakes since the 2006 Pb AQCD, indicate that Pb is bioaccumulated in several species. Water snakes spend time in terrestrial and aquatic habitats and could potentially be exposed to atmospherically deposited-Pb in both environments. Average Pb levels in whole body samples of Eastern Ribbon Snakes (*Thamnophis sauritus*) collected from the Mobile-Tensaw River, a large watershed that drains more than 75% of Alabama were 0.35 ± 0.12 mg Pb/kg dry weight) (Albrecht et al., 2007). Burger et al. (2007) measured Pb levels in blood, kidney, liver, muscle and skin from water snakes, (*Nerodia sepedon*) collected from an urban/suburban canal in New Jersey. Pb was highest in skin (0.467 mg Pb/kg wet weight) followed by kidney (0.343 mg Pb/kg wet weight) blood (0.108 mg Pb/kg wet weight), muscle (0.103 mg Pb/kg wet weight) and liver (0.063 mg Pb/kg wet weight). No interspecies differences were observed in blood Pb (range 0.04 to 0.1 mg Pb/kg) from field-collected banded water snakes (*Nerodia fasciata*), brown water snakes (*N. taxispilota*) and cottonmouth (*Agkistrodon piscivorus*) from a reference area and an area contaminated by chemical and radiation releases from the 1950's to the 1980's at the Department of Energy's Savannah River site in South Carolina (Burger et al., 2006). Cottonmouth and brown water snake from the exposed site had significantly higher levels of Pb in tail muscle when compared to the reference creek.

Mammals

Pb bone levels in Eurasian otters (*Lutra lutra*) measured in dead individuals collected in southwest England fell by 73% between 1992 and 2004 (Chadwick et al., 2011). Annual mean bone Pb levels were 446 µg Pb/kg in 1992 and 65 µg Pb/kg in 2004. The 73% decline of Pb in otter bones from 1992 to 2004 was found to coincide with legislative controls on Pb emissions implemented in the U.K. starting in 1986. A positive correlation with stream sediment Pb and bone Pb was also observed in this study. The strength of this correlation decreased with increasing Ca^{2+} in streams.

7.4.4.4 Food Web

In the 2006 Pb AQCD, trophic transfer of Pb through aquatic food chains was considered to be negligible (U.S. EPA, 2006c). Concentrations of Pb in the tissues of aquatic organisms were found to be generally higher in algae and benthic organisms and lower in higher trophic-level consumers indicating that Pb was bioaccumulated but not biomagnified (U.S. EPA, 2006c; Eisler, 2000). Recent literature since the 2006 Pb AQCD, provides evidence of the potential for Pb to be transferred in aquatic food webs. Other studies indicate Pb is decreased with increasing trophic level. This section incorporates recent literature on transfer of Pb through freshwater aquatic food chains including the application of stable isotope techniques to trace the accumulation and dilution of metals through producers and consumers.

Pb was transferred through at least one trophic level in El Niagara reservoir, Aguascalientes, Mexico, a freshwater ecosystem that lacks fishes (Rubio-Franchini et al., 2008). Pb was quantified in sediment (0.55 mg Pb/kg to 21 mg Pb/kg), water (5.8 to 39 µg Pb/L), and zooplankton samples of this freshwater system. BAFs were calculated for predatory and grazing zooplanktonic species. The BAF of the rotifer *A. brightwellii* (BAF 49,300) was up to four times higher than the grazing cladocerans *D. similis* (BAF 9,022) and *M. micrura* (BAF 8,046). According to the authors, since *M. micrura* are prey for *A. brightwellii* this may explain the biomagnifications of Pb observed in the predatory rotifer and provides evidence that Pb biomagnifies at intermediate trophic levels.

The relative contribution of water and food as source of trace metals including Pb was investigated in the larvae of the alderfly *Sialis velata (*Croisetiere et al., 2006*)*. Its prey, the midge (*C. riparius*) was reared in the laboratory and then exposed to trace elements in a metal-contaminated lake for one week prior to being fed to *S. velata*. During the one-week exposure period of *C. riparius* to the contaminated water, five of six trace elements, including Pb, reached steady state within *C. riparius*. Alderfly larvae were held in the lab in uncontaminated lake water and feed one of the treated *C. riparius* per day for up to six

days to measure Pb uptake via prey. A separate group of alderfly larvae were exposed directly to the contaminated lake water for six days and fed uncontaminated *C. riparius* while a third group was exposed to Pb via prey and water. Trace metal concentrations in *S. velata* that consumed contaminated *C. riparius* increased significantly compared to *S. velata* in water-only exposures. Food was concluded to be the primary source of Pb (94%) to these organisms, not Pb in the water.

The trophic transfer of Pb from the sediment dwelling polychaete worm *N. diversicolor* to the invertebrate polychaete predator *Nereis virens* provides additional evidence for assimilation of Pb by a predator and the potential for further transport up the food chain (Rainbow et al., 2006). *N. virens* significantly accumulated Pb from a diet of *N. diversicolor* and there was a significant inverse linear relationship between the trophic transfer coefficient and prey Pb concentration. In the same study, another predator, the decapod *Palaemonetes varians*, did not significantly accumulate Pb from *N. diversicolor* indicating that trophic transfer is dependent on species-specific differences in metal assimilation efficiencies and accumulation patterns.

In a recent dietary metal study, field-collected invertebrates representing ecologically relevant sources of Pb were fed to zebrafish, to assess bioavailability of this metal via food. The polychaete worm *N. diversicolor* was collected from two sites; an estuary contaminated with Pb and a reference site with low metal concentrations (Boyle et al., 2010). Male zebrafish fed Pb-enriched *N. diversicolor* had significant increases in whole-body Pb burden when compared to zebrafish fed prey from the reference site, brine shrimp or flake food diets. There was a trend toward increased Pb levels in females under the same dietary regimen. In this study, deposit feeding invertebrates were shown to mobilize sediment-bound metals in the food chain since zebrafish were exposed only to biologically incorporated metal.

The concentration of Pb in the tissues of various aquatic organisms was measured during the biomonitoring of mining-impacted stream systems in Missouri. Generally, Pb concentrations decreased with increasing trophic level: detritus contained 20 to 60 mg Pb/kg dry weight, while periphyton and algae contained 1 to 30 mg Pb/kg dry weight; invertebrates and fish collected from the same areas exhibited Pb tissue concentrations of 0.1 to 8 mg Pb/kg dry weight (Besser et al., 2007). In addition, Pb concentrations in invertebrates (snails, crayfish, and other benthos) were negatively correlated with Pb concentrations in detritus, periphyton, and algae. Fish tissue concentrations, however, were consistently correlated only with detritus Pb concentrations (Besser et al., 2007).

Other studies have traced Pb in freshwater aquatic food webs and have found no evidence of biomagnification of Pb with increasing trophic level. Watanabe et al. (2008) observed decreasing Pb concentrations through a stream macroinvertebrate food web in Japan from

producers to primary and secondary consumers. In a Brazilian freshwater coastal lagoon food chain, Pb was significantly higher in invertebrates than in fishes (Pereira et al., 2010).

Introduction of exotic species into an aquatic food web may alter Pb concentrations at higher tropic levels. In Lake Erie, the invasive round goby (*Neogobius melanostomus*) and the introduced zebra mussel (*Dreissena polymorpha*) have created a new benthic pathway for transfer of Pb and other metals (Southward Hogan et al., 2007). The goby is a predator of the benthic zebra mussel, while the endemic smallmouth bass (*Micropterus dolomieui*) feed on goby. Since the introduction of goby into the lake, total Pb concentrations have decreased in bass. The authors attribute this decrease of Pb in bass to changes in food web structure, changes in prey contaminant burden or declines in sediment Pb concentrations.

7.4.5 Biological Effects of Pb in Freshwater Systems

This section focuses on the studies of biological effects of Pb on freshwater algae, plants, invertebrates, fish and other biota with an aquatic lifestage (e.g., amphibians) published since the 2006 Pb AQCD. Key studies from the 1977 Pb AQCD, the 1986 Pb AQCD and the 2006 Pb AQCD on biological effects of Pb are summarized where appropriate. Waterborne Pb is highly toxic to aquatic organisms with bioavailability and subsequent toxicity varying depending upon the species and lifestage tested, duration of exposure, the form of Pb tested, and water quality characteristics (e.g., pH, alkalinity, DOC) (Sections 7.4.2 and 7.4.3).

The 2006 Pb AQCD (U.S. EPA, 2006c) noted that the physiological effects of Pb in aquatic organisms can occur at the biochemical, cellular, and tissue levels of biological organization and include inhibition of heme formation, alterations of blood chemistry, and decreases in enzyme levels. A review of the more recent literature corroborated these findings, and added information about induction of oxidative stress by Pb, alterations in chlorophyll, and changes in production and storage of carbohydrates and proteins. Recent studies available since the 2006 Pb AQCD further consider effects of Pb on reproduction and development, growth and survival of aquatic organisms. Alterations to these endpoints can lead to changes at the community and ecosystem levels of biological organization such as decreased abundance, reduced taxa richness, and shifts in species composition (Section 7.1). Effects on reproduction, growth and survival are reported in additional species with some effects occurring in sensitive freshwater organisms at or near ambient levels of Pb (Table 7-2). Because this review is focused on effects of Pb, studies reviewed for this section include only those for which Pb was the only, or

primary, metal to which the organism was exposed. Areas of research not addressed here include literature related to exposure to Pb from ingestion of shot or pellets. Biological effects of Pb on freshwater algae and plant species are considered below, followed by information on effects on freshwater invertebrates and vertebrates. All reported values are from exposures in which concentrations of Pb were analytically verified unless nominal concentrations are stated.

7.4.5.1 Freshwater Plants and Algae

The toxicity of Pb to algae and plants has been recognized in earlier agency reviews of this metal. In the 1977 Pb AQCD, differences in sensitivity to Pb among different species of algae were observed and concentrations of Pb within the algae varied among genera and within a genus (U.S. EPA, 1977). The 1986 Pb AQCD (U.S. EPA, 1986b) reported that some algal species (e.g., Scenedesmus sp.) were found to exhibit physiological changes when exposed to high Pb concentrations in situ. The observed changes included increased numbers of vacuoles, deformations in cell organelles, and increased autolytic activity. Effects of Pb on algae reported in the 2006 Pb AQCD included decreased growth, deformation and disintegration of algae cells, and blocking of the pathways that lead to pigment synthesis, thus affecting photosynthesis. Observations in additional algal species since the 2006 Pb AQCD, support these findings and indicate that Pb exposure is associated with oxidative stress. All of these effects were observed at concentrations of Pb that exceed those found currently in most surface waters (Table 7-2).

Recent studies available since the 2006 Pb AQCD, report additional mechanistic information on Pb toxicity to freshwater macrophytes as well as further evidence for effects on oxidative stress and growth endpoints. However, many of these studies were conducted at nominal concentrations of Pb, complicating the comparisons to Pb quantified in surface waters. Furthermore, their relevance to conditions encountered in natural environments is difficult to establish since modifying factors of bioavailability, such as DOC, are often absent from controlled exposures.

The effect of Pb exposure on the structure and function of plant photosystem II was studied in giant duckweed, *S. polyrrhiza* (Ling and Hong, 2009). The Pb concentration of extracted photosystem II particles was found to increase with increasing Pb concentration, and increased Pb concentration was shown to decrease emission peak intensity at 340 nm, amino acid excitation peaks at 230 nm, tyrosine residues, and absorption intensities. This results in decreased efficiency of visible light absorption by affected plants. The authors theorized that Pb^{2+} may replace either Mg^{2+} or Ca^{2+} in

chlorophyll or the oxygen-evolving center, inhibiting photosystem II function through an alteration of chlorophyll structure.

Pb exposure in microalgae species has been linked to several effects, including disruption of thylakoid structure and inhibition of growth in both *Scenedesmus quadricauda* and *Anabaena flos-aquae (*Arunakumara and Zhang, 2008*).* Arunakumara et al. (2008) determined the effect of aqueous Pb on the algal species *S. platensis* using solutions of Pb nitrate. Exposures at 3,440 µg Pb/L stimulated 10-day algal growth, growth was inhibited at higher concentrations of 6,830, 21,800, 32,800 and 44,500 µg Pb/L by 5, 40, 49, and 78%, respectively. In addition to growth inhibition, algal chlorophyll *a* and *b* content were significantly diminished at the three highest Pb exposures (Arunakumara et al., 2008). Although no specific morphological abnormalities were linked to Pb exposure, filament breakage was observed in *S. platensis* at Pb concentrations >50,000 µg Pb/L. Since the 2006 Pb AQCD, the production of reactive oxygen species following Pb exposure has been measured directly in cells of the freshwater algae *Chlamydomonas reinhardtii* at nominal concentrations of Pb as Pb nitrate (0.02 to 52 µg Pb/L) with the greatest response at 3.15 times more stained cells compared to the control sample following an exposure of 2.5 hours (Szivak et al., 2009). Although this study provides direct evidence for a mechanism of Pb-toxicity at the sub-organism level of biological organization, the relevance of the exposure method to conditions encountered in natural environments is unknown. The concentration data are not reliable in this case since Pb concentrations were not quantified and the lowest reported values are below the analytical detection limit for Pb.

At the time of the 1977 Pb AQCD, there was limited information available on Pb effects on aquatic macrophytes. For plants in general, Pb was recognized to affect photosynthesis, mitosis, and growth, however, the majority of studies reporting Pb toxicity were not conducted with plants grown under field conditions (U.S. EPA, 1977). The mechanism for Pb inhibition of photosynthesis was further elucidated in the 1986 Pb AQCD. Additional evidence of Pb effects on plant growth was also observed, however, the available studies were conducted under laboratory conditions at concentrations that exceeded Pb levels in the environment except near smelters or roadsides (U.S. EPA, 1986b). In the 1986 Pb AQCD, EC_{50} values for plant growth were available for several aquatic plants with the lowest EC_{50} of 1,100 µg Pb/L in *Azolla pinnata* exposed to Pb nitrate for 4 days. Effects of Pb on metabolic processes in aquatic plants reviewed in the 2006 Pb AQCD (U.S. EPA, 2006b) included nitrate uptake, nitrogen fixation, ammonium uptake and carbon fixation at concentrations of 20,000 µg Pb/L and higher.

New information is available on Pb effects on oxidative stress endpoints such as changes in antioxidant enzymes, lipid peroxidation and reduced glutathione in aquatic plant,

algae, and moss species exposed to Pb, however most evidence is from studies with high concentrations where Pb was not quantified in the exposure media. An aquatic moss, *F. antipyretica*, exhibited increased SOD and ascorbate levels following a 2-day exposure to nominal Pb chloride solutions of concentrations of 20, 200, 2,070, 20,700 and 207,200 µg Pb/L. When exposure duration was increased to 7 days, only SOD activity remained significantly increased by Pb exposure (Dazy et al., 2009). Bell-shaped concentration-response curves were commonly observed for the induction of antioxidant enzymes in *F. antipyretica*. The chlorophyll, carotenoid, and protein contents of the aquatic macrophyte *Elodea canadensis* were significantly reduced following Pb accumulation at nominal exposures of 1,000 10,000 and 100,000 µg Pb/L (Dogan et al., 2009). This, along with the induction of some antioxidant systems and the reduction of growth at the highest two exposures, indicated that exposure to the metal caused significant stress, and that toxicity increased with exposure. In addition, native *Myriophyllum quitense* exhibited elevated antioxidant enzyme activity (glutathione-S-transferase, glutathione reductase, peroxidase) following transplantation in anthropogenically polluted areas containing elevated Pb concentrations. These were correlated with sediment Pb concentrations in the range of 5 to 23 mg Pb/g dry weight (Nimptsch et al., 2005).

Since the 2006 Pb AQCD, toxicity and oxidative stress were also observed in coontail (*C. demersum*) rooted aquatic macrophytes following 7-day nominal exposures to aqueous Pb 200 to 20,700 µg Pb/L ,with increasing effects observed with greater exposure concentrations and times. Chlorosis and leaf fragmentation were evident following a 7-day exposure to the highest concentration, while induction of antioxidant enzymes (glutathione, superoxide dismutase, peroxidases, and catalase) was observed at lower exposure concentrations and times. However, as the duration and concentration of Pb exposure was increased, activities of these antioxidant enzymes decreased (Mishra et al., 2006b).

Sobrino et al. (2010) observed reductions in soluble starch stores and proteins with subsequent increases in free sugars and amino acids in *Lemna gibba* plants exposed nominally to Pb (50,000 to 300,000 µg Pb/L); total phenols also increased with increasing Pb exposure. Authors noted that this species exhibited similar responses under extreme temperatures, drought, and disease. According to Odjegba and Fasidi (2006), nominal exposure to 18,600 µg Pb/L as Pb nitrate for 21 days was sufficient to induce a gradual reduction of both chlorophyll and protein content in the macrophyte *Eichhornia crassipes*. Decreased proteins were theorized to be related to inefficient protein formation following disruption of nitrogen metabolism after Pb exposure (Odjegba and Fasidi, 2006). Foliar proline (which is thought to act as an antioxidant) concentrations were

found to increase in a concentration-dependent manner as Pb concentrations increase from 20,720 to 1,036,000 µg Pb/L.

Following 72-hour aqueous exposure to 8,495 µg Pb/L as Pb nitrate, phytochelatin and glutathione concentrations in the freshwater algae *Scenedesmus vacuolatus* were significantly increased over that of non-exposed algal cultures (Le Faucheur et al., 2006). The 72-hour Pb exposure also significantly reduced *S. vacuolatus* growth, and of all the metals tested (Cu, Zn, Ni, Pb, Ag, As, and Sb), Pb was determined to be the most toxic to the algae species. In the algae *Chlamydomonas reinhardtii*, phytochelatin concentrations were lower than intracellular Pb and not sufficient to bind to accumulated metal following 72-hour exposure (Scheidegger et al., 2011).

In addition to oxidative stress responses, there is new information since the 2006 Pb AQCD on growth effects observed at high concentrations of Pb summarized in Table 7-5. Growth effects at the species level can lead to effects at the population-level of biological organization and higher (Section 7.1.1). Root elongation was significantly reduced in a number of wetland plant species (*Beckmannia syzigachne*, *Juncus effusus*, *Oenanthe javanica*, *Cyperus flabelliformis*, *Cyperus malaccensis*, and *Neyraudia reynaudiana*) following nominal Pb exposures of 20,000 µg Pb/L as Pb nitrate for 21 days (Deng et al., 2009). Further, while both Zn and Fe exposures exerted some selective pressure on plants, the authors did not observe the same with Pb, leading them to theorize that concentrations of bioavailable Pb were not present in high enough quantities to have such an effect. Lemna sp. aquatic plants were determined to effectively sequester aqueous Pb at nominal exposures of 5,000 and 10,000 µg Pb/L in a 7-day experiment, however, 15,000 µg Pb/L resulted in plant mortality (Hurd and Sternberg, 2008). In another study with duckweed, Paczkowska et al. (2007) observed that nominal Pb exposures of 2,070 to 20,700 µg Pb/L for 9 days stimulated the growth of *Lemna minor* cultures, although there was concurrent evidence of chlorosis and induction of antioxidant enzymes. Additionally, Cd was found to be more toxic than Pb, although the authors determined that this resulted from poor uptake of Pb by *L. minor* (Paczkowska et al., 2007). Pb exposure (as Pb nitrate) caused oxidative damage, growth inhibition, and decreased biochemical parameters, including photosynthetic pigments, proteins, and monosaccharides, in *Wolffia arrhiza* plants. Fresh weight of plants was reduced following both 7- and 14-day exposures to Pb concentrations greater than 2,120 µg Pb/L while chlorophyll *a* content was decreased at 210 µg Pb/L and higher (Piotrowska et al., 2010).

Effects of Pb on algae reported in the 2006 Pb AQCD (U.S. EPA, 2006b) included decreased growth, deformation and disintegration of algae cells, and blocking of the pathways that lead to pigment synthesis, thus affecting photosynthesis. Observations in additional algal species since the 2006 Pb AQCD support these findings. Effects on

plants supported by additional evidence in this review and evidence from previous reviews include oxidative damage, decreased photosynthesis and reduced growth. Elevated levels of antioxidant enzymes are commonly observed in aquatic plant, algae, and moss species exposed to Pb. All of the observed effects on aquatic macrophytes and algae occur at concentrations not typically encountered in surface waters of the U.S.

7.4.5.2 Freshwater Invertebrates

Few studies on biological effects of Pb in freshwater invertebrates had been conducted at the time of the 1977 Pb AQCD. One study reported an effect on reproduction in *Daphnia magna* at 30 µg Pb/L (U.S. EPA, 1977). In the 1986 Pb AQCD (U.S. EPA, 1986b), increased mortality was observed in the freshwater snail *Lymnaea palustris* as low as 19 µg Pb/L and reproductive impairment was reported as low as 27 µg Pb/L for Daphnia sp. Population-level endpoints of Pb reviewed in the 2006 Pb AQCD included reproduction, growth, and survival. Pb was recognized to be more toxic in longer-term exposures than shorter-term exposures with chronic toxicity thresholds for reproduction in water fleas (*D. magna*) ranging as low as 30 µg Pb/L. In aquatic invertebrates, Pb has also been shown to affect stress responses and osmoregulation (U.S. EPA, 2006c). Recent evidence that supports previous findings of Pb effects on reproduction and growth in invertebrates is reviewed here as well as limited studies on behavioral effects associated with Pb exposure. Some of these effects are observed in the range of Pb values found in surveys of U.S. surface waters (median 0.50 µg Pb/L, range 0.04 to 30 µg Pb/L), in the U.S. based on a synthesis of NAWQA data reported in the previous 2006 Pb AQCD (U.S. EPA, 2006c) (Table 7-2). The studies are generally presented in this section from responses at the sub-organismal level of biological organization to consideration of endpoints relevant to ecological risk assessment (growth, reproduction, survival).

Recent literature strengthens the evidence indicating that Pb affects enzymes and antioxidant activity in aquatic invertebrates. These alterations at the sub-organismal level may serve as biomarkers for effects at the organism level and higher. In invertebrate species that have hemoglobin, ALAD activity can be measured as a biomarker for Pb exposure. In the freshwater gastropod *B. glabrata* and the freshwater oligochaete *Lumbriculus variegatus* a significant negative correlation between whole body tissue ALAD enzyme activity and increasing Pb was observed following 48-hour exposure to varying nominal concentrations of the metal (Aisemberg et al., 2005). The concentration at which 50% of enzyme inhibition was measured was much lower in *B. glabrata* (23 to 29 µg Pb/L) than in *L. variegatus* (703 µg Pb/L). A significant negative correlation was also observed between ALAD activity and metal accumulation by the organisms. Sodium and potassium ATPase (Na^+/K^+ATPase) activity in gills of Eastern elliptio mussels was

significantly reduced following a 28-day exposure to 57 µg Pb/L and 245 µg Pb/L (Mosher et al., 2012). A significant reduction in Na^+ and significant increase in Ca^{2+} in hemolymph was only observed at the highest concentration.

Studies of stress responses to Pb in invertebrates, conducted since the 2006 Pb AQCD, include induction of heat shock proteins and depletion of glycogen reserves. Although these stress responses are correlated with Pb exposure, they are non-specific and may be altered with exposure to any number of environmental stressors. Induction of heat shock proteins in zebra mussel exposed to an average concentration of 574 µg Pb/L for 10 weeks exhibited a 12-fold higher induction rate as compared to control groups (Singer et al., 2005). Energetic reserves in the freshwater snail *B. glabrata* in the form of glycogen levels were significantly decreased by 20%, 57% and 78% in gonads compared to control animals following 96-hour exposures to nominal concentrations of 50, 100 and 500 µg Pb/L, respectively (Ansaldo et al., 2006). Decreases in glycogen levels were also observed in the pulmonary and digestive gland region at 50 and 100 µg Pb/L treatment levels. Pb did not exacerbate the effects of sustained hypoxia in the crayfish (*C. destructor*) exposed to 5,000 µg Pb/L for 14 days while being subjected to decreasing oxygen levels in water (Morris et al., 2005). The crayfish appeared to cope with Pb by lowering metabolic rates in the presence of the metal.

The effect of Pb on osmoregulatory response has been studied since the 2006 Pb AQCD. The combined effect of Pb and hyperosmotic stress on cell volume regulation was analyzed in vivo and in vitro in the freshwater red crab, *Dilocarcinus pagei* (Amado et al., 2006). Crabs held in either freshwater or brackish water lost 10% of their body weight after one day when exposed to 2,700 µg Pb^{2+}/L as Pb nitrate. This weight loss was transient and was not observed during days 2-10 of the exposure. In vitro, muscle from red crabs exposed to hyperosmotic saline solution had increased ninhydrin-positive substances and muscle weight decreased in isosmotic conditions upon exposure to Pb indicating that this metal affects tissue volume regulation in crabs although the exact mechanism is unknown.

Behavioral responses of aquatic invertebrates to Pb reviewed in the 2006 Pb AQCD (U.S. EPA, 2006b) included avoidance. A limited number of recent studies have considered additional behavioral endpoints. Feeding rate of the blackworm *L. variegatus* was significantly suppressed by day 6 of a 10 day sublethal test in Pb-spiked sediments (Penttinen et al., 2008) as compared to feeding rates at the start of the experiment. However, this decrease of approximately 50% of the initial feeding rate was also observed in the controls; therefore it is likely caused by some other factor other than Pb exposure. Aqueous soil leachates containing multiple metals, including Pb, had no effect on *D. magna* mobility. Authors noted that although some concentrations (13 to

686 µg Pb/L) exceeded Canadian Environmental Quality Guidelines, no significant correlation could be established between Pb exposure and *D. magna* mobility; in fact, the cladocerans were more sensitive to Fe and Al in the leachate than to Pb (Chapman et al., 2010).

Alterations in reproductive and developmental endpoints at the species level can lead to effects at the population-level of biological organization and higher (Section 7.1.1). For example, reduced fecundity may lead to a decreased population size and developmental defects can compromise the ability of an organism to escape predation. Recent evidence of reproductive and developmental effects of Pb on freshwater invertebrates available since the 2006 Pb AQCD, include data from previously untested species as well as further characterization of reproductive effects in commonly tested organisms such as Daphnia sp (Table 7-5). However, many of these studies are conducted at nominal Pb concentration complicating direct comparison to Pb quantified in freshwater environments. Sublethal concentrations of Pb negatively affected the total number of eggs, hatching success and embryonic survival of the freshwater snail *B. glabrata* exposed to nominal concentrations of 50, 100, or 500 µg Pb/L as Pb nitrate (Ansaldo et al., 2009). Following exposure of adult snails for 96 hours, adults were removed and the eggs were left in the Pb solutions. The total number of eggs was significantly reduced at the highest concentration tested (500 µg Pb/L). Time to hatching was doubled and embryonic survival was significantly decreased at 50 and 100 µg Pb/L, while no embryos survived in the highest concentration. Theegala et al. (2007) observed that the rate of reproduction was significantly impaired in *Daphnia pulex* at >500 µg Pb/L in 21-day exposures at nominal concentrations of Pb. In a 21-day reproductive test in *D. magna* the number of neonates born per female was significantly reduced at nominal concentrations of 25, 250, and 2,500 µg Pb/L (Ha and Choi, 2009). *C. dubia* reproduction was also impacted by a seven-day exposure to 50 to 500 µg Pb/L. Both DOC, and, to a lesser degree, alkalinity were observed to ameliorate the effects of Pb on *C. dubia* reproduction. As DOC increased from 100 µmol C/L to 400 and 600 µmol C/L, the calculated mean EC_{50} values for *C. dubia* reproduction increased from approximately 25 µg Pb/L to 200 µg Pb/L and greater than 500 µg Pb/L, respectively (Mager et al., 2011a). Reproductive variables including average lifespan, rate of reproduction, generation time and rate of population increase were adversely affected in the rotifer *Brachionus patulus* under conditions of increasing turbidity and Pb concentration (García-García et al., 2007).

In larvae of the mosquito, C*ulex quinquefasciatus*, exposed to 50 µg Pb/L, 100 µg Pb/L or 200 µg Pb/L (as Pb nitrate), exposure was found to significantly reduce hatching rate and egg-production at all concentrations and larval emergence rate at 200 µg Pb/L (Kitvatanachai et al., 2005). Larval emergence rates of 78% (F0), 86% (F1) and 86% (F2)

were observed in the control group while emergence rates decreased in each generation 46% (F0), 26% (F1) and 58% (F2) in mosquitoes reared in a concentration of 200 µg Pb/L. The time to first emergence also increased slightly to 10 days in the Pb-exposed group as compared to the control group where emergence was first observed on day 9. In the F2 generation of parents exposed to 200 µg Pb/L, the ratio of female to male offspring was 3.6:1.0. No effects were observed on oviposition preference of adult females, larval weight or larval deformation.

Impacts to growth can lead to effects at the population-level of biological organization and higher (Section 7.1.1). As noted in the 2006 Pb AQCD (U.S. EPA, 2006b), Pb exposure negatively affects the growth of aquatic invertebrates. Some studies reviewed in the previous Pb AQCD suggested that juveniles do not discriminate between the uptake of essential and non-essential metals (Arai et al., 2002). In recent literature (summarized in Table 7-5), the freshwater pulmonate snail *Lymnaea stagnalis* has been identified as a species that is extremely sensitive to Pb exposure. Growth of juveniles was inhibited at EC_{20} <4 µg Pb/L. (Grosell and Brix, 2009; Grosell et al., 2006b). In *L. stagnalis* exposed to 18.9 µg/L Pb for 21 days, Ca^{2+} influx was significantly inhibited and model estimates indicated 83% reduction in growth of newly hatched snails after 30 days at this exposure concentration (Grosell and Brix, 2009). The authors speculate that the high Ca^{2+} demand of juvenile *L. stagnalis* for shell formation and interference of the Ca^{2+} uptake pathway by Pb result in the sensitivity of this species.

In a study of the combined effects of temperature (22 ^{0}C or 32 ^{0}C), nominal Pb concentration (50, 100 and 200 µg Pb/L as Pb chloride) and presence of a competitor, the population growth rate of two freshwater rotifer species, *Brachionus havanaensis* and *B. rubens*, as measured by quantifying the number of live rotifers for 15 days, responded to presence of stressors (Montufar-Melendez et al., 2007). At the lowest temperature, *B. rubens* suppressed population growth of *B. havanaensis* at 50 µg Pb/L and higher and *B. rubens* population growth did not increase at any Pb concentration at 32 ^{0}C, a temperature more suited for *B. havanaensis*. In situ toxicity testing with the woodland crayfish (*Orconectes hylas*) indicated that crayfish survival and biomass were significantly lower in streams impacted by Pb mining and that concentrations of Pb and other metals in water, detritus, macroinvertebrates, fish and crayfish were significantly higher at mining sites (Allert et al., 2009a).

Although Pb is known to cause mortality when invertebrates are exposed at sufficiently high concentrations, species that are tolerant of Pb may not exhibit significant mortality even at high concentrations of Pb. Odonates are highly tolerant of Pb with no significant differences in survival of dragonfly larvae *Pachydiplax longipennis* and *Erythemis simplicicollis* exposed for 7 days to nominal concentrations of Pb as high as

185,000 µg Pb/L (Tollett et al., 2009). This apparent tolerance to Pb may be even more pronounced in natural environments where the presence of multiple modifying factors (e.g., pH, alkalinity, hardness, DOC) influences Pb bioavailability. Other species are more sensitive to Pb in the environment and these responses are reviewed in Section 7.4.6.

7.4.5.3 Freshwater Vertebrates

The 1977 Pb AQCD reported on Pb effects to domestic animals, wildlife and aquatic vertebrates. The available Pb studies were from exposure to Pb via accidental poisoning or ingestion of Pb shot (U.S. EPA, 1977). Studies on aquatic vertebrates reviewed in the 1986 Pb AQCD were limited to hematological, neurological and developmental responses in fish (U.S. EPA, 1986b). In the 2006 Pb AQCD, effects on freshwater vertebrates included recent data for fish specifically considering the effects of water quality parameters on toxicity, as well as limited information on sensitivity of turtles and aquatic stages of frogs to Pb (U.S. EPA, 2006c). Biological effects of Pb on freshwater fish that have been studied since the 2006 Pb AQCD are reviewed here, and limited recent evidence of Pb effects on amphibians are considered. This section presents recent information available on the mechanism of Pb as a neurotoxicant in fish and effects of this metal on blood chemistry. Additional mechanisms of Pb toxicity have been elucidated in the gill and the renal system of fish since the 2006 Pb AQCD. Further supporting evidence of reproductive effects of Pb on fish is discussed along with limited new information on behavioral effects of Pb.

Freshwater Fish

Evidence of toxicity of Pb and other metals to freshwater fish goes back to early observations whereby contamination of natural areas by Pb mining lead to extirpation of fish from streams (U.S. EPA, 1977). At the time of the 1977 Pb AQCD, documented effects of Pb on fish included anemia, mucous secretion, functional damage to inner organs, physical deformities and growth inhibition. Additionally, the role of temperature, pH, hardness and other water quality parameters on Pb toxicity was discussed in the 1977 Pb AQCD. The 1986 Pb AQCD reported that hematological and neurological responses were the most commonly observed effects in fish and the lowest exposure concentration causing either hematological or neurological effects was 8 µg Pb/L. These findings were additionally supported in the 2006 Pb AQCD, where observed effects of Pb on fish included inhibition of heme formation, alterations in brain receptors, effects on blood chemistry, and decreases in some enzyme activities (U.S. EPA, 2006c). Functional

responses resulting from Pb exposure included increased production of mucus, changes in growth patterns, and gill binding affinities. According to Eisler (2000) and reviewed in the 2006 Pb AQCD, the general symptoms of Pb toxicity in fish include production of excess mucus, lordosis, anemia, darkening of the dorsal tail region, degeneration of the caudal fin, destruction of spinal neurons, ALAD inhibition, growth inhibition, renal pathology, reproductive effects, growth inhibition and mortality.

Evidence of Pb effects on fish available since the 2006 Pb AQCD generally supports the findings in previous Pb reviews and further elucidates the mechanisms of Pb-associated toxicity on some physiological responses. At the sub-organism level, new information on Pb effects on DNA, specific enzymes, ionoregulation and other biochemical responses is presented followed by a discussion of new information on population-level endpoints (i.e., growth reproduction summarized in Table 7-5).

Since the 2006 Pb AQCD evidence of direct interaction of Pb with fish DNA has become available as well as additional studies on the genotoxic effects of Pb exposure to fish. Hong et al. (2007a) observed covalent binding of Pb with kidney DNA from silver crucian carp (*Carassius auratus gibelio*) though extended X-ray absorption fine structure spectroscopy. This study suggests that exposure to Pb results in effects to DNA but the exposure method (in vitro) makes it difficult to estimate the natural environmental conditions that would be equivalent to the experimental one. In the freshwater fish *Prochilodus lineatus*, blood, liver, and gill cells were sampled from fish treated with nominal concentration of 5,000 µg Pb/L as Pb nitrate for 6, 24 and 96-hours and then DNA damage was assessed by comet assay (Monteiro et al., 2011). DNA breaks were observed in all cell types after 96-hour exposure. The concentrations used in this study were high compared to Pb concentrations currently encountered in freshwater (Table 7-2), however, it presents supporting evidence for a possible mechanism of Pb toxicity to fish.

Upregulation of antioxidant enzymes in fish is a well-recognized response to Pb exposure. Since the last review, additional studies demonstrating antioxidant activity as well as evidence for production of reactive oxygen species following Pb exposure are available. Silver crucian carp injected with nominal concentration of 10, 20 or 30 mg Pb/kg wet weight Pb chloride showed a significant increase in the rate of production of superoxide ion and hydrogen peroxide in liver (Ling and Hong, 2010). In the same fish, activities of liver SOD, catalase, ascorbate peroxidase, and glutathione peroxidase were significantly inhibited. Both glutathione and ascorbic acid levels decreased and malondialdehyde content increased with increasing Pb dosage, suggesting that lipid peroxidation was occurring and the liver was depleting antioxidants. Although this exposure pathway is unlikely to be relevant for air related deposition of Pb, it provides

evidence for the mechanism of toxicity (production of reactive oxygen species) and the responses of antioxidant enzymes observed in this study are supported by findings in studies from fish from nominal water-only exposures. For example, in the freshwater fish Nile tilapia, liver catalase, liver alkaline phosphatase, Na^+/K^+ATPase, and muscle Ca^{2+}ATPase activities were quantified in various tissues following a 14-day exposure to nominal concentrations (1,000, 2,000 and 4,000 µg Pb/L)of Pb nitrate (Atli and Canli, 2007). Liver catalase activity significantly increased in the 1,000 and 4,000 µg Pb/L concentrations while liver alkaline phosphatase activity was significantly increased only at the 4,000 µg Pb/L concentration. No significant change in alkaline phosphatase activity was observed in intestine or serum. Ca^{2+}ATPase activity was significantly decreased in muscle. Na^+/K^+ATPase was elevated in gill in the highest concentration of Pb while all concentrations resulted in significant decreases of this enzyme in intestine. Serum alanine aminotransferase and aspartate aminotransferase activities were elevated in Nile tilapia exposed to 50 µg Pb/L in 4 and 21 day aqueous exposures while elevations in alkaline phosphatase and lactate dehydrogenase were only observed at 21 days (Fırat et al., 2011). In another study with Nile tilapia, Pb had no effect on glutathione measured in liver, gill, intestine, muscle and blood and liver metallothionein levels following a 14-day exposure to 1,000, 2,000 and 4,000 µg Pb/L concentrations of Pb as Pb nitrate (Atli and Canli, 2008).

Metabolic enzyme activity in teleosts has also been measured following dietary exposures. Alves and Wood (2006) in a 42 day chronic dietary Pb study with 45 and 480 mg Pb/kg found that gill Na^+/K^+ATPase activity was not affected in rainbow trout while increased Na^+/K^+ATPase was observed in the anterior intestine. Metabolic activities measured in liver and kidney of Nile tilapia following 60 day dietary administration of 100, 400, and 800 mg Pb/kg indicated that alanine transaminase, aspartate transaminase, and lactate dehydrogenase activities significantly decreased in kidney in a concentration-dependent manner (Dai et al., 2009b) and increased in liver with increasing concentration of dietary Pb. In a subsequent study using the same exposure paradigm, the digestive enzymes amylase, trypsin and lipase in tilapia were inhibited by dietary Pb in a concentration-dependent manner (Dai et al., 2009a). Lesions were also evident in histological sections from livers of Pb-exposed fish from this study and included irregular hepatocytes, cell hypertrophy, and vacuolation although no quantification of lesions by dose-group was presented.

There is also evidence for Pb exposure leading to changes in hepatic CYP450 content although relevance of these in vitro and injection studies to air related exposures to Pb is unknown. Pb was shown to inhibit hepatic cytochrome P450 in vitro in carp (*C. carpio*), silver carp (*Hypothalmichtys molitrix)* and wels catfish (*Silurus glanis*) in a concentration-dependent manner from 0 to 4 µg/mL (Pb^{2+}) (Henczova et al., 2008). The

concentrations of Pb that resulted in 50% inhibition of EROD and 7-ethoxycoumarin-o-deethylase (ECOD) isoenzymes varied with the fish species. Silver carp was the least sensitive to the inhibitory effects of Pb (EROD 1.21, ECOD 1.52 µg Pb/mL) while carp EROD activity was inhibited at 0.76 µg Pb/mL. Interaction of Pb with cytochrome P450 was verified by spectral changes using Fourier Transform Infrared (FTIR) spectroscopy. In the same study, CYP450 content was elevated and EROD isoenzyme activities were decreased in vivo in silver carp for two days following an injection of 2 mg Pb/kg as Pb acetate and returned to control values by 6 days. Liver damage to African catfish exposed to nominal concentrations of Pb (50-1,000 µg Pb/L) for 4 or 8 weeks included hepatic vacuolar degeneration followed by necrosis of hepatocytes (Adeyemo, 2008b). The severity of observed histopathological effects in the liver was proportional to the duration of exposure and concentration of Pb.

In environmental assessments of metal-impacted habitats, ALAD is a recognized biomarker of Pb exposure (U.S. EPA, 2006c). For example, lower ALAD activity has been significantly correlated with elevated blood Pb concentrations in wild caught fish from Pb-Zn mining areas although there are differences in species sensitivity (Schmitt et al., 2007b; Schmitt et al., 2005). Suppression of ALAD activity in brown trout transplanted to a metal contaminated stream was linked to Pb accumulation on gills and in liver in a 23-day exposure (Heier et al., 2009). Alves Costa et al. (2007) observed inhibition of ALAD in hepatocytes of the neotropical traira (*Hoplias malabaricus*) following dietary dosing of 21 mg Pb/kg every 5 days for 70 days. Cytoskeletal and cytoplasmic disorganization were observed in histopathological examination of affected hepatocytes. In fathead minnow exposed to Pb in either control water (33 µg Pb/L), $CaSO_4$ (37 µg Pb/L) or (39 µg Pb/L) humic acid-supplemented water for 30 days and subsequently analyzed by quantitative PCR analysis there were no significant changes in ALAD mRNA gene response leading the authors to speculate that water chemistry alone does not influence this gene response (Mager et al., 2008). In the same study, glucose-6-phosphate dehydrogenase, glutathione-S-transferase and ferritin were upregulated, in microarray analysis, however, no changes in whole body ion concentrations were observed (Mager et al., 2008).

In fish, changes in blood chemistry associated with Pb exposure were noted in the 2006 Pb AQCD (U.S. EPA, 2006b), however, only limited recent studies consider effects on blood parameters. In a 70-day feeding study with traira exposed to dietary doses (21 mg Pb/kg as Pb nitrate via prey [Astyanax sp.]) each five days (corresponding to daily nominal doses of approximately 4 mg Pb/kg), there were no significant changes to leukocytes or hemoglobin concentration and volume (Oliveira Ribeiro et al., 2006). Significant differences in area, elongation and roundness of erythrocytes were observed in the Pb-exposed individuals using light microscopy image analysis. Other studies

available since the 2006 Pb AQCD have only shown effects on blood chemistry at high aqueous concentrations of Pb that are not representative of Pb concentrations in U.S. surface waters. For example, in the African catfish packed cell volume decreased with increasing nominal concentration of Pb (25,000 to 200,000 µg Pb/L as Pb nitrate) and platelet counts increased in a 96-hour exposure (Adeyemo, 2007). Red blood cell counts also decreased in some of the treatments when compared to controls, although the response was not dose-dependent and so may not have been caused by Pb exposure.

Disruption of ionoregulation is one of the major modes of action of Pb toxicity. The gill has long been recognized as a target of Pb in teleosts. Acute Pb toxicity at the fish gill primarily involves disruption of Ca^{2+} homeostasis as previously characterized in the 2006 Pb AQCD (Rogers and Wood, 2004; Rogers and Wood, 2003). In addition to this mechanism, Pb was found to induce ionoregulatory toxicity at the gill of rainbow trout through a binding of Pb with Na^+/K^+ATPase and rapid inhibition of carbonic anhydrase activity thus enabling noncompetitive inhibition of Na^+ and Cl^- influx (Rogers et al., 2005). Alves et al. (2006) administered a diet of three concentrations of Pb (7, 77 and 520 mg Pb/kg dry weight) to rainbow trout for 21 days, and measured physiological parameters including Na^+ and Ca^{2+} influx rate from water. Dietary Pb had no effect on brachial Na^+ and Ca^{2+} rates except on day 8 where Na^+ influx rates were significantly elevated. These studies suggest that Pb is intermediate between purely Ca^{2+} antagonists such as Zn^{2+} and Cd^{2+} and disruptors of Na^+ and Cl^- balance such as Ag^+ and Cu^{2+}. This finding has implications for BLM modeling since it suggests that both Ca^{2+} and Na^+ need to be considered as protective cations for Pb toxicity. Indeed, protection from Pb toxicity by both Na^+ and Ca^{2+} has been documented in freshwater fish (Komjarova and Blust, 2009b).

Additional experiments conducted since the 2006 Pb AQCD provide supporting evidence for underlying mechanisms of Pb toxicity. It was previously established that long-term exposures of Pb can impact gill structure and function. Histopathological observations of gill tissue in the catfish (*C. gariepinus*) following an 8-week aqueous exposure to nominal concentrations of Pb nitrate revealed focal areas of epithelial hyperplasia and necrosis at the lower exposure concentrations (50 µg Pb/L and 100 µg Pb/L) (Adeyemo, 2008a). Hyperplasia of mucous cells and epithelial cells were apparent in the tissue from fish exposed the highest concentrations of Pb in the study (500 µg Pb/L and 1,000 µg Pb/L). In vitro incubation of gill tissue from fathead minnow with Pb concentrations of 2,500, 12,500 and 25,000 µg Pb/L for 60 minutes decreased the ratio of reduced glutathione to oxidized glutathione, indicating that lipid peroxidation at the gill likely contributes to Pb toxicity at low water hardness (Spokas et al., 2006). It is difficult to extrapolate these observations to natural environments due to the methods used for exposure and the use of nominal exposure concentrations.

In addition to recent evidence of Pb interruption of Na^+ and Cl^- at the gill (Rogers et al., 2005), Pb can interfere with the ionoregulation of Na^+ and Cl^- and tubular reabsorption of Ca^{2+}, Mg^{2+}, glucose, and water in the teleost kidney (Patel et al., 2006). Renal parameters including urine flow rate, glomerular filtration rate, urine pH, and ammonia excretion were monitored in a 96-hour exposure of rainbow trout to analytically verified concentration of 1,200 µg Pb/L as Pb nitrate. Rates of Na^+ and Cl^- excretion decreased by 30% by 48 hours while Mg excretion increased two-to-three fold by 96 hours. Urine flow rate was not altered by Pb exposure, although urinary Pb excretion rate was significantly increased. After 24 hours of Pb exposure, the urine excretion rate of Ca^{2+} increased significantly by approximately 43% and remained elevated above the excretion rate in the control group for the duration of the exposure. Glomerular filtration rate significantly decreased only during the last 12 hours of the exposure. Ammonia excretion rate increased significantly at 48 hours as urine pH correspondingly decreased. At the end of the experiment glucose excretion was significantly greater in Pb-exposed fish. Although the exposures in this study approached the 96-hour LC_{50}, nephrotoxic effects of Pb indicate the need to consider additional binding sites for this metal in the development of biotic ligand modeling (Patel et al., 2006). Additional evidence for Pb effects on ion levels were observed in serum of Nile tilapia; Na^+ and Cl^- were decreased and K^+ levels were elevated following a 21 day nominal exposure to 50 µg Pb/L as Pb nitrate (Fırat et al., 2011).

Neurological responses of fish to Pb exposure were reported in the 1986 Pb AQCD (U.S. EPA, 1986b). Additional evidence of the neurotoxic effects of Pb on teleosts has become available since the 2006 Pb AQCD. The mitogen-activated protein kinases (MAPK), extracellular signal-regulated kinase (ERK)1/2 and $p38^{MAPK}$ were identified for the first time as possible molecular targets for Pb neurotoxicity in a teleost (Leal et al., 2006). The phosphorylation of ERK1/2 and $p38^{MAPK}$ by Pb was determined in vitro and in vivo in the catfish (*Rhamdia quelen*). *R. quelen* exposed to a nominal concentration of 1,000 µg Pb/L (as Pb acetate) for two days showed a significant increase in phosphorylation of ERK1/2 and $p38^{MAPK}$ in the nervous system. Incubation of cerebellar slices for 3 hours in 1,035 and 2,070 µg Pb/L as Pb acetate also showed significant phosphorylation of MAPKs. The observed effects of Pb on the MAPK family of signaling proteins have implications for control of brain development, apoptosis and stress response. In the neotropical fish traira, muscle cholinesterase was significantly inhibited after 14 dietary doses of 21 mg Pb/kg wet weight (Rabitto et al., 2005). Histopathological observations of brains of African catfish exposed to nominal concentrations of 500 µg Pb/L or 1,000 µg Pb/L Pb as Pb nitrate for 4 weeks included perivascular edema, focal areas of malacia, and diffuse areas of neuronal degeneration (Adeyemo, 2008b). As in the observed effects of Pb on gill function and ionoregulation, it is difficult to assess the significance of these findings to fish in natural environments due to the methods used for exposure.

Evidence from the 2006 Pb AQCD (U.S. EPA, 2006b) and earlier Pb reviews indicate that Pb can impair both cognitive and motor function in fish. Reduced locomotion and foraging ability were observed in Chinese sturgeon juveniles exhibiting abnormal body curvature following nominal exposure to either 800 or 1,600 µg Pb/L for 112 days (Hou et al., 2011). Actual concentrations of Pb were quantified at the end of the 112-day exposure period (30 to 50% of test media was renewed daily): 129 µg Pb/L (200 µg Pb/L, nominal), 458 µg Pb/L (800 µg Pb/L nominal), and 1,276 µg Pb/L (1,600 µg Pb/L, nominal). These chondrostean fish gradually recovered from deformities during a depuration period and were able to swim and forage effectively 6 weeks after transfer into clean water

Since the 2006 Pb AQCD, several studies integrating behavioral and physiological measures of Pb toxicity have been conducted on fish. Some of these observations are reported to occur at concentrations of Pb reported in freshwater. Zebrafish embryos exposed nominally to low concentrations of Pb as Pb chloride (2.0 and 6.0 µg Pb/L prepared from serial dilutions of a stock solution) until 24 hours post-fertilization and then subsequently tested as larvae or adult fish exhibited behavioral disruptions in response to mechanosensory and visual stimuli (Rice et al., 2011) Although Pb was not measured in the water, Pb uptake in the embryos was quantified during the first 24 hours post-fertilization (approximately 0.08 nM/100 embryos at 2.0 µg Pb/L and 0.32 nM Pb/100 embryos at 6.0 µg Pb/L). Startle response time in larvae measured as maximum head turn velocity and escape time decreased in a concentration-dependent pattern following a directional, mechanical stimulus (tapping). The pattern of escape swimming was altered in larvae of Pb-exposed embryos compared to controls. In the adult fish hatched from Pb-exposed embryos (6.0 µg Pb/L), visual response to a rotating black bar against a white background (ability to detect contrast) was significantly degraded. These findings provide evidence for behavioral effects of Pb at concentrations lower than previously reported in fish (U.S. EPA, 2006c), however, aqueous exposure concentrations were not analytically verified.

Sloman et al. (2005) investigated the effect of Pb on hierarchical social interactions and the corresponding monoaminergic profiles in rainbow trout. Trout were allowed to establish dominant-subordinate relationships for 24 hours, and then were exposed to 46 µg Pb/L or 325 µg Pb/L (Pb nitrate) for 48 hours to assess effects on behavior and brain monoamines. In non-exposed fish, subordinate individuals had higher concentrations of circulating plasma cortisol and telencephalic 5-hydroxyindoleacetic acid/5-hydroxytryptamine (serotonin) (5-HIAA/5-HT) ratios. In the high concentration of Pb, there was significant uptake of Pb into gill, kidney and liver when compared with the control group and dominant fish appeared to have elevated hypothalamic 5-HIAA/5HT ratios. Uptake of Pb into the liver was higher in subordinate fish when compared to the

dominant fish. No significant differences were observed in cortisol levels or behavior after metal exposure.

Mager et al. (2010) conducted prey capture assays with 10 day old fathead minnow larvae born from adult fish exposed to 120 µg Pb/L for 300 days, then subsequently tested in a breeding assay for 21 days. The time interval between 1st and 5th ingestion of 10 prey items (*Artemia nauplii*) was used as a measure of behavior and motor function of offspring of Pb-exposed fish. Larvae were offered 10 Artemia and the number ingested within 5 minutes was scored. The number of larvae ingesting 5 Artemia decreased within the time period in offspring of Pb-exposed fish as compared to the control group, leading the authors to suggest this behavior is indicative of motor/behavioral impairment. In another study with fathead minnows, swimming performance measured as critical aerobic swim speed was significantly impaired in minnows in 24-hour acute (139 µg Pb/L) and chronic 33 to 57 day (143 µg Pb/L) exposures, however, no significant difference in swim speed was observed in chronic exposures to 33 µg Pb/L (Mager and Grosell, 2011).

Alterations in reproductive and developmental endpoints at the species level can lead to effects at the population-level of biological organization and higher (Section 7.1.1). For example, reduced fecundity may lead to a decreased population size and developmental effects may decrease the ability of a fish to escape predators or reduce spawning mobility. Reproductive and developmental effects of Pb in fish have been reported for several decades. In the 1977 Pb AQCD, second generation brook trout (*Salvelinus fontinalis*) exposed to 235 or 474 µg Pb/L were shown to develop severe spinal deformities (lordoscoliosis) (U.S. EPA, 1977). Pb concentration of 120 µg Pb/L produced spinal curvature in rainbow trout (*Oncorhynchus mykiss*) and spinal curvatures were observed in developing eggs of killifish as reviewed in the 1986 Pb AQCD (U.S. EPA, 1986b). Recent studies on reproductive effects of Pb in fish from oocyte formation to spawning are summarized in Table 7-5.

Reproductive performance of zebrafish as measured by incidence of spawning, numbers of eggs per breeding pair or hatch rate of embryos was unaffected following a 63 day diet of field-collected Pb-contaminated polychaetes that were representative of a daily dose of 0.3-0.48 mg Pb/kg·day (dry weight diet/wet weight fish) through food (Boyle et al., 2010). Mager et al. (2010) conducted 21 day breeding exposures at the end of chronic 300 day toxicity testing with fathead minnow. Non-exposed breeders were switched to water containing Pb and Pb-exposed breeders were moved to control tanks and effects on egg hatchability and embryo Pb accumulation were assessed. Fish in the high Pb concentration with HCO_3^- (113 µg Pb/L) and DOC (112 µg Pb/L) and the low Pb concentration with HCO_3^- (31 µg Pb/L) reduced total reproductive output, while a significant increase in average egg mass was observed in the high Pb HCO_3^- and DOC

treatments as compared to egg mass size in controls and in low HCO_3^- and DOC treatments with Pb. No significant differences were present between treatments in egg hatchability.

The effects of metals on embryonic stage of fish development in *C. carpio* and other species were reviewed in Jezierska et al. (2009) and included developmental abnormalities during organogenesis as well as embryonic and larval malformations. The authors concluded that the initial period of embryonic development, just after fertilization, and the period of hatching are the times at which developing embryos are most sensitive to metals. Additional nominal exposure studies provide supporting evidence for embryo malformations associated with Pb-exposure. A significant concentration-dependent increase in morphological malformations was observed in African catfish embryos exposed to nominal concentrations of 100 µg Pb/L, 300 µg Pb/L or 500 µg Pb/L Pb nitrate from 6 hours post-fertilization to 168 hours post-fertilization (Osman et al., 2007b). Hatching was delayed with increasing Pb concentration and hatch success of the embryos decreased from 75% in the controls to 40% in the group exposed to 500 µg Pb/L. Chinese sturgeon exposed to nominal concentrations of 200 µg Pb/L, 800 µg Pb/L or 1,600 µg Pb/L for 112 days (96 hour post-fertilized eggs through juvenile stages) exhibited body curvatures in the two highest concentrations (Hou et al., 2011). During a 42 day depuration period in clean water following exposure, the degree of curvature in affected individuals decreased with decreasing tissue concentrations of Pb.

Reproductive and endocrine effects of Pb have also been reported at the cellular level in fish, including alterations in gonadal tissue and hormone secretions that are associated with Pb-exposure, however, recent studies that report these effects are limited to experiments where only nominal concentrations of Pb were tested. Histopathological observations of ovarian tissue in the African catfish following an 8-week aqueous exposure to Pb nitrate indicated necrosis of ovarian follicles at the lowest concentration tested (50 µg Pb/L) (Adeyemo, 2008a). Severe degeneration of ovarian follicles was observed in the highest concentrations of 500 µg Pb/L and 1,000 µg Pb/L. Chaube et al. (2010) considered the effects of Pb on steroid levels through 12 and 24 hour in vitro exposures of post-vitellogenic ovaries from the catfish (*Heteropneustes fossilis*) to nominal concentrations of Pb as Pb nitrate (0, 10, 100, 1,000, 3,000 and 10,000 µg Pb/L). Progesterone, 17-hydroxyprogesterone, 17, 20 beta-dihydroxyprogesterone, corticosterone, 21-deoxycortisol and deoxycorticosterone were inhibited in a dose-dependent manner. Pb was stimulatory on the steroids estradiol-17-β, testosterone and cortisol at low concentrations, and inhibitory at higher concentrations. The authors propose that the disruption of steroid production and altered hormone secretion patterns observed at the lower concentrations of Pb in this study are suggestive of the potential for impacts to fish reproduction (Chaube et al., 2010).

There is also evidence for alterations in steroid levels associated with Pb exposure in other species of fish although these studies were all conducted with nominal concentrations of Pb and the actual exposure concentrations were not verified. Carp (*Cyprinus carpio*) exposed for 35 days to nominal concentration of 410 µg Pb/L experienced altered plasma cortisol and prolactin levels. Plasma cortisol levels significantly increased throughout the study period while plasma prolactin increased up to day 14 and then declined and was not significantly different from controls by the end of the experiment (Ramesh et al., 2009). Cortisol levels were significantly decreased in Nile tilapia exposed to 50 µg Pb/L (nominal) for 4 days but were followed by a return to control levels at 21 days of exposure (Fırat et al., 2011). In a comparative study between in vitro and in vivo estrogenic activity of Pb, vitellogenin was reported to be significantly induced in juvenile goldfish (*Carassius auratus*) following 96-hour exposure to nominal concentration of 0.2 and 0.02 µg Pb/L when compared to control fish (Isidori et al., 2010). In the same study, estrogenicity of Pb was detected in vitro using a proliferation assay with estrogen receptor-positive human MCF-7 cells. The estrogenic effects of Pb reported by the authors were observed at concentrations at or below that of Pb typically encountered in freshwaters, however, actual concentrations of Pb were not measured and the reported concentrations were at or below analytical detection limits for Pb. The observations of effects of Pb on vitellogenin are interesting; however, additional studies are warranted considering the difficulty in maintaining these low concentrations of Pb. The relevance of the observed in vitro activity to air related exposure to Pb in natural environments is unknown.

Reduction of growth in fish was noted as an effect of Pb exposure in the 2006 Pb AQCD. Recent studies available since the 2006 Pb AQCD do not present consistent evidence of growth reduction in fish associated with Pb (Table 7-5). In a series of exposures in which Ca^{2+}, DOC and pH were varied to assess effects on Pb toxicity to fathead minnows, Grosell et al. (2006a) observed a significant increase in growth in some groups exposed to higher concentrations, however, the increase in body mass was noted to have occurred in tanks with high mortality earlier in the exposure (Grosell et al., 2006a). Fathead minnows exposed to 33 µg Pb/L to test swimming performance had significantly greater body length and body mass compared to control fish following a mean Pb exposure duration of 41 days (range 33 to 57 days) (Mager and Grosell, 2011). In 30 day chronic tests in which a range of pH values (6.4, 7.5 and 8.3) were tested with low (25-32 µg Pb/L), intermediate (82-156 µg Pb/L) and high (297-453 µg Pb/L) concentrations of Pb, Mager et al. (2011b) did not observe growth impairment in fathead minnows at environmentally relevant concentrations of Pb. However, two 60-day early lifestage tests with rainbow trout showed differences in LOEC for reduced growth (Mebane et al., 2008). In the first test, a 69-day exposure, the LOECs for mortality and

reduced growth were the same (54 µg Pb/L). In the second test, a 62-day exposure of Pb to rainbow trout, the LOEC for fish length was 18 µg Pb/L with an EC_{20} of >87 µg Pb/L.

No effects on growth were observed in recently conducted feeding studies with fish. Growth and survival were not significantly affected in juvenile rainbow trout, fathead minnow and channel catfish (*Ictalurus punctatus*) fed a live diet of *L. variegatus* contaminated with Pb (846-1,000 µg Pb/L·g dry mass for 30 days). (Erickson et al., 2010). No effects on growth rates were observed in rainbow trout administered a diet containing three concentrations of Pb (7, 77 and 520 mg Pb/kg dry weight) for 21 days (Alves et al., 2006) or in Nile tilapia fed diets with nominal concentration of 100, 400, or 800 mg/kg Pb dry weight for 60 days (Dai et al., 2009b).

In one recent field study, faster growth rates were associated with lower whole-body trace element concentrations in salmon (*Salmo salar*) across several streams in New Hampshire and Massachusetts, U.S., regardless of whether accumulation was from prey items or from water (Ward et al., 2010). In sites where conditions in the streams were conducive to rapid salmon growth, Pb concentrations were 86% lower than in streams where salmon were smaller.

Amphibians

Amphibians move between terrestrial and aquatic habitats and can therefore be exposed to Pb both on land and in water. The studies reviewed here are all aquatic or sediment exposures. Biological effects of Pb on amphibians in terrestrial exposure scenarios are reviewed in Sections 7.3.3.3 and 7.3.4.3. Amphibians lay their eggs in or around water making them susceptible to water-borne Pb during swimming, breeding and development. In the 2006 Pb AQCD amphibians were considered to be relatively tolerant to Pb. Observed responses to Pb exposure included decreased enzyme activity (e.g., ALAD reduction) and changes in behavior summarized in Table AX7-2.4.3 (U.S. EPA, 2006c). Since the 2006 Pb AQCD, studies conducted within two orders of magnitude of the range of published Pb concentrations for surface waters and sediments of the U.S. (Section 7.2.3) have indicated sublethal effects on tadpole endpoints including growth, deformity, and swimming ability. Genotoxic and enzymatic effects of Pb following chronic exposures have been assessed in laboratory bioassays, however, these studies were limited to nominal exposures.

The genotoxic potential of Pb to larvae of the frog (*X. laevis*) was assessed by determining the number of micronucleated erythrocytes per thousand (MNE) following a 12-day exposure to nominal concentrations of Pb as Pb nitrate (Mouchet et al., 2007). The lowest Pb concentrations with *X. laevis* (10 and 100 µg Pb/L) did not exhibit

genotoxic effects while both 1,000 and 10,000 µg Pb/L significantly increased MNE to 14 and 202, respectively compared to the control (6 MNE). In another chronic genotoxic study, erythrocytic micronuclei and erythrocytic nuclear abnormalities were significantly increased with increasing Pb concentrations (700 µg Pb/L, 1,400 µg Pb/L, 14,000 µg Pb/L, 70,000 µg Pb/L) during 45, 60, and 75-day exposures of tadpoles *Bufo raddei (*Zhang et al., 2007b*)*. The authors noted that the erythrocytic micronuclei and erythrocytic nuclear abnormalities frequencies generally decreased with increasing exposure time and that this may be indicative of regulation of genotoxic factors by tadpoles.

Endpoints of oxidative damage were measured in testes of the black-spotted frog (*Rana nigromaculata*) treated with nominal concentrations of 100 µg Pb/L, 200 µg Pb/L, 400 µg Pb/L, 800 µg Pb/L or 1,600 µg Pb/L Pb nitrate by epidermal absorption for 30 days (Wang and Jia, 2009). All doses significantly increased MDA, a product of oxidative stress, and glutathione levels were elevated in all but the lowest treatment group. In the same study, damage to DNA assessed by DNA tail length showed effects at >200 µg Pb/L and DNA tail movement showed effects at >400 µg Pb/L. The authors concluded that the effects on endpoints of oxidative stress and DNA damage detected in testes indicated a possible reproductive effect of Pb to black-spotted frogs. The exposure method and use of nominal concentration in this study make it difficult to determine the relevance of this study to exposure scenarios under natural environmental conditions.

Various sublethal endpoints (growth, deformity, swimming ability, metamorphosis) were evaluated in northern leopard frog (*R. pipiens*) tadpoles exposed to nominal concentrations of 3, 10, and 100 µg Pb/L as Pb nitrate from embryonic stage to metamorphosis (Chen et al., 2006b). In this chronic study, the concentrations represent the range of Pb found in surface freshwaters across the U.S. The lowest concentration of 3 µg Pb/L approaches the EPA chronic criterion for Pb of 2.5 µg Pb/L at a hardness of 100 mg/L or 4.5 µg Pb/L at a hardness of 170 mg/L (U.S. EPA, 2002b). No effects were observed in the lowest concentration. In the 100 µg Pb/L treatment, tadpole growth rate was slower (Gosner stages 25-30), 92% of tadpoles had lateral spinal curvature (compared with 6% in the control) and maximum swimming speed was significantly slower than the other treatment groups. In this study, Pb concentrations in the tissues of tadpoles were quantified and the authors reported that they were within the range of reported tissue concentrations from wild-caught populations.

The effects of Pb-contaminated sediment on early growth and development were assessed in the southern leopard frog (Sparling et al., 2006). Tadpoles exposed to Pb in sediment (45, 75, 180, 540, 2,360, 3,940, 5,520, and 7,580 mg Pb/kg dry weight) with corresponding sediment pore water concentrations of 123, 227, 589, 1,833, 8,121, 13,579,

19,038 and 24,427 µg Pb/L from embryonic stage to metamorphosis exhibited sublethal responses to Pb in sediment at levels below 3,940 mg Pb/kg. There was 100% mortality in the 3,940, 5,520 and 7,580 mg Pb/kg exposures by day 5. The authors noted that the most profound effects of Pb on the tadpoles were on skeletal development. At 75 mg Pb/kg, subtle effects on skeletal formation such as clinomely and brachydactyly were observed. Skeletal malformations increased in severity at 540 mg Pb/kg and included clinodactyly, brachymely and spinal curvature and these effects persisted after metamorphosis. At the highest concentration with surviving tadpoles (2,360 mg Pb/kg) all individuals displayed severe skeletal malformations that impacted mobility. Other sublethal effects of Pb observed in this study were reduced rates of early growth of tadpoles at concentrations ≤ 540 mg Pb/kg and increased time to metamorphosis in the 2,360mg Pb/kg (8,121µg Pb/L sediment pore water) treatment.

Birds

As reviewed in Koivula and Eeva (2010) measurement of enzymes associated with oxidative stress in birds is a well-established biomarker of exposure to metals, however, little is known about the effects of this stress response in wild populations or at higher levels of ecological organization. Changes in ALAD activity and other oxidative stress biomarkers at low levels of Pb exposure were recently documented in mallards and coots (*Fulica atra*) from a lagoon in Spain impacted by Pb shot (Martinez-Haro et al., 2011). ALAD ratio in mallards decreased linearly with blood Pb levels between 6 and 40 µg Pb/dL, and at Pb levels of <20 µg Pb/dL effects on several antioxidant enzymes were observed in coots. Although the primary route of exposure to the birds was via ingestion of Pb shot, effects were observed lower than 20 µg Pb/dL, the background level frequently applied to Pb exposures in birds (Martinez-Haro et al., 2011; Brown et al., 2006).

Consideration of toxicity of Pb to vertebrate embryos that develop surrounded by a protective egg shell has been expanded since the 2006 Pb AQCD. Pb treatment of mallard duck (*Anas platyrhynchos*), eggs by immersion in an analytically verified concentration of 100 µg Pb/L for 30 minutes on day 0 of development did not increase malformations or mortality of embryos (Kertész and Fáncsi, 2003). However, immersion of eggs in 2,900 µg Pb/L under the same experimental conditions resulted in increased rate of mortality and significant malformations including hemorrhages of the body, stunted growth, and absence of yolk sac circulatory system (Kertész et al., 2006). The second study was conducted to emulate environmental levels of Pb following a dam failure in Hungary.

7.4.6 Exposure and Response of Freshwater Species

Evidence regarding exposure-response relationships and potential thresholds for Pb effects on aquatic populations can inform determination of standard levels that are protective of aquatic ecosystems. The Annex of the 2006 Pb AQCD (U.S. EPA, 2006c) summarized data on exposure-response functions for invertebrates (Table AX7-2.4.1) and fish (Table AX7-2.4.2). The recent exposure-response studies in this section expand on the findings from the 2006 Pb AQCD with information on newly-tested organisms (including microalgae, invertebrate, amphibian and fish species). Overall, new data for freshwater invertebrates generally support the previous finding of sensitivity of juvenile lifestages and indicates some effects of Pb observed in some species at concentrations of Pb reported in freshwater environments. (Table 7-2). All reported values are from exposures in which concentrations of Pb were analytically verified unless nominal concentrations are stated.

The aquatic macrophyte *Lemna minor* (duckweed) exhibited a EC_{50} for growth inhibition of 6,800 µg Pb/L in a 4-day exposure and 5,500 µg Pb/L for a 7-day exposure to a range of Pb concentrations from 100 to 9,970 µg Pb/L (Dirilgen, 2011). Growth (measured as biomass) was slightly increased at 100 and 200 µg Pb/L and then decreased in subsequent concentrations. In an assay using nominal concentrations of Pb the aquatic freshwater microalgae *Scenedesmus obliquus* was significantly more sensitive to Pb exposure than *Chlorella vulgaris* algae, although these authors stated that both appeared to be very tolerant of the heavy metal. Laboratory 48-hour standard toxicity tests were performed with both of these species and respective EC_{50} values of 4,040 and 24,500 µg Pb/L for growth as measured by cell division rate were derived (Atici et al., 2008).

Exposure-response data for freshwater invertebrates provide evidence for effects of Pb at concentrations of Pb encountered in U.S. surface waters. In the 2006 Pb AQCD, effects of Pb-exposure in amphipods (*H. azteca*) and water fleas (*D. magna*) were reported at concentrations as low as 0.45 µg Pb/L. Effective concentrations for aquatic invertebrates were found to range from 0.45 to 8,000 µg Pb/L. Since the 2006 Pb AQCD, recent studies have identified the freshwater snail *L. stagnalis* as a species that is extremely sensitive to Pb exposure (Grosell and Brix, 2009; Grosell et al., 2006b). Growth of juvenile *L. stagnalis* was inhibited below the lowest concentration tested resulting in an EC_{20} of <4 µg Pb/L. In the same study, the NOEC was 12 µg Pb/L and the LOEC was 16 µg Pb/L. In contrast, freshwater juvenile ramshorn snails *M. cornuarietis* were less sensitive to Pb with the same LOEC for hatching rate and $LC_{50,}$ calculated to be about 10,000 µg Pb/L based on nominal exposure data (Sawasdee and Köhler, 2010).

Additional studies on Pb effects in aquatic invertebrates published since the 2006 Pb AQCD provide further evidence for differences in sensitivity of different

lifestages of aquatic organisms to Pb. In the freshwater mussel, *L. siliquoidea* (fatmucket) a Pb concentration response was observed in which newly transformed (5-day-old) juveniles were the most sensitive lifestage in a 96-hour toxicity test when compared to acute and chronic results with other lifestages (Wang et al., 2010e). The 96-hour EC_{50} values for the 5-day-old *L. siliquoidea* in two separate toxicity tests were 142 and 298 µg Pb/L (mean EC_{50} 220 µg Pb/L) in contrast to older juveniles (2 months old) with an EC_{50} >426 µg/L. The 24-hour median effect concentration for glochidia (larvae) of *L. siliquoidea* in 48-hour acute toxicity tests was >299 µg/L. A 28-day exposure chronic value of 10 µg Pb/L was obtained from 2-month-old *L. siliquoidea* juveniles, and was the lowest genus mean chronic value ever reported for Pb (Wang et al., 2010e). A 96-hour test on newly transformed juveniles was also conducted on *Lampsilis rafinesqueana* (Neosho mucket), a mussel that is a candidate for the endangered species list. The EC_{50} for this species was 188 µg Pb/L.

Different lifestages of chironomids have been shown to have varying sensitivity to Pb exposure in several studies available since the 2006 Pb AQCD. The acute toxicity of Pb to first-instar *C. riparius* larvae was tested in soft water, with hardness of 8 mg/L as $CaCO_3$ (Béchard et al., 2008). The 24-hour LC_{50} of 610 µg Pb/L for first instar *C. riparius* larvae was much lower than previous values reported for later instars in harder water. In a chronic test with *Chironomus tentans*, (8 day-old larvae exposed to Pb until emergence [approximately 27 days]), the NOEC was 109, and the LOEC was 497 µg Pb/L (Grosell et al., 2006b). The EC_{20} for reduced growth and emergence of the midge *Chironomus dilutus* was 28 µg Pb/L, observed in a 55-day exposure, while the same species had a 96-hour LC_{50} of 3,323 µg Pb/L (Mebane et al., 2008). In fourth instars of the freshwater midge larvae *Chironomus javanus* the 24, 48, 72 and 96 hour LC_{50}'s were 20,490, 6,530, 1,690 and 720 µg Pb/L, respectively (Shuhaimi-Othman et al., 2011c). This was comparable to the 96-hour LC_{50} (400 µg Pb/L) in the midge larvae *Culicoides furens* (Vedamanikam and Shazilli, 2008a). In the same study, the 96-hour LC_{50} for *Chironomus plumosus* ranged from 8,300 µg Pb/L to 16,210 µg Pb/L under different temperatures indicating the role of environmental factors in modulation of toxicity and differences in sensitivity to Pb even among related species.

Cladocerans are commonly tested aquatic organisms, with data from three species: *D. magna*, *D. pulex* and *Ceriodaphnia dubia*, representing approximately 70% of available metal toxicological literature on this group (Wong et al., 2009). Recent studies have been conducted with *C. dubia* and acute toxicity values for other cladocerans as well as sublethal endpoints for *D. magna* are available. In a series of 48 hour acute toxicity tests with *C. dubia* conducted in a variety of natural waters across North America, LC_{50} values ranged from 29 to 1,180 µg Pb/L and were correlated with DOC (Esbaugh et al., 2011). Median lethal concentrations for *Moina micrura* (LC_{50}

690 µg Pb/L), *Diaphanosoma birgei* (LC_{50} 3,160 µg Pb/L), and *Alona rectangular* (LC_{50} 7,060 µg Pb/L) indicate differences in sensitivity to Pb in these freshwater cladocerans from Mexico (García-García et al., 2006). Several additional studies available since the 2006 Pb AQCD report exposure response values for Daphnia that are based an nominal data: an acute study of Pb with *D. pulex* identified a 48-hour LC_{50} of 4,000 µg/L for this species (Theegala et al., 2007) and the EC_{50} for swimming inhibition in neonate *D. magna* exposed to Pb nitrate for 24 hours was 18,153 µg Pb/L (Ha and Choi, 2009).

Rotifers are among the most sensitive aquatic genera to Pb with wide variation in LC_{50} values reported between species (Pérez-Legaspi and Rico-Martínez, 2001). For example, in the rotifer genus *Lecane*, a 22-fold difference in LC_{50} values was observed in 48-hour exposure to Pb between *L. hamata, L. luna* and *L. quadridentata*. (Pérez-Legaspi and Rico-Martínez, 2001). *L. luna* was most sensitive to Pb toxicity with a 48-hour LC_{50} of 140 µg Pb/L. In a 48-hour toxicity test with the rotifer *Brachionus calyciflorus*, an NOEC (194 µg Pb/L), an LOEC (284 µg Pb/L), and an EC_{20} of 125 µg Pb/L was established for this species (Grosell et al., 2006b). The freshwater rotifer *Euchlanis dilatata* 48 hour LC_{50} was 35 µg Pb/L using neonates hatched from asexual eggs (Arias-Almeida and Rico-Martínez, 2011). In this study the authors estimated the NOEC to be 0.1 µg Pb/L and the LOEC to be 0.5 µg Pb/L. In contrast, for rotifer *Brachionus patulus* neonates, the 24-hour LC_{50} was 6,150 µg Pb/L, however, this value was based on nominal exposures (García-García et al., 2007).

Exposure-response assays on other freshwater species have been conducted since the 2006 Pb AQCD. The 24-hour LC_{50} for larvae of *C. quinquefasciatus* mosquitoes was 180 µg Pb/L (Kitvatanachai et al., 2005). A 48-hour LC_{50} of 5,200 µg Pb/L was observed in water-only exposures of the blackworm *Lumbriculus variegatus (*Penttinen et al., 2008*)*. In the mayfly *Baetis tricaudatus*, the 96-hour LC_{50} was 664 µg Pb/L (Mebane et al., 2008). An EC_{20} value of 66 µg Pb/L was derived for *B. tricaudatus* by quantifying the reduction in the number of molts over a 10-day exposure to Pb (Mebane et al., 2008). The number of molts was significantly less than the control (average of 14 molts over 10 days) at concentrations of 160 µg Pb/L and higher with the lowest number of molts (average of 5.3 molts over 10 days) observed in the highest concentration (546 µg Pb/L). In the freshwater ostracod *Stenocypris major*, the 96-hour LC_{50} was 526 µg Pb/L (Shuhaimi-Othman et al., 2011b). In another freshwater crustacean, the prawn *Macrobrachium lancesteri*, the 96-hour LC_{50} was 35 µg Pb/L in soft water (<75 mg/L as $CaCO_3$) (Shuhaimi-Othman et al., 2011a).

In the studies reviewed for the 2006 Pb AQCD, freshwater fish demonstrated adverse effects at concentrations ranging from 10 to >5,400 µg Pb/L, generally depending on water quality parameters (e.g., pH, hardness, salinity) (U.S. EPA, 2006c). Pb tended to be

more toxic in longer-term exposures and correlated to Pb-uptake in tissues. Table AX7-2.4.2 of the 2006 Pb AQCD summarizes effects of Pb to fish. A series of studies published since the 2006 Pb AQCD have been conducted and have further elucidated the influence of water chemistry parameters on Pb uptake and toxicity in fathead minnow resulting in additional dose-response data for this species. Grosell et al. (2006b) conducted a series of 30-day exposures with larval fathead minnow in which varying concentrations of Ca^{2+} (as $CaSO_4$) and DOC were tested. The effects of reduced pH (6.7) and increased pH (8.1) compared to a control pH of 7.4 on Pb toxicity were also assessed in this study. DOC, $CaSO_4$ and pH influenced Pb toxicity considerably over the range of water parameters tested. The 30-day LC_{50} for low hardness (19 mg $CaSO_4$/L) in basic test water was 39 µg dissolved Pb/L and the highest LC_{50} value (obtained from the protection from increased concentrations of DOC and $CaSO_4$) was 1,903 µg dissolved Pb/L (Grosell et al., 2006a). This range in LC_{50} values for larval fathead minnows for differing pH and concentrations of DOC and hardness clearly demonstrates the importance of the chemistry of the exposure medium to Pb toxicity.

Mager et al. (2010) conducted 300-day chronic toxicity tests at 35 and 120 µg Pb/L with fathead minnow under conditions of varied DOC and alkalinity to assess the effects of these water quality parameters on fish growth and Pb-uptake. In additional tests with fathead minnow, Mager et al. (2011b) conducted both 96-hour acute and 30-day chronic tests to further characterize Ca^{2+}, DOC, pH, and alkalinity values on Pb toxicity. Increased Ca^{2+}, DOC and $NaHCO_3$ concentration afforded protection to minnows in acute studies. The role of pH in Pb toxicity is complex and likely involves Pb speciation and competitive interaction of H^+ with Pb^{2+} (Mager et al., 2011b). In a series of 96-hour acute toxicity tests with fathead minnow conducted in a variety of natural waters across North America, LC_{50} values ranged from 41 to 3,598 µg Pb/L and no Pb toxicity occurred in three highly alkaline waters (Esbaugh et al., 2011).

In the 2006 Pb AQCD, fish lifestage was recognized as an important variable in determining the sensitivity of these organisms to Pb. Recent data available since the 2006 Pb AQCD (U.S. EPA, 2006c) support the findings of increased sensitivity of juvenile fish to Pb when compared to adults. Acute (96-hour) and chronic (60-day) early-lifestage test exposures were conducted with rainbow trout to develop acute-chronic ratios (ACR's) for this species (Mebane et al., 2008). Two early-lifestage chronic tests were conducted, the first with an exposure range of 12-384 µg Pb/L (69 days) at 20 mg $CaCO_3$/L water hardness and the second with an exposure range of 8 to 124 µg Pb/L (62 days) and a water hardness of 29 mg $CaCO_3$/L. In the 69-day test, the following chronic values were observed for survival: NOEC=24 µg Pb/L, maximum acceptable toxicant concentration (MATC)=36 µg Pb/L, EC_{10}=26 µg Pb/L, EC_{20}=34 µg Pb/L, and LC_{50}=55 µg Pb/L. Results from the 62-day test, with fish length as the endpoint, were

NOEC=8 µg Pb/L, MATC=12 µg Pb/L, EC_{10}=7µg Pb/L, EC_{20}=102 µg Pb/L and LC_{50}=120 µg Pb/L. In acute tests with rainbow trout run concurrently with the chronic tests, 96-hour LC_{50} values were 120 and 150 µg Pb/L, respectively. Data from this study resulted in ACR's for trout lower than previously reported. The low ACR values were due to the acute tests which produced LC_{50} values that were 10 to 25 times lower than earlier studies with trout (Mebane et al., 2008). The authors speculated that the lower LC_{50} values were due to the age of the fish used in the study (two to four week old fry) and that testing with larger and older fish may not be protective of more sensitive lifestages.

There have been only a few recent exposure-response studies in amphibians since the 2006 Pb AQCD. Southern leopard frog tadpoles exposed to Pb in sediment (45 to 7,580 mg Pb/kg dry weight) with corresponding sediment pore water concentrations from 123 to 24,427 µg Pb/L from embryonic stage to metamorphosis exhibited concentration-dependent effects on survival (Sparling et al., 2006). The LC_{50} value for Pb in sediment was 3,738 mg Pb/kg, which corresponds to 12,539 µg Pb/L in sediment pore water. In the same study, concentration-dependent effects on skeletal development were observed. The 40 day-EC_{50} for deformed spinal columns in the tadpoles was 1,958 mg Pb/kg (corresponding to 6,734 µg Pb/L sediment pore water) and the 60 day-EC_{50} was 579 mg Pb/kg (corresponding to 1,968 µg Pb/L sediment pore water) (Sparling et al., 2006).

7.4.7 Freshwater Community and Ecosystem Effects

As discussed in the 1986 Pb AQCD (U.S. EPA, 1986b) and the 2006 Pb AQCD (U.S. EPA, 2006b), exposure to Pb is likely to have impacts in aquatic environments via effects at several levels of ecological organization (organisms, populations, communities, or ecosystems). These effects resulting from toxicity of Pb would be evidenced by changes in species composition and richness, in ecosystem function, and in energy flow. The 2006 Pb AQCD concluded that, in general, there was insufficient information available for single materials in controlled studies to permit evaluation of specific impacts on higher levels of organization (beyond the organism). Furthermore, Pb rarely occurs as a sole contaminant in natural systems making the effects of Pb difficult to ascertain. New information on effects of Pb at the population, community, and ecosystem level is reviewed below.

In laboratory studies reviewed in the 2006 Pb AQCD and in more recent studies, Pb exposure has been demonstrated to alter predator-prey interactions, as well as feeding and avoidance behaviors. In aquatic ecosystems there are field studies reviewed in the 1977 Pb AQCD (U.S. EPA, 1977), the 1986 Pb AQCD (U.S. EPA, 1986b) , the

2006 Pb AQCD (U.S. EPA, 2006b) and more recent studies that report reductions of species abundance, richness or diversity particularly in benthic macroinvertebrate communities coexisting with other metals where the sources of Pb were from mining or urban effluents. Additionally, field studies have linked Pb contamination to reduced primary productivity and respiration, and to altered energy flow and nutrient cycling. However, because of the complexity inherent in defining such effects, there are relatively few available population, community, or ecosystem level studies that conclusively relate Pb exposure to aquatic ecosystem effects. In addition, most of the available work is related to point-source Pb contamination, with very few studies considering the effects of diffuse Pb pollution. Both plant species and habitat type were determined to be factors affecting the rate of Pb accumulation from contaminated sediments. While the rooted aquatic plant *E. canadensis* was observed to accumulate the highest concentrations of Pb, the authors concluded that submerged macrophytes (versus emergent plants) as a group were the most likely to accumulate Pb and other heavy metals (Kurilenko and Osmolovskaya, 2006). This would suggest that certain types of aquatic plants, such as rooted and submerged species, may be more susceptible to aerially-deposited Pb contamination, resulting in shifts in plant community composition as a result of Pb pollution.

Alteration of macrophyte community composition was demonstrated in the presence of elevated surface water Pb concentrations at three lake sites impacted by mining effluents (Mishra et al., 2008). A total of 11 species of macrophytes were collected. Two sites located 500 meters and 1,500 meters downstream from the mine discharge point (study sites 2 and 3) exhibited similar dissolved Pb concentrations (78 to 92 µg Pb/L, depending on season) and contained six and eight unique macrophyte species, respectively. The site nearest the discharge point of the mine effluent (study site 1) had the highest Pb concentrations (103 to 118 µg Pb/L) and the lowest number of resident macrophyte species; these included *E. crassipes*, *L. minor*, *Azolla pinnata* and *S. polyrrhiza*. Based on analysis of plant tissue Pb concentrations, the authors theorized that certain species may be more able to develop Pb tolerant eco-types that can survive at higher Pb concentrations (Mishra et al., 2008). In field studies available for certain freshwater habitats, exposure to Pb has been shown to result in significant alterations of invertebrate communities. Macroinvertebrate community structure in mine-influenced streams was determined to be significantly correlated to Pb sediment pore water concentrations. Multiple invertebrate community indices, including Ephemeroptera, Plecoptera, Trichoptera (EPT) taxa richness, Missouri biotic index, and Shannon-Wiener diversity index, were integrated into a macroinvertebrate biotic condition score (Poulton et al., 2010). These scores were determined to be significantly lower at sample sites downstream from mining sites where Pb pore water and bulk sediment concentrations were elevated. Sediment Pb, Cd, and Zn levels were inversely correlated to mussel taxa

richness in the Spring River basin encompassing sites in Kansas, Missouri and Oklahoma overlapping a former Pb and Zn mining and processing area (Angelo et al., 2007). In sites upstream of the mining area, 21 to 25 species of mussels were present whereas in sites downstream, only 6 to 8 species were observed.

Rhea et al. (2006) examined the effects of multiple heavy metals in the Boulder River, Montana, watershed biofilm on resident macroinvertebrate assemblages and community structure, and determined that, among all the metals, biofilm Pb concentrations exerted the greatest influence on the macroinvertebrate community indices. Pb biofilm concentrations were significantly correlated with reduced EPT taxa richness, reduced EPT abundance, and an increase in Diptera species abundance. Interestingly, Pb concentrations in invertebrate tissues were correlated to an increase in Hydropsychidae caddisfly abundance, but this may have resulted from the intrinsically high variability in tissue Pb concentrations. The authors concluded that Pb-containing biofilm represented a significant dietary exposure for impacted macroinvertebrate species, thus altering invertebrate community metrics (Rhea et al., 2006).

Kominkova and Nabelkova (2005) examined ecological risks associated with metal contamination (including Pb) in small urban streams. Although surface water Pb concentrations in monitored streams were determined to be very low, concentrations of the metal in sediment were high enough to pose a risk to the benthic community (e.g., 34 to 101 mg Pb/kg). These risks were observed to be linked to benthic invertebrate functional feeding group, with collector-gatherer species exhibiting larger body burdens of heavy metals than other groups (Kominkova and Nabelkova, 2005). In contrast, benthic predators and collector-filterers accumulated significantly lower metals concentrations. Consequently, it is likely that sediment-bound Pb contamination would differentially affect members of the benthic invertebrate community, potentially altering ecosystems dynamics.

Invertebrate functional feeding group may also affect invertebrate Pb body burdens in those systems where Pb bioconcentration occurs. The predaceous zooplanktonic rotifer, *A. brightwellii* collected from a Pb-impacted freshwater reservoir in Mexico, contained 384 ng Pb/mg and exhibited a water-to-tissue BCF of 49,344. The authors theorized that Pb biomagnification may have been observed in this case because the cladoceran *M. micrura* is both a known Pb accumulator and a favorite prey item of the rotifer (Rubio-Franchini et al., 2008). They showed that *M. micrura* had twice the Pb body burden of *D. similis*, another grazing cladoceran species present in the reservoir. These two species exhibited average Pb tissue concentrations of 57 and 98 ng Pb/mg, respectively, with respective water column BCFs of 9,022 and 8,046. Conversely, an examination of the simultaneous uptake of dissolved Pb by the algae *P. subcapitata* and

the cladoceran *D. magna* suggests that the dietary exposure route for the water column filter-feeder is minor. Although Pb accumulated in the algal food source, uptake directly from the water column was determined to be the primary route of exposure for *D. magna* (Komjarova and Blust, 2009c).

For many invertebrate species, sediment Pb concentrations may be the most important driver in determining Pb uptake. For instance, while Hg and Cd body burdens in lentic invertebrates were affected by lake ecological processes (e.g., eutrophication), a similar effect was not observed for Pb concentrations in crayfish tissue, despite a high variability between sites (Larsson et al., 2007). Although this may be a result of differing bioaccumulation tendencies, the authors suggested that other factors, including the potential for sediment exposures, may be responsible for Pb uptake in lentic invertebrates.

A field survey of fishes in the Viburnum Trend Pb-Zn mining district in southeast Missouri available since the 2006 Pb AQCD, found that species richness and species density of riffle-swelling benthic fishes were negatively correlated with metal concentrations in pore water and in fish in mining impacted streams (Allert et al., 2009b). Density of Ozark sculpin (*Cottus hypselurus*) and banded sculpin (*Cottus carolinae*) were positively correlated with distance from mining sources.

In addition to the ecological effects discussed above, there is additional evidence that Pb exposure could alter bacterial infection (and potentially disease transmission) in certain fish species. Following 96-hour exposures to 4,000 µg Pb/L, bacterial density in *Channa punctatus* fish was observed to be significantly altered when compared to non-exposed fish. Bacteria population densities in fish spleen, gills, liver, kidneys and muscle tissues were higher following Pb exposure, with bacterial abundance in the gills too numerous to quantify (Pathak and Gopal, 2009). In addition, bacteria inhabiting Pb-exposed fish were more likely to exhibit antibacterial resistance than colonies isolated from non-exposed fish. Although the mechanism remains unknown, this study suggests that Pb exposure may increase the likelihood of infection in fish, potentially affecting fish abundance and recruitment.

In summary, despite the fact that alterations of macrophyte communities may be highly visible effects of increased sediment Pb concentrations, several recently published papers propose that ecological impacts on invertebrate communities are also significant, and can occur at environmental Pb concentrations lower than those required to impact plant communities. High sediment Pb concentrations were linked to shifts in amphipod communities inhabiting plant structures, and potentially to alterations in ecosystem nutrient processing through selective pressures on certain invertebrate functional feeding groups (e.g., greater bioaccumulation and toxic effects in collector-gatherers versus

predators or filter-feeders). Increased sediment pore water Pb concentrations were demonstrated to likely be of greater importance to invertebrate communities, as well. Interestingly, recent research also suggests that Pb exposure can alter bacterial infestations in fish, increasing both microbial density and resilience, and potentially increasing the likelihood of serious disease outbreak.

7.4.8 Critical Loads in Freshwater Systems

The general concept and definition of critical loads is introduced in Section 7.1.3 of this chapter [also see Section 7.4 of the 2006 Pb AQCD (U.S. EPA, 2006c)]. Critical load values are linked to critical limits of Pb for endpoints/receptors of interest in the ecosystems, such as blood Pb. Some important critical limits for Pb in aquatic ecosystems are discussed in this section along with information on aquatic critical loads for Pb.

Unit World Models (UWM) have been used to calculate critical loads for metals in aquatic ecosystems. These models couple an ecotoxicity model, the BLM, to a speciation/complexation model, the Windermere Humic Adsorption Model (WHAM), then to the multi-species fate model, TRANsport-SPECiation (TRANSPEC). Gandhi et al. apply the UWM to estimate speciation/complexation, fate and critical loads using lakes of three different trophic status. A high percentage of colloidal-bound Pb was found in the eutrophic and mesotrophic lakes (75-80%) versus the oligotrophic lakes (2%), owing the high affinity of Pb to DOM. Pb concentrations were lowest for mesotrophic and highest for oligotrophic systems. Critical loads were not calculated for Pb; however, for the other metals tested the critical load was lowest in the oligotrophic and highest in the eutrophic systems.

A critical load of 39.0 g Pb/m^2·yr (0.19 mol Pb/ m^2·yr) was calculated for a generalized lake in the Sudbury area of the Canadian Shield using TICKET-UWM based on acute toxicity data for *D. magna*. (Farley et al., 2011). The model was set up to calculate critical loads of metals by specifying free metal ion activity or the critical biotic ligand concentration. This critical load for Pb was much higher than for Cu, Ni and Zn and the authors attribute this difference to the strong binding of Pb to particulate organic matter and the sequestration of $PbCO_3$ in sediment.

As stated previously in Section 7.3.7, in the short term, metal emissions generally have greater effects on biota in freshwater systems than in terrestrial systems because metals are more readily immobilized in soils than in sediment. However, over the longer term, terrestrial systems may be more affected particularly by those metals with a long soil residence time, such as Pb. Thus, for a particular locale, either the terrestrial or the aquatic ecosystem at that site may have the lower critical load. Given the heterogeneity of

ecosystems affected by Pb, and the differences in expectations for ecosystem services attached to different land uses, it is expected that there will be a range of critical load values for Pb for soils and waters within the U.S. Refer to Section 7.4.6 of the 2006 Pb AQCD for additional discussion of critical loads of Pb in aquatic systems.

7.4.9 Characterization of Sensitivity and Vulnerability in Freshwater Systems

Data from the literature indicate that exposure to Pb may affect survival, reproduction, growth, metabolism, and development in a wide range of freshwater aquatic species. Often, species differences in metabolism, sequestration, and elimination rates control relative sensitivity and vulnerability of exposed organisms. Diet and lifestage at the time of exposure also contribute significantly to the determination of sensitive and vulnerable populations and communities. Further, environmental conditions in addition to those discussed as affecting bioavailability (Sections 7.4.3 and 7.4.4) may also alter Pb toxicity. The 2006 Pb AQCD (U.S. EPA, 2006b) reviewed the effects of genetics, age, and body size on Pb toxicity. While genetics appears to be a significant determinant of Pb sensitivity, effects of age and body size are complicated by environmental factors that alter metabolic rates of aquatic organisms. A review of the more recent literature corroborated these findings, and identified seasonally-affected physiological changes and lifestage as other important determinants of differential sensitivity to Pb.

7.4.9.1 Seasonally-Affected Physiological Changes

A study by Duman et al. (2006) identified species and seasonal effects of Pb uptake in aquatic plants. *P. australis* accumulated higher root Pb concentrations than *S. lacustris*. Additionally, the *P. australis* Pb accumulation factor was significantly higher during the winter versus other seasons, while the Pb accumulation factor for *S. lacustris* was greatest in spring and autumn. The Pb accumulation factor for a third species, *P. lucens*, was greatest in autumn (Duman et al., 2006). Most significantly, these changes in bioaccumulation were not linked with biomass increases, indicating that species-dependent seasonal physiological changes may control Pb uptake in aquatic macrophytes (Duman et al., 2007). Significant interspecies differences in Pb uptake were observed for plants representing the same genus (Sargassum), indicating that uptake of Pb by aquatic plants also may be governed by highly species-dependent factors (Jothinayagi and Anbazhagan, 2009).

Heier et al. (2009) established the speciation of Pb in water draining from a shooting range in Norway and looked at the time dependent accumulation in brown trout. They

found that high molecular weight (>10 kDa) cationic Pb species correlated with high flow episodes and accumulation of Pb on gills and in the liver. Thus, high flow episodes can remobilize metals from a catchment and induce stress to aquatic organisms.

7.4.9.2 Increased Nutrient Uptake

Singh et al. (2010) proposed that metal-resistant plants have the capacity to not only up-regulate antioxidant synthesis, but also have the ability to increase nutrient consumption and uptake to support metal sequestration and detoxification via production of antioxidants (Singh et al., 2010). Therefore, it is likely that such plant species would be significantly less susceptible to Pb exposure than those species without those abilities.

7.4.9.3 Temperature and pH

Water temperature also appears to affect the toxicity of Pb to aquatic organisms, with higher temperatures leading to greater responses. Pb toxicity to crayfish increased 7 to 10% when the water temperature was increased by 4 °C, and by 14% when the temperature increased by 7 °C. The authors determined that the increased toxicity was a result of the negative impact of Pb on crayfish respiration, which was exacerbated by the lower dissolved oxygen concentrations at higher water temperatures (Khan et al., 2006). In a study of the combined effects of temperature and Pb concentration on two freshwater rotifer species, *Brachionus havanaensis* and *B. rubens*, population growth was measured in three nominal concentrations of Pb as Pb chloride (50, 100 and 200 µg Pb/L) for 15 days at either 22^0C or 32^0C (Montufar-Melendez et al., 2007). At 22^0C, population growth of *B. havanaensis* was suppressed by *B. rubens* regardless of Pb treatment. At the higher temperature, there was no population increase of *B. rubens* at any Pb concentration. In the controls, population growth rates of *B. havanaensis*, but not *B. rubens*, increased with an increase in temperature. These studies highlight the role of temperature in Pb toxicity in organisms adapted to low temperatures.

The sequestration ability of *L. minor* macrophytes was similarly impacted by increased surface water temperature; plants absorbed a maximum Pb concentration of 8.6 mg /g at 30 °C, while uptake at 15 °C was only 0.3 mg/g (Uysal and Taner, 2009). Decreased pH was also demonstrated to increase the uptake of environmental Pb in aquatic plants (Wang et al., 2010b; Uysal and Taner, 2009). Lower pH was shown to result in increased sensitivity to Pb in juvenile fathead minnows in 30-day exposure to Pb of varying concentrations (Grosell et al., 2006a). Additionally, Birceanu et al. (2008) determined that fish (specifically rainbow trout) were more susceptible to Pb toxicity in acidic, soft

waters characteristic of sensitive regions in Canada and Scandinavia. Hence, fish species endemic to such systems may be more at risk from Pb contamination than fish species in other habitats.

7.4.9.4 Lifestage

It is clear that certain stages of a life cycle are more vulnerable to Pb. A comparison of *C. riparius* Pb LC_{50} values derived from toxicity tests with different instars indicates a significant effect of lifestage on Pb sensitivity for aquatic invertebrates. Béchard et al. (2008) calculated a first instar *C. riparius* 24-hour LC_{50} value of 613 µg Pb/L, and contrasted this value with the 24-hour and 48-hour LC_{50} values derived using later instar larvae—350,000 and 200,000 µg Pb/L, respectively. This disparity would suggest that seasonal co-occurrence of aquatic Pb contamination and sensitive early instars could have significant population-level impacts (Béchard et al., 2008). Similarly, Wang et al. (2010e) demonstrated that the newly transformed juvenile mussels, *L. siliquoidea* and *L. rafinesqueana*, at 5 days old were more sensitive to Pb exposure than were glochidia or two to six month- old juveniles, suggesting that Pb exposure at particularly sensitive lifestages could have a significant influence on population viability (Wang et al., 2010e).

Evidence for differences in susceptibility to Pb at distinct lifestages is also available for freshwater fish. In chronic (60-day) early-lifestage test exposures conducted with rainbow trout to develop ACR's for this species the study resulted in ACR's for rainbow trout lower than previously reported due to the acute tests which produced LC_{50} values that were 10 to 25 times lower than earlier studies with trout. (Mebane et al., 2008). The authors speculated that the lower LC_{50} values were due to the age of the fish used in the study (two to four week old fry) and that testing with larger and older fish may not be protective of more sensitive lifestages. Post-hatching stages of the African catfish were more sensitive than the embryonic stage to Pb-exposure and the authors attributed this apparent protective effect to the presence of a hardened chorion in embryos (Osman et al., 2007a).

7.4.9.5 Species Sensitivity

Species-specific Ca^{2+} requirements have been shown to affect the vulnerability of aquatic organisms to Pb. The snail, *L. stagnalis*, exhibits an unusually high Ca^{2+} demand due to $CaCO_3$ formation required for shell production and growth, and exposure to Pb prevents the uptake of needed Ca^{2+}, leading to toxicity. Consequently, aquatic species that require high assimilation rates of environmental Ca^{2+} for homeostasis are likely to be more

sensitive to Pb contamination (Grosell and Brix, 2009). Grosell and colleagues also noted that reduced snail growth following chronic Pb exposure was likely a result of reduced Ca^{2+} uptake (Grosell et al., 2006b).

There is some indication that molting may comprise an additional sequestration and excretion pathway for aquatic animals exposed to Pb (Soto-Jiménez et al., 2011a; Mohapatra et al., 2009; Tollett et al., 2009; Bergey and Weis, 2007). Libellulidae dragonfly nymphs (Tollett et al., 2009) have been shown to preferentially sequester Pb in exoskeleton tissue. Consequently, aquatic arthropod species and those species that shed their exoskeleton more frequently may be able to tolerate higher environmental Pb concentrations than non-arthropods or slow-growing molting species, as this pathway allows them to effectively lower Pb body burdens.

In contrast, the effect of Pb exposure on fish bacterial loads demonstrated by Pathak and Gopal (2009) suggest that infected fish populations may be more at risk to the toxic effects of Pb than healthier species. Aqueous Pb was demonstrated to both increase bacteria density in several fish organs and to improve the likelihood of antibacterial resistance (Pathak and Gopal, 2009).

Tolerance to prolonged Pb exposure may develop in aquatic invertebrates and fish. Multi-generational exposure Pb appears to confer some degree of metal tolerance in invertebrates such as *C. plumosus* larvae; consequently, previous population Pb exposures may decrease species' susceptibility to Pb contamination (Vedamanikam and Shazilli, 2008b). However, the authors noted that metal tolerant larvae were significantly smaller than larvae reared under clean conditions, and that transference of Pb-tolerant *C. plumosus* larvae to clean systems resulted in a subsequent loss of tolerance. Evidence of acclimation to elevated Pb in fathead minnow was suggested in the variations in ionoregulatory parameters that were measured on day 10 and 30 in fish exposed to 115 µg Pb/L for 30 days. At the end of the experiment, whole body Ca^{2+} was elevated while Na^{+} and K^{+} recovered from elevated levels at 30 days (Grosell et al., 2006a).

A series of species sensitivity distributions constructed by Brix et al. (2005) in freshwater systems indicated that sensitivity to Pb was greatest in crustacean species, followed by coldwater fish, and warmwater fish and aquatic insects, which exhibited a similar sensitivity. Further, analysis of both acute and chronic mesocosm data sets indicated that Pb-contaminated systems exhibited diminished species diversity and taxa richness following both types of exposure (Brix et al., 2005). Wong et al. (2009) constructed Pb species sensitivity distributions for both cladoceran and copepod freshwater species. A comparison of the two curves indicated that cladoceran species, as a group, were more sensitive to the toxic effects of Pb than were copepods, with respective hazardous concentration values for 5% of the species (HC5) values of 35 and 77 µg Pb/L. This

difference in sensitivities would indicate that cladoceran species are more likely to be impacted at lower environmental Pb concentrations than copepods, potentially altering community structures or ecosystem functions (Wong et al., 2009).

7.4.9.6 Ecosystem Vulnerability

Relative vulnerability of different freshwater ecosystems to effects of Pb can be inferred from the information discussed above on species sensitivity and the influence of water quality variables on the bioavailability and toxicity of Pb. It is, however, difficult to categorically state that certain freshwater plant, invertebrate or vertebrate communities are more vulnerable to Pb than others, since toxicity is dependent on many variables and data from field studies are complicated by co-occurrence of other metals and alterations of pH, such as in mining areas. Aquatic ecosystems with low pH and low DOM are likely to be the most sensitive to the effects of atmospherically-deposited Pb. Examples of such systems are acidic, soft waters such as sensitive regions in Canada and Scandinavia (Birceanu et al., 2008). In the U.S., aquatic systems that may be more sensitive to effects of Pb include habitats that are acidified due to atmospheric deposition of pollutants, runoff from mining activities or lakes and streams with naturally occurring organic acids. Hence, fish and invertebrate species endemic to such systems may be more at risk from Pb contamination than corresponding species in other habitats.

7.4.10 Ecosystem Services Associated with Freshwater Systems

Pb deposited on the surface of, or taken up by organisms has the potential to alter the services provided by freshwater biota to humans although the directionality of impacts is not always clear. For example, aquatic macrophytes provide a service by sequestering Pb. At the same time, the uptake of Pb by plants may result in toxicological effects associated with Pb exposure and decreased capacity of wetland species to remove contaminants. At this time, few publications address Pb impacts on ecosystem services associated with freshwater systems and most studies focus on wetlands rather than lakes and streams. Pb can affect the ecological effects in each of the four main categories of ecosystem services (Section 7.1.2) as defined by Hassan et al. (2005). These effects are sorted into ecosystem services categories and summarized here:

- Supporting: food for higher trophic levels, biodiversity
- Provisioning: clean drinking water, contamination of food by heavy metals, decline in health of fish and other aquatic species

- Regulating: water quality
- Cultural: ecosystem and cultural heritage values related to ecosystem integrity and biodiversity, wildlife and bird watching, fishing

Freshwater wetlands are sinks for atmospheric Pb as well as Pb from terrestrial runoff (Landre et al., 2010; Watmough and Dillon, 2007). Several studies have addressed the response of natural wetlands to Pb (Odum, 2000; Gambrell, 1994). Recent reviews of pollution control (Mander and Mitsch, 2009) or removal of metals (Marchand et al., 2010) by constructed wetlands and phytoremediation of metals by wetland plants (Rai, 2008) indicate that these systems can remove Pb from the aquatic environment and are important for water quality, sediment stabilization, nutrient cycling and shelter for aquatic biota. The use of plants as a tool for immobilization of Pb and other metals from the environment is not limited to wetland species. Recent advances in the phytoremediation of metals are reviewed in Dickinson et al. (2009). The impact of Pb on ecological services provided by specific components of aquatic systems has been considered in a limited number of studies. For example, Theegala et al. (2007) discuss the high uptake rate of Pb by *D. pulex* as the basis for a possible Daphnia-based remediation for aquatic systems.

7.4.11 Synthesis of New Evidence for Pb Effects in Freshwater Ecosystems

This synthesis of the effects of Pb on freshwater ecosystems covers information from the publication of the 2006 Pb AQCD to present. It is followed in Section 7.4.12 by determinations of causality that take into account evidence dating back to the 1977 Pb AQCD.

Evidence assessed in the present document supports the findings of the previous Pb AQCDs that waterborne Pb is highly toxic to freshwater organisms, with toxicity varying with species and lifestage, duration of exposure, form of Pb, and water quality characteristics. The studies that are available for freshwater plants, invertebrates and vertebrates include studies where Pb concentration was analytically verified and those that reported nominal concentrations (Table 7-5). Many of the studies that report nominal concentrations in media are uptake studies that subsequently quantify Pb in tissues, however, measurement of Pb in water or sediment at the beginning of an exposure is desirable when comparing laboratory studies to concentrations of Pb in freshwater systems. As reported in Section 7.2.3 and Table 7-2, the median and range of Pb concentrations in surface waters (median 0.50 µg Pb/L, range 0.04 to 30 µg Pb/L) and

sediments (median 28 mg Pb/kg dry weight, range 0.5 to 12,000 mg Pb/kg dry weight) in the U.S. based on a synthesis of NAWQA data was reported in the previous 2006 Pb AQCD (U.S. EPA, 2006c).

Recent studies provide further evidence for the role of modifying factors such as pH, DOC and hardness on the effects of Pb on plants, invertebrates and vertebrates. The same Pb concentration added to water or sediment produces far greater effects under some conditions, than others. Many studies reviewed in the ISA included concentrations that were higher than Pb found near contaminated areas. However, when multiple concentrations were used, effects gradually increased with increasing Pb exposure. Effects at lower concentrations can be implied from many studies since an exposure-response relationship to Pb was observed, although uncertainty remains in relating these findings to reported concentrations of Pb in freshwater. Many studies only report an LC_{50} value when an LOEC or LC_{10} would be more relevant for consideration of effects on organisms since an effect occurring at the LC_{50} would most likely not maintain a stable population. Most available studies only report acute toxicity and are conducted at higher concentrations of Pb than found in sampling from U.S. surface waters (Table 7-2), however, exposure to Pb in freshwater systems is most likely characterized as a chronic low dose exposure.

Plants

Most recent studies on effects of Pb in freshwater algal species reviewed in Section 7.4.5.1 were conducted with nominal media exposures and effect concentrations greatly exceeded Pb reported in surface water. In studies where Pb was quantified, effect concentrations for growth (EC_{50}) for aquatic macrophytes were much higher than currently reported ambient Pb, however, some sublethal endpoints such as effects on chlorophyll were observed at lower concentrations. For example, chlorophyll a content was significantly inhibited at 210 µg Pb/L and higher in *W. arrhiza* (Piotrowska et al., 2010). An increase in biomass was reported in *L. minor* exposed to 100 or 200 µg Pb/L with inhibition observed at higher concentrations (Dirilgen, 2011). There were also numerous studies conducted at nominal Pb concentration that report effects on enzyme activities and protein content in freshwater aquatic plant species. Exposure-response relationships in which increasing concentrations of Pb lead to increasing effects were consistently observed for freshwater aquatic plants.

Recent studies on bioavailability of Pb in aquatic plants and algae support the findings of previous Pb AQCDs that plants tend to sequester larger amounts of Pb in their roots than in their shoots and provide additional evidence for species differences in compartmentalization of sequestered Pb and responses to Pb in water and sediments.

Given that atmospherically-derived Pb is likely to become sequestered in sediments, uptake by aquatic plants is a significant route of Pb removal from sediments, and a potential route for Pb mobilization into the aquatic food web. Although there are some similarities to Pb accumulation observed in terrestrial plants (e.g., preferential sequestration of the metal in root tissue), Pb appears to be more bioavailable in sediment than it is in soil.

Invertebrates

The largest body of evidence for effects of Pb at or near concentrations of this metal found in surveys of surface waters of the U.S. is for invertebrates and recent studies reviewed in Sections 7.4.5.2 and 7.4.6 further support this observation. Exposure-response relationships in which increasing concentrations of Pb lead to increasing effects were consistently observed for freshwater invertebrates. Among the most sensitive species, growth of juvenile freshwater snails *L. stagnalis* was inhibited at an EC_{20} of <4 µg Pb/L. (Grosell and Brix, 2009; Grosell et al., 2006b). A chronic value of 10 µg Pb/L obtained in 28-day exposures of 2-month-old fatmucket mussel, *L. siliquoidea* juveniles was the lowest genus mean chronic value ever reported for Pb (Wang et al., 2010e). The 96-hour EC_{50} values for 5-day-old juveniles in two separate toxicity tests with this species were 142 and 298 µg Pb/L (mean EC_{50} 220 µg Pb/L).

Recent studies (Sections 7.4.5.2 and 7.4.6) have further elucidated the role of water quality on Pb toxicity. In freshwater invertebrates some effects were observed at concentrations occasionally encountered in U.S. surface waters (Table 7-2). In a 7-day exposure of the cladoceran *C. dubia* to 50 to 500 µg Pb/L, increased DOC leads to an increase in mean EC_{50} for reproduction ranging from approximately 25 µg Pb/L to >500 µg Pb/L (Mager et al., 2011a). The 48-hour LC_{50} values for the cladoceran *C. dubia* tested in eight natural waters across the U.S. varied from 29 to 1,180 µg Pb/L and were correlated with DOC (Esbaugh et al., 2011).

Additional new evidence reviewed in Sections 7.4.5.2 and 7.4.6 for effects near the upper range of concentrations of Pb available from surveys of U.S. surface waters include studies with rotifer, midge and mayfly species. The freshwater rotifer *E. dilatata* 48 hour LC_{50} was 35 µg Pb/L using neonates hatched from asexual eggs (Arias-Almeida and Rico-Martínez, 2011). An EC_{20} for reduced growth and emergence of the midge *C. dilutus* was reported to be 28 µg Pb/L, observed in a 55-day exposure, while the same species had a 96-hour LC_{50} of 3,323 µg Pb/L (Mebane et al., 2008) The EC_{10} for molting in the mayfly *B. tricaudatus* was 37 µg Pb/L (Mebane et al., 2008). All of these effect concentrations provide additional evidence for Pb effects on freshwater invertebrates.

Vertebrates

For freshwater fish (Sections 7.4.5.3 and 7.4.6), most recent studies available since the 2006 Pb AQCD, were conducted with fathead minnow, *P. promelas*, or rainbow trout, *O. mykiss*. In a series of 96-hour acute toxicity tests with fathead minnow conducted in a variety of natural waters across North America, LC_{50} values ranged from 41 to 3,598 µg Pb/L (Esbaugh et al., 2011). Reproductive effects associated with water quality parameters were also noted with this species (Mager et al., 2010). In trout, no effects of Pb were observed in dietary studies. In chronic aqueous exposures with trout the following endpoints were reported: NOEC=24 µg Pb/L, EC_{10}=26 µg Pb/L, EC_{20}=34 µg Pb/L, and LC_{50}=55 µg Pb/L. In a separate test with the same species an NOEC=8 µg Pb/L, EC_{10}=7µg Pb/L, EC_{20}=102 µg Pb/L and LC_{50}=120 µg Pb/L were reported. In acute tests with rainbow trout run concurrently with the chronic tests, 96-hour LC_{50} values were 120 and 150 µg Pb/L, respectively (Mebane et al., 2008). These reported effects provide additional evidence for toxicity of Pb to fish and chronic NOEC and EC_{10} values reported for trout, a sensitive species, are within the upper range of Pb currently reported in U.S. surface waters (Table 7-2).

In Section 7.4.5.3, a study with the frog *R. pipiens* exposed nominally to Pb, tissue concentrations were quantified at the end of the study and found to be in the range of Pb tissue concentrations in wild-caught tadpoles. Growth rate was significantly slower in the 100 µg Pb/L nominal concentration and more than 90% of tadpoles developed lateral spinal curvature. Time to metamorphosis was also delayed at this treatment level.

Food Web

In the 2006 Pb AQCD, trophic transfer of Pb through aquatic food chains was considered to be negligible. Concentrations of Pb in the tissues of aquatic organisms were generally higher in algae and benthic organisms than in higher trophic-level consumers indicating that Pb was bioaccumulated but not biomagnified (U.S. EPA, 2006c; Eisler, 2000). Some studies published since the 2006 Pb AQCD, (see Section 7.4.4.4) support the potential for Pb to be transferred in aquatic food webs, while other studies indicate that Pb concentration decreases with increasing trophic level (biodilution).

Community and Ecosystem Effects

New evidence of effects of Pb at the community and ecosystem levels of biological organization reviewed in Section 7.4.7 include shift in community composition in macrophytes. Effects on reproduction, growth or survival (summarized in Table 7-5) may lead to effects at the population-level of biological organization and higher. Additional

evidence for community and ecosystem level effects of Pb have been observed primarily in microcosm studies or field studies with other metals present.

7.4.12 Causal Determinations for Pb in Freshwater Systems

In the following sections, organism-level effects on reproduction and development, growth and survival are considered first since these endpoints can lead to effects at the population level or above and are important in ecological risk assessment. Neurobehavioral effects are considered next followed by sub-organismal responses (hematological effects, physiological stress) for which Pb has been shown to have an impact in multiple species and across taxa, including humans. Causal determinations for terrestrial, freshwater and saltwater ecological effects are summarized in Table 7-3.

7.4.12.1 Reproductive and Developmental Effects-Freshwater Biota

Evaluation of the findings in previous Pb AQCDs and recent literature on Pb effects in aquatic fauna indicates that exposure to Pb is associated with reproductive effects at or near ambient concentrations of this metal (Table 7-2) in some freshwater species. Impaired fecundity at the organismal level can result in a decline in abundance and/or extirpation of populations, decreased taxa richness, and decreased relative or absolute abundance at the community level (Suter et al., 2005; U.S. EPA, 2003a). Various endpoints have been measured in freshwater organisms to assess the effect of Pb on fecundity, development and hormone homeostasis. However, there are typically only limited studies available from different taxa. Recent evidence available since the 2006 Pb AQCD for effects of Pb on reproductive endpoints in freshwater invertebrates and vertebrates is summarized in Table 7-5.

There are no studies reviewed in the ISA or previous Pb AQCDs on development and reproductive effects of Pb in freshwater aquatic algae or macrophytes.

Experimental data from freshwater invertebrates provide evidence for increasing reproductive effects associated with increasing exposure to Pb. The exposure-response relationship is used in judging causality (Table I Preamble). Reproductive effects of Pb in freshwater aquatic invertebrates are well-characterized in previous Pb AQCDs, the draft Ambient Water Quality Criteria for Pb (U.S. EPA, 2008b) and in the current ISA and have been observed at or near current ambient concentrations (median 0.5 µg Pb/L, range 0.04 to 30 µg Pb/L) (U.S. EPA, 2006c) in some species in laboratory exposures. In the 1986 Pb AQCD reproductive effects were reported to begin at 19 µg Pb/L for the freshwater snail *Lymnaea palustris* and 27 µg Pb/L for Daphnia sp. (U.S. EPA, 1986b).

In the 2006 Pb AQCD (U.S. EPA, 2006b) the number of neonates per surviving adult was significantly decreased in the amphipod *H. azteca* during chronic 42-day exposures to Pb (Besser et al., 2005). In the group exposed to Pb in water-only exposures, the LOEC for reproductive effects was 16 µg Pb/L while in amphipods receiving both water-borne and dietary Pb the LOEC for reproduction was 3.5 µg Pb/L.

New evidence in freshwater invertebrates (Table 7-5 and Section 7.4.5.2) show consistency of the observed association between reproductive endpoints and Pb exposure. In the freshwater rotifer *B. calyciflorus*, reproductive output was measured as total number of individuals and intrinsic growth rate. The EC_{20} for number of rotifers was 125 µg Pb/L and the 48 hour EC_{20} for intrinsic rate of population increase was 307 µg Pb/L with an NOEC of 194 µg Pb/L (Grosell et al., 2006b). In a 7-day exposure of the cladoceran *C. dubia* to 50 to 500 µg Pb/L, increased DOC leads to an increase in mean EC_{50} for reproduction ranging from approximately 25 µg Pb/L to >500 µg Pb/L (Mager et al., 2011a). Additional reproductive impairment endpoints for freshwater cladocerans are reported in Table 6 of the draft Ambient Aquatic Life Water Quality Criteria for Pb (U.S. EPA, 2008b). It is not clear how these laboratory-derived values for freshwater invertebrates compare to Pb exposures in natural systems due to the role of modifying factors (i.e., pH, hardness, and DOC) which affect Pb speciation and bioavailability, however, results under controlled conditions have consistently shown reproductive effects of Pb in sensitive taxa (amphipods, cladocerans) at concentrations at or near Pb quantified in freshwater environments.

In freshwater aquatic vertebrates there is evidence for reproductive and developmental effects of Pb. Pb exposure in frogs has been demonstrated to delay metamorphosis, decrease larval size and produce skeletal malformations. For example, in northern leopard frog *R. pipiens* exposed to nominal concentrations of 100 µg Pb/L from embryonic stage to metamorphosis, maximum swimming speed was significantly slower than other treatment groups and 92% of tadpoles exposed to 100 µg Pb/L had lateral spinal curvature (compared with 6% in the control) (Chen et al., 2006b). Pb tissue concentrations were quantified in frogs following exposure and fell within the range of tissue concentrations in wild-caught tadpoles.

The weight of evidence for reproductive and developmental effects in freshwater vertebrates is from studies with fish. Pb AQCDs have reported developmental effects in fish, specifically spinal deformities in brook trout (*Salvelinus fontinalis*) exposed to 119 µg Pb/L for three generations (U.S. EPA, 1977), and in rainbow trout as low as 120 µg Pb/L (U.S. EPA, 1986b). Reproductive behaviors of fathead minnows including reduced time spent in nest preparation by males, increased interspawn periods and reduced oviposition by females was observed following a 4-week exposure to

500 µg Pb/L (Weber, 1993). In the 2006 Pb AQCD (U.S. EPA, 2006b), decreased spermatocyte development in rainbow trout was reported at 10 µg Pb/L and, in fathead minnow testicular damage occurred at 500 µg Pb/L. In a recent study, reproductive effects in fathead minnows were influenced by water chemistry parameters (alkalinity and DOC) in breeding exposures following 300 day chronic toxicity testing with Pb (Mager et al., 2010). Specifically, in fish treated in both 35 and 120 µg Pb/L with HCO_3^- and with 120 µg Pb/L with DOC, total reproductive output was decreased and average egg mass production increased as compared to egg mass size in controls and in low HCO_3^- and DOC treatments with Pb. No significant differences were present between treatments in egg hatchability. In a feeding study, Reproductive performance was unaffected in zebrafish exposed to Pb-via consumption of contaminated prey (Boyle et al., 2010). In fish, there is evidence for alteration of steroid profiles and additional reproductive parameters although most of the available studies were conducted using nominal concentrations of Pb.

Observations of Pb toxicity to reproductive and developmental endpoints in freshwater fauna are further supported by evidence in terrestrial invertebrates and vertebrates (Section 7.3.12.1), marine invertebrates (Section 7.4.21.1) and from laboratory animals (Section 5.8). Pb appears to affect multiple endpoints associated with reproduction and development in aquatic invertebrates and vertebrates. A few sensitive invertebrate taxa (amphipods, cladocerans) have been identified where effects are observed in laboratory studies at concentrations of Pb that occur in the environment. Overall, there is a dearth of information on reproductive effects of Pb in natural environments, however, the weight of evidence is sufficient to conclude that there is a causal relationship between Pb exposures and developmental and reproductive effects in freshwater invertebrates and vertebrates. In freshwater plants, the evidence is inadequate to conclude that there is a causal relationship between Pb exposures and plant developmental and reproductive effects.

7.4.12.2 Growth Effects-Freshwater Biota

Alterations in the growth of an organism can impact population, community and ecosystem level variables. Growth is a commonly measured endpoint in aquatic plants, however, reported effects typically occur at concentrations that exceed Pb quantified in freshwater habitats. Growth effects of Pb on plants include visible growth responses and reduction of photosynthetic rate, inhibition of respiration, cell elongation, root development or premature senescence (U.S. EPA, 1986b). In the 2006 Pb AQCD (U.S. EPA, 2006b), both freshwater algae and plants had EC_{50} values for growth in the range of 1,000 to >100,000 µg Pb/L with minimal inhibition of growth observed as low as

100 µg Pb/L (U.S. EPA, 2006c). The most sensitive aquatic macrophyte reported in the 2006 Pb AQCD was *A. pinnata* with an EC_{50} for relative growth rate of 1,100 µg Pb/L following a 4-day exposure to Pb (Gaur et al., 1994). An LOEC of 25 µg Pb/L for reduced chlorophyll in Coontail (*Ceratophyllum demersum*), and 50 µg Pb/L in Cattail (*T. latifolia*) following 12-day exposure to Pb (as Pb acetate) were the lowest reported concentrations of growth-related effects in freshwater plants in the draft Ambient Aquatic Life Water Quality Criteria for Pb (U.S. EPA, 2008b) and were near the upper range of Pb values reported from sampling of U.S. surface waters (Table 7-2). Additional growth studies in freshwater algae and plants summarized in Table 6 of the draft Ambient Aquatic Life Water Quality Criteria for Pb and Table 7-5 of the present document report growth effects in laboratory studies at concentrations that exceed measured levels of Pb in the aquatic environment (U.S. EPA, 2008b).

Most of the evidence for growth effects of Pb in freshwater biota is for invertebrates. Some of these studies report inhibition of growth in sensitive species occurring at or near the current upper range of Pb in surface waters (median 0.50 µg Pb/L, range 0.04 to 30 µg Pb/L) (U.S. EPA, 2006c). Growth effects of Pb on aquatic invertebrates are reviewed in the draft Ambient Aquatic Life Water Quality Criteria for Pb (U.S. EPA, 2008b) and the 2006 Pb AQCD. The lowest reported LOEC for growth in the 2006 Pb AQCD (16 µg Pb/L) was in amphipods (*H. azteca*) in a 42-day chronic exposure (Besser et al., 2005).

Recent studies provide additional evidence for effects on growth of freshwater aquatic invertebrates at ≤ 10 µg Pb/L. Growth effects observed in invertebrates underscores the importance of lifestage to overall Pb sensitivity. In general, juvenile organisms are more sensitive than adults. Growth of juvenile freshwater snails *L. stagnalis* was inhibited below the lowest concentration tested resulting in an EC_{20} <4 µg Pb/L (Grosell and Brix, 2009; Grosell et al., 2006b). In the same study, the NOEC was 12 µg Pb/L and the LOEC was 16 µg Pb/L. The authors indicated that the observed effect level for Pb was very close to the current U.S. EPA water quality criteria for Pb (3.3 µg Pb/L normalized to test water hardness) (Grosell and Brix, 2009). In the freshwater mussel, fatmucket (*L. siliquoidea*) juveniles were the most sensitive lifestage (Wang et al., 2010e). In this study, growth of juvenile mussels at the end of a 28-day exposure in 17 µg Pb/L was significantly reduced from growth in the controls. A chronic value of 10 µg Pb/L in 2-month-old fatmucket juveniles was the lowest genus mean chronic value ever reported for Pb. The EC_{10} and EC_{20} for reduced growth and emergence of the midge *C. dilutus* in a 55-day exposure were 28 µg Pb/L and 55 µg Pb/L, respectively, while the same species had a 96-hour LC_{50} of 3,323 µg Pb/L (Mebane et al., 2008) The EC_{10} and EC_{20} for molting in the mayfly *B. tricaudatus* were 37 µg Pb/L and 66 µg Pb/L, respectively (Mebane et al., 2008). In natural freshwater systems the effects of Pb are influenced by

additional factors (i.e., pH, hardness, and DOC) which may modulate the toxicity of Pb observed under laboratory conditions.

Evidence for growth effects of Pb in freshwater aquatic vertebrates is limited to a few studies in amphibians and fish. In the 2006 Pb AQCD growth effects of Pb were reported in frogs at concentrations typically higher than currently found in the environment. A recent study supports findings of growth effects in frogs and suggests that these effects may be occurring at lower concentrations: the growth rate of tadpoles of the northern leopard frog exposed nominally to 100 µg Pb/L from embryo to metamorphosis was slower than the growth rate of the controls (Chen et al., 2006b). In this study, Pb concentrations in the tissues of tadpoles were quantified and the authors reported that they were within the range of reported tissue concentrations reported in wild-caught populations.

Reports of Pb-associated growth effects in freshwater fish are inconsistent (Mager, 2012). In a review cited in the 2006 Pb AQCD, general symptoms of Pb toxicity in fish included growth inhibition (Eisler, 2000) however, other studies with Pb have shown no effects on growth (Mager, 2012). In the studies reviewed for the current ISA no growth effects were observed in fish exposed to Pb via dietary intake. Recent aqueous exposure studies with fathead minnows showed significant increases in body length and body mass following chronic low Pb exposure, however, the authors noted that some effects were observed in tanks with high mortality early in the exposure (Mager and Grosell, 2011; Grosell et al., 2006a). Other studies with fathead minnows have shown growth reductions with Pb exposure, however, concentrations of observed effects typically exceeded the 96-hour LC_{50} value (Mager, 2012; Mager et al., 2010; Grosell et al., 2006a). Two 60-day early lifestage tests with rainbow trout showed differences in LOEC for reduced growth (Mebane et al., 2008). In the first test, a 69-day exposure, the LOECs for mortality and reduced growth were the same (54 µg Pb/L). In the second test, a 62-day exposure of Pb to rainbow trout, the LOEC for fish length was 18 µg Pb/L with an EC_{20} of >87 µg Pb/L.

Evidence of effects of Pb exposure on growth in terrestrial plants (Section 7.3.12.2) is highly coherent with evidence from freshwater plants. Although there is a lack of evidence in freshwater plants for growth effects at concentrations of Pb typically encountered in U.S. surface waters, several studies suggest that minimal growth inhibition can occur within one to two orders of magnitude of the reported range for freshwater. Due to the concentration-response relationship observed between Pb exposure and freshwater plants, growth is likely impacted at lower, more ecologically relevant EC_{10} or LOEC values, than the typically reported EC_{50} values which may not be suitable for a maintaining a sustainable population.

There is a large body of evidence to support growth effects of Pb on aquatic plants at concentrations that greatly exceed those typically found in U.S. surface waters. Less evidence is available at current concentrations of Pb measured in U.S. surface waters and within one to two orders of magnitude above the range of these measured values. The available evidence is, however, sufficient to conclude that a causal relationship is likely to exist between Pb exposures and growth effects in freshwater plants. The evidence is sufficient to conclude that there is a causal relationship between Pb exposures and growth effects in aquatic invertebrates. Available evidence is inadequate to conclude that there is a causal relationship between Pb exposures and growth effects in aquatic vertebrates.

7.4.12.3 Survival-Freshwater Biota

The relationship between Pb exposure and survival has been well demonstrated in freshwater species as presented in Section 7.4.5 and Table 7-5 of the present document and in the previous Pb AQCDs. Pb exposure can either result in direct lethality or produce sublethal effects that diminish survival probabilities. Survival is a biologically important response that can have a direct impact on population size. However, the concentration typically reported at which there is 50% mortality of test organisms (LC_{50}) is a poor measure for consideration of effects at ecologically-relevant concentrations. LC_{50} is a measure for acute toxicity whereas Pb effects on ecosystem receptors are likely characterized as a chronic, cumulative exposure rather than acute exposure. Furthermore, a scenario in which 50% of a population does not survive is likely not a sustainable population. From the LC_{50} data on Pb in this review and previous Pb AQCDs, a wide range of sensitivity to Pb is evident across taxa and within genera. However, the LC_{50} is usually much higher than current environmental levels of Pb in the U.S, even though physiological dysfunction that adversely impacts the fitness of an organism often occurs at concentrations well below lethal ones. When available, LC_{10}, NOEC or LOEC are therefore reported.

There are no studies reported in the previous Pb AQCDs or the current ISA for aquatic plants that indicate phytotoxicity at current concentrations of Pb in freshwater environments.

There are considerable data available on toxicity of Pb to aquatic invertebrates as reviewed in the previous Pb AQCDs and *Ambient Water Quality Criteria for Lead* (U.S. EPA, 1985) (U.S. EPA, 2008b). Table AX7-2.4.1 from the 2006 Pb AQCD summarizes LC_{50} data and other endpoints for freshwater and marine invertebrates (U.S. EPA, 2006c). Recent studies available since the 2006 Pb AQCD and draft Aquatic Life Water Quality Criteria for Pb that report mortality data are summarized in Table 7-5. Freshwater

invertebrates are generally more sensitive to Pb exposure than other taxa, with survival impacted in a few species at or near concentrations that are encountered in aquatic environments (Table 7-2). These impacted species may include candidate or endangered species. For example, the freshwater mussel *L. rafinesqueana* (Neosho mucket), is a candidate for the endangered species list. The EC_{50} for foot movement (a measure of viability) for newly transformed juveniles of this species was 188 µg Pb/L. (Wang et al., 2010e).

Most of the evidence for Pb effects on survival in freshwater invertebrates is from sensitive species of gastropods, amphipods, cladocerans and rotifers (Sections 7.4.5.2 and 7.4.6). In some of these organisms, increased mortality is observed in the upper range of Pb concentration values found in surveys of U.S. surface waters (median 0.50 µg Pb/L, range 0.04 to 30 µg Pb/L) (U.S. EPA, 2006c), although the toxicity of Pb is highly dependent upon water quality variables such as DOC, hardness and pH. In the 1986 Pb AQCD, increased mortality was reported in the freshwater gastropod *Lymnaea palutris* at Pb concentration as low as 19 µg Pb/L effectively reducing total biomass production (Borgmann et al., 1978). Toxicity testing with amphipods under various water conditions indicate these organisms are sensitive to Pb at <10 µg Pb/L (U.S. EPA, 2006c) and the present document). A 7 day LC_{50} of 1 µg Pb/L was observed in soft water with the amphipod *H. azteca (*Borgmann et al., 2005*)*. In this same species, the 96-hour LC_{50} for Pb at pH of 5 was 10 µg Pb/L (Mackie, 1989). In 42-day chronic exposures of *H. azteca* exposed to Pb via water and diet, the LC_{50} was 16 µg Pb/L (Besser et al., 2005). At higher pH and water hardness, amphipods are less sensitive to Pb (U.S. EPA, 2006c). In a series of 48 hour acute toxicity tests with the cladoceran *C. dubia* conducted in a variety of natural waters across North America, LC_{50} values ranged from 29 to 1,180 µg Pb/L (NOEC range 18 to <985 µg Pb/L) and were most significantly influenced by DOC and water ionic strength (Esbaugh et al., 2011). In the 2006 Pb AQCD the range of 48 hour LC_{50} values for *C. dubia* were reported from 280 to >2,700 µg Pb/L when tested at varying pH levels (U.S. EPA, 2006c). In the rotifer genus *Lecane,* a 22-fold difference in LC_{50} values was observed in 48-hour exposure to Pb between *L. hamata, L. luna* and *L. quadridentata*. (Pérez-Legaspi and Rico-Martínez, 2001). *L. luna* was most sensitive to Pb toxicity with a 48-hour LC_{50} of 140 µg Pb/L. In neonate rotifers, *E. dilatata* the 48-hour LC_{50} was 35 µg Pb/L (Arias-Almeida and Rico-Martínez, 2011). A wide range of LC_{50} values were reported for chironomid species (Table 7-5), however, the available evidence suggests these freshwater invertebrates are less sensitive to Pb than amphipods, cladocerans and rotifers. Other freshwater invertebrates such as odonates may be tolerant of Pb concentrations that greatly exceed concentrations of Pb reported in environmental media. Some invertebrates are able to detoxify Pb such as through sequestration of Pb in the exoskeleton which is subsequently molted.

There is considerable historic information on Pb toxicity to freshwater fish. Early observations from mining areas where Pb and other metals were present indicated local extinction of fish from streams (U.S. EPA, 1977). The lowest LC_{50} for fish reported in the 1977 Pb AQCD was 1,000 µg Pb/L in soft water for rainbow trout *O. mykiss* (reclassified from *Salmo gairdneri*) following 96-hour exposure to Pb (U.S. EPA, 1977). Additional LC_{50} values for freshwater fish are summarized in the 1985 Ambient Water Criteria for Pb (U.S. EPA, 1985) and the draft Ambient Aquatic Life Water Quality Criteria for Pb (U.S. EPA, 2008b). An LC_{50} of 236 µg Pb/L adjusted to a total hardness of 50 mg/L $CaCO_3$ was reported for *O. mykiss* in the draft Ambient Aquatic Life Water Quality Criteria for Pb.

More recently reviewed studies using fish have considered the role of water quality variables and bioavailability on Pb toxicity. Higher toxicity tends to occur in acidic waters where more free-Pb ion is available for uptake. The interactive effects of Pb concentration and water quality variables on toxicity may result in equivalent toxicity for a broad range of Pb concentrations. In a series of 96-hour acute toxicity tests with juvenile fathead minnow conducted in a variety of natural waters across North America, LC_{50} values ranged from 41 to 3,598 µg Pb/L and no Pb toxicity occurred in three highly alkaline waters (Esbaugh et al., 2011). In the 2006 Pb AQCD, the 96-hr LC_{50} values in fathead minnow ranged from 810->5,400 µg Pb/L in varying pH and hardness (U.S. EPA, 2006c).

Decreased survival is also a function of age of the fish. Thirty day LC_{50} values for larval fathead minnows ranged from 39 to 1,903 µg Pb/L in varying concentrations of DOC, $CaSO_4$ and pH (Grosell et al., 2006b). In a recent study of rainbow trout fry at 2 to 4 weeks post swim-up, the 96-hour LC_{50} was 120 µg Pb/L at a hardness of 29 mg/L as $CaCO_3$, a value much lower than in testing with older fish (Mebane et al., 2008). In the same study, two chronic (>60 day) tests were conducted with rainbow trout and the NOECs for survival were 24 and 87 µg Pb/L and the LOECs were 54 and 125 µg Pb/L, respectively. In contrast to aqueous exposures, 30 day dietary studies with rainbow trout fathead minnow, and channel catfish fed a live diet of *L. variegatus* contaminated with Pb showed no statistically significant effects on survival (Erickson et al., 2010).

Freshwater fish are less sensitive to Pb than freshwater invertebrates, however, recent studies have highlighted the importance of considering pH, hardness and additional modifying factors in assessing toxicity since effects can vary over several orders of magnitude. Fish mortalities occur above the concentrations of Pb encountered in U.S. surface waters although, in some cases, the observed effects may be just above the upper measured range of Pb in some aquatic environments (Table 7-2). Furthermore, although LC_{50} values are the most commonly reported, effects are occurring at lower

concentrations. A more relevant indication of exposure impacts would be an LC_{10} or LOEC, however, these values are not always provided. The evidence is sufficient to conclude that there is a causal relationship between Pb exposures and survival in freshwater invertebrates and vertebrates. The evidence is inadequate to conclude that there is a causal relationship between Pb exposures and survival in freshwater plants.

7.4.12.4 Neurobehavioral Effects-Freshwater Biota

Evidence from laboratory studies and limited data from field studies reviewed in this chapter, in the draft Ambient Aquatic Criteria document for Pb which updates the 1985 Ambient Water Quality Criteria for Pb (U.S. EPA, 1985), and in previous Pb AQCDs have shown effects of Pb on neurological endpoints in aquatic animal taxa. These include changes in behaviors that may decrease the overall fitness of the organism such as avoidance responses, decreased ability of an organism to capture prey or escape predators, and alterations in feeding behaviors. Evidence of alteration in behaviors at the level of the organism is a potential endpoint for effects at population or community levels of biological organization (U.S. EPA, 2003a).

In the 1977 Pb AQCD behavioral impairment of a conditioned response (avoidance of a mild electric shock) in goldfish was observed as low as 70 µg Pb/L (Weir and Hine, 1970). In the 2006 Pb AQCD several studies were reviewed in which Pb was shown to affect predator-prey interactions, including alteration in prey size choice and delayed prey selection in juvenile fathead minnows following 2-week pre-exposure to 500 µg Pb/L (Weber, 1996). In limited studies available on worms, snails, tadpoles, hatchling turtles and fish there is evidence that Pb may affect the ability to escape or avoid predation. For example, in the tubificid worm *T. tubifex* the 96 hour EC_{50} for immobilization was 42 µg Pb/L (Khangarot, 1991). Some organisms exhibit behavioral avoidance while others do not seem to detect the presence of Pb (U.S. EPA, 2006c). Additional behavioral endpoints reported in the Draft Ambient Aquatic Life Quality Criteria for Pb include an EC_{50} of 140 µg Pb/L for feeding inhibition in the freshwater cladoceran *C. dubia* and deceased learning acquisition in bullfrogs at 500 µg Pb/L (31.51 µg Pb/L adjusted to a total hardness of 50 mg/L $CaCO_3$). All of these effects occur at concentrations that exceed Pb concentration values found in surveys of U.S. surface waters although within the range of Pb detected near some mining-disturbed areas (Table 3-11).

Recent information since the 2006 Pb AQCD provides evidence for Pb impacts on behaviors that may affect feeding and predator avoidance in freshwater environments at concentrations near the range of Pb detected in U.S. surface waters (Table 7-2 and Section 7.4.5.3). Prey capture ability was decreased in 10 day old fathead minnow larvae

born from adult fish exposed to 120 µg Pb/L for 300 days, then subsequently tested in a 21-day breeding assay (Mager et al., 2010). Another study in fish reported effects at low µg Pb/L concentration, however, the findings are not considered as strong evidence for causality since exposure concentrations in water were not analytically verified. Specifically, zebrafish embryos exposed nominally to concentrations of Pb (2.0 to 6.0 µg Pb/L) until 24 hours post-fertilization and then subsequently tested as larvae exhibited decreased startle response time and altered pattern of escape swimming (Rice et al., 2011). In adult fish raised from the exposed embryos (6.0 µg Pb/L), the ability to detect visual contrast was degraded. Although this study was conducted with nominal concentration of Pb in media, uptake of Pb by embryos was quantified and more Pb was measured in tissues of embryos exposed to the higher concentration of Pb when compared to the lower exposure concentration. Additional studies are needed in fish to support these initial findings of effects on ecologically relevant behavioral impairments.

Findings in laboratory animals support the limited evidence for neurobehavioral effects of Pb in freshwater invertebrates and vertebrates. In animal toxicological studies Pb induced changes in learning and memory (Section 5.3.2.3), as well as attention and motor skills (Section 5.3.3.1). New behaviors induced by exposure to Pb reviewed in Chapter 5 that are relevant to effects of Pb observed in freshwater systems include effects on visual and auditory sensory systems and changes in structure and function of neurons and supporting cells in the brain. Mechanisms that include the displacement of physiological cations, oxidative stress and changes in neurotransmitters and receptors are also reviewed. Central nervous system effects in fish recognized in previous Pb AQCDs include effects on spinal neurons and brain receptors. New evidence from this review identifies the MAPKs ERK1/2 and $p38^{MAPK}$ as possible molecular targets for Pb neurotoxicity in catfish (Leal et al., 2006). Evidence in terrestrial ecosystems (Section 7.3.12.4) is not as extensive, but it is highly coherent with findings in aquatic ecosystems. Overall, the evidence from available studies on neurobehavioral effects of Pb in aquatic systems is limited, but sufficient to conclude that a causal relationship is likely to exist between Pb exposures and neurobehavioral effects in aquatic invertebrates and vertebrates.

7.4.12.5 Hematological Effects-Freshwater Biota

Hematological responses are commonly reported effects of Pb exposure in aquatic invertebrates and vertebrates. Anemia was recognized as a symptom of chronic Pb poisoning in fish in the 1977 Pb AQCD and has been subsequently reported in various fish species using common hematological endpoints (e.g., red blood cell counts, hematocrit, Hb concentrations) (Mager, 2012). In the 1986 Pb AQCD, hematological

effects of Pb exposure on fish included decrease in red blood cells and inhibition of ALAD (U.S. EPA, 1986b). Inhibition of ALAD activity under various test conditions is reported in Table 6 of the draft Ambient Aquatic Life Water Quality Criteria for Pb for freshwater fish species (*O. mykiss* (Rainbow Trout), *S. fontinalis* (Brook Trout), *C. auratus* (Goldfish) and *Lepomis gibbosus* (Pumpkinseed)) (U.S. EPA, 2008b). In these studies, Rainbow Trout was the most sensitive with inhibition of ALAD activity reported in multiple studies within the upper range of Pb in surface waters of the U.S. (median 0.5 µg Pb/L, range 0.04 to 30 µg Pb/L) (U.S. EPA, 2006c).

Laboratory studies with freshwater invertebrates have also indicated considerable species differences in ALAD activity in response to Pb. For example, the concentration at which 50% ALAD inhibition was measured in the freshwater gastropod *B. glabrata* (23 to 29 µg Pb/L) was much lower than in the freshwater oligochaete *L. variegatus* (703 µg Pb/L) based on nominal exposure data (Aisemberg et al., 2005).

Findings in laboratory studies are additionally supported by evidence from field-collected organisms providing coherence to the observations of Pb effects on ALAD activity. In environmental assessments of metal-impacted habitats, ALAD is a recognized biomarker of Pb exposure (U.S. EPA, 2006c). ALAD activity is negatively correlated with total Pb concentration in freshwater bivalves, and lower ALAD activity has been correlated with elevated blood Pb levels in field-collected fish as well. Further evidence from the 2006 Pb AQCD and this review of Pb effects on ALAD enzymatic activity, including effects in bacteria, amphibians and additional field and laboratory studies on freshwater fish, confirms that the decreased activity in this enzyme is an indicator for Pb exposure across a wide range of taxa and that a common mode of action is likely for invertebrates and vertebrates. The finding that the hematological system is a target for Pb in natural systems is also supported by some evidence of Pb-induced alterations of serum profiles and changes in white blood cell counts in fish (U.S. EPA, 2006c) and amphibians. This evidence is strongly coherent with evidence from terrestrial vertebrates (Section 7.3.12.5). It is also coherent with observations from human epidemiologic and animal toxicology studies (Section 5.7) where there is consistent evidence that exposure to Pb induces adverse effects on hematological endpoints, including altered heme synthesis mediated through decreased ALAD and ferrochelatase activities, decreased red blood cell survival and function, and increased red blood cell oxidative stress. The overall weight of epidemiologic and toxicological evidence for humans was sufficient to conclude that a causal relationship exists between exposure to Pb and hematological effects (Section 5.7).

Based on observations in freshwater organisms and additionally supported by findings in terrestrial systems, saltwater invertebrates (Section 7.4.21.5), and by toxicological and epidemiologic evidence on human health effects, evidence is sufficient to conclude that

there is a causal relationship between Pb exposures and hematological effects in freshwater vertebrates. Evidence is sufficient to conclude that a causal relationship is likely to exist between Pb exposures and hematological effects in freshwater invertebrates.

7.4.12.6 Physiological Stress-Freshwater Biota

Building on the body of evidence presented in the 2006 Pb AQCD (U.S. EPA, 2006c) recent studies provide consistent and coherent evidence of upregulation of antioxidant enzymes and increased lipid peroxidation associated with Pb exposure within one or two orders of magnitude above current or ambient conditions in many species of freshwater plants, invertebrates and vertebrates. A few studies provide evidence of effects at concentrations of Pb encountered in some sediments of the U.S. (Table 7-2). In aquatic plants, increases of antioxidant enzymes with Pb exposure occur in algae, mosses, and floating and rooted aquatic macrophytes. Most available evidence for antioxidant responses in aquatic plants are from laboratory studies lasting from 2 to 7 days and at concentrations higher than typically found in the environment. However, data from transplantation experiments from non-polluted to polluted sites indicate that elevated enzyme activities are associated with Pb levels measured in sediments. For example, the freshwater macrophyte *Myriophyllum quitense* exhibited elevated antioxidant enzyme activity (glutathione-S-transferase, glutathione reductase, peroxidase) following transplantation in anthropogenically polluted areas containing elevated Pb concentrations. These were correlated with sediment Pb concentrations in the range of 5 to 23 mg Pb/g dry weight (Nimptsch et al., 2005).There is evidence for antioxidant activity in response to Pb exposure in freshwater invertebrates (i.e., bivalves). Markers of oxidative damage are also observed in fish, amphibians and mammals in laboratory studies. Across all organisms, there are differences in the induction of antioxidant enzymes that appear to be species-dependent.

Additional stress responses to Pb in a few aquatic invertebrates have been reported since the 2006 Pb AQCD, and included elevated heat shock proteins, osmotic stress, lowered metabolism and decreased glycogen levels associated with Pb exposure. Although these stress responses are correlated with Pb exposure, they are non-specific and may be altered with exposure to any number of environmental stressors. Heat shock protein induction has been observed in zebra mussels exposed to 500 µg Pb/L for 10 weeks (Singer et al., 2005). Crayfish exposed for 14 days to 500 µg Pb/L exhibited a Pb-induced hypometabolism under conditions of environmental hypoxia in the presence of the metal (Morris et al., 2005). Glycogen levels in the freshwater snail *B. glabrata* were

significantly decreased following 96-hour exposures at 50 µg/L and higher (Ansaldo et al., 2006).

Evidence for stress responses observed in freshwater plants, invertebrates and vertebrates is coherent with findings in terrestrial species (Section 7.3.12.6) and saltwater invertebrates (Section 7.4.21.6). It is also coherent with evidence from human and experimental animal studies of oxidative stress following impairment of normal metal ion functions (Section 5.2.4). Upregulation of antioxidant enzymes and increased lipid peroxidation are considered to be reliable biomarkers of stress, and provide evidence that Pb exposure induces a stress response in those organisms which may increase susceptibility to other stressors and reduce individual fitness. Evidence is sufficient to conclude that a causal relationship is likely to exist between Pb exposures and physiological stress in freshwater aquatic plants, invertebrates and vertebrates.

7.4.12.7 Community and Ecosystem Level Effects-Freshwater Biota

Most direct evidence of community- and ecosystem-level effects in freshwater systems is from heavily contaminated sites where Pb concentrations are higher than typically observed environmental concentrations for this metal. Impacts of Pb on aquatic habitats that receive runoff from contaminated areas have been studied for several decades. For aquatic systems, the literature focuses on evaluating ecological stress from Pb originating from urban and mining effluents rather than atmospheric deposition. Ecosystem-level field studies are complicated by the confounding of Pb exposure with other factors such as the presence of trace metals and acidic deposition and by the variability inherent in natural systems. In natural systems, Pb is often found co-existing with other stressors, and observed effects may be due to cumulative toxicity.

In laboratory studies and simulated ecosystems, where it is possible to isolate the effect of Pb, this metal has been shown to alter competitive behavior of species, predator-prey interactions and contaminant avoidance. These dynamics may change species abundance and community structure at higher levels of ecological organization. Uptake of Pb into aquatic and terrestrial organisms and subsequent effects on mortality, growth, developmental and reproductive endpoints at the organism level are expected to have ecosystem-level consequences, and thus provide consistency and plausibility for causality in ecosystem-level effects.

In aquatic ecosystems, field studies reviewed in the 2006 Pb AQCD (summarized in Table AX7-2.5.2) and more recent studies report reductions of species abundance, richness or diversity. This is particularly the case for benthic macroinvertebrate communities where sources of Pb were mining or urban effluents, and Pb coexisted with

other metals. The results often indicate a correlation between the presence of one or more metals and the negative effects observed. For example, in the 2006 Pb AQCD, the Coeur d'Alene River watershed in Idaho, U.S. was used as a case study for Pb effects at the population and community level. Significant negative correlations were observed between Pb in water column and total taxa richness and EPT taxa richness in the river. In a simulated aquatic microcosm a reduction in abundance and richness of protozoan species was observed with increasing Pb concentration from 50 to 1,000 µg Pb/L (Fernandez-Leborans and Antonio-Garcia, 1988).

Since the 2006 Pb AQCD, there is further evidence for effects of Pb in sediment-associated communities. Sediment-bound Pb contamination appears to differentially affect members of the benthic invertebrate community, potentially altering ecosystems dynamics in small urban streams (Kominkova and Nabelkova, 2005). Although surface water Pb concentrations in monitored streams were determined to be very low, concentrations of the metal in sediment were high enough to pose a risk to the benthic community (e.g., 34 to 101 mg Pb/kg). These risks were observed to vary with benthic invertebrate functional feeding group, with collector-gatherer species exhibiting larger body burdens of heavy metals than benthic predators and collector-filterers.

In a recent study conducted since the 2006 Pb AQCD, changes to aquatic plant community composition have been observed in the presence of elevated surface water Pb concentrations at three lake sites impacted by mining effluents. The site with highest Pb concentration (103-118 µg Pb/L) had lowest number of aquatic plant species when compared to sites with lower Pb concentrations (78-92 µg Pb/L) (Mishra et al., 2008). Certain types of plants such as rooted and submerged aquatic plants may be more susceptible to aerially deposited Pb resulting in shifts in Pb community composition. High Pb sediment concentrations are linked to shifts in amphipod communities inhabiting plant structures.

Avoidance response to Pb exposure varies widely in different species and this could affect community composition and structure and species abundance. For example, frogs and toads lack avoidance response while snails and fish avoid higher concentrations of Pb (U.S. EPA, 2006c).

In the Annex to the 2006 Pb AQCD, the Coeur d'Alene River basin in Idaho was presented as a case study for a watershed impacted by Pb and other metals. A significant negative correlation was observed between Pb in water column (0.5 to 30 µg Pb/L) and total taxa richness, EPT taxa richness, and the number of metal-sensitive mayfly species (Maret et al., 2003). Additional lines of evidence including mine density, metal concentrations, and bioaccumulation in caddisfly tissue were included. Since the 2006 Pb AQCD, additional research at this site and model development has resulted in

further characterization of the effects of Pb on waterfowl and other aquatic organisms in this heavily contaminated ecosystem. Mean Pb concentrations in Coeur d'Alene sediment range from 14 to 5,009 mg Pb/kg dry weight (Spears et al., 2007). Modeling of sediment and Pb levels in waterfowl predict a sediment Pb effects range of 147-944 mg Pb/kg dry weight and a mortality effects level of 1,652 mg/kg dry weight (Spears et al., 2007). In a 6-week feeding study with mallard (*Anas platyrhynchos*) ducklings, ingestion of Pb-contaminated sediments from the Coeur d' Alene basin was shown to result in decreased brain growth and altered brain chemistry (Douglas-Stroebel et al., 2004). These findings support previous observations of altered behavior and hematological, hepatotoxic, and histopathological endpoints in waterfowl from Lake Coeur d'Alene that ingest Pb contaminated sediments and vegetation during feeding.

In addition to the evidence from microcosm and field studies presented above, effects on reproduction (Section 7.4.12.1), growth (Section 7.4.12.2) and survival (Section 7.4.12.3) have been clearly demonstrated in freshwater species. These endpoints can have effects at the population-level and community-level of biological organization which may lead to ecosystem-level impacts. Although the evidence is strong for effects of Pb on growth, reproduction and survival in certain species in experimental settings at or near the range of Pb concentrations reported in surveys of U.S. freshwater systems, considerable uncertainties exist in generalizing effects observed under small-scale, particular conditions up to predicted effects at the ecosystem level of biological organization. In many cases it is difficult to characterize the nature and magnitude of effects and to quantify relationships between ambient concentrations of Pb and ecosystem response due to presence of multiple stressors, variability in field conditions and to differences in Pb bioavailability at that level of organization. Bioavailability of Pb is influenced by pH, alkalinity, total suspended solids, and DOC among other factors and can vary greatly in natural environments. Nevertheless, evidence of ecosystem effects in aquatic systems is coherent with similar evidence in terrestrial systems, and based on the cumulative evidence from laboratory studies and field observations, a causal relationship is likely to exist between Pb exposures and the alteration of species richness, species composition and biodiversity in freshwater aquatic ecosystems.

7.4.13 Introduction to Bioavailability and Biological Effects of Pb in Saltwater Ecosystems

Saltwater ecosystems include salt marsh, estuaries, embayments, beaches, and other coastal areas; and encompass a range of salinities from just above that of freshwater to that of seawater. These ecosystems may receive Pb contributions from direct atmospheric deposition and/or via runoff from terrestrial systems. A range of 0.01 to 27 µg Pb/L

including coastal areas, estuaries and open ocean was reported by Sadiq (1992) with the higher values associated with sites involving human activity, however, these values are not specific to the U.S. (Table 7-2). In an earlier publication, levels of Pb in the North Atlantic and North Pacific surface waters ranged from 0.005 to 0.4 µg Pb/L but the range of values in coastal waters and estuaries were approximately equal to the range of Pb in freshwater (Leland and Kuwabara, 1985). Additional information on Pb levels in water is available in Sections 7.2.3 and 3.6. The 2006 Pb AQCD provided an overview of regulatory considerations for water and sediments in addition to consideration of biological effects and major environmental factors that modify the response of marine organisms to Pb exposure. Regulatory guidelines for Pb in saltwater have not changed since the 2006 Pb AQCD and are summarized below. This section is followed by new information on bioavailability and biological effects of Pb in saltwater since the 2006 Pb AQCD.

The most recent ambient water quality criteria for Pb in saltwater were released in 1985 (U.S. EPA, 1985) by the EPA Office of Water which employed empirical regressions between observed toxicity and water hardness to develop hardness-dependent equations for acute and chronic criteria. These criteria are published pursuant to Section 304(a) of the Clean Water Act and provide guidance to states and tribes to use in adopting water quality standards for the protection of aquatic life and human health in surface water. The ambient water quality criteria for Pb are currently expressed as a criteria maximum concentration (CMC) for acute toxicity and criterion continuous concentration (CCC) for chronic toxicity (U.S. EPA, 2009b). In saltwater, the CMC is 210 µg Pb/L and the CCC is 8.1 µg Pb/L. The 2006 Pb AQCD summarized two approaches for establishing sediment criteria for Pb based on either bulk sediment or equilibrium partitioning as reviewed in the present document in Section 7.4.2.

In the following sections, recent information available since the 2006 Pb AQCD on Pb in marine and estuarine ecosystems will be presented. Throughout the sections, brief summaries of conclusions from the 1977 Pb AQCD (U.S. EPA, 1977), the 1986 Pb AQCD (U.S. EPA, 1986b) and the 2006 Pb AQCD (U.S. EPA, 2006b) are included where appropriate. Recent research on the bioavailability and uptake of Pb into saltwater organisms including plants, invertebrates and vertebrates is presented in Section 7.4.14. Toxicity of Pb to marine flora and fauna including growth, reproductive and developmental effects (Section 7.4.15) are followed with data on exposure and response of saltwater organisms (Section 7.4.16). Responses at the community and ecosystem levels of biological organization are reviewed in Section 7.4.17 followed by characterization of sensitivity and vulnerability of saltwater ecosystem components (Section 7.4.18) and a discussion of ecosystem services (Section 7.4.19). The saltwater sections conclude with a synthesis of the new data for Pb effects on saltwater plants,

invertebrates and vertebrates (Section 7.4.20) and causal determinations based on evidence from previous Pb AQCDs and recent studies (Section 7.4.21).

7.4.14 Bioavailability of Pb in Saltwater Systems

Bioavailability was defined in the 2006 Pb AQCD as "the proportion of a toxin that passes a physiological membrane (the plasma membrane in plants or the gut wall in animals) and reaches a target receptor (cytosol or blood)". In 2007, EPA took cases of bioactive adsorption into consideration and revised the definition of bioavailability as "the extent to which bioaccessible metals absorb onto, or into, and across biological membranes of organisms, expressed as a fraction of the total amount of metal the organism is proximately exposed to (at the sorption surface) during a given time and under defined conditions" (U.S. EPA, 2007c)

Factors affecting bioavailability of Pb to marine organisms are the same as those in freshwater systems (Sections 7.4.2 and 7.4.4). However, although routes of exposure and physiological mechanisms for storage and excretion influence uptake of metals by all organisms, they may be different in marine organisms, particularly for ion transport mechanisms (Niyogi and Wood, 2004). Marine environments are characterized by higher levels of ions, such as Na^+, Ca^{2+}, and Mg^{2+}, which compete for potential binding sites on biotic ligands such as gills, thereby generally reducing the effective toxicity of metal ions as compared to freshwater environments. However, because the concentrations of these ions are relatively constant, bioavailability may be more predictable in marine systems that are little influenced by freshwater than in freshwater systems, varying mostly with amount and type of dissolved organic matter. In estuaries and embayments, changing salinities and proximity to anthropogenic loading of pollutants add to the complexity of predicting Pb speciation in these dynamic systems. BLMs (Figure 7-3) now being developed for marine organisms are functionally similar to those applied to freshwater organisms (Section 7.4.4).

Although in freshwater systems the presence of humic acid is considered to reduce the bioavailable fraction of metals in freshwater, there is evidence that DOC/DOM does not have the same effect on free Pb ion concentration in marine systems (see Section 7.4.2.4 for detailed discussion). For the sea urchin *P. lividus*, the presence of humic acid increased both the uptake and toxicity of Pb possibly by enhancing uptake of Pb via membrane Ca^{2+} channels (Sanchez-Marin et al., 2010b). This also was observed in the marine diatom *Thalassiosira weissflogii*, where humic acids absorbed to cell surfaces increased metal uptake (Sanchez-Marin et al., 2010b). Formation of a ternary complex that is better absorbed by biological membranes was another proposed mechanism that

could describe the increased bioavailability to marine invertebrates of Pb bound to humic acid (Sánchez-Marín et al., 2007).

Sanchez-Marin et al. (2011) subsequently have shown that different components of DOM have different effects on Pb bioavailability in marine systems. Their initial research using Aldrich humic acid found that increasing humic acid concentrations increased Pb uptake by mussel gills and increased toxicity to sea urchin larvae in marine environments (Sánchez-Marín et al., 2007). In contrast, a subsequent investigation found that fulvic acid reduced Pb bioavailability in marine water (Sánchez-Marín et al., 2011). The contradictory effects of different components of DOM on marine bioavailability likely reflect their distinct physico-chemical characteristics. More hydrophobic than fulvic acid, humic acid may adsorb directly with cell membranes and enhance Pb uptake through some (still unidentified) mechanism (Sánchez-Marín et al., 2011). Pb AVS-measurements were also determined to accurately predict uptake by mussels (*Mytilus* sp.) in the presence of 2.5 to 20 mg/L fulvic acid (Sánchez-Marín et al., 2011). However, the effects of DOM on Pb bioavailability to mussels were underpredicted by AVS Pb concentration measurements, potentially as a result of adsorption of DOM-Pb complexes.

Based on the above, BLMs (see Section 7.4.4 and Figure 7-3) used to predict bioavailability of Pb to aquatic organisms (Di Toro et al., 2005), may require modifications for application to marine organisms. Of particular importance is the finding that in marine aquatic systems, surface water DOM was found to increase (rather than decrease) uptake of Pb by fish gill structures, potentially through the alteration of membrane Ca^{2+} channel permeability. Veltman et al. (2010) proposed integrating BLM and bioaccumulation models in order to more accurately predict metal uptake by fish and invertebrates, and calculated metal absorption efficiencies for marine fish species from both types of models. They noted that affinity constants for Ca^{2+}, Cd, Cu, Na, and Zn were highly similar across different aquatic species, including fish and invertebrates (Veltman et al., 2010). These findings suggest that the BLM can be integrated with bioaccumulation kinetics to account for both environmental chemical speciation and biological and physiological factors in both marine and freshwater systems.

7.4.14.1 Saltwater Plants and Algae

In the 1977 Pb AQCD, the cordgrass *Spartina alterniflora* was found to reduce by a small amount the quantity of Pb in sediments (U.S. EPA, 1977). Limited data on marine algal species reviewed in the 1986 Pb AQCD and 2006 Pb AQCD provided additional evidence for Pb uptake. Recent data available since the 2006 Pb AQCD includes Pb bioaccumulation studies conducted with five species of marine algae, (*Tetraselmis chuii*,

Rhodomonas salina, *Chaetoceros* sp., *Isochrysis galbana* and *Nannochloropsis gaditana*). In this study it was demonstrated that bioaccumulation rates varied with species following 72-hour exposure to Pb. *I. galbana* accumulated the lowest concentrations of Pb (0.01 and 0.6 pg Pb/cell at water concentrations of 51 and 6,348 µg Pb/L), while *Chaetoceros* sp. was observed to be the most efficient Pb bioaccumulator, adsorbing 0.04 and 54 pg Pb/cell at 51 and 6,348 µg Pb/L (Debelius et al., 2009).

Recent uptake studies of Pb in plants associated with marine environments are also available. The roots of two salt marsh species, *Sarcocornia fruticosa* and *Spartina maritima*, significantly accumulated Pb, to maximum concentrations of 2,870 mg Pb/kg and 1,755 mg Pb/kg, respectively (Caetano et al., 2007). Roots had similar isotopic signature to those of sediments in vegetated zones indicating that Pb uptake by plants reflects the input in sediments. BCFs for Pb in root tissue from mangrove tree species range between 0.09 and 2.9, depending on the species and the habitat, with an average BCF of 0.84. The average BCF for mangrove species leaf tissue was considerably less (0.11), as these species are poor translocators of Pb (MacFarlane et al., 2007).

7.4.14.2 Saltwater Invertebrates

Uptake and subsequent bioaccumulation of Pb in marine invertebrates varies greatly between species and across taxa as previously characterized in the 2006 Pb AQCD. This section expands on the findings from the 2006 Pb AQCD on bioaccumulation and sequestration of Pb in saltwater invertebrates. In the case of invertebrates, Pb can be bioaccumulated from multiple sources, including the water column, sediment, and dietary exposures, and factors such as proportion of bioavailable Pb, lifestage, age, and metabolism can alter the accumulation rate. In this section, new information on Pb uptake and subsequent tissue and subcellular distribution will be considered, followed by a discussion on dietary and water routes of exposure and strategies for detoxification of Pb in marine invertebrates.

In marine invertebrates, sites for Pb accumulation include the gill and digestive gland/hepatopancreas. The gills were the main sites of Pb accumulation in pearl oyster, *Pinctada fucata* followed by mantle, in 72-hour exposures to 103.5 µg Pb/L (Jing et al., 2007). Following a 10-day exposure to 2,500 µg Pb/L as Pb nitrate, accumulation of Pb was higher in gill than digestive gland of *Mytilus edulis*: after a 10 day depuration, Pb content was decreased in the gills and digestive gland of these mussels (Einsporn et al., 2009). In blue crabs, *Callinectes sapidus*, collected from a contaminated and a clean

estuary in New Jersey, U.S., the hepatopancreas was found to be the primary organ for Pb uptake (Reichmuth et al., 2010).

There is more information now on the cellular and subcellular distribution of Pb in invertebrates than there was at the time of writing the 2006 Pb AQCD. Specifically, localization of Pb at the ultrastructural level has been assessed in the marine mussel (*M. edulis*) through an antibody-based detection method (Einsporn et al., 2009; Einsporn and Koehler, 2008). Dissolved Pb was detected mainly within specific lysosomal structures in gill epithelial cells and digestive gland cells and was also localized in nuclei and mitochondria. Transport of Pb is thought to be via lysosomal granules associated with hemocytes (Einsporn et al., 2009). In the digestive gland of the variegated scallop *(Chlamys varia*), Pb was also mainly bound to organelles, (66% of the total metal burden) (Bustamante and Miramand, 2005). In the digestive gland of the cephalopod *Sephia officinalis*, (cuttlefish) most of the Pb was found in the organelles (62%) (Bustamante et al., 2006). In contrast, only 7% of Pb in the digestive gland of the octopus (*Octopus vulgaris*) was associated with the fraction containing nuclei, mitochondria, lysosome and microsomes: the majority of Pb in this species was found in cytosolic proteins (Raimundo et al., 2008).

Metian et al. (2009) investigated the uptake and bioaccumulation of ^{210}Pb in variegated scallop and king scallop to determine the major accumulation route (seawater or food) and then assess subsequent tissue distribution. Dietary Pb from phytoplankton in the diet was poorly assimilated (<20%) while more than 70% of Pb in seawater was retained in the tissues. In seawater, ^{210}Pb was accumulated more rapidly in variegated scallop than king scallop and soft tissue distribution patterns differed between the species. Variegated scallop accumulated Pb preferentially in the digestive gland (50%) while in king scallop, Pb was equally distributed in the digestive gland, kidneys, gills, gonad, mantle, intestine, and adductor muscle with each tissue representing 12-30% of ^{210}Pb body load. An additional test with Pb-spiked sediment in king scallop showed low bioaccumulation efficiency of Pb from spiked sediment.

Recently, several studies have attempted to establish biodynamic exposure assessments for various contaminants. In an in situ metal kinetics field study with the mussel *M. galloprovincialis*, simultaneous measurements of metal concentrations in water and suspended particles with mussel biometrics and physiological indices were conducted to establish uptake and excretion rates in the natural environment (Casas et al., 2008). The mean logarithmic ratio of metal concentration in mussels (ng/kg of wet-flesh weight) to metal concentration in water (ng/L) was found to be 4.3 in *M. galloprovincialis*, based on the rate constants of uptake and efflux in a series of transplantation experiments between

contaminated and clean environments. Equilibrium concentrations of Pb in mussels leveled out at approximately 30 days with a concentration of 6.7 mg Pb/kg.

The protective barrier against Pb toxicity formed by the egg structure in some invertebrates was recognized in the 2006 Pb AQCD. Consideration of toxicity of Pb to embryos that develop surrounded by a protective egg shell has been expanded since the 2006 Pb AQCD. In a study with cuttlefish (*S. officinalis*) eggs, radioisotopes were used to assess the permeability of the egg to Pb at low exposure concentrations (^{210}Pb activity concentration corresponding to 512 µg/L Pb) (Lacoue-Labarthe et al., 2009). Retention and diffusion properties of the cuttlefish egg change throughout the development of the embryo and since the eggs are fixed on substrata in shallow coastal waters they may be subject to both acute and chronic Pb exposures. In the radiotracer experiments, ^{210}Pb was never detected in the internal compartments of the egg during the embryonic development stage, while concentrations in the eggshell increased throughout the 48-day exposure. These results are consistent with a study of cuttlefish eggs collected from natural environments in which Pb was only detected in the eggshell. These studies indicate that the cuttlefish egg provides a protective barrier from Pb toxicity (Miramand et al., 2006).

Aquatic invertebrate strategies for detoxifying Pb were reviewed in the 2006 Pb AQCD and include sequestration of Pb in lysosomal-vacuolar systems, excretion of Pb by some organisms, and deposition of Pb to molted exoskeleton. Molting of the exoskeleton can result in depuration of Pb from the body (see Knowlton et al. (1983) and Anderson et al. (1997), as cited in the 2006 Pb AQCD). New research has provided further evidence of depuration of Pb via molting in invertebrates. Mohapatra et al. (2009) observed that Pb concentrations in body tissues were lower in the newly molted mud crabs (*Scylla serrata*) than in the pre-molt, hard-shelled crabs. However, the carapace of hard shelled crabs had lower concentrations of Pb than the exuvium of the soft shell crabs, leading the authors to speculate that some of the metal might be partially excreted during the molting process, rather than entirely through shedding of the previous exoskeleton. Bergey and Weis (2007) showed that differences in the proportion of Pb stored in exoskeleton and soft tissues changed during intermolt and immediate postmolt in two populations of fiddler crabs (*Uca pugnax*) collected from New Jersey. One population from a relatively clean estuary eliminated an average of 56% of Pb total body burden during molting while individuals from a site contaminated by metals eliminated an average of 76% of total Pb body burden via this route. Pb distribution within the body of crabs from the clean site shifted from exoskeleton to soft tissues prior to molting. The authors observed the opposite pattern of Pb distribution in fiddlers from the contaminated site where larger amounts of Pb were depurated in the exoskeleton. The exact dynamics of Pb depuration through molting in crabs are thus still not completely characterized.

7.4.14.3 Saltwater Vertebrates

Saltwater Fish

In comparison to freshwater fish, fewer studies have been conducted on Pb uptake in marine fish. Since marine fish drink seawater to maintain osmotic homeostasis, Pb can be taken up via both gills and intestine (Wang and Rainbow, 2008). Pb was significantly accumulated in gill, liver, plasma, kidney, rectal gland, intestine, skin, and muscle of the elasmobranch spotted dogfish (*Scyliorhinus canicula*) exposed to 2,072 µg Pb/L for one week (De Boeck et al., 2010). In contrast to Pb distribution patterns in freshwater teleosts, high Pb concentrations were present in this species in the skin and rectal gland. Egg cases of the spotted dogfish exposed to ^{210}Pb in seawater for 21 days, accumulated radiolabeled Pb rapidly and the metal was subsequently detected in embryos indicating the permeability of shark eggs to Pb in coastal environments (Jeffree et al., 2008). A study of Pb bioaccumulation in five marine fish species (*Chloroscombrus chrysurus*, *Sardinella aurita*, *Ilisha africana*, *Galeoides decadactylus*, *Caranx latus*) found that *C. chrysurus* was an especially strong bioaccumulator, yielding Pb concentrations of 6 to 10 mg Pb/kg (Gnandi et al., 2006). However, *C. chrysurus* metal content was not correlated to the Pb concentrations along the mine tailings gradient from which they were collected (8.5 and 9.0 µg Pb/L for minimum and maximum tissue concentrations, respectively). This lack of correlation was also observed for fish species that were considered to be weaker Pb bioaccumulators, indicating that unidentified sources of Pb (e.g., in sediments or in dietary sources) may be contributing to Pb uptake by marine fish.

In grunt fish *H. scudderi*, exposed to Pb via dietary uptake through a simulated marine food chain, mean total Pb body burden increased from 0.55 to 3.32 mg Pb/kg in a 42-day feeding study (Soto-Jiménez et al., 2011b). Pb was accumulated to the highest relative concentration in liver with less than 3% of total Pb accumulated in gills. Most of the Pb based on total body mass was accumulated in skeleton, skin, scales and muscle.

The 2006 Pb AQCD considered detoxification mechanisms in fish including mucus production and Pb removal by shedding of scales in which Pb is chelated with keratin. Since the 2006 Pb AQCD review, additional Pb detoxification mechanisms in marine fish have been further elucidated. Mummichog (*Fundulus heteroclitus*) populations in metal-polluted salt marshes in New York exhibited different patterns of intracellular partitioning of Pb although body burden between sites was not significantly different (Goto and Wallace, 2010). Mummichogs at more polluted sites stored a higher amount of Pb in metal rich granules as compared to other detoxifying cellular components such as heat-stable proteins, heat-denaturable proteins and organelles.

Marine Mammals

Studies that consider uptake of Pb in aquatic mammals are limited. Kannan et al. (2006) compared trace element concentrations in livers of free-ranging sea otters (*Enhydra lutris nereis*) found dead along the California coast. They detected Pb in all individuals sampled (N=80) in a range of 0.019 to 1.06 mg Pb/kg. The otters were classified by cause of death (infectious causes, non-infectious causes, emaciated condition) and trace element patterns of tissue distribution were compared. Livers from emaciated otters had significantly elevated levels of Pb compared to non-diseased individuals.

7.4.14.4 Marine Food Web

As discussed in Section 7.4.4.4 trophic transfer of Pb through aquatic food chains was considered to be negligible in the 2006 Pb AQCD (U.S. EPA, 2006c). Measured concentrations of Pb in the tissues of aquatic organisms were found to be generally higher in algae and benthic organisms and lower in higher trophic-level consumers, indicating that Pb was bioaccumulated but not biomagnified (U.S. EPA, 2006c; Eisler, 2000). Recent literature since the 2006 Pb AQCD, provides evidence of the potential for Pb to be transferred in marine food webs while other studies indicate Pb is decreased with increasing trophic level. This section incorporates recent literature on transfer of Pb through marine food chains.

In a dietary study using environmentally realistic concentrations of Pb in prey through four levels of a simplified marine food chain, biological responses including decreased growth and survival and changes in behavior were observed at different trophic levels. However, the concentration of Pb did not increase along the trophic gradient (Soto-Jiménez et al., 2011b; Soto-Jiménez et al., 2011a). The base of the simulated food chain was the microalgae *Tetraselmis suecica* (phytoplankton) grown in 20 µg Pb/L. Pb-exposed cultures of *T. suecica* had significantly less cell divisions per day (growth), biomass and total cell concentrations than control microalgae at 72 hours of exposure. The microalgal cultures were then fed to *Artemia franciscana* (crustacean, brine shrimp) which were then fed to *Litopenaeus vannamei* (crustacean, whiteleg shrimp) and finally to *Haemulon scudderi* (fish, grunt). Effects on behavior, growth and survival were observed in shrimp and in grunt fish occupying the intermediate and top levels of the simulated marine food chain. The authors speculate that the species used in the simulated food chain were able to regulate and eliminate Pb (Soto-Jiménez et al., 2011b).

Partial evidence for biomagnification was observed in a subtropical lagoon in Mexico with increases of Pb concentration occurring in 14 of the 31 (45.2%) of trophic interactions considered (Ruelas-Inzunza and Páez-Osuna, 2008). The highest rate of

transference of Pb as measured in muscle tissue occurred between the prey species whiteleg shrimp (*Litopenaeus vannamei*) and mullet (*Mugil cephalus*) to pelican (*Pelecanus occidentalis*).

Other studies have traced Pb in marine food webs and have found no evidence of biomagnification of Pb with increasing trophic level. In the southeastern Gulf of California, Mexico, Pb was not positively transferred (biomagnification factor <1) through primary producers (seston, detritus) and 14 consumer species in a lagoon food web (Jara-Marini et al., 2009). In a planktonic food web in Bahía Blanca estuary, Argentina, Pb levels in macrozooplankton and mesozooplankton exhibited temporal fluctuations, however no biomagnification was observed between mesozooplankton and macrozooplankton (Fernández Severini et al., 2011). It is important to note, however, that even in the absence of biomagnification, aquatic organisms can bioaccumulate relatively large amounts of metals and become a significant source of dietary metal to their predators (Fairbrother et al., 2007; Reinfelder et al., 1998).

7.4.15 Biological Effects of Pb in Saltwater Systems

This section focuses on the studies of biological effects of Pb on marine and estuarine algae, plants, invertebrates, fish and mammals published since the 2006 Pb AQCD. Key studies from the 1977 Pb AQCD, the 1986 Pb AQCD and the 2006 Pb AQCD on biological effects of Pb are summarized where appropriate. Biological effects of Pb on saltwater algae and plant species are considered below, followed by information on effects on marine invertebrates and vertebrates. Alterations to reproduction, growth and survival of saltwater organisms can lead to changes at the community and ecosystem levels of biological organization such as decreased abundance, reduced taxa richness, and shifts in species composition (Section 7.1). New evidence for Pb effects on reproduction, growth and survival in saltwater plants, invertebrates and vertebrates is summarized in Table 7-6. In general, Pb toxicity to saltwater organisms is less well characterized than toxicity of Pb in freshwater ecosystems due to the fewer number of available studies on marine species. Because this review is focused on effects of Pb, studies reviewed for this section include only those for which Pb was the only, or primary, metal to which the organism was exposed. All reported values are from exposures in which concentrations of Pb were analytically verified unless nominal concentrations are stated.

7.4.15.1 Saltwater Algae and Plants

New evidence on toxicity of Pb to marine algae indicates that species exhibit varying sensitivities to Pb in saltwater. The lowest 72-hour EC_{50} for growth inhibition reported for marine algae was 105 µg Pb/L in *Chaetoceros* sp (Debelius et al., 2009). The microalgae *T. suecica*, had statistically significant decreased biomass yield, growth rate and cell count following 72 hours nominal exposure to 20 µg Pb/L (Soto-Jiménez et al., 2011b). Pb tested at nominal concentrations up to ~2,000 µg Pb/L over a 14-day period did not affect photosynthetic activity in seven species of marine macroalgae (*Ascophyllum nodosum, Fucus vesiculosus, Ulva intestinalis, Cladophora rupestris, Chondrus crispus, Palmaria palmate, Polysiphonia lanosa*) as measured by pulse amplitude modulation chlorophyll fluorescence yield although Pb was readily accumulated by these species (Baumann et al., 2009). In a recent review of the production of phytochelatins and glutathione by marine phytoplankton in response to metal stress, Kawakami et al. (2006) included several studies in which Pb exposure was shown to induce glutathione and phytochelatin at high concentrations in a few species.

7.4.15.2 Saltwater Invertebrates

No studies with marine invertebrates were reviewed in the 1977 Pb AQCD or the 1986 Pb AQCD. Effects of Pb on marine invertebrates reported in the 2006 Pb AQCD included impacts on embryo development in bivalves with an EC_{50} of 221 µg Pb/L for embryogenesis, gender differences in sensitivity to Pb in copepods and increasing toxicity with decreasing salinity in mysids. Survival, growth and reproduction are affected by Pb in marine organisms. Pb has also been shown to affect stress responses, antioxidant activity and osmoregulation.

Recent literature strengthens the evidence indicating that Pb affects enzymes and antioxidant activity in marine invertebrates. Most of these studies only report nominal concentrations of Pb. Activity of enzymes associated with the immune defense system in the mantle of pearl oyster were measured at 0, 24, 48 and 72 hour nominal exposure to 100 µg Pb/L (Jing et al., 2007). Activity of AcPase, a lysosomal marker enzyme, was detected at 24 hours and subsequently decreased. Phenoloxidase activity was depressed compared with controls and remained significantly lower than control after 72 hours of exposure to Pb. Increased SOD activity was observed in the mantle but decreased with time, although always remaining higher than in the control animals (Jing et al., 2007). Activity of Se-dependent glutathione peroxidase did not change with Pb exposure. SOD, catalase, and glutathione peroxidase were significantly reduced at environmentally relevant concentrations of Pb (2 µg Pb/L as measured in Bohai Bay, China) in the

digestive gland of the bivalve *Chlamys farreri (*Zhang et al., 2010b*)*. In contrast, Einsporn et al. (2009) observed no change in catalase activity in the digestive gland and gill of blue mussel *M. edulis* following nominal exposure to 2,500 µg Pb/L as Pb nitrate for 10 days and again following a 10 day depuration period. However, in this same species, glutathione-S-transferase activity was elevated in the gills after Pb exposure and remained active during depuration while no changes to glutathione-S-transferase activity were observed in the digestive gland. In black mussel (*M. galloprovincialis*) exposed 10 days to sublethal nominal concentrations of Pb, fluctuations in SOD activity were observed over the length of the exposure and MDA levels were increased in mantle and gill (Vlahogianni and Valavanidis, 2007). Catalase activity was decreased in the mantle of these mussels but fluctuated in their gills, as compared with the control group. In the bivalve *C. farreri* exposed to Pb, there was induction of lipid peroxidation measured as MDA of 24% and a 37% reduction in 7-ethoxyresorufin-o-deethylase (EROD) activity when compared to controls (Zhang et al., 2010b). In red fingered marsh crab, *Parasesarma erythrodactyla*, collected from sites along an estuarine lake in New South Wales, Australia, elevated glutathione peroxidase activity was correlated with individuals with higher metal body burdens (MacFarlane et al., 2006).

ALAD is a recognized biomarker of exposure across a wide range of taxa including bacteria (Korcan et al., 2007), invertebrates and vertebrates. Since the 2006 Pb AQCD, there are additional studies measuring changes in ALAD activity in field-collected bivalves and crustaceans from saltwater habitats. In the bivalve *Chamelea gallina* collected from the coast of Spain, ALAD inhibition was greater with higher concentrations of Pb measured in whole tissue (Kalman et al., 2008). In another study conducted in Spain, ALAD activity was negatively correlated with total Pb concentration in seven marine bivalves (*C. gallina*, *Mactra corallina*, *Donax trunculus*, *Cerastoderma edule*, *M. galloprovincialis*, *Scrobicularia plana* and *Crassostrea angulata*). However, the authors of this study indicated the need to consider variability of responses between species when using ALAD as a biomarker for Pb (Company et al., 2011). Pb content varied significantly among species and was related to habitat (sediment versus substrate) and feeding behavior.

Behavioral responses of aquatic invertebrates to Pb reviewed in the 2006 Pb AQCD included avoidance. A limited number of recent studies have considered additional behavioral endpoints in marine organisms. Valve closing speed was used as a measure of physiological alterations due to Pb exposure in the Catarina scallop (Sobrino-Figueroa and Caceres-Martinez, 2009). The average valve closing time increased from under one second in the control group to 3 to 12 seconds in juvenile scallops exposed to analytically verified concentrations of Pb as Pb nitrate (40 µg/L to 400 µg/L) for 20 days. Damage to

sensory cilia of the mantle was observed following microscopic examination of Pb-exposed individuals.

Since the 2006 Pb AQCD, limited studies on marine invertebrates have indicated effects of Pb on reproduction. In a long term (approximately 60 days) sediment multigenerational bioassay with the estuarine-sediment dwelling amphipod *Elasmopus laevis*, onset to reproduction was significantly delayed at 118 mg Pb/kg compared to controls. In the higher concentrations, start of offspring production was delayed further; 4 days in 234 mg Pb/kg and 8 days in 424 mg Pb/kg (Ringenary et al., 2007). Fecundity and time of first offspring production was also reduced with increasing Pb concentration in sediment above 118 mg Pb/kg. The authors indicate that this concentration is below the current marine sediment regulatory guideline for Pb (218 mg Pb/kg sediment) (NOAA, 1999) and that reproductive endpoints are more sensitive than survival in this species. Exposure of gametes to Pb prior to fertilization resulted in a decrease of the fertilization rates of the marine polychaete *Hydroides elegans* (Gopalakrishnan et al., 2008). In sperm pretreated in 97 µg Pb/L filtered seawater for 20 minutes, fertilization rate decreased by approximately 70% compared to controls. In a separate experiment, eggs were pretreated with Pb prior to addition of an untreated sperm suspension. The fertilization rate of eggs pretreated in 48 µg Pb/L filtered seawater decreased to 20% of the control. In another test with *H. elegans* in which gametes were not pre-treated, but instead added directly to varying concentrations of Pb for fertilization, there appears to be a protective effect following fertilization due to the formation of the fertilization membrane during the first cell division that may prevent Pb from entering the oocytes (Gopalakrishnan et al., 2007).

As noted in the 2006 Pb AQCD and supported by recent studies, Pb exposure negatively affects the growth of marine invertebrates. Wang et al., (2009d) observed growth of embryos of the Asian Clam (*Meretrix meretrix*) was significantly reduced by Pb with an EC_{50} of 197 µg/L. In juvenile Catarina scallop, *Argopecten ventricosus*, exposed to Pb for 30 days, the EC_{50} for growth was 4,210 µg Pb/L (Sobrino-Figueroa et al., 2007). Rate of growth of the deposit feeding *Capitella* sp. polychaetes decreased significantly from the controls in 3 and 6-day exposures, however, the observed changes did not exhibit a clear dose response with increasing Pb concentration (Horng et al., 2009).

Although Pb is known to cause mortality when invertebrates are exposed to sufficiently high concentrations, some species may not exhibit significant mortality even at high concentrations. In a 10-day Pb-spiked sediment exposure (1,000 mg Pb/kg and 15 µg Pb/L dissolved Pb in pore water), 100% of individuals of the Australian estuarine bivalve *Tellina deltoidalis* survived (King et al., 2010). In the deposit feeding *Capitella* sp., polychaetes, exposure to varying concentrations of Pb associated with spiked

sediment up to 870 mg Pb/kg had no effect on survival (Horng et al., 2009). No differences in adult survival were observed in 28 and 60 day sediment exposures to a range of Pb concentrations from 58 mg Pb/kg to 424 mg Pb/kg in the amphipod *E. laevis* (Ringenary et al., 2007). Other species are more sensitive to Pb and these responses are reviewed in Section 7.4.16.

7.4.15.3 Saltwater Vertebrates

Saltwater Fish

There is a dearth of information in previous Pb AQCDs on Pb effects in saltwater fish. Recent data available since the 2006 Pb AQCD include a study with a marine elasmobranch. De Boeck et al. (2010) exposed the spotted dogfish (*S. canicula*) to 2,072 µg Pb/L for one week and measured metallothionein induction in gill and liver tissue, and the electrolytes Na, K, Ca^{2+} and Cl, in plasma. No effects were observed in Pb-exposed fish for any of the physiological variables measured in this study, although Pb was detected in all organs (De Boeck et al., 2010).

Since the 2006 Pb AQCD, several studies integrating behavioral and physiological measures of Pb toxicity have been conducted on marine fish. The ornate wrasse (*Thalassoma pavo*) was exposed nominally to sublethal (400 µg Pb/L) or a maximum acceptable toxicant concentration (1,600 µg Pb/L) dissolved in seawater for one week to assess the effects of Pb on feeding and motor activities (Giusi et al., 2008). In the sublethal concentration group, hyperactivity was elevated 36% over controls. In the high concentration, a 70% increase in hyperactivity was observed and hyperventilation occurred in 56% of behavioral observations. Elevated expression of heat shock protein 70/90 orthologs was detected in the hypothalamus and mesencephalic areas of the brains of Pb-treated fish and neuronal damage was observed in the posterior hypothalamic area and optic tectum. No changes in feeding activity were noted between non-treated and treated fish.

Additional behavioral studies in fish consider effects of dietary Pb. The grunt fish *H. scudderi*, occupying the top level of a simulated marine food chain, exhibited lethargy and decreased food intake during the last week of a 42-day feeding study (Soto-Jiménez et al., 2011b). The fish were fed white shrimp exposed to Pb via brine shrimp that were in turn fed microalgae cultured at a nominal concentration of 20 µg Pb/L. Pb was quantified in shrimp and fish. The authors noted a few of the fish exposed to Pb via dietary transfer through the food chain were observed surfacing and speculated that this behavior was air breathing as a response to stress.

Evidence for reproductive effects of Pb in saltwater fish is limited to a field study in which decreased oocyte diameter and density in the toadfish (*Tetractenos glaber*) were associated with elevated levels of Pb in the gonad of fish collected from contaminated estuaries in Sydney, Australia (Alquezar et al., 2006). The authors state this is suggestive of a reduction in egg size which ultimately may lead to a decline in female reproductive output.

Mammals

Although Pb continues to be detected in tissues of marine mammals in U.S. coastal waters (Bryan et al., 2007; Stavros et al., 2007; Kannan et al., 2006) few studies exist that consider biological effects associated with Pb exposure. Pb effects on immune variables, including cell viability, apoptosis, lymphocyte proliferation, and phagocytosis were tested in vitro on phagocytes and lymphocytes isolated from the peripheral blood of bottlenose dolphin (*Tursiops truncates*) (Cámara Pellissó et al., 2008). No effects on viability of immune cells, apoptosis, or phagocytosis were observed in 72-hour exposure to nominal concentrations of 1,000, 10,000, 20,000 and 50,000 µg Pb/L. Proliferative response of bottlenose dolphin leukocytes was significantly reduced at 50,000 µg Pb/L, albeit by only 10% in comparison to the control. This in vitro exposure with nominal concentrations of Pb is likely not relevant for assessing effects of atmospherically-deposited Pb on marine mammals, however, no additional studies were available for review on the effects on Pb on these organisms.

7.4.16 Exposure and Response of Saltwater Species

Evidence regarding exposure-response relationships and potential thresholds for Pb effects on saltwater populations can inform determination of standard levels that are protective of marine ecosystems. The Annex of the 2006 Pb AQCD (U.S. EPA, 2006c) summarized data on exposure-response functions for invertebrates (Table AX7-2.4.1) (Table AX7-2.4.2). The recent exposure-response studies reviewed in this section expand on earlier findings with information on microalgal and invertebrate species. Studies specific to growth, reproduction and survival endpoints are summarized in Table 7-6. All reported values are from exposures in which concentrations of Pb were analytically verified unless nominal concentrations are stated.

A series of 72-hour Pb toxicity tests were conducted with five marine microalgae species (*T. chuii, R. salina*, Chaetoceros sp., *I. galbana* and *N. gaditana*) to determine the relative Pb sensitivities as measured by growth inhibition. The respective 72-hour EC_{50} values derived were 2,640, 900, 105, 1,340, and 740 µg Pb/L (Debelius et al., 2009). The

authors noted that species cellular size, sorption capacity, or taxonomy did not explain differences in sensitivity to Pb, leaving the mechanism of response still open to question.

In the deposit feeding polychaete, *Capitella* sp. an LOAEL of 85 mg Pb/kg sediment was established in 3 day and 6 day growth experiments (Horng et al., 2009). Other studies of marine invertebrates published since the 2006 Pb AQCD (U.S. EPA, 2006c) have indicated differences in sensitivity of different lifestages of aquatic organisms to Pb. In a series of seawater and sediment exposures using adult and juvenile amphipods *Melita plumulosa*, juveniles were more sensitive to Pb than adults (King et al., 2006). In the seawater-only exposures, the 96-hour LC_{50} was 1,520 µg Pb/L for juveniles and 3,000 µg Pb/L for adults. In comparison,10 day juvenile sediment test results were LC_{50} 1,980, NOEC 580 and LOEC 1,020 mg Pb/kg dry weight compared to the LC_{50}, NOEC, and LOEC value for the adults exposed in sediment (3,560 mg Pb/kg dry weight). A 24-hour LC_{50} of 4,500 µg Pb/L for adult black mussel (*M. galloprovincialis*) suggests that, in general, juvenile bivalves are more sensitive to Pb exposure than adults although this value was based on nominal exposure data (Vlahogianni and Valavanidis, 2007).

Since the 2006 Pb AQCD , Pb toxicity to larval stages of marine species has been assessed at sublethal and lethal concentrations. The effective concentrations at which Pb resulted in 50% of abnormal embryogenesis of the Asian clam (*M. meretrix*) was 297 µg Pb/L. The 96-hour LC_{50} for larvae of the same species was 353 µg Pb/L (Wang et al., 2009d). In comparison, juvenile Catarina scallop (*A. ventricosus*) had a LC_{50} of 830 µg Pb/L in a 96-hour exposure (Sobrino-Figueroa et al., 2007). In the marine polychaete *H. elegans*, EC_{50} values of gametes, embryos, larvae (blastula to trochophore and larval settlement), and adults, exhibited dose-responses to Pb that reflected the differential sensitivity of various lifestages of this organism (Gopalakrishnan et al., 2008). The EC_{50} values for sperm and egg toxicity were 380 and 690 µg Pb/L respectively. Larval settlement measured as the metal concentration causing 50% reduction in attachment was most sensitive to Pb with an EC_{50} of 100 µg Pb/L, while the EC_{50} for abnormal development of embryos was 1,130 µg Pb/L. The LC_{50} values for adult worms in 24-hour and 96-hour tests were 25,017 and 946 µg Pb/L, respectively. Manzo et al. (2010) established a LOEC of 500 µg Pb/L and a maximum effect at 3,000 µg Pb/L in an embryotoxicity assay with sea urchin *P. lividus* exposed to nominal concentrations of Pb. The EC_{50} for developmental defects in this species was 1,250 µg Pb/L with a NOEL of 250 µg Pb/L. In a study using nominal concentrations of Pb, morphological deformities were observed in 50% of veliger larvae of blacklip abalone (*Haliotis rubra*) at 4,100 µg Pb/L following a 48-hour exposure, suggesting this species is not as sensitive to Pb as other marine invertebrate larvae (Gorski and Nugegoda, 2006).

7.4.17 Community and Ecosystem Effects in Saltwater Systems

As discussed in the 1986 Pb AQCD and the 2006 Pb AQCD (U.S. EPA, 2006c), exposure to Pb is likely to have impacts in aquatic environments via effects at several levels of ecological organization (organisms, populations, communities, or ecosystems). But fewer studies explicitly consider community and ecosystem-level effects in marine and brackish waters than in freshwater. Reduced species abundance and biodiversity of protozoan and meiofauna communities were observed in laboratory microcosm studies with marine water and marine sediments reviewed in the 2006 Pb AQCD as summarized in Table AX7-2.5.2 (U.S. EPA, 2006c). In a laboratory study with larval mummichogs reviewed in the 2006 Pb AQCD, feeding and predator avoidance behaviors were altered in this marine fish species following a 4-week exposure to Pb. Observations from field studies reviewed in the 2006 Pb AQCD included findings of a negative correlation between Pb and species richness and diversity indices of macroinvertebrates associated with estuary sediments and changes in species distribution and abundance in fish, crustaceans and macroinvertebrates correlated with Pb levels in marine sediments. The 2006 Pb AQCD concluded that, in general, information from controlled studies for single pollutants was insufficient to permit evaluation of specific impacts on higher levels of organization (beyond the organism). In studies from natural saltwater ecosystems, Pb rarely occurs as a sole contaminant making its effects difficult to ascertain. New information on effects of Pb at the population, community and ecosystem level in coastal ecosystems is reviewed below.

The faunal composition of seagrass beds in a Spanish coastal saltwater lagoon was found to be impacted by Pb in sediment, plants, and biofilm (Marín-Guirao et al., 2005). Sediment Pb concentrations ranged from approximately 100 to 5,000 mg Pb/kg and corresponding biofilm concentrations were 500 to 1,600 mg Pb/kg, with leaf concentrations up to 300 mg Pb/kg. Although multiple community indices (abundance, Shannon-Wiener diversity, Simpson dominance index) did not vary from site to site, multivariate analysis and similarity analysis indicated significant differences in macroinvertebrate communities between sites with different sediment, biofilm, and leaf Pb concentrations. Differences were largely attributable to three amphipod species (*Microdeutopus* sp., *Siphonoecetes sabatieri*, *Gammarus* sp.). This indicates that, although seagrass abundance and biomass were unaffected by Pb exposure, organisms inhabiting these plants still may be adversely impacted.

Caetano et al. (2007) investigated the mobility of Pb in salt marshes using total content and stable isotope signature. They found that roots had similar isotopic signature to sediments in vegetated zones indicating that Pb uptake by plants reflects the input in sediments. At one site, there was a high anthropogenic Pb content while at the other

natural mineralogical sources dominated. The roots of *S. fruticosa* and *S. maritima* significantly accumulated Pb, having maximum concentrations of 2,870 mg Pb/kg and 1,755 mg Pb/kg, respectively, indicating that below-ground biomass played an important role in the biogeochemical cycling of Pb.

Exposure to three levels of sediment Pb contamination (322, 1,225, and 1,465 mg Pb/kg dry weight) had variable effects on different species within a marine nematode community (Mahmoudi et al., 2007). Abundance, taxa richness, and species dominance indices were altered at all Pb exposures when compared with unexposed communities. Further, while the species *Oncholaimellus mediterraneus* dominated control communities (14% of total abundance), communities exposed to low and medium Pb concentrations were dominated by *Oncholaimus campylocercoides* (36%) and *Marylynnia stekhoveni* (32%), and *O. campylocercoides* (42%) and *Chromadorina metulata* (14%), respectively. Communities exposed to the highest Pb sediment concentrations were dominated by *Spirinia gerlachi* (41%) and *Hypodontolaimus colesi* (29%). Given this, the authors concluded that exposure to Pb significantly reduced nematode diversity and resulted in profound restructuring of the community structure.

In another laboratory microcosm experiment with nematodes, nematode diversity and community structure was altered with a mean number of 8 genera present in microcosms contaminated with Pb compared to the control with 20 genera. The spiked sediments used in the study were collected from the Swartkop River estuary, South Africa. Pb (3 to 6,710 mg Pb/kg sediment dry weight) was tested alone and in combination with Cu, Fe, and Zn (Gyedu-Ababio and Baird, 2006). The synergistic effect of the four metals on nematode community structure was greater than the individual metals and the effects of Pb could not be distinguished from Cu, Fe and Zn.

7.4.18 Characterization of Sensitivity and Vulnerability in Saltwater Species

Species differences in metabolism, sequestration, and elimination rates have been shown to control relative sensitivity and vulnerability of exposed organisms and effects on survival, reproduction, growth, metabolism, and development. Diet and lifestage at the time of exposure also contribute significantly to the determination of sensitive and vulnerable populations and communities. Further, environmental conditions in addition to those discussed as affecting bioavailability may also alter Pb toxicity. The 2006 Pb AQCD (U.S. EPA, 2006c) reviewed the effects of genetics, age, and body size on Pb toxicity. While genetics appears to be a significant determinant of Pb sensitivity, effects of age and body size are complicated by environmental factors that alter metabolic rates of saltwater organisms. A review of the more recent literature corroborated these findings, and identified seasonal physiological changes and lifestage as other important determinants of differential sensitivity to Pb.

7.4.18.1 Seasonally Affected Physiological Changes

Couture et al. (2010) investigated seasonal and decadal variations in Pb sources to mussels (*M. edulis*) from the French Atlantic shoreline. Pb concentrations in the mussels were 5-66 times higher than the natural background value for the north Atlantic. The $^{206}Pb/^{207}Pb$ signature indicated that the bioaccumulated Pb was anthropogenic in origin. The signature was not, however, the same as that emitted in western Europe, as a result of leaded gasoline combustion, although that was a major emission source to the atmosphere during a large part of the study period (1985-2005). Instead, it was most similar to that of Pb released into the environment from wastewater treatment plants, municipal waste incinerators and industries such as metal refineries and smelters. Thus continental runoff rather than atmospheric deposition was identified as the main source of Pb to the French coastal area. The strong seasonal variations in $^{206}Pb/^{208}Pb$ were used to conclude that resuspension of Pb triggered by high river runoff events was a key factor affecting bioaccumulation of Pb in *M. edulis*.

In another monitoring study, Pearce and Mann (2006) investigated variations in concentrations of trace metals in the U.K. including Pb in the shells of pod razor shell (*Ensis siliqua*). Pb concentration varied from 3.06-36.2 mg Pb/kg and showed a regional relationship to known sources, e.g., former metal mining areas such as Cardigan Bay, Anglesey, and industrial activity in Liverpool Bay. Seasonal variations were also found for Pb in both Cardigan Bay and Liverpool Bay, relating to increased winter fluxes of Pb (and other metals) into the marine environment. In contrast, levels of Pb and other metals

were highest in summer and lowest in winter in oysters *Crassostrea corteziensis* collected from Sonora, Mexico (García-Rico et al., 2010).

Carvalho et al. (2011) quantified ^{210}Pb in *M. galloprovincialis* sampled at coastal locations in Portugal and noted that the apparent seasonal fluctuation in radionuclide concentrations in mussel soft tissues was mostly attributable to changes in physiological condition (i.e., fat content , gonadal development) and not to radionuclide body burden fluctuation. The authors caution that since concentrations of contaminants are dependent upon tissue composition, corrections for mussel physiological condition are need to compare results from different seasons and different locations.

7.4.18.2 Lifestage

Lifestages of the marine polychaete *H. elegans* including embryogenesis, sexual maturation, and offspring development were shown to be differentially affected by Pb exposure. Pb water concentrations of 91 µg Pb/L and greater significantly affected fertilization and embryonic development, but the greatest effects were exhibited by 24-hour-old larvae (Gopalakrishnan et al., 2007). The authors suggested that timing of Pb exposure may have different impacts on marine polychaete populations, if life cycles are offset (Gopalakrishnan et al., 2007). Further, given that the adult lifestage is sedentary, reduction of the mobile early lifestage as a result of Pb exposures may disproportionally affect sessile polychaetes. For instance, larval settlement was significantly reduced at Pb exposures of 48 µg Pb/L and greater (Gopalakrishnan et al., 2008).

7.4.18.3 Species Sensitivity

Both inter- and intra-specific differences in Pb uptake and bioaccumulation may occur in macroinvertebrates of the same functional feeding group. Data from 20 years of monitoring of contaminant levels in filter-feeding mussels of the *Mytilus* species and *Crassostrea virginica* oysters in coastal areas of the U.S. through the National Oceanic and Atmospheric Administration (NOAA) Mussel Watch program indicate that Pb is on average three times higher in mussels than in oysters (Kimbrough et al., 2008). Limpet (Patella sp.) from the Lebanese Coast had Pb BAF values ranging from 2,500 to 6,000 and in the same field study Pb BAF values for a mussel (*Brachidontes variabilis*) ranged from 7,500-8,000 (Nakhle et al., 2006).

There is some indication that molting may comprise an additional sequestration and excretion pathway for aquatic animals exposed to Pb (Soto-Jiménez et al., 2011a; Mohapatra et al., 2009; Tollett et al., 2009; Bergey and Weis, 2007). Crab species

U. pugnax (Bergey and Weis, 2007) and *Scylla serrata (*Mohapatra et al., 2009*)*, and white shrimp *L. vannamei* (Soto-Jiménez et al., 2011a) have been shown to sequester Pb preferentially in exoskeleton tissue, where it is later shed along with other tissue. Consequently, aquatic arthropod species and those species that shed their exoskeleton more frequently may be able to tolerate higher environmental Pb concentrations than non-arthropods or slow-growing molting species, as this pathway allows them to effectively lower Pb body burdens.

Some tolerant species of fish (e.g., mummichog) have the ability to sequester accumulated Pb in metal-rich granules or heat-stable proteins (Goto and Wallace, 2010). Fish with such abilities are more likely to thrive in Pb-contaminated environments than other species.

7.4.19 Ecosystem Services Associated with Saltwater Systems

Pb deposited on the surface of (or taken up by) organisms has the potential to alter the services provided by saltwater biota to humans although the directionality of impacts is not always clear. For example, oysters and mussels provide a service by sequestering Pb. At the same time, the uptake of Pb by these bivalves may result in toxicological effects associated with Pb exposure and decreased value of shellfish as a commodity. At this time, a few publications address Pb impacts on ecosystem services associated with saltwater ecosystems. Pb can affect the ecological effects in each of the four main categories of ecosystem services (Section 7.1.2) as defined by Hassan et al. (2005). These effects are sorted into ecosystem services categories and summarized here:

- Supporting: food for higher trophic levels, biodiversity
- Provisioning: contamination of food by heavy metals, decline in health of fish and other aquatic species
- Regulating: water quality
- Cultural: ecosystem and cultural heritage values related to ecosystem integrity and biodiversity, wildlife and bird watching, fishing

A few recent studies explicitly consider the impact of Pb and other heavy metals on ecosystem services provided by salt marsh (Gedan et al., 2009) and estuaries (Smith et al., 2009b). These systems are natural sinks for metals and other contaminants. Pb can be toxic to salt marsh plant species and decaying plant detritus may result in resuspension of Pb into the aquatic food chain (Gedan et al., 2009). Salt marsh and estuaries provide habitat and breeding areas for both terrestrial and marine wildlife and are locations for

bird watching. Using a modeling approach designed to assess the degree of risk of Pb and Hg to wading birds in estuarine habitats in the U.K., the authors found a high probability that Pb poses an ecologically relevant risk to dunlin, *Calidris alpina (*Smith et al., 2009b*)*. However, the authors noted that a major source of uncertainty in this study was the NOAEL values for Pb.

The impact of Pb on ecological services provided by specific components of aquatic systems has been considered in a limited number of studies. Recent research has suggested that dietary Pb (i.e., Pb adsorbed to sediment, particulate matter, and food) may contribute to exposure and toxicity in primary and secondary order consumers (including humans). Aquatic fauna can take up and bioaccumulate metals. If the bioaccumulating species is a food source, the uptake of metals may make it toxic or more dangerous for people or other wildlife to consume. For example, oysters and mussels bioaccumulate Pb from anthropogenic sources, including atmospheric deposition, and are a food source that is widely consumed by humans and wildlife (Couture et al., 2010). Their capacity to bioaccumulate Pb makes them good bioindicators of environmental contamination and they have been used as monitors of coastal pollutants by the NOAA Mussel Watch program since 1986. Although bioaccumulation may render aquatic fauna toxic to consumers, bioaccumulation is a way to sequester the metals and remove them from waters and soils. Sequestration for this purpose is itself an ecosystem service and has been quantified. For example, the total ecological services value of a constructed intertidal oyster (*Crassostrea* sp.) reef in improving water quality and sequestering metals including Pb was calculated in the Yangtze River estuary to be about $500,000 per year (Quan et al., 2009).

7.4.20 Synthesis of New Evidence for Pb Effects in Saltwater Systems

This synthesis of the effects of Pb on saltwater ecosystems covers information from the publication of the 2006 Pb AQCD (U.S. EPA, 2006c) to present. It is followed in Section 7.4.21 by determinations of causality that take into account evidence dating back to the 1977 Pb AQCD. In general, evidence for toxicity to saltwater organisms is less well characterized than toxicity of Pb in freshwater ecosystems due to the fewer number of available studies on marine species. The studies that are available for marine plants, invertebrates and vertebrates include studies where Pb concentration was analytically verified and those that reported nominal concentrations (Table 7-6). Many of the studies that report nominal concentrations in media are uptake studies that subsequently quantify Pb in tissues; however, measurement of Pb in water or sediment at the beginning of an exposure is desirable when comparing laboratory studies to concentrations of Pb in marine systems. In Section 7.2.3 and Table 7-2, a range of 0.01 to 27 µg Pb/L was

reported for saltwater, including estuaries and open ocean, with the higher values associated with sites involving human activity (Sadiq, 1992).

Most studies on marine organisms reviewed in the present document included concentrations that were higher than Pb encountered in seawater. However, when multiple concentrations were used, effects generally increased with increasing Pb exposure. Effects at lower concentrations can be implied from many reported studies since an exposure response relationship to Pb was observed. In marine and estuarine systems, exposure to Pb from air is most likely characterized as a chronic low dose exposure, however, most studies only report an acute LC_{50} value when an LOEC or LC_{10} would be more appropriate measurement for consideration of effects on organisms since an effect occurring at the LC_{50} value would most likely not maintain a stable population.

Plants

Only a few studies were available since the 2006 Pb AQCD, that consider effects of Pb on marine algae (Section 7.4.15.1). A 72-hour EC_{50} for growth inhibition was reported in the marine algae *Chaetoceros* sp. at 105 µg Pb/L (Debelius et al., 2009). A study with the green alga *T. suecica* reports a statistically significant decease in growth rate, total dry biomass and final cell concentration between control cultures and algae cultured in 20 µg Pb/L (Soto-Jiménez et al., 2011b). Both of these studies suggest growth effects at or near the highest recorded values of Pb in seawater (27 µg Pb/L), however, effects are likely to occur at lower concentrations since only EC_{50} values are reported.

Invertebrates

In saltwater invertebrates (Section 7.4.15.2 and 7.4.16) there are studies that consider Pb-effects on supporting endpoints (stress responses, hematological effects and neurobehavior) as well as studies that assess Pb impacts to reproduction, growth, and survival; endpoints that have the potential to alter population, community and ecosystem—levels of biological organization. Many studies, especially those that consider enzymatic responses to Pb exposure, were conducted with nominal Pb concentrations. Two of these studies; Jing et al. (2007) and Zhang et al., (2010b) consider Pb nominal exposures at 100 µg Pb/L or lower and reported significant decreases in antioxidant enzyme activity. The Zhang et al. (2010b) study observed effects on enzymatic activity at a nominal exposure of 2 µg Pb/L. Although these effects are near reported Pb concentrations in seawater they were not analytically verified.

Other studies that report sub-organismal responses in saltwater organisms have quantified Pb exposure. Field studies with bivalves collected off the coast of Spain correlated

ALAD activity with measured levels of Pb in tissue (Company et al., 2011; Kalman et al., 2008). An increase in valve closing time with increasing Pb exposure in the range of 40 to 400 µg Pb/L was observed in the scallop, *A.ventricosus* (Sobrino-Figueroa and Caceres-Martinez, 2009). Although the concentrations in this study exceed reported levels of Pb in seawater, the lower range is near 27 µg Pb/L reported by Sadiq (1992).

Evidence for effects on reproduction, growth and survival in marine invertebrates (Table 7-6) are primarily from studies in which Pb in the exposure media was quantified. In the amphipod, *E. laevis*, onset to reproduction was significantly delayed at 118 mg/Pb kg sediment; a concentration that the authors indicate is below the current marine sediment regulatory guideline for Pb (218 mg Pb/kg sediment) (Ringenary et al., 2007; NOAA, 1999). In the same study, no effects of Pb on adult survival in 28 and 60 day sediment exposures were observed. In another study with amphipods, juvenile *M. plumosa* were more sensitive than adults in 10-day sediment exposures with an NOEC of 580 mg Pb/kg dry weight compared to an NOEC of 3,560 mg Pb/kg dry weight for adults (King et al., 2006). Effects of Pb on gametes of the marine polycheate *H. elegans* were observed at 48 µg Pb/L (Gopalakrishnan et al., 2008), a concentration near the upper range of Pb in seawater reported by Sadiq (1992). Specifically, fertilization rate of eggs pretreated with 48 µg Pb/L decreased to 20% of control. Life stages of *H. elegans* varied in their sensitivity to Pb with the most sensitive period being larval settlement with an EC_{50} of 100 µg Pb/L.

There are only a few recent studies that considered effects of Pb on growth of marine invertebrates (Sections 7.4.15.2 and 7.4.16). In the polychaete *Capitella* sp. growth was decreased significantly from controls, however, there was not a clear dose-response relationship between increasing Pb concentrations and observed effects (Horng et al., 2009). The authors reported a LOAEL of 85 mg Pb/kg in the sediment exposure. In the Asian Clam *M. meretrix*, an EC_{50} of 197 µg Pb/L was reported for growth (Wang et al., 2009d). Other marine invertebrate growth effects were observed at much higher Pb concentrations (Table 7-6).

Survival was a less sensitive endpoint in marine invertebrates than reproduction or growth with no effects reported at concentrations typically observed in seawater (Table 7-6). In the amphipod *M. plumulosa* an NOEC of 400 µg Pb/L for juveniles and an NOEC of 850 µg Pb/L was reported for adults in 96-hour seawater only exposures (King et al., 2006). In 10 day sediment tests with the same species, juveniles were also more sensitive than adults. Other concentrations at which survival effects were reported in marine invertebrates also greatly exceeded concentrations of Pb typically found in seawater.

Vertebrates

There is not sufficient new evidence for saltwater vertebrates especially for reproductive, growth and survival endpoints that may have relevance to the population-level of biological organization and higher.

Food Web

Some studies published since the 2006 Pb AQCD (see Section 7.4.14.4) support the potential for Pb to be transferred in saltwater food webs, while other studies have found no evidence for biomagnification.

Ecosystem Level Effects

Evidence for effects at higher levels of biological organization in saltwater habitats is primarily supported by observations in a small number of microcosm and field studies where shifts in community structure are the most commonly observed effects of Pb (Section 7.4.17). Effects on reproduction, growth or survival (summarized in Table 7-6) may lead to effects at the population-level of biological organization and higher.

7.4.21 Causal Determinations for Pb in Saltwater Systems

In the following sections, organism-level effects on reproduction and development, growth and survival are considered first since these endpoints can lead to effects at the population level or above and are important in ecological risk assessment. Neurobehavioral effects are considered next followed by sub-organismal responses (hematological effects, physiological stress) for which Pb has been shown to have an impact in multiple species and across taxa, including humans. Causal determinations for terrestrial, freshwater and saltwater ecological effects are summarized in Table 7-3.

7.4.21.1 Reproductive and Developmental Effects-Saltwater Biota

Reproductive effects of Pb have been reported in a few marine organisms and the majority of the available studies are with invertebrate species. In a study reviewed in the 2006 Pb AQCD (U.S. EPA, 2006c), embryo development in two commercial bivalves *Ruditapes decussatus* and *M. galloprovincialis* was inhibited by Pb (Beiras and Albentosa, 2003). In *R. decussatus* an EC_{50} range of 156 to 312 µg Pb/L and LOEC of 156 µg Pb/L were observed for inhibition of embryonic development while in

M. galloprovincialis the EC_{50} was 221 µg Pb/L and the LOEC was 50 µg Pb/L. Larvae of the mussel *M. edulis* were sensitive to Pb exposure with an EC_{50} of 476 µg Pb/L for abnormal development of embryos following 48-hour exposure to Pb during embryogenesis (Martin et al., 1981). The LOEC for embryogenesis in the marine bivalve *M. galloprovincialis* was 50 µg Pb/L with an EC_{50} for embryogenesis of 221 µg Pb/L (Beiras and Albentosa, 2003).

Recent evidence for reproductive effects of Pb on marine invertebrates is summarized in Table 7-6. In the marine polychaete *H. elegans* an EC_{50} of 261 µg Pb/L was observed for unhatched or abnormal larvae following 20 hour incubation with Pb (Gopalakrishnan et al., 2008). The EC_{50} for the metal concentration causing 5% reduction in larval attachment was 100 µg Pb/L. The EC_{50} values for sperm and egg toxicity were 380 and 692 µg Pb/L, respectively. The EC_{50} for embryogenesis in the clam *M. meretrix* was 297 µg Pb/L (Wang et al., 2009d). In a multigenerational bioassay with the marine amphipod *E. laevis*, statistically significant delays in onset of reproduction (4 to 8 days), sexual maturation and first offspring were observed at concentrations of 188 mg Pb/kg sediment and higher (Ringenary et al., 2007). The authors indicate that this concentration is below the current sediment regulatory guideline for Pb (218 mg Pb/kg sediment) (NOAA, 1999) and that reproductive effects are a more sensitive endpoint than lethality. Although LC_{50} values are typically reported for Pb effects on reproductive endpoints in saltwater invertebrates, a concentration dependent relationship between reproductive impairment and increasing concentration of Pb is reported in most studies. This exposure-response relationship implies that effects on reproduction are occurring at concentrations lower than the LC_{50} value.

Reproductive effects are only characterized in a few species and endpoints for marine systems. The weight of the current evidence for reproductive effects is limited to laboratory-based studies with saltwater invertebrates in which observed effects occur at Pb concentrations that are higher than Pb concentrations encountered in the marine environment. Evidence for reproductive effects of Pb on marine plant species is limited to one study on the red alga (*Champia parvula*) reviewed in the draft Ambient Aquatic Life Water Quality Criteria for Pb (U.S. EPA, 2008b). In one study from a saltwater fish, field-collected smooth toadfish (*T. glaber*) from metal contaminated estuaries in Sydney, Australia had elevated Pb levels in gonad and decreased oocyte diameter and density. Evidence is, therefore, inadequate to conclude that there is a causal relationship for reproductive effects in saltwater plants, and vertebrates. The available studies on marine invertebrates are suggestive that there is a causal relationship between Pb exposure and reproductive effects.

7.4.21.2 Growth Effects-Saltwater Biota

There are few studies that measure growth effects of Pb on marine organisms; available information is limited to marine flora and invertebrates. Growth studies in saltwater plant species are summarized in Table 4 and Table 6 of the draft Ambient Aquatic Life Water Quality Criteria for Pb (U.S. EPA, 2008b) and Table 7-6 of the present document.

Diatoms are among the most sensitive algae; however, growth effects are typically observed at concentrations of Pb higher than the range of values available from saltwater locations [0.01 to 27 µg Pb/L, (Sadiq, 1992)]. In studies available since the draft Ambient Aquatic Life Water Quality Criteria for Pb, the lowest 72-hour EC_{50} for growth inhibition reported in marine diatoms was 105 µg Pb/L in Chaetoceros sp (Debelius et al., 2009) and the growth of the green alga *T. suecica* exposed nominally to 20 µg Pb/L was 40% lower than control cultures (Soto-Jiménez et al., 2011b). The microalgae was the base of a simulated marine food chain including primary, secondary and tertiary level consumers and effects on survival were observed at the higher trophic levels that originated from Pb exposure via consumption of the primary producer. The majority of growth effects reported in saltwater algae exceed concentrations of Pb in seawater by several orders of magnitude. Effects of Pb on growth in two species of brown algae, *Fucus vesiculosus* and *Fucus serratus* are summarized in Table 6 of the draft Ambient Aquatic Life Water Quality Criteria for Pb (U.S. EPA, 2008b). Concentrations where growth impairment was observed in these species greatly exceed available values for Pb measured in seawater.

In saltwater invertebrates, evidence for growth effects is limited to a few species at concentrations that exceed Pb concentrations reported in seawater. Growth inhibition in the bivalve *Macoma balthica* (EC_{50}=453.4 µg Pb/L) is reported in Table 6 of the draft Ambient Aquatic Life Water Quality Criteria for Pb (U.S. EPA, 2008b). Recent studies include Wang et al., (2009d) in which observed growth of embryos of the Asian Clam (*M. meretrix*) was significantly reduced by Pb with an EC_{50} of 197 µg Pb/L. In juvenile Catarina scallop, *A. ventricosus*, exposed to Pb for 30 days, the EC_{50} for growth was 4,210 µg Pb/L (Sobrino-Figueroa et al., 2007). Rate of growth of the deposit feeding polychaete Capitella sp. exposed to Pb-spiked sediments from polluted estuaries decreased significantly from the control; however, changes were inconsistent with increasing concentration of Pb (Horng et al., 2009). Evidence is therefore inadequate to conclude that there is a causal relationship between Pb exposure and growth effects in saltwater plants, invertebrates and vertebrates.

7.4.21.3 Survival-Saltwater Biota

There are no studies reported in the previous Pb AQCDs or the current ISA for aquatic plants that indicate phytotoxicity at or near current concentrations of Pb in saltwater [0.01 to 27 µg Pb/L, (Sadiq, 1992)].

Mortality data for saltwater invertebrate species are summarized in the draft Ambient Aquatic Life Water Quality Criteria for Pb (U.S. EPA, 2008b) and reported LC_{50} values greatly exceed Pb concentrations encountered in seawater. Recent studies available since the 2006 Pb AQCD, and draft Aquatic Life Water Quality Criteria for Pb that report mortality data are summarized in Table 7-6. In general, marine fauna are less sensitive to this metal than freshwater fauna and the highest toxicity is observed in juveniles. A 144-hour LC_{50} of 680 µg Pb/L was reported for juvenile scallop *A. ventricosus* (Sobrino-Figueroa et al., 2007) and a 96-hour LC_{50} of 353 µg Pb/L for embryos of the clam *M. meretrix* (Wang et al., 2009d). In the amphipod *M. plumulosa*, juveniles were more sensitive to Pb than adults in 96 hour seawater-only exposures and 10 day sediment exposures (King et al., 2006). The 96-hour LC_{50} was 1,520 µg Pb/L and the NOEC was 400 µg Pb/L for juveniles in comparison to adults (96-hour LC_{50} =3,000 µg Pb/L; NOEC=1,680 µg Pb/L). In the 10-day sediment exposures, the NOEC for juveniles was 580 mg Pb/kg dry weight compared to an adult NOEC of 3,560 mg Pb/kg dry weight. In 10-day exposures to Pb nitrate spiked sediment, all individuals of the bivalve *T. deltoidalis* survived at 1,000 mg/Pb kg with 15 µg Pb/L dissolved in pore water (King et al., 2010). No effects on survival were observed in either the amphipod *E. laevis* exposed 60 days to Pb-spiked sediment up to 424 mg Pb/kg (Ringenary et al., 2007), or in the polychaete *Capitella* sp. exposed to sediment for 3 or 6 days up to 871 mg Pb/kg (Horng et al., 2009).

Effects of Pb on survival have been demonstrated though a simulated marine food chain in which the primary producer, the microalgae *T. suecica*, was exposed nominally to 20 µg Pb/L and subsequently fed to brine shrimp *A. franciscana*, (mean Pb content 12 to 15 mg Pb/kg) which were consumed by white-leg shrimp *L. vannamei*, itself consumed by grunt fish *H. scudderi* representing the top of the marine food chain (Soto-Jiménez et al., 2011b). Survival of brine shrimp was 25 to 35% lower than the control and both white shrimp and grunt fish had significantly higher mortalities than controls.

Data on Pb toxicity to eight species of marine fishes are summarized in Table 1 of the draft Ambient Aquatic Life Water Quality Criteria for Pb (U.S. EPA, 2008b). All of the LC_{50} values for these fish (range 1,500 to 315,000 µg Pb/L) greatly exceed concentrations of Pb reported in seawater. Additionally, in the 2006 Pb AQCD (U.S. EPA, 2006c) the acute toxicity of Pb to plaice (*Pleuronectes platessa*) was reported to range from 50 µg Pb/L to 300,000 µg Pb/L depending on the form of Pb (Eisler, 2000).

The existing evidence on toxicity of Pb to marine vertebrates is limited to laboratory-based studies conducted under different salinities and exposure conditions. Considerable uncertainties exist in applying laboratory observations to actual conditions in the field where other modulating factors can affect Pb bioavailability and toxicity.

Although evidence exists for increased mortality of marine fish at very high concentrations of Pb, the focus of the causal determinations are on studies where effects were observed within one to two orders of magnitude of Pb measured in the environment (Preamble Table II). Evidence is therefore inadequate to conclude that there is a causal relationship between Pb and survival in saltwater plants, invertebrates and vertebrates.

7.4.21.4 Neurobehavioral Effects-Saltwater Biota

In marine organisms evidence for neurobehavioral effects of Pb is limited to a few studies on bivalves and fish. In a study reviewed in the 2006 Pb AQCD (U.S. EPA, 2006c), prey capture rate and predator avoidance was affected in mummichogs starting at 300 µg Pb/L (Weis and Weis, 1998). Recent studies support previous findings of decreased ability to escape predation associated with Pb exposure. In juvenile Catarina scallops exposed to Pb (40 µg/L to 400 µg/L) for 20 days, the average valve closing time increased from under one second in the control group to 3 to 12 seconds in juvenile scallops A decrease in valve closing speed in these bivalves may impact escape swimming behaviors important for predator avoidance (Sobrino-Figueroa and Caceres-Martinez, 2009). Behavioral effects in grunt fish *H. scudderi*, occupying the top level of a simulated marine food chain included lethargy and decreased food intake in a 42-day feeding study (Soto-Jiménez et al., 2011b). These fish were fed white shrimp exposed to Pb via brine shrimp that were initially fed microalgae cultured at a nominal concentration of 20 µg Pb/L. In the same study, surfacing, reduction of motility, and erratic swimming were observed in the white shrimp after 30 days of exposure to Pb via diet. The ornate wrasse, *T. pavo*, was exposed nominally to sublethal (400 µg Pb/L) or a maximum acceptable toxicant concentration (1,600 µg Pb/L) dissolved in seawater for one week to assess the effects of Pb on feeding and motor activities (Giusi et al., 2008). In the sublethal concentration group, hyperactivity was elevated 36% over controls. In the high concentration, a 70% increase in hyperactivity was observed and hyperventilation occurred in 56% of behavioral observations, however, no changes in feeding activity were noted between non-treated and treated fish.

Most of the evidence for neurobehavioral changes in marine organisms is observed with concentrations of Pb that exceed the range of Pb values available for saltwater of 0.01 to 27 µg Pb/L (Sadiq, 1992)], with the exception of the food chain study discussed above in

which behavioral effects were observed in shrimp and their fish predators following ingestion of microalgae cultured in nominal concentration of 20 µg Pb/L and then quantified in prey (Soto-Jiménez et al., 2011b). Marine species are typically underrepresented in toxicity testing of behavioral endpoints with metals. There are considerable uncertainties in applying observations from laboratory-based studies to field scenarios including the role of environmental factors such as salinity and DOM on Pb bioavailability. Evidence is inadequate to conclude that there is a causal relationship between Pb exposures and neurobehavioral endpoints in saltwater invertebrates and vertebrates.

7.4.21.5 Hematological Effects-Saltwater Biota

Evidence for hematological effects of Pb on saltwater organisms is limited primarily to field monitoring studies on bivalves. Several recent field studies using a multi-biomarker approach to study the sources and impacts of Pb in marine environments have measured ALAD activity in bivalve species and found positive correlations between increased tissue Pb levels and ALAD inhibition (e.g., Company et al. (2011), Kalman et al (2008)). Generally, these studies have noted that Pb content varies significantly among species and is related to habitat and feeding behavior. There is precedent, especially in Europe, for the inclusion of ALAD as a biomarker of exposure to Pb in marine invertebrates. The mechanism of ALAD inhibition in response to Pb exposure is likely mediated through a common pathway in both marine and freshwater invertebrates (Section 7.4.12.5) as well as in terrestrial species (Section 7.3.12.5) and humans (Section 5.7). Evidence is therefore, suggestive of a causal relationship between Pb exposure and hematological effects in saltwater invertebrates. Evidence is inadequate to conclude that there is a causal relationship between hematological effects and saltwater vertebrates.

7.4.21.6 Physiological Stress-Saltwater Biota

Most studies on physiological stress responses in marine invertebrates are laboratory-based exposures where effects are observed at Pb concentrations that exceed those known to occur in seawater [0.01 to 27 µg Pb/L (Sadiq, 1992), Table 7-2]. However, some recent evidence for invertebrate antioxidant response in bivalves and crustaceans indicates effects may occur at Pb concentrations that are detected in the marine environment. For example, SOD, catalase, and glutathione peroxidase activities were significantly reduced in the digestive gland of the marine bivalve *C. farreri* at 2 µg Pb/L (as measured in Bohai Bay, China) (Zhang et al., 2010b). In red fingered marsh crabs, *P. erythrodactyla* collected from an estuarine lake in Australia, elevated glutathione

peroxidase activity was correlated with individuals with higher metal body burdens (MacFarlane et al., 2006).

Additional evidence from environmental monitoring studies that compared biomarker responses between reference and contaminated sites indicated a correlation between the amount of Pb with changes in antioxidant enzyme activity [e.g., (Serafim et al., 2011; Cravo et al., 2009)]. Marine bivalves are the organisms typically sampled for these biomonitoring studies since both metals and enzymatic activities can be readily measured in these invertebrates. Although these studies show clear evidence of alterations in antioxidant stress markers in response to marine pollution, these effects cannot be attributed solely to Pb in the environment due to the presence of other metals and contaminants. Evidence for stress responses in marine organisms is typically limited to invertebrates, however, elevated expression of heat shock protein orthologs were reported for the first time in the hypothalamic and mesencephalic brain regions of Pb-treated fish (Giusi et al., 2008).

Evidence for physiological stress responses in saltwater invertebrates are supported by evidence in freshwater species (Section 7.4.12.6) and terrestrial species (Section 7.3.12.6) as well as in humans and experimental animal studies of oxidative stress following impairment of normal metal ion functions (Section 5.2.4). Stress responses may increase susceptibility to other stressors and reduce individual fitness. Evidence is suggestive of a causal relationship between Pb exposures and physiological stress in saltwater invertebrates. The evidence is inadequate to conclude that there is a causal relationship between Pb exposure and physiological stress in saltwater plants and vertebrates.

7.4.21.7 Community and Ecosystem Level Effects-Saltwater Biota

No studies on community and ecosystem level effects of Pb in marine systems were reviewed in the 1977 Pb AQCD (U.S. EPA, 1977), or the 1986 Pb AQCD (U.S. EPA, 1986a). Observations from field studies reviewed in the 2006 Pb AQCD (U.S. EPA, 2006c) included findings of a negative correlation between Pb and species richness and diversity indices of macroinvertebrates associated with estuary sediments (summarized in Table AX7-2.5.2 of the 2006 Pb AQCD). Additional findings in marine environments included changes in species distribution and abundance in fish, crustaceans and macroinvertebrates correlated with Pb levels in marine sediments.

New evidence for community and ecosystem level effects of Pb in saltwater ecosystems includes laboratory microcosm studies as well as observations from field-collected sediments, biofilm and plants in which changes in community structure were observed. In a recent study, significant differences in macroinvertebrate communities associated with

seagrass beds were reported between sites with different sediment, biofilm, and leaf Pb concentrations (Marín-Guirao et al., 2005). Sediment Pb concentrations ranged from approximately 100 to 5,000 mg Pb/kg and corresponding biofilm concentrations were 500 to 1,600 mg Pb/kg, with leaf concentrations up to 300 mg Pb/kg. In a laboratory microcosm experiment conducted with estuarine sediments from South Africa, total meiofauna density decreased (range 3 to 5 taxa) after 32 days in Pb-treated (1,886 to 6,710 µg/Pb g sediment dry weight) sediments compared to 9 taxa in the control (3 µg/Pb g sediment dry weight) (Gyedu-Ababio and Baird, 2006). In a microcosm experiment, exposure to three levels of sediment Pb contamination (322, 1,225, and 1,465 mg Pb/kg dry weight) significantly reduced marine nematode diversity and resulted in profound restructuring of the community structure (Mahmoudi et al., 2007).

There is not sufficient information at this time to characterize and to quantify relationships between ambient concentrations of Pb and response in saltwater communities and ecosystems. Fewer studies are available for saltwater organisms when compared to freshwater systems. There are likely differences in uptake and bioaccumulation in marine species due to physiological characteristics for adaptation in salt water. Additional uncertainties in evaluating the effects of Pb in marine environments include the presence of multiple stressors, inherent natural variability, and differences in Pb bioavailability across saltwater ecosystems. Evidence is inadequate to establish if there is a causal relationship between Pb exposures and the alteration of species richness, species composition and biodiversity in saltwater ecosystems.

7.5 Causal Determinations for Ecological Effects of Pb

This section summarizes the key conclusions regarding causality for welfare effects of Pb. Causal determinations for reproductive, growth, survival, neurobehavioral, hematological and physiological stress endpoints are presented separately for terrestrial, freshwater and saltwater organisms (Sections 7.3.12, 7.4.12, and 7.4.21). In Section 2.7.3, causal determinations for the same endpoints are further integrated across terrestrial, freshwater and saltwater taxa. Evidence considered in establishing causality was drawn from findings presented in the 1977 (U.S. EPA, 1977), 1986 (U.S. EPA, 1986a) and 2006 Pb AQCDs (U.S. EPA, 2006c), integrated with an exhaustive review of more recent evidence. The causal statements for terrestrial, freshwater and saltwater effects are divided into two categories: (1) endpoints that are commonly used in ecological risk assessment (reproduction, growth and survival) because they clearly can lead to population-level (e.g., abundance, production, extirpation), community-level (taxa richness, relative abundance) and ecosystem-level effects (Ankley et al., 2010; Suter et al., 2005), and (2) organism and sub-organism responses such as neurobehavioral effects,

hematological effects and physiological stress. There are many different effects at the molecular and cellular levels, and chronic toxicity of Pb in ecosystems is thus likely attained through multiple modes of action. Furthermore, the effects of Pb on ecosystems necessarily begin with some initial effects at the molecular level of specific organisms within the ecosystem (U.S. EPA, 1986b).

Experimental settings for studies used in making causal determinations for the ecological effects of Pb include controlled exposures in the laboratory, microcosm experiments and field observations. Controlled exposure studies in laboratory or small-to medium-scale field settings provide the most direct evidence for causality, but their scope of inference may be limited. In contrast, microcosms and field studies where exposure is not controlled include potentially confounding factors (e.g., other metals) or factors known to interact with exposure (e.g., pH), thus increasing the uncertainty in associating effects with exposure to Pb specifically. A large majority of the available studies of Pb exposures are laboratory toxicity tests on single species, in which an organism is exposed to a known concentration of Pb and the effect on a specific endpoint is evaluated. These studies provide evidence for a temporal sequence between Pb exposure and an effect, an aspect important in judging causality (Table I Preamble). As detailed in the Framework for Causality (see Preamble), coherence between different types of studies also provides strong support to a determination of causality. Evidence from laboratory studies conducted under controlled conditions provides the largest amount of information used in the causal determinations summarized in Table 7-3, but their coherence with microcosm and field-based studies plays an important role in those determinations. Biological gradients (Table I Preamble) are often found in studies of the effects of Pb, and add support to causality where present. For some ecological endpoints, support for causal determinations is additionally supported by toxicological findings reviewed in the chapters of the ISA that evaluate evidence for human health effects associated with Pb exposure, particularly when a common mode of action is documented.

The amount of Pb in ecosystems is a result of a number of inputs and it is not currently possible to determine the contribution of atmospherically-derived Pb from total Pb in terrestrial, freshwater or saltwater systems. The causal determinations are, therefore, not specific to Pb from atmospheric deposition since atmospherically-derived Pb may ultimately be present in water, sediments, soils and biota (Section 7.2 and Figure 7-1). The causal determinations encompass findings of studies at concentrations of Pb reported from environmental media (Table 7-2), and up to one to two orders of magnitude above the range of these values (Preamble Table II). Studies at the upper range of Pb concentrations are generally conducted at and near heavily exposed sites such as mining and metal industries-disturbed areas. Studies at those higher concentrations were used only when they were part of a range of concentrations that also included more typical

values, or when they informed understanding of modes of action and illustrated the wide range of sensitivity to Pb across taxa.

The exposure values at which Pb elicits a specific effect in terrestrial and aquatic systems are difficult to establish, due the influence of other environmental variables on Pb bioavailability and toxicity and to substantial differences among biological species in their sensitivity to Pb. In the 1977 Pb AQCD (U.S. EPA, 1977), no correlation could be established between toxic effects in invertebrates, fish, birds or small mammals and environmental concentrations of Pb. At the time of the 1986 Pb AQCD additional data were available on toxicity but there was still little information on the exposure values that can cause toxic effects in small mammals or birds (U.S. EPA, 1986b). In the 2006 Pb AQCD (U.S. EPA, 2006c) several studies on effects of Pb exposure on natural ecosystem structure and function advanced the characterization of Pb levels in the environment that occur near contaminated sites (i.e., smelters, mining, industry). According to the 2006 Pb AQCD, natural terrestrial ecosystems near significant Pb sources exhibited a number of ecosystem-level effects, including decreased species diversity, changes in floral and faunal community composition, and decreasing vigor of terrestrial vegetation. These findings were summarized in Table AX7-2.5.2 of the Annex to the 2006 Pb AQCD (U.S. EPA, 2006c). The 2006 Pb AQCD concluded that, in general, there was insufficient information available for single materials in controlled studies to permit evaluation on higher levels of biological organization (beyond the organism). Furthermore, Pb rarely occurs as a sole contaminant in natural systems making the effects of Pb difficult to ascertain. Recent information available since the 2006 Pb AQCD, includes additional field studies in both terrestrial and aquatic ecosystems, but the connection between air concentration and ecosystem exposure continues to be poorly characterized for Pb and the contribution of atmospheric Pb to specific sites is not clear.

Table 7-3 Summary of Pb causal determinations for plants, invertebrates and vertebrates.

Level		Effect	Terrestrial[a]	Freshwater[a]	Saltwater[a]
Community and Ecosystem		Community and Ecosystem Effects	Likely Causal	Likely Causal	Inadequate

[a]Based on the weight of evidence for causal determination in Table II of the ISA Preamble. Ecological causal determinations are based on doses or exposures generally within one to two orders of magnitude of the range of Pb currently measured in the environment (Table 7-2).

7.6 Supplemental Material

Table 7-4 Terrestrial plants, invertebrates and vertebrates; growth, reproduction and survival.

Species	Exposure Concentration (Nominal)	Exposure Concentration (Measured)	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Plants							
Buckwheat (*Fagopyrum esculentum*)		**Contaminated soil**: HCl extractable: 6,643 mg Pb/kg Acetate extractable: 832 mg Pb/kg Water leachate: 0.679 mg Pb/kg **Control soil:** HCl extractable: 5 mg Pb/kg Acetate extractable: ND Water leachate: ND	Plants were grown for 8 weeks in contaminated soil collected from a shooting range, and control soil.	**Contaminated soil** Sand: 62.3% Silt: 36.7% Clay: 1.0% pH: 6.0 CEC: 13.0 **Control soil** Sand: 87.7% Silt: 12.3% Clay: ND pH: 6.3 CEC: 7.6	**Growth:** No effect on growth **Survival:** No effect on survival		Tamura et al. (2005)
Canola (*Brassica napus*)	0; 22; 45; and 67 mg Pb/kg		Plants of four cultivars were grown for 40 days in soil amended with Pb chloride.		**Growth:** Shoot and root dry weight decreased with increasing Pb Zn, Cu, Fe, Mn content decreased with increasing Pb. N, P, K, and Ca^{2+} content decreased to a lesser degree.		Ashraf et al. (2011)

Species	Exposure Concentration (Nominal)	Exposure Concentration (Measured)	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Chinese cabbage (*Brassica pekinensis*)		46; 874; 1,703 mg Pb/kg dry soil	Plants were grown for 12 days in soil amended with Pb acetate.		**Growth:** Shoot biomass decreased with increasing Pb (91% and 84% of lowest exposure).		Xiong et al. (2006)
Corn (*Zea mays*)	0; 0.007; 0.7; 7 mg Pb/L		Seeds were germinated on paper soaked in P-sulfate. Plants were grown for 21 days in washed sand with Pb-sulfate amended nutrient solution.		**Reproduction:** Germination%, germination index, plant decreased with increasing Pb. **Growth:** Shoot length, plant dry weight, water use efficiency decreased with increasing Pb.		Ahmad et al. (2011)
Grass pea (*Lathyrus sativus*)	16; 31; 63; 125; 188 mg Pb/L		Plants were grown in soil amended with Pb nitrate.		**Reproduction:** Germination decreased with increasing Pb (control 100%, highest exposure 30%). Chromosomal abnormalities increased with increasing Pb (control 0%, highest exposure 72%). **Growth:** Shoot length decreased with increasing Pb (highest exposure was 50% of control).		Kumar and Tripathi (2008)

Species	Exposure Concentration (Nominal)	Exposure Concentration (Measured)	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Lettuce (*Lactuca sativa*)		2,000 mg Pb/kg, but soil was mixed with 50% V/V vermiculite following amendment with Pb nitrate. Tissue Pb: 3.22-233 mg Pb/kg	Plants were grown for 40 days in 21 soils with varying native CEC, OC, pH, and amorphous Fe and Al oxides, which were then all amended with Pb nitrate and mixed with 50% V/V vermiculite.	After amendment: pH: 3.8-7.8 CEC: 3.01-32.04 $cmol_c/kg$ OC: 5 - 30 g/kg Fe/Al oxides: 0.009-0.195 mol/kg	**Reproduction:** Germination 50 – 92% Germination was greater in amended soils. **Growth:** 2.5 – 88.5% of control In the presence of the same amount of $Pb(NO_3)_2$, OC was the main determinant of effects, although CEC had a strong influence, but mediated by its effect on pH and Fe/Al oxides		Dayton et al. (2006)
Mustard (*Brassica juncea*)	0;31; 62; 124; 186; 249; 311 mg Pb/L		Plants were grown for 60 days in field soil amended with Pb acetate.		**Growth:** Root and shoot length decreased with increasing Pb, and the decrease was greater with time. After 60 days, roots were two times longer in controls than in the highest Pb exposure shoot length was 75% greater.		John et al. (2009)
Radish (*Raphanus sativus*)	0; 21; 105 mg Pb/L		Plants were grown for 35 days in sand with a full nutrient solution amended with Pb nitrate.		**Growth:** Leaf area, root volume, shoot and root dry weight decreased with increasing Pb. (total dry weight at 21 mg Pb/L was 30% smaller than control, 52% smaller at 105 mg Pb/L).		Gopal et al. (2008)

Species	Exposure Concentration (Nominal)	Exposure Concentration (Measured)	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Wheat (*Triticum aestivum*) Lettuce (*Lactuca sativa*)		69-9,714 mg Pb/kg	Wheat plants were grown for 6 weeks in undisturbed core samples from four locations in each two Pb-contaminated sites Lettuce seeds were germinated in the leachate.	pH: 4.25-7.26 OC: 6.2-47.6%	**Growth:** No effects were found on germination or growth of either species.		Chapman et al. (2010)
Invertebrates							
Cabbage aphid (*Brevicoryne brassicae*)	0.87 mg Pb/L in watering solution used for plants		Aphids were reared for several generations on radish and cabbage plants grown in soil amended with Pb nitrate.		**Reproduction:** In aphids fed Pb-contaminated plants, development time was longer, and relative fecundity and rate of population increase were lower than in control aphids. **Survival:** Mortality was higher in exposed aphids, both adults and offspring.		Görür (2007)

Species	Exposure Concentration (Nominal)	Exposure Concentration (Measured)	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Collembolan (*Folsomia candida*)		Approximate range was 12 mg Pb/kg soil to 15,000 mg Pb/kg soil; Pore water approximately 0.002 Pb/L to 1,000 mg Pb/L (Concentrations were measured, but not reported).	Springtails were reared for 28 days in soil collected at seven locations along each of three transects with increasing Pb concentrations within each transect (21 locations). Lowest concentration soils from each of the three transects were then amended with Pb nitrate to match the gradient, and one set of the amended samples were then leached, for a total of 57 concentrations of Pb.	pH was constant in transects, but decreased with increasing addition of $Pb(NO_3)_2$ in both amended and amended-and-leached soils. pH decreased by 3 units in the highest addition, regardless of subsequent leaching.	**Reproduction:** Reproduction decreased by up to 50% in transect soils Amended soils Pb concentrations 2,207 mg Pb/kg or lower never had a significant effect on reproduction.	Transect **A 28 day** EC_{50} in mg Pb/kg dry weight: native: >5,690 amended: 2,570 amended and leached: 2,060 Transect **B 28 day** EC_{50} in mg Pb/kg dry weight: native: >14,400 amended: 3,210 amended and leached: 2,580 Transect **C 28 day** EC_{50} in mg Pb/kg dry weight: native: >5,460 amended: 2,160 amended and leached: 2,320	Lock et al. (2006)
Collembolan (*Folsomia candida*)	0; 100; 200; 400; 800; 1,600; 3,200 mg Pb/kg dry soil		Springtails were reared for 10 days in field soil amended with Pb chloride.		**Reproduction:** Hatching success decreased with increasing Pb.	EC_{50} (hatching): 2,361 mg Pb/kg dry soil	Xu et al. (2009b)

Species	Exposure Concentration (Nominal)	Exposure Concentration (Measured)	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Collembolan (*Sinella curviseta*)	0; 100; 200; 400; 800; 1,600; 3,200 mg Pb/kg dry soil		Springtails were reared for 28 days in field soil amended with Pb chloride.		There was a small effect of Pb on survival and growth, and a stronger effect on reproduction.	**Survival**: LC_{10}/EC_{10}: 1,838 mg Pb/kg **Reproduction**: LC_{10}/EC_{10}: 642 mg Pb/kg EC_{50}: 3,212 mg/kg Pb **Body Size**: LC_{10}/EC_{10}: 4,094 mg Pb/kg	Xu et al. (2009a)
Collembolan (*Paronychiurus kimi*)	Toxicity run: 100; 500; 1,000; 2,000 mg Pb/kg Reproduction run: 0; 250; 500; 1,000; 2,000; 3,000 mg/kg Pb		Springtails were reared for 28 days on artificial soil amended with Pb chloride in two separate runs.		**Survival:** Survival decreased with increasing Pb. **Reproduction:** Offspring production and instantaneous rate of increase values decreased with increasing Pb.	**Survival LC_{50}:** 7 day: 1,322 mg Pb/kg 28 day: 1,299 mg Pb/kg **EC_{50}** 28 day: 428 mg Pb /kg NOEC r**eproduction**: EC_{50} 28 day: 428 mg Pb/kg NOEC: 250 mg Pb/kg LOEC: 500 mg Pb/kg	Son et al. (2007)

Species	Exposure Concentration (Nominal)	Exposure Concentration (Measured)	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Collembolans (*Sinella coeca, Folsomia candida*)	10; 50; 100; 500; 1,000 mg Pb/kg		Springtails were reared for 42 or 45 days in artificial soil amended with Pb nitrate.		***S. coeca*:** **Survival:** Mortality significantly increased with increasing concentration in adult population. **Reproduction:** Juvenile production not significantly compromised at 10-500 mg Pb/kg, reduced at 1,000 mg Pb/kg ***F. candida*:** **Survival:** Increase in mortality with increasing concentration **Reproduction:** Juvenile production not significantly reduced between 10-500 mg Pb/kg, significant effect at 1,000 mg Pb/kg	**LC_{50}:** ***S. coeca*:** Could not be determined ***F. candida*:** Could not be determined **EC_{50} reproduction**: ***S. coeca*:** 490 mg Pb/kg Pb on dry soil ***F. candida*:** Could not be calculated with accuracy; Ranged from 500-1,000 mg Pb/kg	Menta et al. (2006)
Earthworm (*Eisenia andrei*)	2,000 mg Pb/kg in soil Internal concentration of Pb in earthworms varied among the amended soils, between 29 and 782 mg Pb/kg dry weight.		Earthworms were reared for 28 days in 21 soils with varying native CEC ,OC, pH, and amorphous Fe and Al oxides, which were then all amended with Pb nitrate.	After amendment pH: 3.8 - 7.8 CEC: 3.01 - 32.04 $cmol_c$/kg OC: 5 - 30 g/kg Fe/Al oxides: 0.009 - 0.195 mol/kg	**Survival:** Mortality ranged between 0 and 100%. In the presence of potentially lethal amounts of Pb, the main determinant of mortality was pH, with little or no effect from OC, CEC, or Fe/Al oxides. **Reproduction:** Reproduction relative to controls ranged between 0 and 167%. Effects of Pb on reproduction are dependent principally on Fe/Al oxides, with some influence of CEC		Bradham et al. (2006)

Species	Exposure Concentration (Nominal)	Exposure Concentration (Measured)	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Earthworm (*Eisenia fetida*)		18-9,311 mg Pb/kg	Earthworms were reared for 14 days in OECD-standard toxicity testing soil with 7 concentrations of Pb, either one or 10 earthworms per container.	pH decreased with increasing Pb nitrate addition NH_3 concentration increased with Pb concentration and time	**Survival:** Mortality increased from 0 to 100% with increasing Pb, with 100% reached at 4,500 mg Pb/kg after 7 days and 14 days. Number of worms per container had no effect on mortality. **Growth:** Worm weight decreased with increasing Pb, and faster in multiple-worm containers.	**LC_{50}** (multiple-occupancy): 2,662 mg Pb/kg at 7 days and 2,589 mg Pb/kg at 14 days or 2,827 mg Pb/kg at both 7 and 14 days	Currie et al. (2005)
Earthworm (*Eisenia fetida*)	0; 300; 711; 1,687; 2,249 mg Pb/kg	Mean: 79% of nominal	Earthworms were reared for 14 days in soil amended with five levels of Pb nitrate and artificially aged.	pH 6.72 prior to amendment OC 0.7% CEC 11 meq/100 g	**Survival:** Mortality was only observed at the highest exposure.		Jones et al. (2009b)
Earthworm (*Eisenia fetida*)	Soil 1: 0; 355; 593; 989; 1,650 mg Pb/kg Soil 2: 59; 297; 593; 2,965 mg Pb/kg Soil 3: 386; 771; 1,929; 3,857 mg Pb/kg		Earthworms were reared for 28 days in three soils amended with five levels of Pb nitrate without aging, after which they were removed from the containers. Containers were then kept in the same conditions for another 28 days, after which cocoons were extracted.	pH 6.72; 5.48; 6.75 (prior to amendment) OC 0.7; 1.2; 5.2% CEC 11; 8; 27 meq/100g	**Reproduction:** Soil 1: Juvenile and cocoon count decreased from 19 and 45, respectively, to near 0 with increasing Pb. Soil 2: Cocoon count decreased to 40% of control at highest Pb. Soil 3: Cocoon count was 0 at all concentrations.		Jones et al. (2009b)

Species	Exposure Concentration (Nominal)	Exposure Concentration (Measured)	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Earthworm (*Pheretima guillelmi*)	Toxicity run: 0, 1,000; 1,400; 2,000; 2,800; 3,800; 5,400; 7,500 mg Pb/kg dry weight (form of Pb not reported). Sublethal toxicity run: 1,000; 1,400; 1,800; 2,500 mg Pb/kg dry weight (form of Pb not reported).		Earthworms were reared for 14 days in OECD-standard soil amended with Pb (form of Pb unreported). There were two runs with different concentrations.		**Survival:** Mortality increased with increasing Pb.(0% in control, 100% at 7,500 mg Pb/kg after 14 days). **Growth:** Weight decreased with increasing Pb(2.5 g in control, 1.4 g at 5.400 mg Pb/kg after 14 days). **Reproduction:** Sperm abnormalities increased with increasing Pb (10% of control, 21% at 2,500 mg Pb/kg after 14 days).		Zheng and Li (2009)
Earthworms (*Eisenia andrei, Lumbricus rubellus, Aporrectodea caliginosa*)		0; 1,000; 3,000; 4,000; 5,000; 7,500; 10,000 mg Pb/kg	Earthworms were reared for 28 days in sterilized Kettering Loam watered with Pb nitrate solution.	Temperature: 20 °C (*E. andrei*); 15 °C (*L. rubellus* and *A. caliginosa*) pH Day 7 : 4.57-5.83, Day 28: 4.71-5.83, increasing with decreasing Pb	**Growth:** Weight decreased with increasing concentration and time, severity of weight decrease varied with species. **Survival:** Mortality increased with increasing concentration and time, and varied with species 100% mortality for all species at higher concentrations after 28 days.	**LC_{50}:** ***E. andrei*:** 5,824 mg Pb/kg ***L. rubellus*:** 2,867 mg Pb/kg ***A. caliginosa*:** 2,747mg Pb/kg **EC_{50}:** ***E. andrei*:** 2,841 mg Pb/kg ***L. rubellus:*** 1,303 mg Pb/kg ***A. caliginosa*:** 1,208 mg Pb/kg	Langdon et al. (2005)

Species	Exposure Concentration (Nominal)	Exposure Concentration (Measured)	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Nematode (*Caenorhabditis elegans*)		0.5; 10; 21 mg Pb/L	Nematodes at various developmental stages were exposed to $Pb(NO_3)_2$ for four hours. Late larval nematodes (L4) were exposed for one or three days.		**Reproduction:** Brood size decreased with increasing Pb , but the decrease was smaller with increasing developmental age. Generation time increased with increasing Pb, and the increase was smaller with increasing developmental age. These effects were greater in late larval nematodes when exposure duration increased from four hours to one and three days.		Guo et al. (2009)
Nematode (*Caenorhabditis elegans*)	5; 10; 16; 21 mg Pb/L		Nematodes were placed for 48 hours in growing medium with 4 concentrations of Pb.		**Survival:** No effect		Vigneshkumar et al. (In Press)
Nematode (*Caenorhabditis elegans*)	0.5; 16; 41 mg Pb/L		Nematodes were placed for three days in growth medium amended with Pb nitrate.		**Growth:** Life span, body size decreased with increasing Pb. **Reproduction:** Generation time and brood size increased with increasing Pb. All effects were present and of comparable magnitude in progeny of exposed nematodes.		Wang and Peng (2007)

Species	Exposure Concentration (Nominal)	Exposure Concentration (Measured)	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Snail (*Achatina achatina*)		1.33; 70.98; 134.61; 339.40; 674. 86; 1,009.22; 1,344.39 mg Pb/kg	Snails were reared for 12 weeks on a diet amended with Pb chloride.		**Survival:** no effect **Growth:** Small decrease in feeding at highest exposure, small decrease in weight gain with increasing Pb (over 12 weeks, snails in the highest exposure gained 12% less weight than in the lowest exposure).		Ebenso and Ologhobo (2009a)
Snail (*Achatina achatina*)		0.56; 20.37; 200.42; 1,200.30 mg Pb/Kg	Snails from laboratory source were reared for 12 weeks in bottomless enclosures at four locations within the grounds of an abandoned battery factory.	pH: 4.42 - 6.29, decreasing with increasing Pb OC: 1.39 - 3.45%, decreasing with increasing Pb CEC: 3.32 - 5.37 cmol/kg, increasing with increasing Pb.	**Growth:** Feeding, weight gain and shell thickness all decreased with increasing Pb (13; 17; and 19% lower in highest exposure than in lowest).		Ebenso and Ologhobo (2009b)
Snail (*Theba pisana*)	0; 50; 100; 500; 1,000; 5,000; 10,000; 15,000 mg Pb/Kg		Snails were reared for 5 weeks on Pb-amended diet.		**Growth:** Feeding and weight gain decreased with increasing Pb and time (snails in 0 added Pb gained 45% more weight than in highest Pb). **Survival:** No effect		El-Gendy et al. (2011)
Snails (*Cantareus aspersus, Helix aspersa*)		Total Soil Pb: 1740-2060 mg Pb/kg $CaCl_2$ extractable; 4-80 mg Pb/kg Dissolved (estimated): 0.007-0.09 mg Pb/L	Snails were reared for 7 - 9 weeks in field soil amended with varying amounts of Pb-sulfate, clay, peat, and $CaCO_3$.	Clay content 11 - 16% Organic matter 1.2 - 10% pH 4.6 - 7.49	**Growth:** No effect **Survival:** No effect		Pauget et al. (2011)

Species	Exposure Concentration (Nominal)	Exposure Concentration (Measured)	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Vertebrates							
Japanese quail (*Coturnix coturnix japonica*)		Drinking water Pb: 0; 5; 50 mg Pb/L Tissue Pb: 0;1.1; 10.7 mg/kg wet weight	Quails were given Pb-amended water for 7 weeks.		**Growth:** Feed intake and growth rate not affected. **Survival:** Morbidity/mortality was lower in highest exposure than in control. Incidence of pericarditis, airsacculitis, perihepatitis, and arthritis was lower in highest exposure than in control.		Nain and Smits (2011)
Pied flycatchers (*Ficedula hypoleuca*)		**Blood Pb in nestlings at mining site** while active: 41 mg Pb/100 kg wet weight; after closing: 29 mg Pb/100 kg wet weight. **Blood Pb in nestlings at reference site** while active: 2 mg Pb/100 kg wet weight; after closing: 0.4 mg Pb/100 kg wet weight.	Data were collected in wild flycatchers near a Pb mine and at a reference site for three years while the mine was active, and for three years five years after mine closing.		**Reproduction:** Clutch size and breeding success were lower at the mine site, but did not change after closure of the mine (clutch size 5.6 reference, 4.9 mining site; breeding success 80% reference site, 76% mining site). Nestling mortality was higher at the mine site , and increased after closure (5% reference site, 11% mining site while active; 11% reference site, 26% mining site after closure).		Berglund et al. (2010)

Species	Exposure Concentration (Nominal)	Exposure Concentration (Measured)	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Pig (*Sus domestica*)		**Feed Pb** control: unreported exposed: 10 mg Pb/kg **Blood Pb** control: 1.44 µg/dL exposed: 2.08 µg/dL	Pigs were reared for 120 days with Pb-sulfate-amended feed.		**Growth:** Significant decrease in body weight, average day gain, average day feed intake, and feed efficiency. Increase in feed conversion ratio. **Reproduction:** No effect on ovary and uterus weight		Yu et al. (2005)

[a]References included are those which were published since the 2006 Pb AQCD.

Table 7-5 Freshwater plants, invertebrates and vertebrates; growth, reproduction and survival.

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Algae/Plants						
Blue-green algae *(Spirulina (Arthrospira) platensis)*	5,000; 10,000; 30,000; 50,000; and 100,000 µg Pb/L (nominal concentration at day 0 and then Pb in media was measured every two days thereafter).	10-day exposure to Pb nitrate in Zarrouk liquid medium.	Temperature: 25 ± 1 °C pH: 7.0 Light dark cycle of 14:10 hours.	**Growth:** 10-day algal growth (measured turbidimetrically at 560 nm) was stimulated by 3.7% in the lowest concentration, growth was inhibited at higher concentrations of 30,000; 50,000; and 100,000 µg Pb/L by 40; 49; and 78%, respectively. Chlorophyll *a* and *b* content were significantly diminished at the three highest exposures.	**LC_{50}**: 75,340 µg/L	Arunakumara et al. (2008)
Microalgae *(Scenedesmus obliquus)*	5,000 to 300,000 µg Pb/L (nominal)	48 and 96-hour acute toxicity test with Pb nitrate in BG11 medium.	Plants were incubated at normal room temperature	**Growth:** In growth studies (measured as cell division rate) *S. obliquus* was significantly more sensitive to Pb exposure than *C. vulgaris*	**48 hour EC_{50}:** 4,040 µg Pb/L *S. obliquus*	Atici et al. (2008)
Microalgae *(Chlorella vulgaris)*			(not provided)		**48 hour EC_{50}:** 24,500 µg/L *C. vulgaris*	
Duckweed *(Lemna minor)*	100; 200; 490; 900; 2,000; 5,020; 7,990; and 9,970 µg Pb/L (measured)	4 day or 7-day exposures to Pb chloride in static test conditions with Jacob culture medium under continuous illumination.	Temperature: 25 ± 2 °C pH 6.0	**Growth:** Growth (measured as biomass) of the duckweed was promoted up to 103% at 100 µg Pb/L and 200 µg Pb/L. However, growth was inhibited monotonically at all other test levels with increasing concentrations. Overall, the relative growth rate was reduced to 37–38% at the highest concentration.	**4 day EC_{50}:** 6,800 µg Pb/L **7 day EC_{50}:** 5,500 µg/L	Dirilgen (2011)
Duckweed *(Lemna minor)*	2,070; 10,360; 20,700; and 103,600 µg Pb/L (nominal)	9-day exposures to Pb nitrate in a growth chamber on Knopp's medium under a 14-hour photoperiod.		**Growth:** At lower Pb doses, growth was slightly stimulated. Fresh weight was lower by 65% at the highest dose. Pb-induced chlorosis occurred and the enzymes of the antioxidative system were modified due to Pb exposure in all concentrations.		Paczkowska et al. (2007)

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Duckweed *(Wolffia arrhiza)*	210; 2,120; 20,720; and 207,200 µg Pb/L (analytically verified)	14-day exposure to Pb as Pb nitrate in sterile 1/50 dilution of Hutner's medium, day to night cycle of 16:8 hours.	Temperature: 25 ± 0.5 °C pH: 7.0	**Growth:** Biomass decreased proportionally with increasing Pb concentration; Chlorophyll *a* content was significantly inhibited at 210 µg Pb/L and greater; carotenoid, monosaccharide and protein content significantly decreased in higher concentrations.		Piotrowska et al. (2010)
Waterweed *(Elodea canadensis)*	1,000; 10,000; and 100,000 µg/L (nominal)	Plants were exposed 5 days to Pb as Pb acetate in a 10% nutrient solution and then assayed for pigment content, total ascorbic acid, and protein content.	Temperature: 25–27°C pH 6.5-6.7 10% Hoagland & Arnon nutrient solution	**Growth:** The chlorophyll, carotenoid, and protein contents of *E. canadensis* were significantly reduced following Pb accumulation.		Dogan et al. (2009)
Wetland plants *(Beckmannia syzigachne, Alternanthera philoxeroides, Juncus effusus, Oenanthe javanica, Cyperus flabelliformis, Cyperus malaccensis, Polypogon fugax, Leersia hexandra, Panicum paludosum, Neyraudia reynaudiana)*	20,000 µg/L (nominal) Metals were analyzed in plant samples.	Field-collected tillers or seedlings (from various locations in China) for each species were used in 21-day experiments to determine Pb tolerance as inferred from measuring the elongation of the longest root in a hydroponic system in a Pb nitrate solution.		**Growth:** Root elongation was significantly reduced in a number of wetland species (*B. syzigachne, J. effusus, O. javanica, C. flabelliformis, C. malaccensis, and N. reynaudiana*). Metal tolerance was related to root anatomy and spatial pattern of radical oxygen loss.		Deng et al. (2009)

Invertebrates						
Rotifer *(Brachionus calyciflorus)*	67; 194; 284; 390; and 700 µg Pb/L (measured)	Cysts of rotifers were obtained from Florida Aqua farms in Dade City, Florida, U.S. Tests with Pb nitrate were performed in total darkness for 48 hours.	Temperature: 25 ± 1 °C pH: 8.19	**Reproduction:** The total number of rotifers and the intrinsic rate of population increase exhibited concentration-dependent responses at the end of the 48 hour incubation period.	**EC_{20} for number of rotifers:** 125 µg Pb/L **48-hour EC_{20} for intrinsic rate of population increase:** 307 µg Pb/L **NOEC:** 194 µg Pb/L **LOEC:** 284 µg Pb/L	Grosell et al. (2006b)
Rotifer *(Brachionus patulus)*	1,250; 2,500; 4,000; 5,000; and 8.000 µg Pb/L (nominal) for acute toxicity tests. Chronic exposures used nominal concentration of 60 and 600 µg Pb/L with varying turbidity levels.	24-hour exposures to Pb chloride in the presence and absence of sediments using rotifers originally isolated from the Chimaliapan wetland, Toluca, Mexico. Three week chronic toxicity tests were also conducted.	Temperature: 20 °C	**Reproduction:** In chronic tests, net reproductive rate and rate of population increase decreased under conditions of increasing turbidity and Pb concentration. **Survival:** 24-hour LC_{50} reported for this species. In chronic tests, average life span and life expectancy at birth decreased under conditions of increasing turbidity and Pb concentration.	**24-hour LC_{50}**: 6,150 µg/L	García-García et al. (2007)
Rotifer *(Euchlanis dilatata)*	0.1; 0.5; 50; 100; 250; 1,000; 2,500 µg Pb/L (analytically verified, actual concentrations not reported)	48-hour acute toxicity tests with rotifer neonates exposed to Pb nitrate in synthetic moderately hard water. Adult rotifers were collected in a reservoir in Aguascalientes, Mexico.	Temperature: 25 ± 2 °C pH: 7.5 Hardness: 80–100 mg/L $CaCO_3$	**Survival:** Based on 48-hour LC_{50} *E. dilatata* is among the most sensitive rotifer species to Pb. *E. dilatata* may be a more suitable test organism for ecotoxicology in Mexico, where this study was conducted, instead of *D. magna,* a species that is not been found in Mexico reservoirs.	**48-hour** **NOEC**: 0.1 µg/L **LOEC**: 0.5 µg/L **LC_{50}:** 35 µg/L (estimated from analytically verified concentrations)	Arias-Almeida and Rico-Martínez (2011)

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Cladoceran *(Ceriodaphnia dubia)*	Measured but not reported. Predicted concentration of major Pb chemical species in the natural water bioassays is provided in Table 4 of Esbaugh et al. (2011).	Acute toxicity of Pb to *C. dubia* was assessed in 48-hour exposures to two lab generated reference waters and eight natural waters from across North America selected to include a range of water quality parameters. Waters were spiked with varying concentrations of Pb as Pb nitrate.	Temperature: 26°C Water chemistry of the field-collected waters are reported in Table 1 of Esbaugh et al. (2011) including pH (range 5.5 to 8.5), Ca^{2+} (range 24 to 1,934 µM), DOC (range 36 to 1,244 µM) and hardness (range 4 to 298 mg/L)	**Survival:** LC_{50} values ranged from 29 to 1,180 µg Pb/L. Sensitivity to Pb varied greatly with water chemistry. DOC was correlated with protection from acute toxicity.	**48-hour LC_{50} range:** 29 to 1,180 µg Pb/L **NOEC range:** 18 to <985 µg Pb/L. **LOEC range:** 52 to 1,039 µg Pb/L	Esbaugh et al. (2011)
Cladoceran *(Ceriodaphnia dubia)*	A range of 5 to 6 Pb concentrations (measured but not reported) were prepared with varying pH, hardness and alkalinity.	Chronic 7-day static renewal 3 times per week in 2:1 dechlorinated, aerated tap water:deionized water to determine the effects of hardness (as $CaSO_4$ and $MgSO_4$), alkalinity, pH, and DOM on Pb toxicity.	Temperature: 25 °C pH: 6.4-8.2 Hardness: 22-524 mg/L	**Survival:** DOM and alkalinity have a protective effect against chronic toxicity of Pb. $CaSO_4$ and $MgSO_4$ do not have a protective influence of water hardness; Pb toxicity increased at elevated Ca^{2+} and Mg^{2+}. Low pH increases the toxicity of Pb. **Reproduction:** Increased DOC leads to an increase in mean EC_{50} for reproduction ranging from approximately 25 µg Pb/L to >500 µg Pb/L.	**Control base water EC_{20}:** 45 µg Pb/L **5.0 mM $CaSO_4$ EC_{20}:** 22 µg Pb/L **32 mg/L DOM EC_{20}:** 523 µg Pb/L **2.5 mM $NaHCO_3$ EC_{20}:** 73 µg Pb/L Additional EC_{20} and all EC_{50} values were reported in the study.	Mager et al. (2011a)
Cladoceran *(Diaphanosoma birgei)*	2,000 to 5,500 µg Pb/L (analytically verified)	24-hour exposure to Pb chloride in moderately hard water.	Temperature: 23 °C pH: 7.0–7.5	**Survival:** LC_{50} reported	**24 hour LC_{50}** 3,160 µg Pb/L	García-García et al. (2006)
Cladoceran *(Moina micrura)*	1,000 to 8,000 µg Pb/L (analytically verified)	24-hour exposure to Pb chloride in moderately hard water	Temperature: 23 °C pH: 7.0–7.5	**Survival:** *M. micrura* was more sensitive to Pb than *D. birgei* and *A. rectangular.*	**24 hour LC_{50}** 690 µg Pb/L	García-García et al. (2006)
Cladoceran *(Alona rectangular)*	3,000 to 10,000 µg Pb/L (analytically verified)	24-hour exposure to Pb chloride in moderately hard water	Temperature: 23 °C pH: 7.0–7.5	**Survival:** *A. rectangular* was more resistant to Pb than the other species tested	**24 hour LC_{50}** 7,000 µg Pb/L	García-García et al. (2006)

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Cladoceran *(Daphnia magna)*	**Acute test:** Concentrations not provided **Chronic test:** 25 µg Pb/L 250 µg Pb/L 2,500 µg Pb/L (nominal)	24 hour acute toxicity test and 21 day toxicity test with Pb nitrate, static renewal every two days.	Temperature: 20 ± 1 °C	**Reproduction:** Significant concentration-dependent decrease in number of neonates per female; Significant long-term effects on reproduction. Negative correlation between hemoglobin gene expression and reproduction outcomes.	**24-hour EC_{50}** (immobility): 18,153 µg Pb/L	Ha and Choi (2009)
Cladoceran *(Daphnia pulex)*	**Acute test:** 250; 500; 1,000; 2,000; 5,000 µg Pb/L (nominal) **Chronic test:** 250; 500; 1,000 µg Pb/L (nominal).	48-hour acute toxicity test and two 21-day exposures to Pb nitrate in dechlorinated tap water.		**Reproduction:** Reproduction rates (cumulative neonates) significantly decreased at 1,000 µg Pb/L in the first chronic toxicity test and at 500 µg Pb/L in a second test. **Survival:** LC_{50} values reported	**48-hour LC_{50}:** 4,000 µg Pb/L	Theegala et al. (2007)
Ostracod *(Stenocypris major)*	475; 1,160; 3,410; 4, 829; 8,972 µg Pb/L (measured)	96-hour static renewal with Pb nitrate in dechlorinated tap water. Ostracods were collected from a filter system of a fish pond in Bangi, Selangor, Malaysia.	Temperature: 28-30 °C pH: 6.5 ± 0.01 Conductivity: 244.3 ± 0.6 µS/cm DO: 6.3 ± 0.06 mg/L Total hardness: 15.6 mg/L as $CaCO_3$ Light dark cycle of 12:12 hours.	**Survival:** LC_{50} values reported	**24-hour LC_{50}:** 6,583 **µg** Pb/L **48-hour LC_{50}:** 2,886 µg Pb/L **72-hour LC_{50}:** 1,491 µg Pb/L **96-hour LC_{50}:** 526 µg Pb/L	Shuhaimi-Othman et al. (2011b)

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Midge *(Chironomus dilutus,* formerly *C. tentans)*	29; 57; 75; 115; 128; 152 µg Pb/L (measured)	96-hour static renewal test 20 day midge life cycle test in Pb chloride spiked water, flow through, and emergence at 55 days. The *C. dilutus* culture was initially started with egg cases from Aquatic Biosystems, Fort Collins, CO, USA.	**Average ± SD (range):** Temperature: 22.2 ± 1.0 °C (19.7-24.4 °C) pH: 7.26 ± 0.21 (6.9 - 7.7) Hardness: 32 ± 3.2 mg/L as $CaCO_3$ Alkalinity: 31 ± 3.0 mg/L as $CaCO_3$ Conductivity: 76 ± 4.9 µs DO: 7.8 ± 0.8 mg/L	**Growth:** Growth and emergence decreased as concentration increased. **Reproduction:** No effect **Survival:** No effect	**96-hour LC_{50}:** 3,323 µg Pb/L **Survival** **NOEC:** 152 µg Pb/L **LOEC:** >152 µg Pb/L **MATC:** >152 µg Pb/L **Weight** **NOEC**: 57 µg Pb/L **LOEC:** 75 µg Pb/L **MATC:** 65 µg Pb/L **EC_{10} (95%)**: 15 µg Pb/L **EC_{20} (95%)**: 28 µg Pb/L **Fecundity** **NOEC:** 152 µg Pb/L **LOEC:** >152 µg Pb/L **MATC:** >152 µg Pb/L **EC_{10} (95%)**: >152 µg Pb/L **EC_{20} (95%)**: >152 µg Pb/L **Emergence** **NOEC**: 115 µg Pb/L **LOEC:** 128 µg Pb/L **MATC:** 121 µg Pb/L **EC_{10}:** 28 µg Pb/L **EC_{20}:** 55 µg Pb/L	Mebane et al. (2008)
Midge *(Chironomus riparius)*	Logarithmic range from 0 to 25,000 µg Pb/L (nominal)	24-hour acute toxicity tests with first-instar larvae exposed to Pb nitrate in synthetic soft water. *C. riparius* culture was from egg masses from Environment Canada.	Temperature: 20 °C Water hardness: 8 mg/L of $CaCO_3$,	**Survival:** Concentration-dependent decrease in survival with increasing Pb. Of the five metals tested in the study (Cd, Cu, Pb, Ni, Zn), Pb was most toxic to first instar *C. riparius*.	**24-hour LC_{50}:** 613 µg Pb/L	Béchard et al. (2008)

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Midge *(Chironomus javanus)*	430; 580,; 1,330; 2,460; 7,670 µg Pb/L (measured)	4-day exposure with fourth instar larvae to Pb nitrate in aerated, filtered, dechlorinated tap water with static aerated renewal at 2 days. Larvae were collected from a filter system of a fish pond in Bangi, Selangor, Malaysia.	Temperature: 28-30 °C pH: 6.51 ± 0.01 Conductivity: 244.3 ± 0.6 µS/cm DO: 6.25 ± 0.06 mg/L Total hardness (Mg^{2+} and Ca^{2+}): 15.63 ± 2.74 mg/L as $CaCO_3$	**Survival:** LC_{50} values reported for this species.	**24 hour LC_{50}:** 20,490 µg Pb/L **48 hour LC_{50}:** 6,530 µg Pb/L **72-hour LC_{50}:** 1,690 µg Pb/L **96 hour LC_{50}:** 790 µg Pb/L	Shuhaimi-Othman et al. (2011c)
Midge *(Culicoides furens)*	100; 290; 510; 800; 2,800 µg Pb/L (measured)	Series of 96-hour exposures to Pb chloride in dechlorinated water under several temperature ranges.	**1st experiment:** Temperature: 25-28 °C **2nd experiment:** Temperature: 20-26 °C **3rd experiment:** Temperature: 10, 15, 20, 23, 25, 28, 30, 35, 40 ± 0.5 °C	**Survival:** Higher and lower temperatures brought about increased toxicities. LC_{50} values generally increased in 10-25°C and decreased in 28-40°C. 40°C temperature produced 100% mortality.	**96 hour LC_{50} values:** **28-25 °C*:** 400 µg Pb/L **26-20 °C*:** 300 µg Pb/L **25 °C:** 400 µg Pb/L **35 °C-25 °C*:** 500 µg Pb/L **23 °C**: 700 µg Pb/L **20 °C**: 400 µg Pb/L **15 °C**: 400 µg Pb/L **10 °C:** 357 µg Pb/L *temperature decreased over the duration of the experiment	Vedamanikam and Shazilla. (2008a)

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Midge *(Chironomus plumosus)*	3,000; 5,400; 8,200; 30,000; 54,000 µg Pb/L (measured)	Series of 96-hour exposures to Pb chloride in dechlorinated water under several temperature ranges.	**1st experiment:** Temperature: 25-28°C **2nd experiment:** 20-26°C **3rd experiment:** 10, 15, 20, 23, 25, 28, 30, 35, 40 ± 0.5 °C	**Survival:** Higher and lower temperatures brought about increased toxicities 40°C temperature produced 100% mortality LC_{50} values generally increased in 10-25°C and decreased in 28-40°C	**96 hour LC_{50} values:** **28-25°C***: 16,200 µg Pb/L **26-20°C*:** 8,300 µg Pb/L **25 °C:** 9,500 µg Pb /L **35 °C:** 700 µg Pb/L **30 °C:** 700 µg Pb/L **28 °C:** 900 µg Pb/L **25 °C:** 900 µg Pb/L **23 °C:** 700 µg Pb/L **20 °C:** 600 µg Pb/L **15 °C:** 600 µg Pb/L **10 °C:** 500 µg Pb/L *temperature decreased over the duration of the experiment	Vedamanikam and Shazilla (2008a)
Oligochaete worm *(Lumbriculus variegatus)*	1,300; 3,200; 8,000; 20,000; 50,000 µg Pb/L (nominal)	24 and 48-hour exposures to Pb nitrate spiked water from Lake Vesijärvi, Finland	Temperature: 20 °C	**Survival:** 48-hour LC_{50} reported	**48-hour LC_{50}:** 5,200 µg Pb/L	Penttinen et al. (2008)
Mayfly *(Baetis tricaudatus)*	69; 103; 160; 222; 350; 546 µg Pb/L (measured)	96-hour static renewal test and 10 day chronic study with aerated Pb chloride spiked water, static renewal every 48 hours. Mayflies were collected from the South Fork Coeur d'Alene River, Idaho.	**Mean ± SD** Temperature: 9.3 ± 0.67 °C pH: 6.64 ± 0.18 Hardness: 20.7 ± 0.58 mg/L as CaCO3 Alkalinity: 19.8 ± 1.04 mg/L as CaCO3 Conductivity: 47.7 ± 1.72 µs DO: 10.1 ± 0.45 mg/L	**Growth:** Consistent dose-dependent reductions in mayfly growth (as number of molts); growth decreased with increased Pb exposure. **Survival:** 96-hour EC_{50} reported for this species. Reduced molting endpoint more sensitive than mortality endpoint.	**96-hour EC_{50}** 664 µg Pb/L **Survival:** **NOEC:** 222 µg Pb/L **LOEC:** 350 µg Pb/L **MATC:** 279 µg Pb/L **EC_{10} (95%):** 169 µg Pb/L **EC_{20} (95%):** 23 µg Pb/L **Molting :** **NOEC:** 103 µg Pb/L **LOEC:** 160 µg Pb/L **MATC:** 130 µg Pb/L **EC_{10} (95%):** 37 µg Pb/L **EC_{20} (95%)**: 66 µg Pb/L	Mebane et al. (2008)

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Mosquito *(Culex quinquefasciatus)*	**Acute test:** 100; 150; 200; 250 µg Pb/L (analytically verified) 50; 150; and 200 µg Pb/L for reproductive studies	24-hour acute toxicity test and several tests to assess reproductive endpoints. All tests were conducted with Pb nitrate in distilled water	Temperature: 25 ± 2 °C pH: 7	**Reproduction:** Hatching rate significantly decreased, lower emergence rates, larval development from L1 to adults took longer. **Survival:** 24 hour LC_{50} reported	**Survival:** **24 hour LC_{50}:** 180 µg Pb/L	Kitvatanachai et al. (2005)
Neosho mucket *(Lampsilis rafinesqueana)*	Concentrations were measured and used to calculate EC_{50} values, reported in supplemental data.	24 and 48-hour exposure with 5 day old juveniles obtained from adults collected from Spring River, KS, U.S.	Temperature: 20 ± 1 °C pH: 7.2-7.6 DOC: >7.0 mg/L Hardness: 40-48 mg/L as $CaCO_3$ Alkalinity: 30-35 mg/L as $CaCO_3$	**Survival:** Neosho mucket is a candidate species for U.S. federal endangered and threatened status. Toxicity testing with newly transformed juveniles indicated that this species is sensitive to Pb exposure.	**24 hour EC_{50}:** 5 day old juveniles >507 µg Pb/L **48 hour EC_{50}:** 5 day old juveniles: 188 µg Pb/L	Wang et al. (2010e)

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Fatmucket mussel *(Lampsilis siliquoidea)*	For 28-day exposure: 0.04; 2.9; 6.1; 17; 36; 83 µg Pb/L (measured)	24 and 48-hour exposure with glochidia, 96-hour exposure with 5 day old, and 2 or 6 month old juveniles and 28-day exposure with 2 or 4 month old mussels in reconstituted soft water. Tests were conducted with glochidia and juveniles obtained from adults collected from the Silver Fork of Perche Creek, MO, U.S.	Temperature: 20 ± 1 °C pH: 7.2-7.6 DOC: >7.0 mg/L Hardness: 40-48 mg/L as $CaCO_3$ Alkalinity: 30-35 mg/L as $CaCO_3$	**Growth:** Growth of juvenile mussels in the 17 µg Pb/L concentration was statistically significantly reduced compared to growth in the controls at the end of 28 days. Growth was not assessed in the higher concentrations due to mortality. **Survival:** The 24-hour EC_{50} values for glochidia and 96-hour EC_{50} values for 2 and 6 month old juveniles were much higher than 96 hour LC_{50} value for 5 day old newly transformed juveniles. Genus mean chronic value was the lowest value ever reported for Pb. Survival was based on foot movement within a 5-minute observation period.	**24 and 48 hour EC_{50}**: glochidia >400 µg Pb/L (test 1) >299 µg Pb/L (test 2) **48 hour EC_{50}:** 5 day old juveniles 465 µg Pb/L (test 1) 392 µg Pb/L (test 2) **96 hour EC_{50}:** 5 day old juveniles 142 µg Pb/L (test 1) 298 µg Pb/L (test 2) **24 and 48 hour EC_{50}:** 2 month old juveniles >426 µg Pb/L **4 day EC_{50}:** >83 µg Pb/L **10 day EC_{50}:** >83 µg Pb/L **21 day EC_{50}:** 29 µg Pb/L **28 day EC_{50}:** 20 µg Pb/L **28-day NOEC** Juvenile fatmucket: 6.1 µg/L **28-day LOEC** Juvenile fatmucket: 17 µg/L **Genus mean chronic value** 10 µg Pb/L	Wang et al. (2010e)
Snail *(Lymnaea stagnalis)*	4; 12; 16; 42; 113; and 245 µg Pb/L (measured)	30-day exposure with newly hatched snails (<24-hour old) in artificial fresh water with Pb nitrate.	Temperature: 23 ± 1 °C	**Growth:** Newly hatched snails exhibited greatly reduced growth in response to Pb exposure **Survival:** No Pb-induced mortality was observed.	**EC_{20}** <4 µg Pb/L **NOEC:** 12 µg Pb/L **LOEC:** 16 µg Pb/L	Grosell et al. (2006b)

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Snail *(Lymnaea stagnalis)*	**1st Experiment:** <0.5 (control), 2.7 and 18.9 µg Pb/L (measured) **2nd Experiment:** 1.3 and 7.5 µg Pb/L (measured)	Pb exposures were performed with juvenile snails (~ 1 g) for 21 days and then 14 days in dechlorinated tap water under flow-through conditions.	Dechlorinated City of Miami tap water ($[Na^+]$ ~1.1 mmol/L $[Ca^{2+}]$ ~0.31 mmol/L $[Cl^-]$ ~1.03 mmol/L $[HCO^{3-}]$ ~0.68 mmol/L, [DOC]~200 µmol/L pH~7.7 at room temperature	**Growth:** In juveniles exposed to 18.9 µg/L Pb for 21 days, Ca^{2+} influx was significantly inhibited and model estimates indicated 83% reduction in growth of newly hatched snails after 30 days at this exposure concentration **Survival:** No Pb-induced mortality was observed		Grosell and Brix (2009)
Snail *(Marisa cornuarietis)*	5,000;10,000; and 15,000 µg Pb/L (nominal)	5-day, 6-day, and 10-day exposure to Pb chloride in deionized or double-distilled water. Snail strain used for egg production was from the Zoological Institute in Frankfurt, Germany.	Temperature: 24 ± 1 °C pH: ~7.5 Conductivity: ~800 µS/cm	**Reproduction:** Significant delay in hatching at 10,000 µg Pb/L **Growth:** Significantly delayed development (reduced visible tentacles, eye formation) at 15,000 µg Pb/L. No effect on fresh weight. **Survival:** Significantly increased mortality at 15,000 µg Pb/L	**LOEC:** 10,000 µg Pb/L	Sawasdee and Köhler (2010)
Snail *(Biomphalaria glabrata)*	50; 100; and 500 µg Pb/L (nominal)	96-hour acute laboratory bioassays	Dechlorinated continuously aerated tap water: Temperature: 22 °C pH: 7.1 ± 0.2 Total hardness: 65 ± 3 mg $CaCO_3$/L Alkalinity: 29 ± 2 mg $CaCO_3$/L Conductivity" 230 ± 17 µS	**Reproduction:** Significant decrease in number of eggs laid at 500 µg Pb/L. **Survival:** Embryonic survival was 12% of the number of eggs laid by the control group at 100 µg Pb/L. Time to hatching increased 3 fold from the control. No embryos survived the highest concentration.		Ansaldo et al. (2009)

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Prawn *(Macrobrachium lancesteri)*	22; 31; 48; 126; 170 µg Pb/L (measured)	4-day exposures in Pb chloride in aerated, filtered, dechlorinated tap water, static aerated, renewal at 2 days. Prawns were purchased from aquarium shops in Bani, Selangor, Malaysia.	Temperature: 28-30 °C pH: 6.51 ± 0.01 Conductivity: 244.3 ± 0.6 µS/cm DO: 6.25 ± 0.06 mg/L Total hardness (Mg^{2+} and Ca^{2+}): 15.63 ± 2.74 mg/L as $CaCO_3$	**Survival:** LC_{50} increased with decrease in mean exposure concentration	**24 hour LC_{50}** 85.9 µg Pb/L **48 hour LC_{50}:** 58.5 µg Pb/L **72 hour LC_{50}:** 45.5 µg Pb/L **96 hour LC_{50}** 35.0 µg Pb/L	Shuhaimi-Othman et al. (2011a)
Crayfish (*Orconectes hylas)*	Reference sites: 0.03 µg Pb/L Mining sites: 0.12 to 1.59 µg Pb/L Downstream sites 0.03 to 0.04 µg Pb/L	in situ 28-day exposure with juvenile crayfish in streams impacted by Pb mining and reference sites in Missouri, USA.	Water quality parameters were measured at each site Temperature 23 to 26 °C pH: 7.9 to 8.1 Conductivity: 282 to 858 DO: 6.3 to 8.4 mg/L) Alkalinity 141 to 182 mg/L as $CaCO_3$ Turbidity: 0.4 to 0.6 NTU Sulfate: 0.3 to 304 mg/L Other metals were present downstream of mining sites	**Survival:** Crayfish survival and biomass were significantly lower in streams impacted by Pb mining Metal concentrations were negatively correlated with caged crayfish survival.		Allert et al. (2009a)

Vertebrates						
Fathead minnow *(Pimephales promelas)*	**Measured: Mean ± SEM** Tap low Pb: 28 ± 1.1 µg Pb/L Tap high Pb: 105 ± 4.8 µg Pb/L HCO_3^- low Pb: 31 ± 1.2 µg Pb/L HCO_3^- high Pb: 113 ± 4.6 µg Pb/L Humic low Pb: 30 ± 1.4 µg Pb/L Humic high Pb: 112 ± 4.5 µg Pb/L	4-day, 10-day, 30-day, 150-day, and 300-day exposures in Pb nitrate spiked dechlorinated tap water with static renewal to study the effects of DOC and alkalinity on Pb toxicity. Breeding assays (21 days) were also performed.	Temperature: 22 ±1 °C **Tap H_2O:** Hardness: 91 mg/L pH: 8.1 **+500 µM $NaHCO_3$:** DOC: 257 µM Hardness: 93 mg/L pH: 8.3 **$NaHCO_3$:** Hardness: 93 mg/L pH: 8.3 **+4 mg/L HA:** Hardness: 93 mg/L pH: 8.0 **Humic:** Hardness: 93 mg/L pH: 8.0	**Growth:** No statistically significant growth differences observed at any age due to water chemistry alone; DOC addition strongly protected against Pb accumulation; increased alkalinity reduced whole body Pb burdens;. Growth inhibited at 4 days, but recovered by 30 days in high Pb concentration. **Reproduction:** HCO_3- reduced 21 day total reproductive output (reduced clutch size and number of clutches produced); addition of HCO_3^- alone actually increased reproductive output; significantly higher fecundity in HCO_3^- treatment; Egg attachment low in both tap water and HCO_3^- treatments; HA promoted attachment; No statistically significant differences in egg hatchability. HCO_3^- and humic acid treatments increased average egg mass; no effects on hatchability in the HCO_3^- and humic acid treatment;		Mager et al. (2010)

Fathead minnow *(Pimephales promelas)*	<0.1 – 3,605 µg Pb/L (measured) Pb was quantified in fish tissues in a separate set of experiments.	30 day flow through exposure to Pb nitrate to determine to the effects of Ca^{2+}, humic acid and pH (6.3 and 8.3) on Pb accumulation and toxicity in juvenile fathead minnows.	Exposure media were made up from a base-water consisting of 2:1 deionized water: dechlorinated tap water. Temperature: 23 °C and had various levels of Ca^{2+}, humics, and pH values: 0.5; 1; 2 mM Ca^{2+} 2; 4; 8; 16 mg humic 6.3; 8.3 pH	**Growth:** No growth inhibition was observed in any treatment. An increase in growth was observed in groups exposed to higher Pb concentrations where there were high initial mortalities. **Survival:** For most treatments, mortalities occurred during the first 5 to 7 days of exposure. The lowest tolerance was observed at low pH (6.8). Addition of DOC or $CaSO_4$ decreased Pb toxicity.	**30 day LC_{50}, EC_{20}, and LOEC values*:** **LC_{50} in µg Pb/L:** 0.5 mM Ca^{2+}: 91 1.0 mM Ca^{2+}: 104 2 mg humic: 255 4 mg humic: 443 8 mg humic: 832 16 mg humic: 1903 pH 6.3: 4.5 pH 8.3: 13 **EC_{20} in µg Pb/L:** 0.5 mM Ca^{2+}: 47 1.0 mM Ca^{2+}2 51 2 mg humic: 189 4 mg humic: 319 8 mg humic: 736 16 mg humic: 1729 pH 6.3: 2.1 pH 8.3: 8.7 **LOEC in µg Pb/L:** 0.5 mM Ca^{2+}: 40 1.0 mM Ca^{2+}: 107 2 mg humic: 199 4 mg humic: 475 8 mg humic: 919 16 mg humic: 1751 pH 6.3: 6.2 pH 8.3: 15 *4 day and 10 day LC_{50}, LC_{20}, and LOEC values also reported in the paper.	Grosell et al. (2006a)

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Fathead minnow *(Pimephales promelas)*	Measured but not reported. Figure 1 of Esbaugh et al. (2011) plots the relationship between dissolved and nominal Pb concentrations in three waters with low Pb solubility. Predicted concentration of major Pb chemical species in the natural water bioassays is provided in Table 4 of Esbaugh et al. (2011)	Acute toxicity of Pb to juvenile *P. promelas* (<24 hours old) was assessed in 96-hour static renewal exposures to two lab generated reference waters and seven natural waters from across North America selected to include a range of water quality parameters. Waters were spiked with varying concentrations of Pb as Pb nitrate.	Temperature: 26 °C Water chemistry of the field-collected waters are reported in Table 1 of Esbaugh et al. (2011) including pH (range 5.5 to 8.5), Ca^{2+} (range 24 to 1,934 µM), DOC (range 36 to 1,244 µM) and hardness (range 4 to 298 mg/L)	**Survival:** LC_{50} values ranged from 41 to 3,598 µg Pb/L. DOC had the strongest protective effect. The lowest LC_{50} occurred in the pH 5.5 water. No Pb toxicity was observed in three alkaline natural waters.	**96-hour LC_{50} range:** 41 to 3,598 µg Pb/L. **NOEC: range** 14 to 2,271 µg Pb/L. **LOEC: range** 42 to 5,477 µg Pb/L	Esbaugh et al. (2011)
Fathead minnow *(Pimephales promelas)*	0.2 ± 0.1 µg Pb/L (control) 33 ± 4 µg/L (chronic low) 143 ± 14 µg/L (chronic high) (measured)	33 to 57-day exposures in dechlorinated tap water and deionized water to Pb nitrate to assess swimming performance.	Temperature: 21 ± 1 °C pH: 7.50 ±0 .03 Total CO_2: 543 ± 69 µmol/L DOC: 108 ± 4 µmol carbon/L Hardness: 26 ± 3 mg/L	**Growth:** Fish from the chronic low exposure were significantly larger than control fish (increased mass and body length).		Mager and Grosell (2011)

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Fathead minnow *(Pimephales promelas)*	Fish were feed *L. variegatus* exposed via water to 628 µg Pb/L.	Juvenile fish fed a live diet of the oligochaete *L. variegatus* for 30 days contaminated with Pb.	Water from Lake Superior that was subsequently filtered and UV-treated. Temperature: 25 °C pH: 7.5–8.0, Hardness: 45–50 mg $CaCO_3$, Alkalinity : 40-45 mg $CaCO_3$/L	**Growth**: Not significantly affected **Survival**: Not significantly affected		Erickson et al. (2010)
Zebrafish (*Danio rerio)*	Mean daily dietary dose of 0.417 (0.3-0.48) or 0.1 (0.07 – 0.14) mg Pb/kg/day (measured)	63 day dietary exposure with Pb-enriched polychaete, *Nereis diversicolor.* Adult zebrafish were fed a daily dose of 1% flake food (dry wet diet/wet weight fish), 1% brine shrimp, and 1% *N. diversicolor* collected from either Gannel Estuary, Cornwall, U.K., an estuary with legacy Pb contamination, or Blackwater Estuary, Essex, U.K., (reference site)	Temperature: 29 ± 1 °C	**Reproduction:** No impairment observed to incidence of spawning, numbers of eggs per breeding pair or hatch rate of embryos compared with pre-exposure levels. Metal analyses revealed significant increases in whole-body Pb burdens of male fish fed polychaetes from the contaminated estuary.		Boyle et al. (2010)

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Tilapia *(Oreochromis niloticus)*	Mean concentration of Pb in food pellets: 100; 400; and 800 mg Pb/kg dry weight (nominal)	Fish obtained from an unpolluted fish farm in Hangzhou, China were held in tanks with dechlorinated tap water and were fed diets with Pb nitrate twice daily for 60 days.	Temperature: 25 ± 1 °C pH: 7.1-7.5 DO: 7.5-7.8 mg/L Alkalinity: 109 mg $CaCO_3$/L Hardness: 118 mg $CaCO_3$ / L	**Growth:** No effects on growth were found. **Survival:** Exposure to Pb-contaminated diets did not result in mortality.		Dai et al. (2009b)
Channel catfish *(Ictalurus Punctatus)*	Fish were fed *L. variegatus* exposed via water to 576 µg Pb/L	Juvenile fish fed a live diet of the oligochaete *L. variegatus* for 30 days contaminated with Pb.	Water from Lake Superior that was subsequently filtered and UV-treated. Temperature: 25 °C pH: 7.5–8.0, Hardness: 45–50 mg $CaCO_3$/L Alkalinity: 40-45 mg $CaCO_3$/L	**Growth**: Not significantly affected **Survival**: Not significantly affected		Erickson et al. (2010)
African catfish (*Clarias gariepinus)*	100; 300; and 500 µg Pb/L (nominal) Pb was quantified in tissues following exposure.	24; 42; 90; 138; and 162 hour embryo exposure to Pb nitrate in dechlorinated tap water. These intervals corresponded to 30; 48,; 96; 144; and 168 hours post-fertilization.	Temperature: 24 °C pH: 8.0 Conductivity: 700 µs/cm Oxygen: 90-95% saturation	**Growth:** Malformations observed in exposed embryos (malformed embryos only survived shortly after hatching), delay in development. **Reproduction:** Concentration-dependent delay in hatching, reduced percentage of embryos completing egg stage period from 75% in control to 40% in 500 µg Pb/L.		Osman et al. (2007b)

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Rainbow trout *(Oncorhynchus mykiss)*	**In diet:** 6.9 mg Pb·(g dry mass) (*L. variegatus* exposed via sediments)	Juvenile fish fed a live diet of the oligochaete *L. variegatus* for 30 days contaminated with Pb of varying concentrations of Pb nitrate	Water from Lake Superior that was subsequently filtered and UV-treated. Temperature: 11 °C pH : 7.5–8.0 Hardness: 45–50 mg $CaCO_3$/L Alkalinity : 40-45 mg $CaCO_3$/L	**Growth**: Not significantly affected **Survival**: Not significantly affected		Erickson et al. (2010)
Rainbow trout *(Oncorhynchus mykiss)*	Control Pb-free diet of 0.06 mg Pb/kg dry weight, and three different diets of 7; 77; and 520 mg Pb dry weight (0.02 (control), 3.7; 39.6; and 221.5 mg Pb/day dry weight calculated for food consumption) Pb also quantified in tissues	21-day exposure to juvenile rainbow trout via diet amended with Pb nitrate. Fish were held in aerated tanks with dechlorinated water	Temperature: 11-13 °C pH 7.5-8.0 Hardness: 140 ppm as $CaCO_3$	**Growth:** No effects on growth rates were observed in rainbow trout administered a diet containing three concentrations of Pb. Dietary Pb was poorly absorbed. Comparison of dietary and water-borne exposures suggest that toxicity does not correlate with dietary exposure, but does correlate with gill accumulation from waterborne exposure**.** **Survival:** Not significantly affected by dietary Pb		Alves et al. (2006)

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Rainbow trout *(Oncorhynchus mykiss)*	**ELS (early life stage) test 1:** 12; 24; 54; 143; and 384 µg Pb/L (measured) **ELS test 2:** 8; 18; 37; 87; and 124 µg Pb/L (measured)	96-hour static renewal acute toxicity test with swim-up stage fry (2 to 4 weeks post-hatch) reared from eggs used in the chronic studies. Two 60+ day ELS exposures were conducted in a flow-through system using temperature controlled water from Little North Fork of the South Fork Coeur d'Alene river in ELS 1 (69 days) and water from the South Fork in ELS 2 (62 days).	**ELS 1:** Temperature 9.8 ± 0.6 °C pH: 6.75 ± 0.4 Hardness: 19.7 ± 1.5 mg/L as $CaCO_3$ Conductivity: 45.8 ± 2.2 µs Alkalinity: 19.6 ± 2.2 mg/L as $CaCO_3$ DO: 10.2 ± 0.7 mg/L **ELS 2:** Temperature 12.5 ± 0.9 °C pH: 7.19 ± 0.3 Hardness: 29.4 ± 3.6 mg/L as $CaCO_3$ Conductivity: 69.1 ± 7.4 µs Alkalinity: 27 mg/L ± 2.1 as $CaCO_3$ DO: 9.2 ± 0.9 mg/L	**Growth:** In ELS 1, growth generally decreased as concentration increased, with fish in the highest surviving treatment (143 µg Pb/L) exhibiting severely stunted growth that was statistically different from the control. In ELS 2, growth increased in the highest treatment with a slight reduction in length and wet weight in intermediate exposures. **Survival:** In ELS 1 Survival decreased as concentration increased with complete mortality before the end of the test in the highest treatment (384 µg Pb/L). In ELS 2, survival decreased significantly in the highest treatment with high survival in intermediate exposure. In both tests, the greatest number of mortalities occurred around or shortly after the swim-up stage.	**96-hour LC_{50}:** 120 µg Pb/L **ELS 1: Survival** **NOEC:** 24 µg Pb/L **LOEC:** 54 µg Pb/L **MATC:** 36 µg Pb/L **EC_{10}:** 26 µg Pb/L **EC_{20}** : 34 µg Pb/L **ELS 1:Weight** **NOEC:** 24 µg Pb/L **LOEC:** 54 µg Pb/L **MATC:** 36 µg Pb/L **EC_{10}:** 39 µg Pb/L **EC_{20}:** 55 µg Pb/L **ELS 1: Length** **NOEC**: 54 µg Pb/L **LOEC:** 143 µg Pb/L **MATC:** 88 µg Pb/L **EC_{10}:** 64 µg Pb/L **EC_{20}:** 98 µg Pb/L **ELS 2: Survival** **NOEC:** 87 µg Pb/L **LOEC:** 125 µg Pb/L **MATC:** 104 µg Pb/L **EC_{10}:** 108 µg Pb/L **EC_{20}:** 113 µg Pb/L **ELS 2: Weight** **NOEC:** 37 µg Pb/L **LOEC**: 87 µg Pb/L **MATC:** 57 µg Pb/L **EC_{10}:** 7 µg Pb/L **EC_{20}:** >87 µg Pb/L **ELS 2: Length** **NOEC**: 8 µg Pb/L **LOEC:** 18 µg Pb/L **MATC:** 12 µg Pb/L **EC_{10}:** >87 µg Pb/L **EC_{20}:** >87 µg Pb/L	Mebane et al. (2008)

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Southern leopard frog (*Rana sphenocephala)*	Sediment: 45; 75; 180; 540; 2,360; 3,940; 5,520; 7,580 mg Pb/kg dry weight Corresponding sediment pore water: 123; 227; 589; 1,833; 8,121; 13,579; 19,038; 24,427 µg Pb/L (measured)	20; 40; 61; and 82-day exposures in Pb acetate spiked sediment collected from wetland, static renewal twice per week.	**Mean (SD)** Temperature: 21.6 °C pH: 6.92 DOC: 6.08 mg/L Conductivity: 168 µS/L Hardness: 7.30 mg Ca^{2+}/L Ammonia: 0.39 mg/L **Sediment:** Organic carbon: 8.25% Sand: 22.4% Silt: 38.4% Clay: 39.1%	**Growth:** Snout-vent length and body mass increased through time in all treatments; skeletal deformations (spinal deformations, digits truncated and twisted, long bones curved and truncated) increased with Pb content and length of exposure **Survival:** Exposure to ≥ 3,940 mg/kg sediment Pb (13,579 µg/L) pore water) killed all tadpoles within 5 days; tadpoles that reached climax stage (Gosner 42) had no difference in survival among treatments through the completion of metamorphosis.	**40 day EC_{50}** (for deformed spinal columns in sediment): 1,958 mg/kg Pb **Corresponding EC_{50}** (for deformed spinal columns in pore water): 6,734 µg/L **40 day EC_{50}** (for deformed spinal columns in sediment): 579 mg Pb/kg, and 1,968 µg Pb/L (in pore water). **Sediment: LC_{50}:** 3,728 mg Pb/kg (Corresponding to a **Pore water LC_{50} of:** 12,539 µg Pb/L).	Sparling et al. (2006)
Northern leopard frog *(Rana pipiens)*	3; 10; and 100 µg Pb/L (nominal) (Pb was measured in tissues at the end of the study. Pb tissue concentrations ranged from 0.1 to 224.5 mg Pb/kg dry mass and fell within the range of tissue concentrations in wild-caught tadpoles).	Northern leopard frogs were exposed to Pb as Pb nitrate in dechlorinated water from the embryonic stage to metamorphosis (>66 days post-hatching)	Temperature: 21 to 22 °C pH 7.9 Hardness: 170 mg/L as $CaCO_3$	**Growth:** Tadpole growth was significantly slower in the early stages in 100 µg Pb/L treatment. More than 90% of tadpoles in the 100 µg Pb/L treatment developed lateral spinal curvature, whereas almost all the tadpoles in the other groups were morphologically normal. No significant effect of Pb exposure was found on percentage metamorphosis, snout–vent length, mortality, or sex ratio. Time to metamorphosis was delayed in 100 mg/L treatment.		Chen et al. (2006b)

Algae						
Microalgae (*Tetraselmis chuii, Rhodomonas salina, Chaetoceros* sp., *Isochrysis galbana, Nannochloropsis gaditana)*	50; 100; 250; 500; 800; 1,000; 1,600; 3,000; and 6,000 µg Pb/L, (nominal). Five nominal concentrations were analytically verified: 51; 225; 824; 1,704; 6,348 µg Pb/L (measured)	Populations of each microalgal species were exposed for 72 hours to ten progressively increasing nominal concentrations of Pb in filtered seawater	Temperature: 20 ± 1 °C pH 8.0	**Growth:** Growth inhibition (as measured by flow cytometry) was reported for each species. Species cellular size, sorption capacity, or taxonomy did not explain differences in sensitivity to Pb.	**EC_{50}:** *T. chuii:* 2,640 µg Pb/L *R. salina*: 900 µg Pb/L *Chaetoceros* sp.: 105 µg Pb/L *I. galbana*: 1,340 µg Pb/L *N. gaditana*: 740 µg Pb/L	Debelius et al. (2009)
Microalgae *(Tetraselmis suecica)*	20 µg Pb/L (nominal) *T. suecica* in this study was then fed to *Artemia franciscana* (mean Pb content 12 to 15 mg Pb/kg).	72-hour exposure to Pb nitrate in filtered natural seawater from Mazatlan Bay, Mexico. This was the first step in a four-level food chain.	Temperature: 28 ± 2 °C Salinity: 34.6 ± 1.2 ppt pH: 7.9-8.2 DO saturation: 90-95% (>7 mg/L)	**Growth:** Mean final cell concentrations, growth rate and total dry biomass were significantly reduced (40% lower than control cultures). Effects on primary, secondary and tertiary consumers were observed following Pb-exposure via *T. suecica* at the base of a simulated marine food chain.		Soto-Jiménez et al. (2011b)
Invertebrates						
Polychaete *(Hydroides elegans)*	91; 245; 451; 4,443; 9,210; and 41,060 µg Pb/L (measured)	24-hour exposure of fertilized eggs to Pb chloride. Assay was stopped at 2 hours to assess effects on blastula.	Temperature: 27 ± 1 °C DO (86.5%) Salinity (34 ± 1 ppt) pH (8.1 ± 0.1) Carbonate 24.5 mg/L.	**Reproduction:** Exposure to Pb caused a significant decrease in the number of embryos developing normally to blastula after 2 to 3 hours of exposure to Pb.	**EC_{50}** Fertilization membrane stage : 30,370 µg Pb/L Blastula 1,429 µg Pb/L 24 hour trochophore larva: 231 µg Pb/L.	Gopalakrishnan et al. (2007)

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Polychaete *(Hydroides elegans)*	48; 97; 201; 407; 803; 1,621 µg Pb/L (measured)	A series of experiments were performed from 20 minutes to 4 days in Pb chloride using polychaetes collected from seawater in Chennai, India.	Temperature: 27 ± 1 °C DO: 7–9 mg/L Salinity 34 ± 1ppt pH: 8.1 ± 0.1 Carbonate: 22.5 mg/L	**Reproduction:** Fertilization rate decreased by 70% in sperm pretreated with 97 µg Pb/L for 20 minutes. Fertilization rate of eggs pretreated in 48 µg Pb/L decreased to 20% of control. Life stages of *H. elegans* varied in their sensitivity to Pb. Gametes, embryo and larvae were more sensitive than adults with the larval settlement period being most sensitive to Pb exposure.	**EC_{50}** Sperm toxicity: 380 µg Pb/L Egg toxicity: 692 µg Pb/L Embryo toxicity: 1,130 µg Pb/L Blastula to trochophore: 261 µg Pb/L Larval settlement: 100 µg Pb/L	Gopalakrishnan et al. (2008)
				Survival: LC_{50} reported for adults	**Adult 96-hour LC_{50}** : 946 µg/L	
Polychaete *(Capitella* sp.*)*	85; 137; 251; 392; 487; 738; 871 mg Pb/kg (measured)	3 and 6-day exposure for growth experiments, 96-hour exposure to Pb chloride spiked sediment from Chi-kou Estuary, Taiwan	Aerating circulating seawater Temperature: 20 ± 2 °C Salinity: 30%	**Growth:** Significant differences among growth rates of *Capitella* sp. in different levels of Pb-contaminated sediments, with the exception of 251 mg/kg treatment in the 6-day experiment. Growth rates deceased significantly from the control in the 3-day experiment but changes were inconsistent with increasing Pb concentration. **Survival**: No effect	**Growth LOAEL**: 85 mg Pb/kg	Horng et al., (2009)

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Amphipod (*Elasmopus laevis*)	30-mg Pb/kg (control whole-sediment), 58 mg Pb/kg; 118 mg Pb/kg; 234 mg Pb/kg; 424 mg Pb/kg (measured)	Multi-generational bioassay with amphipods collected in Jamaica Bay, New York exposed 60+ days to sediment spiked with Pb acetate in filtered seawater. 10-day and 28-day bioassays were also conducted.	Temperature: 19-24 °C Salinity: 27-29 g/L DO: >6.57 mg/L	**Reproduction:** Fecundity was reduced as sediment Pb concentration increased. Onset of reproduction and reproduction were delayed as Pb concentration increased. **Survival:** No differences in adult survival among the Pb concentrations tested in 28-day and 60-day exposures.	Fecundity and time of first offspring was significantly reduced with increasing sediment concentration above 118 mg Pb/kg. Onset to reproduction significantly delayed at 118 mg Pb/kg and delayed further at higher tested concentrations.	Ringenary et al. (2007)
Amphipod (*Melita plumulosa)*	Water-only tests ranged from 0 to 4,000 µg Pb/L (analytically verified) **Adult Sediment Test:** 500; 1,000; 2,000; 4,000 mg Pb/kg dry weight (analytically verified) **Juvenile Sediment Test:** 500; 1,000; 2,000 mg Pb/kg dry weight (analytically verified)	Juveniles and adults were tested in 96-hour seawater only or 10 day static-non-renewal exposure spiked sediment collected from intertidal mud flats, Woronora River, New South Wales, Australia. Adults were also tested in 10-day seawater only exposures.	Temperature 21 ± 1 °C, Salinity 30 ± 1%, pH 7.2–8.2, Ammonia (total) <3 mg N/L	**Survival:** Juvenile amphipods were more sensitive to Pb than adults in seawater and sediment exposures.	**96-hour seawater-only** **Adults:** LC_{50} 3,000 µg Pb/L NOEC 850 µg Pb/L LOEC 1,680 µg Pb/L **Juveniles:** LC_{50} 1,530 µg Pb/L NOEC 400 µg Pb/L LOEC 600 µg Pb/L **Seawater-only 10 days:** **Adults:** LC_{50} 1,270 µg Pb/L NOEC 190 µg Pb/L LOEC 390 µg Pb/L **10 days Sediment-only** **Adults:** LC_{50} NOEC, LOEC >3,560, mg Pb/kg **Juveniles:** LC_{50} 1,980 mg Pb/kg NOEC 580 mg Pb/kg LOEC 1,020 mg Pb/kg	King et al. (2006)

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Brine shrimp *(Artemia franciscana)*	Mean Pb content 12 to 15 mg Pb/kg from dietary exposure to Pb.	This was the second step in a four-level food chain. *A. franciscana* feeding on *Tetraselmis suecica* cultured in 20 µg/L Pb, as Pb nitrate.	Temperature: 28 ± 2°C Salinity: 34.6 ± 1.2 ppt pH: 7.9-8.2 DO saturation: 90-95% (>7 mg/L)	**Growth:** A tendency toward lower biomass yields was reported (significant only on day of final harvest). **Survival:** A tendency toward lower survival was reported (significant only on day of final harvest).	Dry biomass was 195 mg/L in control cultures and 153 mg/L in cultures fed Pb exposed *T. suecica*. Mean cell count (individuals/L) on days 19-23 (harvest) was 320 in control and 255 in *A. franciscana* cultures fed Pb-exposed *T. suecica*.	Soto-Jiménez et al. (2011b)
Shrimp *(Litopenaeus vannamei)*	Pb in exoskeleton, hepatopancreas, muscle, and remaining tissues was quantified on days 0; 15; 28; and 42 of the dietary study	This was the third step in a four-level food chain. *L. vannamei*, fed *A. franciscana* (mean Pb content 12 to 15 mg Pb/kg) feeding on *T. suecica* cultured in 20 µg/L Pb as Pb nitrate.	Temperature: 28 ± 2°C Salinity: 34.6 ± 1.2 ppt pH: 7.9-8.2 DO saturation: 90-95% (>7 mg/L)	**Growth:** Tendency toward decreased total length and weight was reported (significant only on day of final harvest)	Total mean length in the shrimp fed the experimental diet was 13 mm and wet weight was 7.1 g compared to mean total length (14.8 mm) and wet weight (8.5 g) at day 42.	Soto-Jiménez et al. (2011b)
				Survival: Tendency toward lower survival was reported (significant only on day of final harvest)	Mean survival in the shrimp fed the experimental diet ranged from 67 to 78% compared to control survival (84 to 90%) at day 42.	
Sea urchin *(Paracentrotus lividus)*	50 to 5,000 µg Pb/L (nominal)	Gametes and embryos exposed 48 to 50 hours in filtered seawater to Pb nitrate from adults collected from the Bay of Naples, Italy.	Filtered sea water Temperature: 18 ± 1 °C Salinity: 38% pH: 8 ± 0.2	**Growth:** Up to LOEC concentration, defects observed in plutei were mainly reduction in size (20%); above LOEC concentration, developmental defects were mainly larvae affected in skeletal or gut differentiation up to 2,000 µg Pb/L, where arrest of development started to increase.	**EC_{50}** 1,250 µg Pb/L **NOEL** 250 µg Pb/L **LOEC** 500 µg Pb/L	Manzo et al. (2010)

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Mussel *(Mytilus galloprovincialis)*	3,500; 4,500; 5,500; 6,000 µg Pb/L (nominal)	24-hour static aerated exposure in seawater with Pb acetate with mussels collected from a mussel farm in Greece.	Temperature: 25 ± 2°C Salinity: 35% DO: 7-8 mg/L	**Survival:** Mortality at high Pb concentrations	**24-hour LC_{50}** 4,500 µg Pb/L	Vlahogianni and Valavanidis (2007)
Clam *(Meretrix meretrix)*	2; 20; 197; 1,016; 7,158 µg Pb/L (measured)	24-hour and 96-hour toxicity test with Pb nitrate in filtered seawater using gametes from adults collected from Wenzhou, China and held under laboratory conditions.	Temperature: 28 ± 1°C Salinity: 20% pH: 7.8	**Reproduction:** Embryo development inhibited by increasing Pb concentrations	**Embryogenesis EC_{50}**: 297 µg Pb/L	Vlahogianni and Valavanidis (2007)
				Growth: Significant concentration-dependent growth inhibition in larvae. Larval metamorphosis rate decreased, no adverse effect on larval settlement at 20.4 µg Pb/L	**Growth:** **EC_{50}:** 197 µg Pb/L **Metamorphosis**: >7,160 µg Pb/L	
				Survival: Significant concentration-dependent survival inhibition of embryos over time	**48-hour LC_{50}:** >7,160 µg Pb/L **96-hour LC_{50}**: 353 µg Pb/L	
Scallop *(Argopecten ventricosus)*	For growth: 10; 100; 1,000; and 10,000 µg/L (analytically verified)	144 hour (survival) or 30 day (growth) exposure to Pb nitrate (static renewal every 48 hours) with juvenile *A. ventricosus* hatched from laboratory cultures held at Universidad Autonoma de Baja California Sur, Mexico.	Temperature: 20°C Salinity: 36 ± 1% DO: >4 mg/L	**Growth:** Juvenile growth rates and weight were significantly reduced at high concentrations of Pb	**EC_{50} for growth**: 4,210 µg Pb/L	Sobrino-Figueroa et al. (2007)
	For survival: 280; 560; 1120; 2,250; and 5,000 µg/L (analytically verified)			**Survival:** Juvenile mortality was significantly different than control at 96 hour LC_{50}	**72-hour LC_{50}:** 4,690 µg Pb/L **96-hour LC_{50}**: 830 µg Pb/L **120-hour LC_{50}**: 680 µg Pb/L **144-hour LC_{50}**: 680 µg Pb/L	

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Bivalve *(Tellina deltoidalis)*	1,000 mg Pb/kg (analytically verified)	10 day direct exposure to Pb nitrate spiked sediment collected from Woronora River, New South Wales, Australia. Adults used in the test were collected from Lane Cove River, Sydney, Australia and held in filtered seawater.	Temperature: 21 ± 1 °C Salinity 30 ± 1%, pH 7.2–8.2 Ammonia (total) <3 mg N/L	**Survival:** All individuals survived.	**10 Day NOEC** Porewater: 15 µg Pb/L dissolved Pb Sediment: 1,000 mg Pb/kg	King et al. (2010)
Vertebrates						
Toadfish *(Tetractenos glaber)*	Measured but not reported	Field-collected fish-Pb sampled from sediments collected in two reference and two metal contaminated estuaries near Sydney, Australia	Temperature : 15 to 16 °C Salinity: 29 to 31%, pH: 8.4 to 8.6, amongst estuaries. Sediment pH: 7.0-7.5 Organic matter: 1.5-2.1%	**Reproduction:** Decreased oocyte diameter and density in the toadfish were associated with elevated levels of Pb in the gonads of field collected fish; authors state that this is suggestive of a reduction in egg size.	N/A	Alquezar et al. (2006)

Species	Concentration	Exposure Method	Modifying factors	Effects on Endpoint	Effect Concentration	Reference[a] (Published since the 2006 Pb AQCD)
Grunt fish *(Haemulon scudderi)*	Mean total Pb body burden increased from 0.55 to 3.32 mg Pb/kg during the feeding experiment.	42-day dietary exposure from simulated marine food chain-shrimp, *L. vannamei*, fed *A franciscana* (mean Pb content 12-15 mg Pb/kg) feeding on *T. suecica* cultured in 20 µg/L Pb as Pb nitrate.	Temperature: 28 ± 2 °C Salinity: 34.6 ± 1.2 ppt pH: 7.9-8.2 DO saturation: 90-95% (>7 mg/L)	**Survival:** No significant differences observed in intermediate and final length, mean wet weight, or Fulton's condition factor: Final survival significantly lower; mean total Pb body burden increased.	Mean survival in the fish fed the experimental diet ranged from 65 to 75% compared to control diet survival (88 to 91%).	Soto-Jiménez et al. (2011b)
